Isoniazid-induced hepatitis is the most common major toxic effect. This is distinct from the minor increases in liver aminotransferases (up to three or four times normal), which do not require cessation of the drug and which are seen in 10–20% of patients, who usually are asymptomatic. Clinical hepatitis with loss of appetite, nausea, vomiting, jaundice, and right upper quadrant pain occurs in 1% of isoniazid recipients and can be fatal, particularly if the drug is not discontinued promptly. There is histologic evidence of hepatocellular damage and necrosis. The risk of hepatitis depends on age. It occurs rarely under age 20, in 0.3% of those age 21–35, 1.2% of those age 36–50, and 2.3% for those age 50 and above. The risk of hepatitis is greater in individuals with alcohol dependence and possibly during pregnancy and the postpartum period. Development of isoniazid hepatitis contraindicates further use of the drug.

Peripheral neuropathy is observed in 10–20% of patients given dosages greater than 5 mg/kg/d, but it is infrequently seen with the standard 300-mg adult dose. Peripheral neuropathy is more likely to occur in slow acetylators and patients with predisposing conditions such as malnutrition, alcoholism, diabetes, AIDS, and uremia. Neuropathy is due to a relative pyridoxine deficiency.

Isoniazid promotes excretion of pyridoxine, and this toxicity is readily reversed by administration of pyridoxine in a dosage as low as 10 mg/d. Central nervous system toxicity, which is less common, includes memory loss, psychosis, ataxia, and seizures. These effects may also respond to pyridoxine.

Miscellaneous other reactions include hematologic abnormalities, provocation of pyridoxine deficiency anemia, tinnitus, and gastrointestinal discomfort.

RIFAMPIN

Rifampin is a semisynthetic derivative of rifamycin, an antibiotic produced by *Ammycolatopsis rifamycinica*, formerly named *Streptomyces mediterranei*. It is active in vitro against Gram-positive organisms, some Gram-negative organisms, such as *Neisseria* and *Haemophilus* species, mycobacteria, and chlamydiae. Susceptible organisms are inhibited by less than 1 mcg/mL. Resistant mutants are present in all microbial populations at approximately 1 in 10^6 organisms and are rapidly selected out if rifampin is used as a single drug, especially in a patient with active infection. There is no cross-resistance to other classes of antimicrobial drugs, but there is cross-resistance to other rifamycin derivatives, eg, rifabutin and rifapentine.

Mechanism of Action, Resistance, & Pharmacokinetics

Rifampin binds to the β subunit of bacterial DNA-dependent RNA polymerase and thereby inhibits RNA synthesis. Resistance results from any one of several possible point mutations in *rpoB*, the gene for the β subunit of RNA polymerase. These mutations result in reduced binding of rifampin to RNA polymerase. Human RNA polymerase does not bind rifampin and is not inhibited by it. Rifampin is bactericidal for mycobacteria. It readily penetrates most tissues and penetrates into phagocytic cells. It can kill organisms that are poorly accessible to many other drugs, such as intracellular organisms and those sequestered in abscesses and lung cavities.

Rifampin is well absorbed after oral administration and excreted mainly through the liver into bile. It then undergoes enterohepatic recirculation, with the bulk excreted as a deacylated metabolite in feces and a small amount excreted in the urine. Dosage adjustment for renal or hepatic insufficiency is not necessary. Usual doses result in serum levels of 5–7 mcg/mL. Rifampin is distributed widely in body fluids and tissues. The drug is relatively highly protein-bound, and adequate cerebrospinal fluid concentrations are achieved only in the presence of meningeal inflammation.

Rifampin strongly induces most cytochrome P450 isoforms (CYP1A2, 2C9, 2C19, 2D6, and 3A4), which increases the elimination of numerous other drugs including methadone, anticoagulants, cyclosporine, some anticonvulsants, protease inhibitors, some nonnucleoside reverse transcriptase inhibitors or integrase strand transfer inhibitors, contraceptives, and a host of others

(see Chapters 4 and 66). Co-administration of rifampin results in significantly lower serum levels of these drugs.

Clinical Uses

A. Mycobacterial Infections

Rifampin, usually 600 mg/d (10 mg/kg/d) orally, must be administered with isoniazid or other antituberculous drugs to patients with active tuberculosis to prevent emergence of drug-resistant mycobacteria. In some short-course therapies, 600 mg of rifampin is given twice weekly. Rifampin, 600 mg daily or twice weekly for 6 months, also is effective in combination with other agents in some atypical mycobacterial infections and in leprosy. Rifampin, 600 mg daily for 4 months as a single drug, is an alternative to isoniazid for patients with latent tuberculosis who are unable to take isoniazid or who have had exposure to a case of active tuberculosis caused by an isoniazid-resistant, rifampin-susceptible strain.

B. Other Indications

Rifampin has other uses in bacterial infections. An oral dosage of 600 mg twice daily for 2 days can eliminate meningococcal carriage. Rifampin, 20 mg/kg (maximum 600 mg) once daily for 4 days, is used as prophylaxis in contacts of children with *Haemophilus influenzae* type b disease. Rifampin combined with a second agent is sometimes used to eradicate staphylococcal carriage. Rifampin combination therapy is also used for treatment of serious staphylococcal infections such as osteomyelitis, prosthetic joint infections, and prosthetic valve endocarditis.

Adverse Reactions

Rifampin imparts a harmless orange color to urine, sweat, and tears (soft contact lenses may be permanently stained). Occasional adverse effects include rashes, thrombocytopenia, and nephritis. Rifampin may cause cholestatic jaundice and occasionally hepatitis, and it commonly causes light-chain proteinuria. If administered less often than twice weekly, rifampin may cause a flu-like syndrome characterized by fever, chills, myalgias, anemia, and thrombocytopenia. Its use has been associated with acute tubular necrosis.

ETHAMBUTOL

Ethambutol is a synthetic, water-soluble, heat-stable compound, the dextro-isomer of the structure shown below, dispensed as the dihydrochloride salt.

Mechanism of Action & Clinical Uses

Ethambutol inhibits mycobacterial arabinosyl transferases, which are encoded by the *embCAB* operon. Arabinosyl transferases are involved in the polymerization reaction of arabinoglycan, an essential component of the mycobacterial cell wall. Resistance to ethambutol is due to mutations resulting in overexpression of *emb* gene products or within the *embB* structural gene. Susceptible strains of *Mycobacterium tuberculosis* and other mycobacteria are inhibited in vitro by ethambutol, 1–5 mcg/mL.

Ethambutol is well absorbed from the gut. After ingestion of 25 mg/kg, a blood level peak of 2–5 mcg/mL is reached in 2–4 hours. About 20% of the drug is excreted in feces and 50% in urine in unchanged form. Ethambutol accumulates in renal failure, and the dose should be reduced to three times weekly if creatinine clearance is less than 30 mL/min. Ethambutol crosses the blood-brain barrier only when the meninges are inflamed. Concentrations in cerebrospinal fluid are highly variable, ranging from 4% to 64% of serum levels in the setting of meningeal inflammation.

As with all antituberculous drugs, resistance to ethambutol emerges rapidly when the drug is used alone. Therefore, ethambutol is always given in combination with other antituberculous drugs. Ethambutol hydrochloride, 15–25 mg/kg, is usually given as a single daily dose in combination with isoniazid, rifampin, and pyrazinamide during the initial intensive phase of active tuberculosis treatment. The higher dose may be used for treatment of tuberculous meningitis. Higher doses have been used with intermittent dosing regimens for directly observed therapy; for example, 25–30 mg/kg three times weekly or 50 mg/kg administered twice weekly. Ethambutol is also used in combination with other agents for the treatment of nontuberculous mycobacterial infections, such as *Mycobacterium avium complex* (MAC) or *M. kansasii*; the typical dose for these infections is 15 mg/kg once daily.

Adverse Reactions

Hypersensitivity to ethambutol is rare. The most common serious adverse event is retrobulbar neuritis, resulting in loss of visual acuity and red-green color blindness. This dose-related adverse effect is more likely to occur at dosages of 25 mg/kg/d continued for several months. At 15 mg/kg/d or less, visual disturbances occur in approximately 2% of patients, typically after at least one month of treatment. Experts recommend baseline and monthly visual acuity and color discrimination testing, with particular attention to patients on higher doses or with impaired renal function. Ethambutol is relatively contraindicated in children too young to permit assessment of visual acuity and red-green color discrimination.

PYRAZINAMIDE

Pyrazinamide (PZA) is a relative of nicotinamide, and it is used only for treatment of tuberculosis. It is stable and slightly soluble in water. It is inactive at neutral pH, but at pH 5.5 it inhibits tubercle bacilli at concentrations of approximately 20 mcg/mL. The drug is taken up by macrophages and exerts its activity against mycobacteria residing within the acidic environment of lysosomes.

Mechanism of Action & Clinical Uses

Pyrazinamide is converted to pyrazinoic acid—the active form of the drug—by mycobacterial pyrazinamidase, which is encoded by *pncA*. Pyrazinoic acid disrupts mycobacterial cell membrane metabolism and transport functions. Resistance may be due to impaired uptake of pyrazinamide or mutations in *pncA* that impair conversion of PZA to its active form.

Serum concentrations of 30–50 mcg/mL at 1–2 hours after oral administration are achieved with dosages of 25 mg/kg/d. Pyrazinamide is well absorbed from the gastrointestinal tract and widely distributed in body tissues, including inflamed meninges. The half-life is 8–11 hours. The parent compound is metabolized by the liver, but metabolites are renally cleared; therefore, PZA should be administered at 25–35 mg/kg three times weekly (not daily) in hemodialysis patients and those in whom the creatinine clearance is less than 30 mL/min. In patients with normal renal function, a dose of 30–50 mg/kg is used for thrice-weekly or twice-weekly treatment regimens.

Pyrazinamide is an important front-line drug used in conjunction with isoniazid and rifampin in short-course (ie, 6-month) regimens as a “sterilizing” agent active against residual intracellular organisms that may cause relapse. Tubercle bacilli develop resistance to pyrazinamide fairly readily, but there is no cross-resistance with isoniazid or other antimycobacterial drugs.

Adverse Reactions

Major adverse effects of PZA include hepatotoxicity (in 1–5% of patients), nausea, vomiting, drug fever, photosensitivity, and hyperuricemia. The latter occurs uniformly and is not a reason to halt therapy if patients are asymptomatic.

SECOND-LINE DRUGS FOR TUBERCULOSIS

The alternative drugs listed below are usually considered only (1) in case of resistance to first-line agents; (2) in case of failure of clinical response to conventional therapy; and (3) in case of serious treatment-limiting adverse drug reactions. Expert guidance is desirable in dealing with the toxic effects of these second-line drugs. For many drugs listed in the following text, the dosage, emergence of resistance, and long-term toxicity have not been fully established.

Streptomycin

The mechanism of action and other pharmacologic features of streptomycin, an aminoglycoside, are discussed in Chapter 45. The typical adult dosage is 1 g/d (15 mg/kg/d). If the creatinine

clearance is less than 30 mL/min or the patient is on hemodialysis, the dosage is 15 mg/kg two or three times per week. Most tubercle bacilli are inhibited by streptomycin, 1–10 mcg/mL, in vitro. Nontuberculous species of mycobacteria other than *Mycobacterium avium* complex (MAC) and *Mycobacterium kansasii* are resistant. All large populations of tubercle bacilli contain some streptomycin-resistant mutants. On average, 1 in 10^8 tubercle bacilli can be expected to be resistant to streptomycin at levels of 10–100 mcg/mL. Resistance may be due to a point mutation in either the *rpsL* gene encoding the S12 ribosomal protein or the *rrs* gene encoding 16S ribosomal RNA, which alters the ribosomal binding site.

Streptomycin penetrates into cells poorly and is active mainly against extracellular tubercle bacilli. The drug crosses the blood-brain barrier and achieves therapeutic concentrations with inflamed meninges.

Clinical Use in Tuberculosis

Streptomycin sulfate is used when an injectable drug is needed or desirable and in the treatment of infections resistant to other drugs. The usual dosage is 15 mg/kg/d intramuscularly or intravenously daily for adults (20–40 mg/kg/d for children, not to exceed 1 g) for several weeks, followed by 15 mg/kg two or three times weekly for several months. Serum concentrations of approximately 40 mcg/mL are achieved 30–60 minutes after intramuscular injection of a 15 mg/kg dose. Other drugs are always given in combination to prevent emergence of resistance.

Adverse Reactions

Streptomycin is ototoxic and nephrotoxic. Vertigo and hearing loss are the most common adverse effects and may be permanent. Toxicity is dose-related, and the risk is increased in the elderly. As with all aminoglycosides, the dose must be adjusted according to renal function (see Chapter 45). Toxicity can be reduced by limiting therapy to no more than 6 months whenever possible.

Ethionamide

Ethionamide is chemically related to isoniazid and similarly blocks the synthesis of mycolic acids. It is poorly water soluble and available only for oral use. It is metabolized by the liver.

Most tubercle bacilli are inhibited in vitro by ethionamide, 2.5 mcg/mL or less. Some other species of mycobacteria also are inhibited by ethionamide, 10 mcg/mL. Serum concentrations in plasma and tissues of approximately 1–5 mcg/mL are achieved by a dosage of 1 g/d. Cerebrospinal fluid concentrations are equal to those in serum.

Ethionamide is administered at an initial dose of 250 mg once daily, which is increased in 250 mg increments to the recommended dosage of 1 g/d (or 15 mg/kg/d), if possible. The 1-g/d dosage, though theoretically desirable, is poorly tolerated because of gastric irritation and neurologic symptoms, often limiting the tolerable daily dose to 500–750 mg. Ethionamide is also hepatotoxic. Neurologic symptoms may be alleviated by pyridoxine.

Resistance to ethionamide as a single agent develops rapidly in vitro and in vivo. There can be low-level cross-resistance between isoniazid and ethionamide.

Capreomycin

Capreomycin is a peptide protein synthesis inhibitor antibiotic obtained from *Streptomyces capreolus*. Daily injection of 15 mg/kg intramuscularly results in peak serum levels of 35–45 mcg/mL 2 hours after a dose. Such concentrations in vitro are inhibitory for many mycobacteria, including multidrug-resistant strains of *M. tuberculosis*.

Capreomycin (15 mg/kg/d) is an important injectable agent for treatment of drug-resistant tuberculosis. Strains of *M. tuberculosis* that are resistant to streptomycin usually are susceptible to capreomycin, though some data suggest cross-resistance with strains resistant to amikacin and kanamycin. Resistance to capreomycin, when it occurs, has been associated with *rrs*, *eis*, or *thyA* gene mutations.

Capreomycin is nephrotoxic and ototoxic. Tinnitus, deafness, and vestibular disturbances occur. The injection causes significant local pain, and sterile abscesses may develop.

Typical dosing of capreomycin is 15 mg/kg/day initially, which is then reduced to two or three times weekly after an initial response has been achieved with a daily dosing schedule. The intermittent dosing regimen may minimize risk of toxicity.

Cycloserine

Cycloserine—a structural analog of D-alanine—inhibits cell wall synthesis, as discussed in Chapter 43. Concentrations of 15–20 mcg/mL inhibit many strains of *M. tuberculosis*. The usual dosage of cycloserine in tuberculosis is 0.5–1 g/d in two divided oral doses. The drug is widely distributed to tissues, including the central nervous system. This drug is cleared renally, and the dose should be reduced by half if creatinine clearance is less than 50 mL/min. Alternatively, it may be reduced to 500 mg three times weekly.

The most serious toxic effects are peripheral neuropathy and central nervous system dysfunction, including depression and psychoses. Pyridoxine, 100 mg or more per day, should be given with cycloserine because this ameliorates neurologic toxicity. Adverse effects, which are most common during the first 2 weeks of therapy, occur in 25% or more of patients, especially at higher doses leading to peak concentrations greater than 35 mcg/mL. Adverse effects can be minimized by monitoring peak serum concentrations. The peak concentration is reached 2–4 hours after dosing. The recommended range of peak concentrations is 20–35 mcg/mL.

Aminosalicyclic Acid (PAS)

Aminosalicyclic acid is a folate synthesis antagonist that is active almost exclusively against *M. tuberculosis*. It is structurally similar to *p*-amino-benzoic acid (PABA) and is thought to have a similar mechanism of action to the sulfonamides (see Chapter 46). In the USA, PAS is commercially available as a 4-g packet of delayed-release granules. In order to protect the integrity of the delayed-release coating, the granules must be administered sprinkled over applesauce or yogurt, or swirled in fruit juice and swallowed whole.

Aminosalicyclic acid (PAS)

Tubercle bacilli are usually inhibited in vitro by aminosalicyclic acid, 1–5 mcg/mL. The granule formulation of aminosalicyclic acid results in improved absorption from the gastrointestinal tract. Peak serum levels are expected to be 20–60 mcg/mL 6 hours after a 4 g oral dose. The dosage is 8–12 g/d orally for adults and 300 mg/kg/d for children, administered in two or three divided doses. The drug is widely distributed in tissues and body fluids except the cerebrospinal fluid. Aminosalicyclic acid is rapidly excreted in the urine, in part as active PAS and in part as the acetylated compound and other metabolic products. To avoid accumulation in renal impairment, the maximum dose is 4 g twice daily when creatinine clearance is less than 30 mL/min. Very high concentrations of aminosalicyclic acid are reached in the urine, which can result in crystalluria.

Aminosalicyclic acid is used infrequently in the USA because other oral drugs are better tolerated. Gastrointestinal symptoms are common but occur less frequently with the delayed-release granules; they may be diminished by giving the drug with meals and with antacids. Peptic ulceration and hemorrhage may occur. Hypersensitivity reactions manifested by fever, joint pains, skin rashes, hepatosplenomegaly, hepatitis, adenopathy, and granulocytopenia often occur after 3–8 weeks of PAS therapy, making it necessary to stop administration temporarily or permanently.

Kanamycin & Amikacin

The aminoglycoside antibiotics are discussed in Chapter 45. Kanamycin had been used for treatment of tuberculosis caused by streptomycin-resistant strains, but it is no longer available in the USA, and less toxic alternatives (eg, capreomycin and amikacin) have taken its place.

Amikacin is playing a greater role in the treatment of tuberculosis due to the prevalence of multidrug-resistant strains. Prevalence of amikacin-resistant strains is low (<5%), and most multidrug-resistant strains remain amikacin-susceptible. *M. tuberculosis* is inhibited at concentrations of 1 mcg/mL or less. Amikacin is also active against atypical mycobacteria. There is no cross-resistance

between streptomycin and amikacin, but kanamycin resistance often indicates resistance to amikacin as well. Peak serum concentrations of 30–45 mcg/mL are achieved 30–60 minutes after a 15-mg/kg intravenous infusion or intramuscular injection. Amikacin is indicated for treatment of tuberculosis suspected or known to be caused by streptomycin-resistant or multidrug-resistant strains. This drug must be used in combination with at least one and preferably two or three other drugs to which the isolate is susceptible for treatment of drug-resistant cases. The recommended dosage is 15 mg/kg once daily initially, followed by intermittent dosing two or three times per week.

Fluoroquinolones

In addition to their activity against many Gram-positive and Gram-negative bacteria (discussed in Chapter 46), ciprofloxacin, levofloxacin, gatifloxacin, and moxifloxacin inhibit strains of *M. tuberculosis* at concentrations less than 2 mcg/mL. They are also active against atypical mycobacteria. Moxifloxacin is the most active against *M. tuberculosis* in vitro. Levofloxacin tends to be slightly more active than ciprofloxacin against *M. tuberculosis*, whereas ciprofloxacin is slightly more active against atypical mycobacteria.

Fluoroquinolones are an important addition to the drugs available for tuberculosis, especially for strains that are resistant to first-line agents. The World Health Organization recommends using a later generation fluoroquinolone such as moxifloxacin or levofloxacin. Resistance, which may result from one of several single point mutations in the gyrase A subunit, develops rapidly if a fluoroquinolone is used as a single agent; thus, the drug must be used in combination with two or more additional active agents. Typically, resistance to one fluoroquinolone indicates class resistance. However, moxifloxacin may retain some activity in strains resistant to ofloxacin. The dosage of levofloxacin is 500–750 mg once a day, and some clinicians increase to 1000 mg daily if tolerated. The dosage of moxifloxacin is 400 mg once a day. Some experts recommend checking peak serum concentrations. Expected levels at about two hours post-dose are 8–12 mcg/mL for levofloxacin and 3–5 mcg/mL for moxifloxacin.

Linezolid

Linezolid (discussed in Chapter 44) inhibits strains of *M. tuberculosis* in vitro at concentrations of 4–8 mcg/mL. It achieves good intracellular concentrations, and it is active in murine models of tuberculosis. Linezolid has been used in combination with other second- and third-line drugs to treat patients with tuberculosis caused by multidrug-resistant strains. Conversion of sputum cultures to negative was associated with linezolid use in these cases. Significant adverse effects, including bone marrow suppression and irreversible peripheral and optic neuropathy, have been reported with the prolonged courses of therapy that are necessary for treatment of tuberculosis. A 600-mg (adult) dose administered once a day (half of that used for treatment of other bacterial infections) seems to be sufficient and may limit the occurrence of these adverse effects. Experts recommend supplemental pyridoxine for patients treated with linezolid. Although linezolid may prove to

be an important new agent for treatment of tuberculosis, at this point it should be used only for multidrug-resistant strains that also are resistant to several other first- and second-line agents. It is generally avoided in patients on concomitant serotonergic agents due to concern for serotonin syndrome.

Rifabutin

Rifabutin is derived from rifamycin and is related to rifampin. It has significant activity against *M tuberculosis*, MAC, and *Mycobacterium fortuitum* (see below). Its activity is similar to that of rifampin, and cross-resistance with rifampin is virtually complete. Some rifampin-resistant strains may appear susceptible to rifabutin in vitro, but a clinical response is unlikely because the molecular basis of resistance, *rpoB* mutation, is the same. Rifabutin is both substrate and inducer of cytochrome P450 enzymes. Because it is a less potent inducer, rifabutin is often used in place of rifampin for treatment of tuberculosis in patients with HIV infection who are receiving antiretroviral therapy with a protease inhibitor, a nonnucleoside reverse transcriptase inhibitor (eg, efavirenz), or an integrase strand transfer inhibitor (eg, dolutegravir), drugs that also are cytochrome P450 or UDP glucuronosyltransferase (UGT) substrates.

The typical dosage of rifabutin is 300 mg/d unless the patient is receiving a protease inhibitor, in which case the dosage should be reduced, typically by half. If efavirenz (also a cytochrome P450 inducer) is used, the recommended dosage of rifabutin is 600 mg/d. Rifabutin may accumulate in severe renal impairment, and the dose should be reduced by half if creatinine clearance is less than 30 mL/min. Rifabutin is associated with similar rates of hepatotoxicity or rash compared to rifampin; it can also cause leukopenia, thrombocytopenia, and optic neuritis.

Rifapentine

Rifapentine is another analog of rifampin. It is active against both *M tuberculosis* and MAC. As with all rifamycins, it is a bacterial RNA polymerase inhibitor, and cross-resistance between rifampin and rifapentine is complete. Like rifampin, rifapentine is a potent inducer of cytochrome P450 enzymes, and it has the same drug interaction profile; however, when rifapentine is administered intermittently, induction of metabolism of other medications is less pronounced compared to rifampin. Toxicity is similar to that of rifampin. Rifapentine and its microbiologically active metabolite, 25-desacetyl-rifapentine, have an elimination half-life of 13 hours. Rifapentine, 600 mg (10 mg/kg) once or twice weekly, has been used for treatment of tuberculosis caused by rifampin-susceptible strains during the continuation phase (ie, after the first 2 months of therapy and ideally after conversion of sputum cultures to negative); however, this regimen has decreased efficacy compared with the standard rifampin-based regimen. Revised guidelines for treatment of drug-susceptible tuberculosis published in 2016 recommend against it. In particular, its use should be avoided in patients at higher risk of failure, including those with positive cultures at the end of the intensive treatment phase and those with evidence of cavitation on chest radiographs. Rifapentine should not be used to treat active tuberculosis in patients

with HIV infection because of an unacceptably high relapse rate with rifampin-resistant organisms. Rifapentine in combination with isoniazid, typically both dosed at 900 mg once weekly for 3 months (12 doses each in total), is an effective short course treatment for latent tuberculosis infection.

Bedaquiline

Bedaquiline, a diarylquinoline, is the first drug with a novel mechanism of action against *M tuberculosis* to be approved since 1971. Bedaquiline inhibits adenosine 5'-triphosphate (ATP) synthase in mycobacteria, has in vitro activity against both replicating and nonreplicating bacilli, and has bactericidal and sterilizing activity in the murine model of tuberculosis. Cross-resistance has been reported between bedaquiline and clofazimine, likely via upregulation of the multisubstrate efflux pump, MmpL5.

Peak plasma concentration and plasma exposure to bedaquiline increase approximately twofold when administered with high-fat food. Bedaquiline is highly protein-bound (>99%), is metabolized chiefly through the cytochrome P450 system, and is excreted primarily via the feces. The mean terminal half-life of bedaquiline and its major metabolite (M2), which is four to six times less active in terms of antimycobacterial potency, is approximately 5.5 months. This long elimination phase probably reflects slow release of bedaquiline and M2 from peripheral tissues. CYP3A4 is the major isoenzyme involved in the metabolism of bedaquiline, and potent inhibitors or inducers of this enzyme cause clinically significant drug interactions.

Current recommendations state that bedaquiline, in combination with at least three other active medications, may be used for 24 weeks of treatment in adults with laboratory-confirmed pulmonary tuberculosis if the isolate is resistant to both isoniazid and rifampin. The recommended dosage for bedaquiline is 400 mg once daily orally for 2 weeks, followed by 200 mg three times a week for 22 weeks taken orally with food in order to maximize absorption. The most common adverse effects, occurring at rates of 25% or more, are nausea, arthralgia, and headache. Bedaquiline has been associated with both hepatotoxicity and cardiac toxicity. The FDA has issued a black-box warning related to the risk of QT_c prolongation and associated mortality. It should be reserved for patients who do not have other treatment options and used with caution in patients with other risk factors for cardiac conduction abnormalities.

■ DRUGS ACTIVE AGAINST NONTUBERCULOUS MYCOBACTERIA

Many mycobacterial infections seen in clinical practice in the United States are caused by nontuberculous mycobacteria (NTM), formerly known as “atypical mycobacteria.” These organisms have distinctive laboratory characteristics, are present in the environment, and are generally not communicable from person to person. As a rule, these mycobacterial species are less susceptible than *M tuberculosis* to antituberculous drugs. On the other hand, agents

TABLE 47–3 Clinical features and treatment options for infections with atypical mycobacteria.

Species	Clinical Features	Treatment Options
<i>M kansasii</i>	Resembles tuberculosis	Amikacin, clarithromycin, ethambutol, isoniazid, moxifloxacin, rifampin, streptomycin, trimethoprim-sulfamethoxazole
<i>M marinum</i>	Granulomatous cutaneous disease	Amikacin, clarithromycin, ethambutol, doxycycline, levofloxacin, minocycline, rifampin, trimethoprim-sulfamethoxazole
<i>M scrofulaceum</i>	Cervical adenitis in children	Amikacin, erythromycin (or other macrolide), rifampin, streptomycin (Surgical excision is often curative and the treatment of choice.)
<i>M avium complex (MAC)</i>	Pulmonary disease in patients with chronic lung disease; disseminated infection in AIDS	Amikacin, azithromycin, clarithromycin, ethambutol, moxifloxacin, rifabutin
<i>M chelonae</i>	Abscess, sinus tract, ulcer; bone, joint, tendon infection	Amikacin, doxycycline, imipenem, linezolid, macrolides, tobramycin
<i>M fortuitum</i>	Abscess, sinus tract, ulcer; bone, joint, tendon infection	Amikacin, cefoxitin, ciprofloxacin, doxycycline, imipenem, minocycline, moxifloxacin, ofloxacin, trimethoprim-sulfamethoxazole
<i>M ulcerans</i>	Skin ulcers	Clarithromycin, isoniazid, streptomycin, rifampin, minocycline, moxifloxacin (Surgical excision may be effective.)

such as macrolides, sulfonamides, and tetracyclines, which are not active against *M tuberculosis*, may be effective for infections caused by NTM. Emergence of resistance during therapy is also a problem with these mycobacterial species, and active infection should be treated with combinations of drugs. *M kansasii* is susceptible to rifampin and ethambutol, partially susceptible to isoniazid, and completely resistant to pyrazinamide. A three-drug combination of isoniazid, rifampin, and ethambutol is the conventional treatment for *M kansasii* infection. A few representative pathogens, with the clinical presentation and the drugs to which they are often susceptible, are given in Table 47–3.

M avium complex (MAC), which includes both *M avium* and *M intracellulare*, is an important and common cause of disseminated disease in late stages of AIDS (CD4 counts < 50/μL). MAC is much less susceptible than *M tuberculosis* to most anti-tuberculous drugs. Combinations of agents are required to suppress the infection. Azithromycin, 500–600 mg once daily, or clarithromycin, 500 mg twice daily, plus ethambutol, 15 mg/kg/d, is an effective and well-tolerated regimen for treatment of disseminated disease. Some authorities recommend use of a third agent, especially rifabutin, 300 mg once daily. Other agents that may be useful are listed in Table 47–3. Azithromycin and clarithromycin are the prophylactic drugs of choice for preventing disseminated MAC in AIDS patients with CD4 cell counts less than 50/μL. Rifabutin in a single daily dose of 300 mg has been shown to reduce the incidence of MAC bacteremia but is less effective than macrolides.

■ DRUGS USED IN LEPROSY

Mycobacterium leprae has never been grown in vitro, but animal models, such as growth in injected mouse footpads, have permitted laboratory evaluation of drugs. Only those drugs with the widest clinical use are presented here. Because of increasing reports of dapsone resistance, treatment of leprosy with combinations of the drugs listed below is recommended.

DAPSONE & OTHER SULFONES

Several drugs closely related to the sulfonamides have been used effectively in the long-term treatment of leprosy. The most widely used is dapsone (diaminodiphenylsulfone). Like the sulfonamides, it inhibits folate synthesis. Resistance can emerge in large populations of *M leprae*, eg, in lepromatous leprosy, particularly if low doses are given. Therefore, the combination of dapsone, rifampin, and clofazimine is recommended for initial therapy of lepromatous leprosy. A combination of dapsone plus rifampin is commonly used for leprosy with a lower organism burden. Dapsone may also be used to prevent and treat *Pneumocystis jiroveci* pneumonia in AIDS patients.

Sulfones are well absorbed from the gut and widely distributed throughout body fluids and tissues. Dapsone's half-life is 1–2 days, and drug tends to be retained in skin, muscle, liver, and kidney. Skin heavily infected with *M leprae* may contain several times more drug than normal skin. Sulfones are excreted into bile and reabsorbed in the intestine. Excretion into urine is variable, and most excreted drug is acetylated. In renal failure, the dose may have to be adjusted. The usual adult dosage in leprosy is 100 mg daily. For children, the dose is proportionately less, depending on weight.

Dapsone is usually well tolerated. Many patients develop some hemolysis, particularly if they have glucose-6-phosphate dehydrogenase deficiency. Methemoglobinemia is common but usually is not clinically significant. Gastrointestinal intolerance, fever, pruritus, and rash occur. During dapsone therapy of lepromatous leprosy, erythema nodosum leprosum often develops. It is sometimes difficult to distinguish reactions to dapsone from manifestations of the underlying illness. Erythema nodosum leprosum may be suppressed by **thalidomide** (see Chapter 55).

RIFAMPIN

Rifampin (see earlier discussion) in a dosage of 600 mg daily is highly effective in leprosy and is given with at least one other drug to prevent emergence of resistance. Even a dose of 600 mg per month may be beneficial in combination therapy.

CLOFAZIMINE

Clofazimine is a phenazine dye used in the treatment of multi-bacillary leprosy, which is defined as having a positive smear from any site of infection. Its mechanism of action has not been clearly established. Absorption of clofazimine from the gut is variable,

and a major portion of the drug is excreted in feces. Clofazimine is stored widely in reticuloendothelial tissues and skin, and its crystals can be seen inside phagocytic reticuloendothelial cells. It is slowly released from these deposits, so the serum half-life may be 2 months. A common dosage of clofazimine is 100–200 mg/d orally. The most prominent adverse effect is discoloration of the skin and conjunctivae. Gastrointestinal side effects are common. This medication is no longer commercially available, but it can be obtained through established programs. For example, an investigational new drug (IND) program is established in the USA through the National Hansen's Disease Program. Internationally, ministries of health can make requests directly to the World Health Organization.

SUMMARY First-Line Antimycobacterial Drugs

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
ISONIAZID	Inhibits synthesis of mycolic acids, an essential component of mycobacterial cell walls	Bactericidal activity against susceptible strains of <i>M tuberculosis</i>	First-line agent for tuberculosis • treatment of latent infection • less active against nontuberculous mycobacteria	Oral, IV • hepatic clearance (half-life 1 h) • reduces levels of phenytoin • <i>Toxicity</i> : Hepatotoxic, peripheral neuropathy (give pyridoxine to prevent)
RIFAMYCINS				
• Rifampin	Inhibits DNA-dependent RNA polymerase, thereby blocking production of RNA	Bactericidal activity against susceptible bacteria and mycobacteria • resistance rapidly emerges when used as a single drug in the treatment of active infection	First-line agent for tuberculosis • nontuberculous mycobacterial infections • eradication of meningococcal colonization, staphylococcal infections	Oral, IV • hepatic clearance (half-life 3.5 h) • potent cytochrome P450 inducer • turns body fluids orange color • <i>Toxicity</i> : Rash, nephritis, thrombocytopenia, cholestasis, flu-like syndrome with intermittent dosing
• Rifabutin: Oral; similar to rifampin but less cytochrome P450 induction and fewer drug interactions • Rifapentine: Oral; long-acting analog of rifampin that may be given once weekly in select cases during the continuation phase of tuberculosis treatment or for treatment of latent tuberculosis				
PYRAZINAMIDE	Not fully understood • pyrazinamide is converted to the active pyrazinoic acid under acidic conditions in macrophage lysosomes	Bacteriostatic activity against susceptible strains of <i>M tuberculosis</i> • may be bactericidal against actively dividing organisms	"Sterilizing" agent used during first 2 months of therapy • allows total duration of therapy to be shortened to 6 months	Oral • hepatic clearance (half-life 9 h), but metabolites are renally cleared so use 3 doses weekly if creatinine clearance <30 mL/min • <i>Toxicity</i> : Hepatotoxic, hyperuricemia
ETHAMBUTOL	Inhibits mycobacterial arabinosyl transferases, which are involved in the polymerization reaction of arabinoglycan, an essential component of the mycobacterial cell wall	Bacteriostatic activity against susceptible mycobacteria	Given in four-drug initial combination therapy for tuberculosis until drug sensitivities are known • also used for nontuberculous mycobacterial infections	Oral • mixed clearance (half-life 4 h) • dose must be reduced in renal failure • <i>Toxicity</i> : Retrobulbar neuritis

PREPARATIONS AVAILABLE*

GENERIC NAME	AVAILABLE AS
DRUGS USED IN TUBERCULOSIS	
Aminosalicylic acid	Paser
Bedaquiline fumarate	Sirturo
Capreomycin	Capastat
Ethambutol	Generic, Myambutol
Ethionamide	Trecator, Trecator-SC
Isoniazid	Generic
Pyrazinamide	Generic
Rifabutin	Generic, Mycobutin
Rifampin	Generic, Rifadin, Rimactane
Rifapentine	Priftin
Streptomycin	Generic
DRUGS USED IN LEPROSY	
Clofazimine	Lamprene
Dapsone	Generic

*Drugs used against nontuberculous mycobacteria are listed in Chapters 43–46.

CASE STUDY ANSWER

The patient should be started on four-drug therapy with rifampin, isoniazid, pyrazinamide, and ethambutol. He should also be started on antiretroviral therapy for HIV. If a protease-inhibitor-based antiretroviral regimen is used to treat his HIV, rifabutin should replace rifampin because of the serious drug-drug interactions between rifampin and protease inhibitors.

If dolutegravir is chosen, it must be administered twice daily due to the interaction with rifampin; alternatively, rifabutin can be used in place of rifampin, and dolutegravir can be dosed once daily. The patient is at increased risk of developing hepatotoxicity from both isoniazid and pyrazinamide given his history of alcohol use.

Antifungal Agents

Harry W. Lampiris, MD, &
Daniel S. Maddix, Pharm D

CASE STUDY

The patient is a 37-year-old African-American man who lives in San Jose, California. He was recently incarcerated near Bakersfield, California and returned to Oakland about 3 months ago. He is currently experiencing one month of severe headache and double vision. He has a temperature of 38.6°C (101.5°F) and the physical exam reveals nuchal rigidity and right-sided sixth cranial nerve palsy. MRI of his brain is normal, and lumbar puncture reveals 330 WBC

with 20% eosinophils, protein 75, and glucose 20. HIV test is negative, TB skin test is negative, CSF cryptococcal antigen is negative, and CSF gram stain is negative. Patient receives empiric therapy for bacterial meningitis with vancomycin and ceftriaxone, and is unimproved after 72 hours of treatment. After 3 days a white mold is identified growing from his CSF culture. What medical therapy would be most appropriate now?

Human fungal infections have increased dramatically in incidence and severity in recent years, owing mainly to advances in surgery, cancer treatment, treatment of patients with solid organ and bone marrow transplantation, the HIV epidemic, and increasing use of broad-spectrum antimicrobial therapy in critically ill patients. These changes have resulted in increased numbers of patients at risk for fungal infections.

For many years, **amphotericin B** was the only efficacious antifungal drug available for systemic use. While highly effective in many serious infections, it is also quite toxic. In the last several decades, pharmacotherapy of fungal disease has been revolutionized by the introduction of the relatively nontoxic **azole** drugs (both oral and parenteral formulations) and the **echinocandins** (only available for parenteral administration). The new agents in these classes offer more targeted, less toxic therapy than older agents such as amphotericin B for patients with serious systemic fungal infections. Combination therapy is being reconsidered, and new formulations of old agents are becoming available. Unfortunately, the appearance of azole-resistant and echinocandin-resistant organisms, as well as the rise in the number of patients at risk for mycotic infections, has created new challenges.

The antifungal drugs presently available fall into the following categories: systemic drugs (oral or parenteral) for systemic infections, oral systemic drugs for mucocutaneous infections, and topical drugs for mucocutaneous infections.

■ SYSTEMIC ANTIFUNGAL DRUGS FOR SYSTEMIC INFECTIONS

AMPHOTERICIN B

Amphotericin A and B are antifungal antibiotics produced by *Streptomyces nodosus*. Amphotericin A is not in clinical use.

Chemistry & Pharmacokinetics

Amphotericin B is an amphoteric polyene macrolide (polyene = containing many double bonds; macrolide = containing a large lactone ring of 12 or more atoms). It is nearly insoluble in water and is therefore prepared as a colloidal suspension of amphotericin B and sodium deoxycholate for intravenous injection. Several formulations have been developed in which amphotericin B is

TABLE 48–1 Properties of conventional amphotericin B and some lipid formulations.¹

Drug	Physical Form	Dosing (mg/kg/d)	C _{max}	Clearance	Nephrotoxicity	Infusional Toxicity	Daily Cost (\$)
Conventional formulation							
Fungizone	Micelles	1	—	—	—	—	24
Lipid formulations							
AmBisome	Spheres	3–5	↑	↓	↓	↓	1300
Amphotec	Disks	5	↓	↑	↓	↑(?)	660
Abelcet	Ribbons	5	↓	↑	↓	↓(?)	570

¹Changes in C_{max} (peak plasma concentration), clearance, nephrotoxicity, and infusional toxicity are relative to conventional amphotericin B.

packaged in a lipid-associated delivery system (Table 48–1 and Box: Lipid Formulation of Amphotericin B).

Amphotericin B

Amphotericin B is poorly absorbed from the gastrointestinal tract. Oral amphotericin B is thus effective only on fungi within the lumen of the tract and cannot be used for treatment of systemic disease. The intravenous injection of 0.6 mg/kg/d of amphotericin B results in average blood levels of 0.3–1 mcg/mL; the drug is more than 90% bound by serum proteins. Although it is mostly metabolized, some amphotericin B is excreted slowly

in the urine over a period of several days. The serum half-life is approximately 15 days. Hepatic impairment, renal impairment, and dialysis have little impact on drug concentrations, and therefore no dose adjustment is required. The drug is widely distributed in most tissues, but only 2–3% of the blood level is reached in cerebrospinal fluid, thus occasionally necessitating intrathecal therapy for certain types of fungal meningitis.

Mechanisms of Action & Resistance

Amphotericin B is selective in its fungicidal effect because it exploits the difference in lipid composition of fungal and mammalian cell membranes. **Ergosterol**, a cell membrane sterol, is found in the cell membrane of fungi, whereas the predominant sterol of bacteria and human cells is **cholesterol**. Amphotericin B binds to ergosterol and alters the permeability of the cell by forming amphotericin B–associated pores in the cell membrane (Figure 48–1). As suggested by its chemistry, amphotericin B combines avidly with lipids (ergosterol) along the double bond-rich side of its structure and associates with water molecules

Lipid Formulation of Amphotericin B

Therapy with amphotericin B is often limited by toxicity, especially drug-induced renal impairment. This has led to the development of lipid drug formulations on the assumption that lipid-packaged drug binds to the mammalian membrane less readily, permitting the use of effective doses of the drug with lower toxicity. Liposomal amphotericin preparations package the active drug in lipid delivery vehicles, in contrast to the colloidal suspensions, which were previously the only available forms. Amphotericin binds to the lipids in these vehicles with an affinity between that for fungal ergosterol and that for human cholesterol. The lipid vehicle then serves as an amphotericin reservoir, reducing nonspecific binding to human cell membranes. This preferential binding allows for a reduction of toxicity without sacrificing efficacy and permits use of larger doses. Furthermore, some fungi contain lipases that may liberate free amphotericin B directly at the site of infection.

Three such formulations are now available and have differing pharmacologic properties as summarized in Table 48–1. Although clinical trials have demonstrated different renal and infusion-related toxicities for these preparations compared with regular amphotericin B, there are no trials comparing the different formulations with each other. Limited studies have suggested at best a moderate improvement in the clinical efficacy of the lipid formulations compared with conventional amphotericin B. Because the lipid preparations are much more expensive, their use is usually restricted to patients intolerant to, or not responding to, conventional amphotericin treatment.

FIGURE 48-1 Targets of antifungal drugs. Except for flucytosine (and possibly griseofulvin, not shown), all currently available antifungals target the fungal cell membrane or cell wall.

along the hydroxyl-rich side. This amphipathic characteristic facilitates pore formation by multiple amphotericin molecules, with the lipophilic portions around the outside of the pore and the hydrophilic regions lining the inside. The pore allows the leakage of intracellular ions and macromolecules, eventually leading to cell death. Some binding to human membrane sterols does occur, probably accounting for the drug's prominent toxicity.

Resistance to amphotericin B occurs if ergosterol binding is impaired, either by decreasing the membrane concentration of ergosterol or by modifying the sterol target molecule to reduce its affinity for the drug.

Antifungal Activity & Clinical Uses

Amphotericin B remains the antifungal agent with the broadest spectrum of action. It has activity against the clinically significant yeasts, including *Candida albicans* and *Cryptococcus neoformans*; the organisms causing endemic mycoses, including *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*; and the pathogenic molds, such as *Aspergillus fumigatus* and the agents of mucormycosis. Some fungal organisms such as *Candida lusitanae* and *Pseudallescheria boydii* display intrinsic amphotericin B resistance.

Owing to its broad spectrum of activity and fungicidal action, amphotericin B remains a useful agent for nearly all life-threatening mycotic infections, although newer, less toxic agents have largely replaced it for most conditions. Amphotericin B is often used as the initial induction regimen to rapidly reduce fungal burden and

then replaced by one of the newer azole drugs (described below) for chronic therapy or prevention of relapse. Such induction therapy is especially important for immunosuppressed patients and those with severe fungal pneumonia, severe cryptococcal meningitis, or disseminated infections with one of the endemic mycoses such as histoplasmosis or coccidioidomycosis. Once a clinical response has been elicited, these patients then often continue maintenance therapy with an azole; therapy may be lifelong in patients at high risk for disease relapse. For treatment of systemic fungal disease, amphotericin B is given by slow intravenous infusion at a dosage of 0.5–1 mg/kg/d. Intrathecal therapy for fungal meningitis is poorly tolerated and fraught with difficulties related to maintaining cerebrospinal fluid access. Thus, intrathecal therapy with amphotericin B is being increasingly supplanted by other therapies but remains an option in cases of fungal central nervous system infections that have not responded to other agents.

Local or topical administration of amphotericin B has been used with success. Mycotic corneal ulcers and keratitis can be cured with topical drops as well as by direct subconjunctival injection. Fungal arthritis has been treated with adjunctive local injection directly into the joint. Candiduria responds to bladder irrigation with amphotericin B, and this route has been shown to produce no significant systemic toxicity.

Adverse Effects

The toxicity of amphotericin B can be divided into two broad categories: immediate reactions, related to the infusion of the drug, and those occurring more slowly.

A. Infusion-Related Toxicity

Infusion-related reactions are nearly universal and consist of fever, chills, muscle spasms, vomiting, headache, and hypotension. They can be ameliorated by slowing the infusion rate or decreasing the daily dose. Premedication with antipyretics, antihistamines, meperidine, or corticosteroids can be helpful. When starting therapy, many clinicians administer a test dose of 1 mg intravenously to gauge the severity of the reaction. This can serve as a guide to an initial dosing regimen and premedication strategy.

B. Cumulative Toxicity

Renal damage is the most significant toxic reaction. Renal impairment occurs in nearly all patients treated with clinically significant doses of amphotericin. The degree of azotemia is variable and often stabilizes during therapy, but it can be serious enough to necessitate dialysis. A reversible component is associated with decreased renal perfusion and represents a form of prerenal renal failure. An irreversible component results from renal tubular injury and subsequent dysfunction. The irreversible form of amphotericin nephrotoxicity usually occurs in the setting of prolonged administration (>4 g cumulative dose). Renal toxicity commonly manifests as renal tubular acidosis and severe potassium and magnesium wasting. There is some evidence that the prerenal component can be attenuated with sodium loading, and it is common practice to administer normal saline infusions with the daily doses of amphotericin B.

Abnormalities of liver function tests are occasionally seen, as is a varying degree of anemia due to reduced erythropoietin production by damaged renal tubular cells. After intrathecal therapy with amphotericin, seizures and a chemical arachnoiditis may develop, often with serious neurologic sequelae.

FLUCYTOSINE

Chemistry & Pharmacokinetics

Flucytosine (5-FC) was discovered in 1957 during a search for novel antineoplastic agents. Though devoid of anti-cancer properties, it became apparent that it is a potent antifungal agent. Flucytosine is a water-soluble pyrimidine analog related to the chemotherapeutic agent 5-fluorouracil (5-FU). Its spectrum of action is much narrower than that of amphotericin B.

Flucytosine

Flucytosine is currently available in North America only in an oral formulation. The dosage is 100 mg/kg/d in divided doses in patients with normal renal function. It is well absorbed (>90%), with serum concentrations peaking 1–2 hours after an oral dose. It is poorly protein-bound and penetrates well into all body fluid

compartments, including the cerebrospinal fluid. It is eliminated by glomerular filtration with a half-life of 3–4 hours and is removed by hemodialysis. Levels rise rapidly with renal impairment and can lead to toxicity. Toxicity is more likely to occur in AIDS patients and those with renal insufficiency. Peak serum concentrations should be measured periodically in patients with renal insufficiency and maintained between 50 and 100 mcg/mL.

Mechanisms of Action & Resistance

Flucytosine is taken up by fungal cells via the enzyme cytosine permease. It is converted intracellularly first to 5-FU and then to 5-fluorodeoxyuridine monophosphate (FdUMP) and fluorouridine triphosphate (FUTP), which inhibit DNA and RNA synthesis, respectively (Figure 48–1). Human cells are unable to convert the parent drug to its active metabolites, resulting in selective toxicity.

Synergy with amphotericin B has been demonstrated in vitro and in vivo. It may be related to enhanced penetration of the flucytosine through amphotericin-damaged fungal cell membranes. In vitro synergy with azole drugs also has been seen, although the mechanism is unclear.

Resistance is thought to be mediated through altered metabolism of flucytosine, and, although uncommon in primary isolates, it develops rapidly in the course of flucytosine monotherapy.

Clinical Uses & Adverse Effects

The spectrum of activity of flucytosine is restricted to *C. neoformans*, some *Candida* sp, and the dematiaceous molds that cause chromoblastomycosis. Flucytosine is rarely used as a single agent because of its demonstrated synergy with other agents and to avoid the development of secondary resistance. At present clinical use is confined to combination therapy with amphotericin B for cryptococcal meningitis, or with itraconazole for chromoblastomycosis. Flucytosine also has limited utility as monotherapy for fluconazole-resistant candidal urinary tract infections.

The adverse effects of flucytosine result from metabolism (possibly by intestinal flora) to the toxic antineoplastic compound fluorouracil. Bone marrow toxicity with anemia, leukopenia, and thrombocytopenia are the most common adverse effects, with derangement of liver enzymes occurring less frequently. A form of toxic enterocolitis can occur. There seems to be a narrow therapeutic window, with an increased risk of toxicity at higher drug levels and resistance developing rapidly at subtherapeutic concentrations. The use of drug concentration measurements may be helpful in reducing the incidence of toxic reactions, especially when flucytosine is combined with nephrotoxic agents such as amphotericin B.

AZOLES

Chemistry & Pharmacokinetics

Azoles are synthetic compounds that can be classified as either imidazoles or triazoles according to the number of nitrogen atoms in the five-membered azole ring, as indicated below. The imidazoles consist of ketoconazole, miconazole, and clotrimazole

FIGURE 48-2 Structural formulas of some antifungal azoles.

(Figure 48-2). The latter two drugs are now used only in topical therapy. The triazoles include itraconazole, fluconazole, voriconazole, isavuconazole, and posaconazole. Other triazoles are currently under investigation.

The pharmacology of each of the azoles is unique and accounts for some of the variations in clinical use. Table 48-2 summarizes the differences among six of the azoles.

Mechanisms of Action & Resistance

The antifungal activity of azole drugs results from the reduction of ergosterol synthesis by inhibition of fungal cytochrome P450

enzymes (Figure 48-1). The selective toxicity of azole drugs results from their greater affinity for fungal than for human cytochrome P450 enzymes. Imidazoles exhibit a lesser degree of selectivity than the triazoles, accounting for their higher incidence of drug interactions and adverse effects.

Resistance to azoles occurs via multiple mechanisms. Once rare, increasing numbers of resistant strains are being reported, suggesting that increasing use of these agents for prophylaxis and therapy may be selecting for clinical drug resistance in certain settings.

Clinical Uses, Adverse Effects, & Drug Interactions

The spectrum of action of azole medications is broad, including many species of *Candida*, *C. neoformans*, the endemic mycoses (blastomycosis, coccidioidomycosis, histoplasmosis), the dermatophytes, and, in the case of itraconazole, posaconazole, isavuconazole, and voriconazole, even *Aspergillus* infections. They are

TABLE 48–2 Pharmacologic properties of six systemic azole drugs.

	Water Solubility	Absorption	CSF: Serum Concentration Ratio	t _{1/2} (hours)	Elimination	Formulations
Ketoconazole	Low	Variable	<0.1	7–10	Hepatic	Oral
Itraconazole	Low	Variable	<0.01	24–42	Hepatic	Oral, IV
Fluconazole	High	High	>0.7	22–31	Renal	Oral, IV
Voriconazole	High	High	>0.21	6	Hepatic	Oral, IV
Posaconazole	Low	High	—	25	Hepatic	Oral, IV
Isavuconazole	High	High	—	130	Hepatic	Oral, IV

also useful in the treatment of intrinsically amphotericin-resistant organisms such as *P. boydii*.

As a group, the azoles are relatively nontoxic. The most common adverse reaction is relatively minor gastrointestinal upset. All azoles have been reported to cause abnormalities in liver enzymes and, very rarely, clinical hepatitis. Adverse effects specific to individual agents are discussed below.

All azole drugs are prone to drug interactions because they affect the mammalian cytochrome P450 enzyme system to some extent. The most significant reactions are indicated below.

KETOCONAZOLE

Ketoconazole was the first oral azole introduced into clinical use. It is distinguished from triazoles by its greater propensity to inhibit mammalian cytochrome P450 enzymes; that is, it is less selective for fungal P450 than are the newer azoles. As a result, systemic ketoconazole has fallen out of clinical use in the USA and is not discussed in any detail here. It is no longer recommended for the treatment of fungal nail or skin infections.

ITRACONAZOLE

Itraconazole is available in oral and intravenous formulations and is used at a dosage of 100–400 mg/d. Drug absorption from capsules is increased by food and by low gastric pH. Like other lipid-soluble azoles, it interacts with hepatic microsomal enzymes, though to a lesser degree than ketoconazole. An important drug interaction is reduced bioavailability of itraconazole when taken with rifamycins (rifampin, rifabutin, rifapentine). It does not affect mammalian steroid synthesis, and its effects on the metabolism of other hepatically cleared medications are much less than those of ketoconazole. While itraconazole displays potent antifungal activity, effectiveness can be limited by reduced bioavailability. Newer formulations, including an oral liquid and an intravenous preparation, have utilized cyclodextrin as a carrier molecule to enhance solubility and bioavailability. Like ketoconazole, itraconazole penetrates poorly into the cerebrospinal fluid. Itraconazole is the azole of choice for treatment of disease due to the dimorphic fungi *Histoplasma*, *Blastomyces*, and *Sporothrix*. Itraconazole has activity against *Aspergillus* sp, but it has been replaced by voriconazole as

the azole of choice for aspergillosis. Itraconazole is used extensively in the treatment of dermatophytoses and onychomycosis.

FLUCONAZOLE

Fluconazole displays a high degree of water solubility and good cerebrospinal fluid penetration. Unlike ketoconazole and itraconazole, its oral bioavailability is high. Drug interactions are also less common because fluconazole has the least effect of all the azoles on hepatic microsomal enzymes. Because of fewer hepatic enzyme interactions and better gastrointestinal tolerance, fluconazole has the widest therapeutic index of the azoles, permitting more aggressive dosing in a variety of fungal infections. The drug is available in oral and intravenous formulations and is used at a dosage of 100–800 mg/d.

Fluconazole is the azole of choice in the treatment and secondary prophylaxis of cryptococcal meningitis. Intravenous fluconazole has been shown to be equivalent to amphotericin B in treatment of candidemia in ICU patients with normal white blood cell counts, although echinocandins may have superior activity for this indication. Fluconazole is the agent most commonly used for the treatment of mucocutaneous candidiasis. Activity against the dimorphic fungi is mainly limited to coccidioid disease, and in particular for meningitis, where high doses of fluconazole often obviate the need for intrathecal amphotericin B. Fluconazole displays no activity against *Aspergillus* or other filamentous fungi.

Prophylactic use of fluconazole has been demonstrated to reduce fungal disease in bone marrow transplant recipients and AIDS patients, but the emergence of fluconazole-resistant fungi has raised concerns about this indication.

VORICONAZOLE

Voriconazole is available in intravenous and oral formulations. The recommended dosage is 400 mg/d. The drug is well absorbed orally, with a bioavailability exceeding 90%, and it exhibits less protein binding than itraconazole. Metabolism is predominantly hepatic. Voriconazole is a clinically relevant inhibitor of mammalian CYP3A4, and dose reduction of a number of medications is required when voriconazole is started. These include cyclosporine, tacrolimus, and HMG-CoA reductase inhibitors.

Iatrogenic Fungal Meningitis

In September 2012, the U.S. Centers for Disease Control and Prevention (CDC) in Atlanta received reports of a number of cases of fungal meningitis in patients who had received injections with the corticosteroid methylprednisolone. An investigation revealed a multistate outbreak of septic arthritis, paraspinal infections, and meningitis due to environmental molds, with the black mold *Exserohilum rostratum* being the most commonly isolated species. The outbreak was traced to the injection of methylprednisolone that was contaminated during its preparation by a compounding pharmacy facility in New England. Methylprednisolone injections are commonly given to patients with joint or back arthritis, and in the affected cases the patients were not only inadvertently injected with spores of environmental molds, but the normal immune response to this infection was inhibited by the potent immunosuppressive effect of the corticosteroid. As of November 2013 more than 750 cases of fungal infection had been identified in 20 states, with over 60 deaths. Treatment of these infections was challenging, and the CDC recommended the use of intravenous voriconazole as first-line therapy, with the addition of liposomal amphotericin B in cases of severe infection.

Observed toxicities include rash and elevated hepatic enzymes. Visual disturbances are common, occurring in up to 30% of patients receiving intravenous voriconazole, and include blurring and changes in color vision or brightness. These visual changes usually occur immediately after a dose of voriconazole and resolve within 30 minutes. Photosensitivity dermatitis is commonly observed in patients receiving chronic oral therapy.

Voriconazole is similar to itraconazole in its spectrum of action, having excellent activity against *Candida* sp (including some fluconazole-resistant species such as *Candida krusei*) and the dimorphic fungi. Voriconazole is less toxic than amphotericin B and is the treatment of choice for invasive aspergillosis and some environmental molds (see Box: Iatrogenic Fungal Meningitis). Measurement of voriconazole levels may predict toxicity and clinical efficacy, especially in immunocompromised patients. Therapeutic trough levels should be between 1 and 5 mcg/mL.

POSACONAZOLE

Posaconazole was originally available only in a liquid oral formulation and is used at a dosage of 800 mg/d, divided into two or four doses. Absorption is improved when taken with meals high in fat. An intravenous form of posaconazole and a sustained acting tablet form with higher bioavailability are now available. Posaconazole is rapidly distributed to the tissues, resulting in high tissue levels but relatively low blood levels. Measurement of posaconazole

levels is recommended in patients with serious invasive fungal infections (especially mold infections); steady-state posaconazole levels should be between 0.5 and 1.5 mcg/mL. Drug interactions with increased levels of CYP3A4 substrates such as tacrolimus and cyclosporine have been documented.

Posaconazole is the broadest-spectrum member of the azole family, with activity against most species of *Candida* and *Aspergillus*. It is the first azole with significant activity against the agents of mucormycosis. It is currently licensed for salvage therapy in invasive aspergillosis, as well as prophylaxis of fungal infections during induction chemotherapy for leukemia, and for allogeneic bone marrow transplant patients with graft-versus-host disease.

ISAVUCONAZOLE (ISAVUCONAZONIUM SULFATE)

Isavuconazonium sulfate is a prodrug of the newest triazole, isavuconazole; 186 mg of the water-soluble prodrug is equivalent to 100 mg of isavuconazole. It is available as highly bioavailable oral capsules and an intravenous formulation. Following a 2-day loading dose of 372 mg administered every 8 hours, isavuconazonium sulfate is given as a single 372-mg daily dose. Food does not significantly impact the oral absorption of isavuconazonium sulfate. Measurement of isavuconazole levels has not been demonstrated to be of benefit. Coadministration with strong 3A4 inhibitors (eg, ritonavir) or inducers (eg, rifampin) is not recommended.

Isavuconazole has an antifungal spectrum similar to that of posaconazole. It is currently licensed for the treatment of invasive aspergillosis and invasive mucormycosis. Data from published clinical trials are limited. Preliminary evidence indicates that it is better tolerated than voriconazole.

ECHINOCANDINS

Chemistry & Pharmacokinetics

Echinocandins are the newest class of antifungal agents to be developed. They are large cyclic peptides linked to a long-chain fatty acid. **Caspofungin**, **micalfungin**, and **anidulafungin** are the only licensed agents in this category of antifungals, although other drugs are under active investigation. These agents are active against *Candida* and *Aspergillus*, but not *C. neoformans* or the agents of zygomycosis and mucormycosis.

Echinocandins are available only in intravenous formulations. Caspofungin is administered as a single loading dose of 70 mg, followed by a daily dose of 50 mg. Caspofungin is water soluble and highly protein-bound. The half-life is 9–11 hours, and the metabolites are excreted by the kidneys and gastrointestinal tract. Dosage adjustments are required only in the presence of severe hepatic insufficiency. Micalfungin displays similar properties with a half-life of 11–15 hours and is used at a dose of 150 mg/d for treatment of esophageal candidiasis, 100 mg/d for treatment of candidemia, and 50 mg/d for prophylaxis of fungal infections.

Anidulafungin has a half-life of 24–48 hours. For esophageal candidiasis, it is administered intravenously at 100 mg on the first day and 50 mg/d thereafter for 14 days. For candidemia, a loading dose of 200 mg is recommended with 100 mg/d thereafter for at least 14 days after the last positive blood culture.

Mechanism of Action

Echinocandins act at the level of the fungal cell wall by inhibiting the synthesis of $\beta(1-3)$ -glucan (Figure 48–1). This results in disruption of the fungal cell wall and cell death.

Clinical Uses & Adverse Effects

Caspofungin is currently licensed for disseminated and mucocutaneous candidal infections, as well as for empiric antifungal therapy during febrile neutropenia, and has largely replaced amphotericin B for the latter indication. Of note, caspofungin is licensed for use in invasive aspergillosis only as salvage therapy in patients who have failed to respond to amphotericin B, and not as primary therapy. Micafungin is licensed for mucocutaneous candidiasis, candidemia, and prophylaxis of candidal infections in bone marrow transplant patients. Anidulafungin is approved for use in esophageal candidiasis and invasive candidiasis, including candidemia.

Echinocandin agents are extremely well tolerated, with minor gastrointestinal side effects and flushing reported infrequently. Elevated liver enzymes have been noted in several patients receiving caspofungin in combination with cyclosporine, and this combination should be avoided. Micafungin has been shown to increase levels of nifedipine, cyclosporine, and sirolimus. Anidulafungin does not seem to have significant drug interactions, but histamine release may occur during intravenous infusion. Clinically significant echinocandin resistance is an emerging concern especially with invasive *Candida glabrata* infections in immunocompromised patients.

■ ORAL SYSTEMIC ANTIFUNGAL DRUGS FOR MUCOCUTANEOUS INFECTIONS

GRISEOFULVIN

Griseofulvin is a very insoluble fungistatic drug derived from a species of penicillium. Its only use is in the systemic treatment of dermatophytosis (see Chapter 61). It is administered in a microcrystalline oral form at a dosage of up to 1 g/d. Absorption is improved when it is given with fatty foods. Griseofulvin's mechanism of action at the cellular level is unclear, but it is deposited in newly forming skin where it binds to keratin, protecting the skin from new infection. Because its action is to prevent infection of these new skin structures, griseofulvin must be administered for 2–6 weeks for skin and hair infections to allow the replacement of infected keratin by the resistant structures. Nail infections may require therapy for months to allow regrowth of the new protected

nail and is often followed by relapse. Adverse effects include an allergic syndrome much like serum sickness, serious skin reactions, a lupus-like syndrome, hepatotoxicity, and drug interactions with warfarin and phenobarbital. Griseofulvin has been largely replaced by newer antifungal medications such as itraconazole and terbinafine.

TERBINAFINE

Terbinafine is a synthetic allylamine that is available in an oral formulation and is used at a dosage of 250 mg/d. It is used in the treatment of dermatophytoses, especially onychomycosis (see Chapter 61). Like griseofulvin, terbinafine is a keratophilic medication, but unlike griseofulvin, it is fungicidal. Like the azole drugs, it interferes with ergosterol biosynthesis, but rather than interacting with the P450 system, terbinafine inhibits the fungal enzyme squalene epoxidase (Figure 48–1). This leads to the accumulation of the sterol squalene, which is toxic to the organism. One 250-mg tablet given daily for 12 weeks achieves a cure rate of up to 90% for onychomycosis and is more effective than griseofulvin or itraconazole. Adverse effects are rare, consisting primarily of gastrointestinal upset and headache, but serious hepatotoxicity has been reported. Terbinafine does not seem to affect the P450 system and has demonstrated no significant drug interactions to date.

■ TOPICAL ANTIFUNGAL THERAPY

NYSTATIN

Nystatin is a polyene macrolide much like amphotericin B. It is too toxic for parenteral administration and is only used topically. Nystatin is currently available in creams, ointments, suppositories, and other forms for application to skin and mucous membranes. It is not absorbed to a significant degree from skin, mucous membranes, or the gastrointestinal tract. As a result, nystatin has little toxicity, although oral use is often limited by the unpleasant taste.

Nystatin is active against most *Candida* sp and is most commonly used for suppression of local candidal infections. Some common indications include oropharyngeal thrush, vaginal candidiasis, and intertriginous candidal infections.

TOPICAL AZOLES

The two azoles most commonly used topically are clotrimazole and miconazole; several others are available (see Preparations Available). Both are available over the counter and are often used for vulvovaginal candidiasis. Oral clotrimazole troches are available for treatment of oral thrush and are a pleasant-tasting alternative to nystatin. In cream form, both agents are useful for dermatophytic infections, including tinea corporis, tinea pedis, and tinea cruris. Absorption is negligible, and adverse effects are rare.

Topical and shampoo forms of ketoconazole are also available and useful in the treatment of seborrheic dermatitis and pityriasis versicolor. Several other azoles are available for topical use (see Preparations Available).

TOPICAL ALLYLAMINES

Terbinafine and naftifine are allylamines available as topical creams (see Chapter 61). Both are effective for treatment of tinea cruris and tinea corporis. These are prescription drugs in the USA.

SUMMARY Antifungal Drugs

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
POLYENE MACROLIDE				
• Amphotericin B	Forms pores in fungal membranes (which contain ergosterol) but not in mammalian (cholesterol-containing) membranes	Loss of intracellular contents through pores is fungicidal • broad spectrum of action	Localized and systemic candidemia • <i>Cryptococcus</i> • <i>Histoplasma</i> • <i>Blastomyces</i> • <i>Coccidioides</i> • <i>Aspergillus</i>	Oral form is not absorbed • IV for systemic use • intrathecal for fungal meningitis • topical for ocular and bladder infections • duration, days • <i>Toxicity</i> : Infusion reactions • renal impairment • <i>Interactions</i> : Additive with other renal toxic drugs
• Lipid formulations: Lower toxicity, higher doses can be used				
PYRIMIDINE ANALOG				
• Flucytosine	Interferes with DNA and RNA synthesis selectively in fungi	Synergistic with amphotericin • systemic toxicity in host due to DNA and RNA effects	<i>Cryptococcus</i> and chromoblastomycosis infections	Oral • duration, hours • renal excretion • <i>Toxicity</i> : Myelosuppression
AZOLES				
• Ketoconazole	Blocks fungal P450 enzymes and interferes with ergosterol synthesis	Poorly selective • also interferes with mammalian P450 function	Broad spectrum but toxicity restricts use to topical therapy	Oral, topical • <i>Toxicity and interactions</i> : Interferes with steroid hormone synthesis and phase I drug metabolism
• Itraconazole	Same as for ketoconazole	Much more selective than ketoconazole	Broad spectrum: <i>Candida</i> , <i>Cryptococcus</i> , blastomycosis, coccidioidomycosis, histoplasmosis	Oral and IV • duration, 1–2 d • poor entry into central nervous system (CNS) • <i>Toxicity and interactions</i> : Low toxicity
• Fluconazole, voriconazole, posaconazole, isavuconazole: Fluconazole has excellent CNS penetration, used in fungal meningitis				
ECHINOCANDINS				
• Caspofungin	Blocks β -glucan synthase	Prevents synthesis of fungal cell wall	Fungicidal <i>Candida</i> sp • also used in aspergillosis	IV only • duration, 11–15 h • <i>Toxicity</i> : Minor gastrointestinal effects, flushing • <i>Interactions</i> : Increases cyclosporine levels (avoid combination)
• Micafungin, anidulafungin: Micafungin increases levels of nifedipine, cyclosporine, sirolimus; anidulafungin is relatively free of this interaction				
ALLYLAMINE				
• Terbinafine	Inhibits epoxidation of squalene in fungi • increased levels are toxic to fungi	Reduces ergosterol • prevents synthesis of fungal cell membrane	Mucocutaneous fungal infections	Oral • duration, days • <i>Toxicity</i> : Gastrointestinal upset, headache, hepatotoxicity • <i>Interactions</i> : None reported

PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
Amphotericin B	
Parenteral:	
Conventional formulation	Generic
Lipid formulations	Abelcet, AmBisome
Anidulafungin	Eraxis
Butenafine	Mentax
Butoconazole	Gynazole-1
Caspofungin	Cancidas
Clotrimazole	Generic, Lotrimin, Mycelex, others
Econazole	Generic, Ecoza
Fluconazole	Generic, Diflucan
Flucytosine	Generic, Ancobon
Griseofulvin	Grifulvin, Gris-Peg
Itraconazole	Generic, Sporanox, Onmel
Ketoconazole	Generic, Nizoral, others
Micafungin	Mycamine
Miconazole	Generic, Oravig, Micatin
Naftifine	Naftin
Natamycin	Natacyn
Nystatin	Generic
Oxiconazole	Generic, Oxistat, others
Posaconazole	Noxafil
Sulconazole	Exelderm
Terbinafine	Generic, Lamisil
Terconazole	Generic, Terazol 3, Terazol 7
Tioconazole	Vagistat-1, Monistat 1
Tolnaftate	Generic, Aftate, Tinactin, others
Voriconazole	Generic, Vfend

CASE STUDY ANSWER

The mold subsequently isolated from the patient's CSF was identified as *Coccidioides immitis*. Patients of African-American and Southeast Asian descent as well as immunocompromised patients are at an increased risk for developing chronic forms of coccidioidomycosis such as meningitis. *C. immitis* is a dimorphic fungus that grows in the soil of the San Joaquin Valley in California, while closely related *C posadasii* is found elsewhere in desert regions of the southwest USA, parts

of Mexico, and Central and South America. Oral therapy with fluconazole was initiated at a dose of 800 mg/day and patient's headache, fever, and double vision resolved within 7 days. Patients experiencing treatment failure with fluconazole may require treatment with intrathecal amphotericin B. Generally, coccidioidal meningitis requires lifelong therapy because of a high incidence of disease relapse with treatment discontinuation and is 100% fatal without antifungal treatment.

Antiviral Agents

Sharon Safrin, MD

CASE STUDY

A 35-year-old white woman who recently tested seropositive for both HIV and hepatitis B virus surface antigen is referred for evaluation. She is feeling well overall but reports a 25-pack-year smoking history. She drinks 3–4 beers per week and has no known medication allergies. She has a history of heroin use and is currently receiving methadone. Physical examination reveals

normal vital signs and no abnormalities. White blood cell count is 5800 cells/mm^3 with a normal differential, hemoglobin is 11.8 g/dL, all liver tests are within normal limits, CD4 cell count is 278 cells/mm^3 , and viral load (HIV RNA) is 110,000 copies/mL. What other laboratory tests should be ordered? Which antiretroviral medications would you begin?

Viruses are obligate intracellular parasites; their replication depends primarily on synthetic processes of the host cell. Therefore, to be effective, antiviral agents must either block viral entry into or exit from the cell or be active inside the host cell. As a corollary, nonselective inhibitors of virus replication may interfere with host cell function and result in toxicity.

Progress in antiviral chemotherapy began in the early 1950s, when the search for anti-cancer drugs generated several new compounds capable of inhibiting viral DNA synthesis. The two first-generation antiviral agents, 5-iododeoxyuridine and trifluorothymidine, had poor specificity (ie, they inhibited host cell DNA as well as viral DNA) that rendered them too toxic for systemic use. However, both agents are effective when used topically for the treatment of herpes keratitis.

Knowledge of the mechanisms of viral replication has provided insights into critical steps in the viral life cycle that can serve as

potential targets for antiviral therapy. Recent research has focused on identifying agents with greater selectivity, higher potency, in vivo stability, and reduced toxicity. Antiviral therapy is now available for herpes simplex virus (HSV), cytomegalovirus (CMV), varicella zoster virus (VZV), hepatitis C virus (HCV), hepatitis B virus (HBV), influenza, human immunodeficiency virus (HIV), and respiratory syncytial virus (RSV). Antiviral drugs share the common property of being virustatic; they are active only against replicating viruses and do not affect latent virus. Whereas some infections require monotherapy for brief periods of time (eg, HSV, influenza), others require multiple drug therapy for indefinite periods (HIV). In chronic illnesses such as viral hepatitis and HIV infection, potent inhibition of viral replication is crucial in limiting the extent of systemic damage.

Viral replication requires several steps (see Figure 49–1). Antiviral agents can potentially target any of these steps.

ACRONYMS & OTHER NAMES

3TC	Lamivudine
AZT	Zidovudine (previously azidothymidine)
CMV	Cytomegalovirus
CYP	Cytochrome P450
d4T	Stavudine
ddC	Zalcitabine
ddI	Didanosine
EBV	Epstein-Barr virus
FTC	Emtricitabine
HBeAg	Hepatitis e antigen
HBV, HCV	Hepatitis B virus, C virus
HHV-6, -8	Human herpesvirus-6, human herpesvirus-8
HIV	Human immunodeficiency virus
HSV	Herpes simplex virus
INSTI	Integrase strand transfer inhibitor
NNRTI	Nonnucleoside reverse transcriptase inhibitor
NRTI	Nucleoside/nucleotide reverse transcriptase inhibitor
PI	Protease inhibitor
RSV	Respiratory syncytial virus
SVR	Sustained viral response
UGT1A1	UDP-glucuronosyltransferase 1A1
VZV	Varicella-zoster virus

■ AGENTS TO TREAT HERPES SIMPLEX VIRUS (HSV) & VARICELLA-ZOSTER VIRUS (VZV) INFECTIONS

Three oral nucleoside analogs are licensed for the treatment of HSV and VZV infections: acyclovir, valacyclovir, and famciclovir. They have similar mechanisms of action and comparable indications for clinical use (see Table 49–1); all are well tolerated.

Comparative trials have demonstrated similar efficacies of these three agents for the treatment of HSV, with shortening of the duration of symptoms by approximately 2 days, the time to lesion healing by 4 days, and the duration of viral shedding by 7 days in first episodes of genital herpes and shortening of the overall time course by 1–2 days in recurrent genital herpes. Treatment of first-episode genital herpes does not alter the frequency or severity of recurrent outbreaks. Long-term suppression with antiherpes agents in patients with frequent recurrences of genital herpes decreases the frequency of symptomatic recurrences and of asymptomatic viral shedding, thus decreasing the rate of sexual transmission. However, outbreaks may resume upon discontinuation of suppression. The efficacy of the antiherpes agents in orolabial herpes is generally less than that in anogenital herpes.

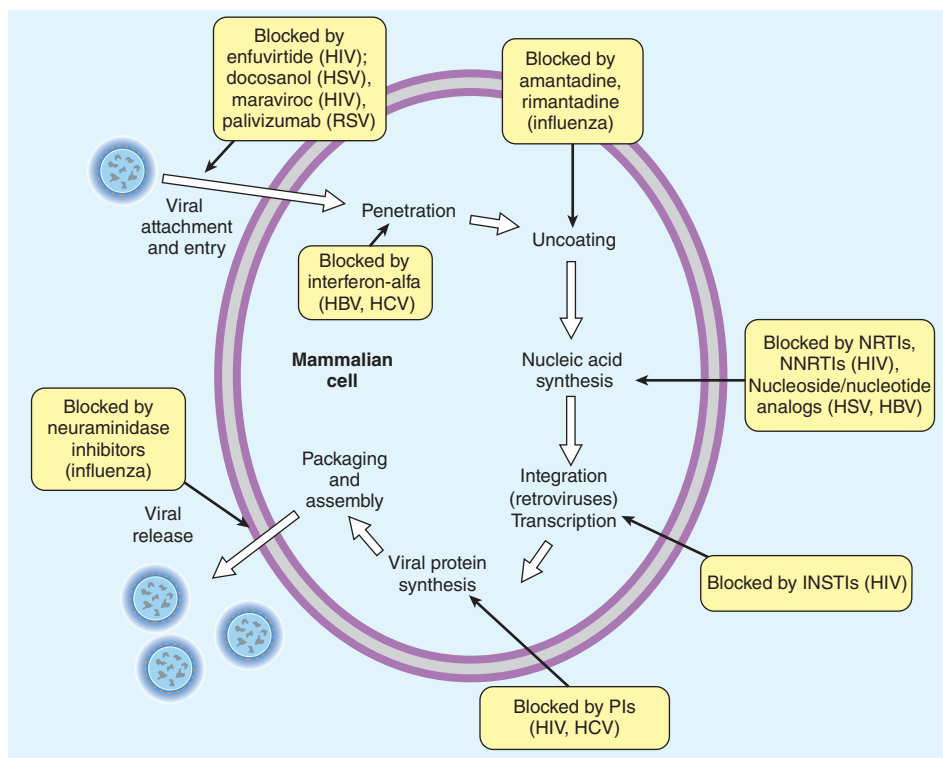

FIGURE 49–1 The major sites of antiviral drug action. Note: Interferon alphas are speculated to have multiple sites of action. TABLE 49–1 Agents to treat or prevent herpes simplex virus (HSV) and varicella-zoster virus (VZV) infections.

Agent	Treatment of First Episode	Treatment of Recurrent Episodes	Suppression
Genital Herpes			
Acyclovir, oral ¹	400 mg tid × 7–10 days or 200 mg 5 times daily	800 mg tid × 2 days or 800 mg bid × 5 days or 400 mg tid × 5 days	400–800 mg bid-tid ²
Famciclovir, oral ¹	250 mg tid × 7–10 days	1000 mg bid × 1 day or 125 mg bid × 5 days or 500 mg once then 250 mg bid × 2 days ²	250–500 mg bid ²
Valacyclovir, oral ¹	1000 mg bid × 10 days	500 mg bid × 3 days or 1 g qd × 5 days	500–1000 mg qd-bid ²
Orolabial herpes			
Acyclovir, oral ¹	400 mg tid × 7–10 days or 200 mg 5 times daily	200–400 mg 5 times daily × 5 days	400–800 mg bid-tid ²
Famciclovir, oral ¹	500 mg tid × 7–10 days	1500 mg once or 750 mg bid	500 mg bid
Valacyclovir, oral ¹	1 g bid × 7–10 days	2 g bid × 1 day	500–1000 mg qd
Acyclovir, topical (5% cream)		5 times daily × 4 days	
Docosanol, topical (10% cream)		5 times daily	
Penciclovir, topical (1% cream)		Every 2 h while awake	
Herpes proctitis, treatment			
Acyclovir, oral ¹	400 mg 5 times daily until healed		
Severe HSV infection or HSV infection in the immunocompromised host, treatment			
Acyclovir, IV ¹	5–10 mg/kg q8h × 7–14 days		
Herpes encephalitis, treatment			
Acyclovir, IV ¹	10–15 mg/kg q8h × 21 days		
Neonatal HSV infection, treatment			
Acyclovir, IV ¹	10–20 mg/kg q8h × 14–21 days		
Herpetic keratoconjunctivitis, treatment			
Ganciclovir, topical (0.15% gel)	5 times daily		
Trifluridine, topical (1% solution)	Every 2 h while awake		
Varicella infection, treatment			
Acyclovir, oral ¹	20 mg/kg (maximum 800 mg) qid × 5 days		
Valacyclovir, oral ¹	20 mg/kg (maximum, 1 g) tid × 5 days		
Zoster infection, treatment			
Acyclovir, oral ¹	800 mg 5 times daily × 7–10 days		
Famciclovir, oral ¹	500 mg tid × 7 days		
Valacyclovir, oral ¹	1 g tid × 7 days		
Severe VZV infection or VZV infection in the immunocompromised host, treatment			
Acyclovir, IV ¹	10–15 mg/kg q8h × ≥7 days		
Acyclovir-resistant HSV or VZV infection, treatment			
Foscarnet, IV ¹	40–60 mg/kg q8h until healed ²		

¹ Dose adjustment is necessary for renal insufficiency.² Higher doses may be necessary in HIV-infected patients.

HIV, human immunodeficiency virus; HSV, herpes simplex virus; IV, intravenous; VZV, varicella-zoster virus.

The antiherpes agents significantly decrease the total number of lesions, duration of symptoms, and viral shedding in patients with varicella (if begun within 24 hours after the onset of rash) or cutaneous zoster (if begun within 72 hours); the risk of post-herpetic neuralgia is also reduced if treatment is initiated early. In comparative trials with acyclovir for the treatment of patients with zoster, rates of cutaneous healing with valacyclovir or famciclovir were similar, but

the latter agents were associated with a shorter duration of zoster-associated pain. Since VZV is less susceptible to the antiherpes agents than HSV, higher doses are required (Table 49–1).

The antiherpes agents may also be administered prophylactically for the prevention of HSV or VZV infection in patients undergoing organ transplantation, as well as for the treatment of these infections should they occur.

ACYCLOVIR

Acyclovir is an acyclic guanosine derivative with clinical activity against HSV-1, HSV-2, and VZV, but it is approximately 10 times more potent against HSV-1 and HSV-2 than against VZV. In vitro activity against Epstein-Barr virus (EBV), cytomegalovirus (CMV), and human herpesvirus-6 (HHV-6) is present but weaker.

Acyclovir requires three phosphorylation steps for activation. It is converted first to the monophosphate derivative by the virus-specified thymidine kinase and then to the di- and triphosphate compounds by host cell enzymes (Figure 49–2). Because it requires the viral kinase for initial phosphorylation, acyclovir is selectively activated—and the active metabolite accumulates—only in infected cells. Acyclovir triphosphate inhibits viral DNA synthesis by two mechanisms: competition with deoxyGTP for the viral DNA polymerase, resulting in binding to the DNA template as an irreversible complex; and chain termination following incorporation into the viral DNA.

The bioavailability of oral acyclovir is low (15–20%) and is unaffected by food. Topical formulations produce high concentrations in herpetic lesions, but systemic concentrations are undetectable by this route.

Acyclovir is cleared primarily by glomerular filtration and tubular secretion. The half-life is 2.5–3 hours in patients with normal renal function and 20 hours in patients with anuria. Acyclovir

diffuses readily into most tissues and body fluids. Cerebrospinal fluid concentrations are 20–50% of serum values.

Acyclovir is the only one of the three antiherpes agents that is available for intravenous use in the United States. Intravenous acyclovir is the treatment of choice for herpes simplex encephalitis, neonatal HSV infection, and serious HSV or VZV infections (Table 49–1). In neonates with central nervous system HSV, oral acyclovir suppression for 6 months following acute treatment improves neurodevelopmental outcomes. In immunocompromised patients with VZV infection, intravenous acyclovir reduces the incidence of cutaneous and visceral dissemination.

Topical acyclovir cream is substantially less effective than oral therapy for primary HSV infection. It is of no benefit in treating recurrent genital herpes.

Resistance to acyclovir can develop in HSV or VZV through alteration in either the viral thymidine kinase or the DNA polymerase, and clinically resistant infections have been reported in immunocompromised hosts. Most clinical isolates are resistant on the basis of deficient thymidine kinase activity and thus are cross-resistant to valacyclovir, famciclovir, and ganciclovir. Agents such as foscarnet, cidofovir, and trifluridine do not require activation by viral thymidine kinase and therefore have preserved activity against the most prevalent acyclovir-resistant strains (Figure 49–2).

Acyclovir is generally well tolerated, although nausea, diarrhea, and headache may occur. Intravenous infusion may be associated with reversible renal toxicity (ie, crystalline nephropathy or interstitial nephritis) or neurologic effects (eg, tremors, delirium, seizures). However, these are uncommon with adequate hydration and avoidance of rapid infusion rates. High doses of acyclovir cause chromosomal damage and testicular atrophy in rats, but there has been no evidence of teratogenicity, reduction in sperm production, or cytogenetic alterations in peripheral blood lymphocytes in patients receiving daily suppression of genital herpes for more than 10 years. A recent study found no evidence of increased birth defects in infants exposed to acyclovir during the first trimester. In fact, the American College of Obstetricians and Gynecologists recommends suppressive acyclovir therapy beginning at week 36 in pregnant women with active recurrent genital herpes to reduce the risk of recurrence at delivery and possibly the need for cesarean section.

Concurrent use of nephrotoxic agents may enhance the potential for nephrotoxicity. Probenecid and cimetidine decrease acyclovir clearance and increase exposure. Somnolence and lethargy may occur in patients receiving concomitant zidovudine and acyclovir.

VALACYCLOVIR

Valacyclovir is the L-valyl ester of acyclovir. It is rapidly converted to acyclovir after oral administration via first-pass enzymatic hydrolysis in the liver and intestine, resulting in serum levels that are three to five times greater than those achieved with oral

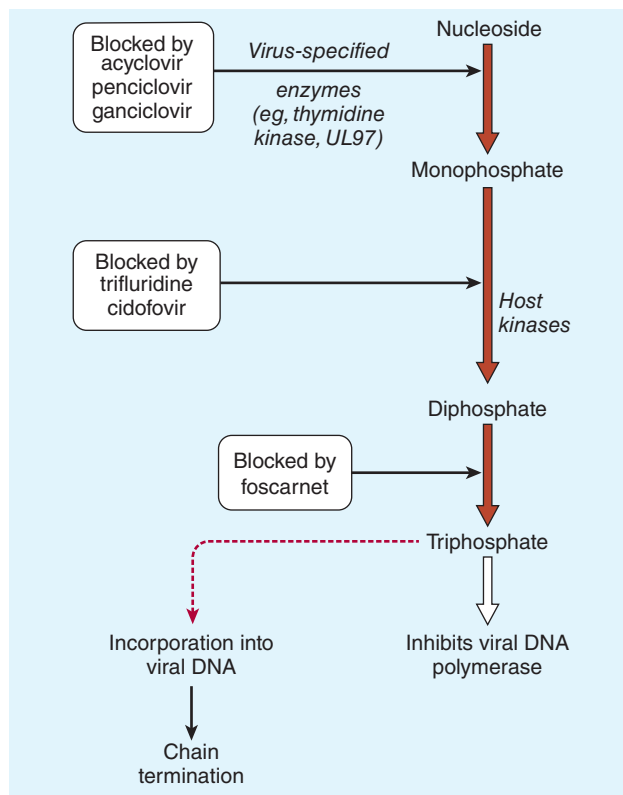

FIGURE 49–2 Mechanism of action of antiherpes agents.

acyclovir and approximate those achieved with intravenous acyclovir. Oral bioavailability is 54–70%, and cerebrospinal fluid levels are about 50% of those in serum. Elimination half-life is 2.5–3.3 hours.

Valacyclovir is generally well tolerated, although nausea, headache, vomiting, or rash may occur. At high doses, confusion, hallucinations, and seizures have been reported. AIDS patients who received high-dosage valacyclovir chronically (ie, 8 g/d) had increased gastrointestinal intolerance as well as thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome; this dose has also been associated with confusion and hallucinations in transplant patients. There is no evidence of an increased risk of birth defects in infants exposed to valacyclovir during pregnancy.

FAMCICLOVIR

Famciclovir is the diacetyl ester prodrug of 6-deoxypenciclovir, an acyclic guanosine analog. After oral administration, famciclovir is rapidly deacetylated and oxidized by first-pass metabolism to penciclovir. It is active in vitro against HSV-1, HSV-2, VZV, EBV, and HBV. As with acyclovir, activation by phosphorylation is catalyzed by the virus-specified thymidine kinase in infected cells, followed by competitive inhibition of the viral DNA polymerase to block DNA synthesis. Unlike acyclovir, however, penciclovir does not cause chain termination. Penciclovir triphosphate has lower affinity for the viral DNA polymerase than acyclovir triphosphate, but it achieves higher intracellular concentrations. The most commonly encountered clinical mutants of HSV are thymidine kinase-deficient; these are cross-resistant to acyclovir and famciclovir.

The bioavailability of penciclovir from orally administered famciclovir is 70%. The intracellular half-life of penciclovir triphosphate is prolonged, at 7–20 hours. Penciclovir is excreted primarily in the urine.

Oral famciclovir is generally well tolerated, although headache, nausea, or diarrhea may occur. As with acyclovir, testicular toxicity has been demonstrated in animals receiving repeated doses. However, men receiving daily famciclovir (250 mg every 12 hours) for 18 weeks had no changes in sperm morphology or motility. In one study, there was no evidence of increased birth defects in infants exposed to famciclovir during the first trimester. The incidence of mammary adenocarcinoma was increased in female rats receiving famciclovir for 2 years.

PENCICLOVIR

The guanosine analog penciclovir, the active metabolite of famciclovir, is available for topical use. Penciclovir cream (1%) shortened the median duration of recurrent herpes labialis by ~17 hours compared to placebo when applied within 1 hour of the onset of prodromal symptoms and continued every 2 hours during waking hours for 4 days. Adverse effects are uncommon, other than application site reactions in ~1%.

DOCOSANOL

Docosanol is a saturated 22-carbon aliphatic alcohol that inhibits fusion between the host cell plasma membrane and the HSV envelope, thereby preventing viral entry into cells and subsequent viral replication. Topical docosanol 10% cream is available without a prescription. When applied within 12 hours of the onset of prodromal symptoms, five times daily, median healing time was shortened by 18 hours compared with placebo in recurrent orolabial herpes. Application site reactions occur in ~2%.

TRIFLURIDINE

Trifluridine (trifluorothymidine) is a fluorinated pyrimidine nucleoside that inhibits viral DNA synthesis in HSV-1, HSV-2, CMV, vaccinia, and some adenoviruses. It is phosphorylated intracellularly by host cell enzymes, and then competes with thymidine triphosphate for incorporation by the viral DNA polymerase (Figure 49–2). Incorporation of trifluridine triphosphate into both viral and host DNA prevents its systemic use. Application of a 1% solution is effective in treating keratoconjunctivitis and recurrent epithelial keratitis due to HSV-1 or HSV-2. Cutaneous application of trifluridine solution, alone or in combination with interferon- α , has been used successfully in the treatment of acyclovir-resistant HSV infections.

INVESTIGATIONAL AGENTS

Two compounds (**pritelivir** and **amenamevir**) belong to the new class of helicase-primase inhibitors and are under development for HSV infection. **Valomaciclovir**, an inhibitor of the viral DNA polymerase, is currently under clinical evaluation for the treatment of patients with acute zoster and acute EBV infection (infectious mononucleosis).

■ AGENTS TO TREAT CYTOMEGALOVIRUS (CMV) INFECTIONS

CMV infections occur primarily in the setting of advanced immunosuppression and are typically due to reactivation of latent infection. Dissemination of infection results in end-organ disease, including retinitis, colitis, esophagitis, central nervous system disease, and pneumonitis. Although the incidence in HIV-infected patients has markedly decreased with the advent of potent antiretroviral therapy, clinical reactivation of CMV infection after organ transplantation is still prevalent.

The availability of oral valganciclovir has decreased the use of intravenous ganciclovir, intravenous foscarnet, and intravenous cidofovir for the prophylaxis and treatment of end-organ CMV disease (Table 49–2). Oral valganciclovir has replaced oral ganciclovir because of its lower pill burden.

TABLE 49–2 Agents to treat cytomegalovirus (CMV) infection.

Agent	Route of Administration	Use	Recommended Adult Dosage
Valganciclovir ¹	Oral	CMV retinitis treatment	Induction: 900 mg bid × 21 days Maintenance: 900 mg daily
	Oral	CMV prophylaxis (transplant patients)	900 mg daily
Ganciclovir ¹	Intravenous	CMV retinitis treatment	Induction: 5 mg/kg q12h × 14–21 days Maintenance: 5 mg/kg/d or 6 mg/kg five times per week
Foscarnet ¹	Intravenous	CMV retinitis treatment	Induction: 60 mg/kg q8h or 90 mg/kg q12h × 14–21 days Maintenance: 90–120 mg/kg/d
Cidofovir ¹	Intravenous	CMV retinitis treatment	Induction: 5 mg/kg/wk × 2 weeks Maintenance: 5 mg/kg every week

¹Dosage must be reduced in patients with renal insufficiency.

GANCICLOVIR

Ganciclovir is an acyclic guanosine analog that requires activation by triphosphorylation before inhibiting the viral DNA polymerase. Initial phosphorylation is catalyzed by the virus-specified protein kinase phosphotransferase UL97 in CMV-infected cells. The activated compound competitively inhibits viral DNA polymerase and causes termination of viral DNA elongation (Figure 49–2). Ganciclovir has in vitro activity against CMV, HSV, VZV, EBV, HHV-6, and HHV-8. Its activity against CMV is up to 100 times greater than that of acyclovir.

Ganciclovir is administered intravenously; the bioavailability of oral ganciclovir is poor, and it is no longer available in the USA. Ganciclovir gel is available for the treatment of acute herpetic keratitis. Cerebrospinal fluid concentrations are approximately 50% of serum concentrations. The elimination half-life is 4 hours, and the intracellular half-life is prolonged at 16–24 hours. Clearance of the drug is linearly related to creatinine clearance. Ganciclovir is readily cleared by hemodialysis.

Intravenous ganciclovir has been shown to delay progression of CMV retinitis in immunocompromised patients. Dual therapy with foscarnet and ganciclovir is more effective in delaying progression of retinitis than either drug alone in patients with AIDS (see Foscarnet), although adverse effects are compounded. Intravenous ganciclovir is also used to treat CMV colitis, esophagitis, and pneumonitis (the latter often in combination with intravenous cytomegalovirus immunoglobulin) in immunocompromised patients. Intravenous ganciclovir, followed by either oral ganciclovir or high-dose oral acyclovir, reduces the risk of CMV infection in transplant recipients. Limited data in infants with symptomatic congenital neurologic CMV disease suggest that treatment with IV ganciclovir may reduce hearing loss. The risk of Kaposi's sarcoma is reduced in AIDS patients receiving long-term ganciclovir, presumably because of activity against HHV-8.

Intravitreal injections of ganciclovir or the intraocular ganciclovir implant may be used to treat CMV retinitis. Concurrent therapy with a systemic anti-CMV agent is necessary to prevent other sites of end-organ CMV disease.

Resistance to ganciclovir increases with duration of use. The more common mutation, in UL97, results in decreased levels of the triphosphorylated (ie, active) form of ganciclovir. The less common UL54 mutation in DNA polymerase results in higher levels of resistance and potential cross-resistance with cidofovir and foscarnet. Antiviral susceptibility testing is recommended in patients in whom resistance is suspected clinically.

The most common adverse effect of intravenous ganciclovir treatment is myelosuppression, which although reversible may be dose-limiting. Other potential adverse effects are nausea, diarrhea, fever, rash, headache, insomnia, and peripheral neuropathy. Central nervous system toxicity (confusion, seizures, psychiatric disturbance) and hepatotoxicity have been rarely reported. Intravitreal ganciclovir has been associated with vitreous hemorrhage and retinal detachment. Ganciclovir is mutagenic in mammalian cells and carcinogenic and embryotoxic at high doses in animals and causes aspermatogenesis; the clinical significance of these preclinical data is unclear.

Levels of ganciclovir may rise in patients concurrently taking probenecid or trimethoprim. Concurrent use of ganciclovir with didanosine may result in increased levels of didanosine.

VALGANCICLOVIR

Valganciclovir is an L-valyl ester prodrug of ganciclovir that exists as a mixture of two diastereomers. After oral administration, both diastereomers are rapidly hydrolyzed to ganciclovir by esterases in the intestinal wall and liver.

Valganciclovir has a bioavailability of 60% and should be taken with food. The AUC_{0–24h} resulting from oral valganciclovir (900 mg once daily) is similar to that after 5 mg/kg once daily of intravenous ganciclovir and approximately 1.65 times that of oral ganciclovir. The major route of elimination is renal, through glomerular filtration and active tubular secretion. Plasma concentrations of valganciclovir are reduced ~50% by hemodialysis.

Valganciclovir is as effective as intravenous ganciclovir for the treatment of CMV retinitis and is also indicated for the prevention

of CMV disease in high-risk solid organ and bone marrow transplant recipients. Adverse effects, drug interactions, and resistance patterns are the same as those associated with ganciclovir.

FOSCARNET

Foscarnet (phosphonoformic acid) is an inorganic pyrophosphate analog that inhibits herpesvirus DNA polymerase, RNA polymerase, and HIV reverse transcriptase directly without requiring activation by phosphorylation. Foscarnet blocks the pyrophosphate binding site of these enzymes and inhibits cleavage of pyrophosphate from deoxynucleotide triphosphates. It has in vitro activity against HSV, VZV, CMV, EBV, HHV-6, HHV-8, HIV-1, and HIV-2.

Foscarnet is available in an intravenous formulation only; poor oral bioavailability and gastrointestinal intolerance preclude oral use. Cerebrospinal fluid concentrations are 43–67% of steady-state serum concentrations. Although the mean plasma half-life is 3–7 hours, up to 30% of foscarnet may be deposited in bone, with a half-life of several months. The clinical repercussions of this are unknown. Clearance of foscarnet is primarily renal and is directly proportional to creatinine clearance. Serum drug concentrations are reduced ~50% by hemodialysis.

Foscarnet is effective in the treatment of end-organ CMV disease (ie, retinitis, colitis, and esophagitis), including ganciclovir-resistant disease; it is also effective against acyclovir-resistant HSV and VZV infections. The dosage of foscarnet must be titrated according to the patient's calculated creatinine clearance before each infusion. Use of an infusion pump to control the rate of infusion is important to prevent toxicity, and large volumes of fluid are required because of the drug's poor solubility. The combination of ganciclovir and foscarnet is synergistic in vitro against CMV and has been shown to be superior to either agent alone in delaying progression of retinitis; however, toxicity is also increased when these agents are administered concurrently. As with ganciclovir, a decrease in the incidence of Kaposi's sarcoma has been observed in patients who have received long-term foscarnet.

Foscarnet has been administered intravitreally for the treatment of CMV retinitis in patients with AIDS, but data regarding efficacy and safety are incomplete.

Resistance to foscarnet in HSV and CMV isolates is due to point mutations in the DNA polymerase gene and is typically associated with prolonged or repeated exposure to the drug. Mutations in the HIV-1 reverse transcriptase gene have also been described. Although foscarnet-resistant CMV isolates are typically cross-resistant to ganciclovir, foscarnet activity is usually maintained against ganciclovir- and cidofovir-resistant isolates of CMV.

Potential adverse effects of foscarnet include renal impairment, hypo- or hypercalcemia, hypo- or hyperphosphatemia, hypokalemia, and hypomagnesemia. Saline preloading helps prevent nephrotoxicity, as does avoidance of concomitant administration of drugs with nephrotoxic potential (eg, amphotericin B, pentamidine, aminoglycosides). The risk of severe hypocalcemia, caused by chelation of divalent cations, is increased with concomitant use of pentamidine. Genital ulcerations associated with foscarnet

therapy may be due to high levels of ionized drug in the urine. Nausea, vomiting, anemia, elevation of liver enzymes, and fatigue have been reported; the risk of anemia may be additive in patients receiving concurrent zidovudine. Central nervous system toxicity includes headache, hallucinations, and seizures; the risk of seizures may be increased with concurrent use of imipenem. Foscarnet caused chromosomal damage in preclinical studies.

CIDOFOVIR

Cidofovir is a cytosine nucleotide analog with in vitro activity against CMV, HSV-1, HSV-2, VZV, EBV, HHV-6, HHV-8, adenovirus, poxviruses, polyomaviruses, and human papillomavirus. In contrast to ganciclovir, phosphorylation of cidofovir to the active diphosphate is independent of viral enzymes (Figure 49–2); thus activity is maintained against thymidine kinase-deficient or altered strains of CMV or HSV. Cidofovir diphosphate acts both as a potent inhibitor of and as an alternative substrate for viral DNA polymerase, competitively inhibiting DNA synthesis and becoming incorporated into the viral DNA chain. Cidofovir-resistant isolates tend to be cross-resistant with ganciclovir but retain susceptibility to foscarnet.

Although the terminal half-life of cidofovir is approximately 2.6 hours, the active metabolite cidofovir diphosphate has a prolonged intracellular half-life of 17–65 hours, thus allowing infrequent dosing. A separate metabolite, cidofovir phosphocholine, has a half-life of at least 87 hours and may serve as an intracellular reservoir of active drug. Cerebrospinal fluid penetration is poor. Elimination is by active renal tubular secretion. High-flux hemodialysis reduces serum levels of cidofovir by approximately 75%.

Intravenous cidofovir is effective for the treatment of CMV retinitis and is used experimentally to treat adenovirus, human papillomavirus, BK polyomavirus, vaccinia, and poxvirus infections. Intravenous cidofovir must be administered with high-dose probenecid (2 g at 3 hours before the infusion and 1 g at 2 and 8 hours after), which blocks active tubular secretion and decreases nephrotoxicity. Before each infusion, cidofovir dosage must be adjusted for alterations in the calculated creatinine clearance or for the presence of urine protein, and aggressive adjunctive hydration is required. Initiation of cidofovir therapy is contraindicated in patients with existing renal insufficiency. Direct intravitreal administration of cidofovir is not recommended because of ocular toxicity.

The primary adverse effect of intravenous cidofovir is a dose-dependent proximal tubular nephrotoxicity, which may be reduced with prehydration using normal saline. Proteinuria, azotemia, metabolic acidosis, and Fanconi's syndrome may occur. Concurrent administration of other potentially nephrotoxic agents (eg, amphotericin B, aminoglycosides, nonsteroidal anti-inflammatory drugs, pentamidine, foscarnet) should be avoided. Prior administration of foscarnet may increase the risk of nephrotoxicity. Other potential adverse effects include uveitis, ocular hypotony, and neutropenia (15–24%). Concurrent probenecid use may result in other toxicities or drug-drug interactions (see Chapter 36). Cidofovir is mutagenic, gonadotoxic, and embryotoxic, and causes hypospermia and mammary adenocarcinomas in animals.

EXPERIMENTAL AGENTS

Brincidofovir is a nucleoside agent with activity against HSV, CMV, adenovirus, BK virus, and poxvirus. It is currently under clinical investigation for CMV and adenovirus infections.

■ ANTIRETROVIRAL AGENTS

Substantial advances have been made in antiretroviral therapy since the introduction of the first agent, zidovudine, in 1987. Six classes of antiretroviral agents are currently available for use: nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), fusion inhibitors, CCR5 co-receptor antagonists, and integrase strand transfer inhibitors (INSTIs) (Table 49–3). These agents inhibit HIV replication at different parts of the cycle (Figure 49–3).

Knowledge of viral dynamics through the use of viral load and resistance testing has made it clear that combination therapy with maximally potent agents will reduce viral replication to the lowest possible level, thereby reducing the number of cumulative mutations and decreasing the likelihood of emergence of resistance. Thus, administration of combination antiretroviral therapy, typically including at least three antiretroviral agents with differing susceptibility patterns, has become the standard of care. Viral susceptibility to specific agents varies among patients and may change with time. Therefore, such combinations must be chosen with care and tailored to the individual, as must changes to a given regimen. In addition to potency and susceptibility, important factors in the selection of agents for any given patient are tolerability, convenience, and optimization of adherence. New drugs with high potency, low toxicity, and good tolerability increase the feasibility of early, lifelong treatment. As new agents have become available, several older ones have had diminished usage, because of either suboptimal safety or inferior efficacy. Zalcitabine (ddC; dideoxycytidine) is no longer marketed, and regimens containing zidovudine (AZT; azidothymidine), ddI (didanosine), or stavudine (d4T) are infrequently recommended as first-line regimens.

Decrease of the circulating viral load by antiretroviral therapy is correlated with enhanced survival as well as decreased morbidity. Also, the use of antiretroviral therapy strongly reduces the risk for heterosexual and same-sex HIV transmission.

Discussion of antiretroviral agents in this chapter is specific to HIV-1. Patterns of susceptibility of HIV-2 to these agents may vary; however, there is innate resistance to the NNRTIs and enfuvirtide as well as a lower barrier of resistance to NRTIs and PIs.

NUCLEOSIDE & NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTIs)

The NRTIs act by competitive inhibition of HIV-1 reverse transcriptase; incorporation into the growing viral DNA chain causes premature chain termination due to inhibition of binding with

the incoming nucleotide (Figure 49–3). Each agent requires intracytoplasmic activation via phosphorylation by cellular enzymes to the triphosphate form.

Typical resistance mutations include M184V, L74V, D67N, and M41L. Lamivudine or emtricitabine therapy tends to select rapidly for the M184V mutation in regimens that are not fully suppressive. While the M184V mutation confers reduced susceptibility to abacavir, didanosine, and zalcitabine, its presence may restore phenotypic susceptibility to zidovudine. The K65R/N mutation is associated with reduced susceptibility to tenofovir, abacavir, lamivudine, and emtricitabine.

All NRTIs may be associated with mitochondrial toxicity, which may manifest as peripheral neuropathy, pancreatitis, lipatrophy, and hepatic steatosis. Less commonly, lactic acidosis may occur, which can be fatal. NRTI treatment should be suspended in the setting of rapidly rising aminotransferase levels, progressive hepatomegaly, or metabolic acidosis of unknown cause. Lipatrophy and insulin resistance may occur most frequently with use of the thymidine analogs stavudine and zidovudine, and least frequently with use of tenofovir, lamivudine, emtricitabine, and abacavir.

ABACAVIR

Abacavir is a guanosine analog that is well absorbed following oral administration (83%) and is unaffected by food. The serum half-life is 1.5 hours. The drug undergoes hepatic glucuronidation and carboxylation. Dosage reduction is recommended in mild hepatic impairment; no data are available for patients with moderate or severe liver disease. Since the drug is metabolized by alcohol dehydrogenase, serum levels of abacavir may be increased with concurrent alcohol (ie, ethanol) ingestion. Cerebrospinal fluid levels are approximately one-third those of plasma. Abacavir is one of the NRTI agents recommended for use in pregnancy (Table 49–5).

Hypersensitivity reactions, occasionally fatal, have been reported in up to 8% of patients receiving abacavir and may be more severe in association with once-daily dosing. Symptoms, which generally occur within the first 6 weeks of therapy, include fever, fatigue, nausea, vomiting, diarrhea, and abdominal pain. Dyspnea, pharyngitis, and cough, and elevations in serum aminotransferase or creatine kinase levels may also be present, with skin rash in ~50% of patients. Rechallenge is contraindicated. Screening for HLA-B*5701 before initiation of abacavir therapy is important to identify patients with an increased risk for abacavir-associated hypersensitivity reaction (see Table 5–4). Although the positive predictive value of this test is only about 50%, it has a negative predictive value approaching 100%.

Rash occurs in approximately 5% of patients, typically in the first 6 weeks of treatment. Less frequent adverse events are fever, nausea, vomiting, diarrhea, headache, dyspnea, fatigue, and pancreatitis. In some studies but not in others, abacavir has been associated with an increased risk of myocardial infarction. The class effects of mitochondrial toxicity and disorders of lipid metabolism seem to be less common with abacavir than with other nucleoside analogs.

TABLE 49–3 Currently available antiretroviral agents.

Agent	Class of Agent	Recommended Adult Dosage	Administration Recommendation	Characteristic Adverse Effects	Comments
Abacavir	NRTI ¹	300 mg bid or 600 mg qd	Test to rule out the presence of the HLA-B5701 allele prior to initiation of therapy.	Rash, hypersensitivity reaction, nausea; possible increase in myocardial infarction	Avoid alcohol.
Atazanavir	PI ²	400 mg qd or 300 mg qd with ritonavir 100 mg qd or cobicistat 150 mg qd; adjust dose in hepatic insufficiency	Take with food. Avoid concomitant antacids. Separate dosing acid-reducing agents by ≥10 h.	Nausea, rash, myalgia, indirect hyperbilirubinemia, diarrhea, ↑ liver enzymes, prolonged PR interval	See footnote 4. Avoid elvitegravir/cobicistat, etravirine, fosamprenavir, nevirapine, tipranavir. Avoid in severe hepatic insufficiency. The oral powder contains phenylalanine.
Darunavir	PI ²	Treatment-naïve: 800 mg qd with ritonavir 100 mg qd or cobicistat 150 mg qd Treatment-experienced: 600 mg bid with ritonavir 100 mg bid	Take with food.	Diarrhea, headache, nausea, rash, hyperlipidemia, ↑ liver enzymes, ↑ serum amylase	See footnote 4. Avoid elvitegravir/cobicistat and simeprevir. Avoid in patients with sulfa allergy.
Delavirdine	NNRTI	400 mg tid	Separate dosing from ddl or antacids by ≥1 h.	Rash, ↑ liver enzymes, headache, nausea, diarrhea	See footnote 4. Avoid concurrent fosamprenavir. Teratogenic in rats.
Didanosine (ddI)	NRTI ¹	Tablets, 400 mg qd or 200 mg bid ³ adjusted for weight Buffered powder, 250 mg bid ³	Take on an empty stomach.	Peripheral neuropathy, pancreatitis, diarrhea.	Avoid concurrent neuropathic drugs (eg, stavudine, zalcitabine, isoniazid), ribavirin, or allopurinol. Chewable tablets contain phenylalanine.
Dolutegravir	INSTI	INSTI-naïve: 50 mg qd If co-administered with efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin or if certain INSTI mutations: 50 mg bid	Separate dosing from antacids and polyvalent cations by ≥2 h.	Insomnia, headache, hypersensitivity reaction, ↑ liver enzymes	Avoid carbamazepine, dofetilide, nevirapine, phenobarbital, phenytoin.
Efavirenz	NNRTI	600 mg qd	Take on an empty stomach, at bedtime.	Neuropsychiatric symptoms, rash, ↑ liver enzymes, headache, nausea	See footnote 4. Avoid elvitegravir/cobicistat, etravirine, indinavir, simeprevir. Teratogenic in primates.
Elvitegravir	INSTI	Treatment-naïve: 150 mg qd with cobicistat 150, emtricitabine 200, and tenofovir Treatment-experienced: 85 mg–150 mg qd with a protease inhibitor	Take with food. Separate dosing from antacids by ≥2 h.	Diarrhea, rash, ↑ liver enzymes	See footnote 4. Avoid efavirenz and nevirapine.
Emtricitabine	NRTI ¹	200 mg qd ³		Headache, diarrhea, nausea, rash, hyperpigmentation	Avoid concurrent lamivudine.

(continued)

TABLE 49-3 Currently available antiretroviral agents. (Continued)

Agent	Class of Agent	Recommended Adult Dosage	Administration Recommendation	Characteristic Adverse Effects	Comments
Enfuvirtide	Fusion inhibitor	90 mg subcutaneously bid		Injection site reactions, hypersensitivity reaction, insomnia, headache, dizziness, nausea, eosinophilia; possible increased bacterial pneumonia	
Etravirine	NNRTI	200 mg bid	Take with food.	Rash, nausea, diarrhea	See footnote 4. Avoid atazanavir, efavirenz, elvitegravir/cobicistat, fosamprenavir, indinavir, tipranavir.
Fosamprenavir	PI ²	1400 mg bid or 700 mg bid with ritonavir 100 mg bid or 1400 mg daily with ritonavir 100–200 mg qd; adjust dose in hepatic insufficiency		Rash, diarrhea, nausea, headache, ↑ liver enzymes	See footnote 4. Avoid elvitegravir/cobicistat, etravirine, lopinavir/ritonavir, nevirapine. Avoid in patients with sulfa allergy or severe hepatic insufficiency. Avoid cimetidine, disulfiram, metronidazole, vitamin E, ritonavir oral solution, and alcohol with the oral solution.
Indinavir	PI ²	800 mg tid or 800 mg bid with ritonavir 100–200 mg bid; adjust dose in cirrhosis	Best on an empty stomach. Drink at least 48 oz liquid daily. Separate dosing from ddl by ≥ 1 h.	Nephrolithiasis, nausea, indirect hyperbilirubinemia, headache, diarrhea; possible increase in myocardial infarction	See footnote 4. Avoid efavirenz and etravirine.
Lamivudine	NRTI ¹	150 mg bid or 300 mg qd ³		Nausea, headache, dizziness, fatigue	Do not administer with emtricitabine or zalcitabine.
Lopinavir/ritonavir	PI/PI ²	400/100 mg bid or 800/200 mg qd	Separate dosing from ddl by 1 h.	Diarrhea, nausea, hypertriglyceridemia, ↑ liver enzymes; possible increase in myocardial infarction	See footnote 4. Avoid darunavir, elvitegravir/cobicistat, fosamprenavir, tipranavir. Avoid disulfiram and metronidazole with oral solution.
Maraviroc	CCR5 inhibitor	300 mg bid; 150 bid with CYP3A inhibitors; 600 mg bid with CYP3A inducers		Cough, muscle pain, diarrhea, sleep disturbance, ↑ liver enzymes; possible increase in myocardial infarction	See footnote 4. Do not administer in patients with severe renal dysfunction.
Nelfinavir	PI ²	750 mg tid or 1250 mg bid	Take with food.	Diarrhea, nausea, flatulence	See footnote 4. The oral powder contains phenylalanine.
Nevirapine	NNRTI	200 mg bid	Dose-escalate from 200 mg daily over 14 days.	Rash, hepatitis (occasionally fulminant), nausea, headache	See footnote 4. Avoid atazanavir, dolutegravir, elvitegravir/cobicistat, fosamprenavir. Contraindicated with moderate or severe hepatic impairment.
Raltegravir	INSTI	400 mg bid		Nausea, headache, fatigue, muscle aches, ↑ amylase levels, ↑ liver enzymes	The chewable tablets contain phenylalanine.
Rilpivirine	NNRTI	25 mg qd	Take with food. Separate dosing from antacids or H ₂ blockers by ≥ 4 h.	Headache, insomnia, depression, rash, ↑ liver enzymes	See footnote 4.

Rilpivirine	PI ²	1000 mg bid with ritonavir 100 mg bid	Take within 2 h of a full meal.	Nausea, diarrhea, abdominal pain, dyspepsia, rash	See footnote 4. Avoid darunavir, garlic capsules, tipranavir and drugs that increase the QT interval. Avoid in severe hepatic insufficiency.
Stavudine	NRTI ¹	30–40 mg bid, depending on weight ³		Peripheral neuropathy, pancreatitis, rapidly progressive ascending neuromuscular weakness (rare)	Avoid zidovudine and neuropathic drugs (eg, ddl, zalcitabine, isoniazid).
Tenofovir alafenamide	NRTI ¹	10 mg qd with emtricitabine plus elvitegravir/cobicistat; 25 mg qd with emtricitabine ± rilpivirine		Gastrointestinal symptoms, headache, ↑ creatinine, proteinuria	Avoid inducers of p-glycoprotein (rifampin, rifabutin, phenytoin, phenobarbital, St John's Wort, tipranavir/ritonavir). Also avoid in severe renal insufficiency.
Tenofovir disoproxil fumarate	NRTI ¹	300 mg qd ³		Nausea, diarrhea, vomiting, flatulence, headache, renal insufficiency	Avoid atazanavir, didanosine, probenecid.
Tipranavir	PI ²	500 mg bid with ritonavir 200 mg bid	Take with food. Separate from ddl by ≥2 h. Avoid antacids.	Diarrhea, nausea, vomiting, abdominal pain, rash, ↑ liver enzymes, hyperlipidemia	See footnote 4. Avoid concurrent atazanavir, elvitegravir/cobicistat, etravirine, fosamprenavir, lopinavir/ritonavir, saquinavir. Avoid in patients with severe hepatic insufficiency, who are at risk for bleeding, or with sulfa allergy. Avoid vitamin E with the oral solution.
Zidovudine	NRTI ¹	200 mg tid or 300 mg bid ³		Macrocytic anemia, neutropenia, nausea, headache, insomnia, myopathy	Avoid concurrent stavudine and myelosuppressive drugs (eg, ganciclovir, ribavirin).

¹All NRTI agents carry the risk of lactic acidosis with hepatic steatosis as a potential adverse event.

²All PI agents carry the risk of hyperlipidemia, fat maldistribution, hyperglycemia, and insulin resistance as potential adverse events.

³Adjust dose in renal insufficiency.

⁴Because of altered systemic exposures, concurrent drugs that interact with the CYP3A4 system should be used with caution, including alfuzosin, amiodarone, aprepitant, artemether/lumefantrine, astemizole, atovaquone, benzodiazepines (diazepam, midazolam, triazolam), bexarotene, bepridil, bosentan, bupropion, calcium channel blockers (diltiazem, felodipine, nifedipine, verapamil), carbamazepine, certinib, cimetidine, cisapride, clopidogrel, colchicine, conivaptan, corticosteroids, cyclosporine, dabrafenib, dapson, desipramine, direct Factor Xa inhibitors (apixaban, rivaroxaban), disopyramide, dofenilide, dronedarone, enzalutamide, ergot alkaloid derivatives, ethinyl estradiol/norethindrone acetate, flecainide, fluticasone, gestodene, idelalisib, irinotecan, ivacaftor, levodopa, lisdacaine, lumacaftor, lurasidone, macrolide agents (clarithromycin, telithromycin), methadone, mitotane, nafcillin, PDE5 inhibitors, phenobarbital, phenytoin, pimozide, primidone, propafenone, protein pump inhibitors, quinidine, ranolazine, rifabutin, salmeterol, spironolactone, statin agents, St. John's wort, tacrolimus, triazole antifungal agents (itraconazole ketoconazole, posaconazole, voriconazole), terfenadine, and warfarin.

INSTI, integrase strand transfer inhibitor; NNRTI, nonnucleoside reverse transcriptase inhibitor; NRTI, nucleoside/nucleotide reverse transcriptase inhibitor; PI, protease inhibitor.

FIGURE 49-3 Life cycle of HIV. Binding of viral glycoproteins to host cell CD4 and chemokine receptors leads to fusion of the viral and host cell membranes via gp41 and entry of the virion into the cell. After uncoating, reverse transcription copies the single-stranded HIV RNA genome into double-stranded DNA, which is integrated into the host cell genome. Gene transcription by host cell enzymes produces messenger RNA, which is translated into proteins that assemble into immature noninfectious virions that bud from the host cell membrane. Maturation into fully infectious virions is through proteolytic cleavage. NNRTIs, nonnucleoside reverse transcriptase inhibitors; NRTIs, nucleoside/nucleotide reverse transcriptase inhibitors.

DIDANOSINE

Didanosine (ddI) is a synthetic analog of deoxyadenosine. Oral bioavailability is approximately 40%. Buffered or enteric-coated formulations are necessary to prevent inactivation by gastric acid. Cerebrospinal fluid concentrations of the drug are approximately 20% of serum concentrations. Serum half-life is 1.5 hours, but the intracellular half-life of the activated compound is 20–24 hours.

The drug is eliminated by both cellular metabolism and renal excretion.

The major clinical toxicities associated with didanosine therapy are peripheral distal sensory neuropathy and dose-dependent pancreatitis. Therefore, co-administration with drugs or conditions that increase the risk of either (eg, alcohol abuse, hypertriglyceridemia, pregnancy, zalcitabine, stavudine, isoniazid, vincristine, ribavirin, and hydroxyurea), should be avoided. Other reported adverse effects

include diarrhea (particularly with the buffered formulation), hepatitis, esophageal ulceration, cardiomyopathy, central nervous system toxicity (headache, irritability, insomnia), and hypertriglyceridemia. Concurrent stavudine increases the risk of lactic acidosis. Reports of retinal changes and optic neuritis in patients receiving didanosine, particularly in adults receiving high doses and in children, mandate periodic retinal examinations.

Increased levels of didanosine when administered with tenofovir necessitate dose reduction. Concurrent allopurinol or ribavirin is contraindicated. The buffer in didanosine tablets interferes with the absorption of delavirdine and nelfinavir, necessitating separation in time. The chewable tablets contain phenylalanine, which can be harmful to patients with phenylketonuria.

EMTRICITABINE

Emtricitabine (FTC) is a fluorinated analog of lamivudine with a long intracellular half-life (>24 hours), allowing for once-daily dosing. Oral bioavailability of the capsules is 93% and is unaffected by food, but penetration into the cerebrospinal fluid is low. Elimination is by both glomerular filtration and active tubular secretion. The serum half-life is about 10 hours.

Emtricitabine is one of the NRTI agents recommended for use in pregnancy (Table 49–5). The combination of tenofovir and emtricitabine is recommended as pre-exposure prophylaxis to reduce HIV acquisition in high-risk persons.

Both emtricitabine and lamivudine may select for the M184V/I mutation and therefore should not be used together.

The most common adverse effects observed in patients receiving emtricitabine are headache, diarrhea, nausea, and rash. Hyperpigmentation of the palms or soles may be observed (~3%), particularly in African Americans (up to 13%). Clinically significant drug-drug interactions involving emtricitabine have not been identified. Due to its activity against HBV, exacerbation of HBV may occur if therapy is interrupted or discontinued in patients co-infected with HIV.

LAMIVUDINE

Lamivudine (3TC) is a cytosine analog with in vitro activity against both HIV-1 and HBV.

Oral bioavailability exceeds 80% and is not food-dependent. The mean cerebrospinal fluid:plasma ratio of lamivudine is 0.1–0.2. Serum half-life is 2.5 hours, whereas the intracellular half-life of the triphosphorylated compound is 11–14 hours. Lamivudine is predominantly eliminated in the urine by active organic cation secretion.

Lamivudine is one of the recommended NRTI agents for use in pregnant women (Table 49–5).

Adverse effects are uncommon but include headache, dizziness, insomnia, fatigue, dry mouth, and gastrointestinal discomfort. Due to its activity against HBV, exacerbation of HBV may occur if therapy is interrupted or discontinued in patients co-infected with HIV and HBV. Since both emtricitabine and lamivudine may select for the M184V/I mutation, these agents should not be used

together. Levels of lamivudine may increase when administered with trimethoprim-sulfamethoxazole. Lamivudine and zalcitabine may inhibit the intracellular phosphorylation of one another; therefore, their concurrent use should be avoided if possible.

STAVUDINE

The thymidine analog stavudine (d4T) has high oral bioavailability (86%) that is not food-dependent. The serum half-life is 1.1 hours, the intracellular half-life is 3.0–3.5 hours, and mean cerebrospinal fluid concentrations are 55% of those of plasma. Excretion is by active tubular secretion and glomerular filtration.

The major toxicity is a dose-related peripheral sensory neuropathy; incidence may be increased with concomitant neurotoxic drugs such as didanosine, vincristine, isoniazid, or ribavirin, or in patients with advanced immunosuppression. Other potential adverse effects are pancreatitis, arthralgias, and elevation in serum aminotransferases. Caution is advised in patients with liver dysfunction. A rare adverse effect is a rapidly progressive ascending neuromuscular weakness. Lactic acidosis with hepatic steatosis, as well as lipodystrophy, appear to occur more frequently in patients receiving stavudine than in those receiving other NRTI agents. Stavudine should not be administered with didanosine due to increased risk of both lactic acidosis and pancreatitis. This combination has been implicated in several deaths in HIV-infected pregnant women. Since zidovudine may reduce the intracellular phosphorylation of stavudine, these two drugs should not be used together.

TENOFOVIR DISOPROXIL FUMARATE

Tenofovir is an acyclic nucleoside phosphonate (ie, nucleotide) analog of adenosine with activity against HIV and HBV. Like the nucleoside analogs, tenofovir competitively inhibits HIV reverse transcriptase and causes chain termination after incorporation into DNA. However, only two rather than three intracellular phosphorylations are required for active inhibition of DNA synthesis.

Tenofovir disoproxil fumarate is a water-soluble prodrug of active tenofovir. The oral bioavailability increases from 25% in the fasted state to 39% after a high-fat meal. The prolonged serum (12–17 hours) and intracellular half-lives allow once-daily dosing. Elimination occurs by both glomerular filtration and active tubular secretion, and dosage adjustment in patients with renal insufficiency is recommended.

Tenofovir disoproxil fumarate is one of the NRTI agents recommended for use in pregnancy (Table 49–5). The combination of tenofovir and emtricitabine is recommended as pre-exposure prophylaxis to reduce HIV acquisition in high-risk persons.

Gastrointestinal complaints (eg, nausea, diarrhea, vomiting, flatulence) are the most common adverse effects but rarely require discontinuation. Since tenofovir is formulated with lactose, these may occur more frequently in patients with lactose intolerance. Cumulative loss of renal function has been observed, possibly increased with concurrent use of boosted PI regimens. Acute renal

failure and Fanconi's syndrome have also been reported. For this reason, tenofovir should be used with caution in patients at risk for renal dysfunction. Serum creatinine levels should be monitored during therapy and tenofovir discontinued for new proteinuria, glycosuria, or calculated glomerular filtration rate <30 mL/min. Tenofovir-associated proximal renal tubulopathy causes excessive renal phosphate and calcium losses and 1-hydroxylation defects of vitamin D; loss of bone mineral density and osteomalacia have been reported. Tenofovir may compete with other drugs that are actively secreted by the kidneys, such as cidofovir, acyclovir, and ganciclovir. Concurrent use of probenecid is contraindicated. Tenofovir levels may increase, and levels of telaprevir decrease, when these agents are co-administered. Due to its activity against HBV, exacerbation of HBV may occur if therapy is interrupted or discontinued in patients co-infected with HIV and HBV.

TENOFOVIR ALAFENAMIDE

Tenofovir alafenamide is a phosphonoamidate prodrug of tenofovir that is currently available in co-formulation with other antiretroviral agents (with emtricitabine, with elvitegravir plus cobicistat plus emtricitabine, and with rilpivirine plus emtricitabine). Plasma levels of active tenofovir in plasma are approximately 90% lower with tenofovir alafenamide than with tenofovir disoproxil, since metabolism occurs in lymphocytes and macrophages (as well as hepatocytes and some other cells) rather than blood.

Tenofovir alafenamide is a substrate of P-glycoprotein, and levels of tenofovir can be affected by inhibitors or inducers of P-glycoprotein. Ritonavir and cobicistat can increase plasma concentrations of tenofovir, while darunavir can decrease tenofovir concentrations.

Tenofovir alafenamide appears to have less renal and bone toxicity than tenofovir disoproxil fumarate; however this is still under investigation. It does not require dose adjustment in patients with creatinine clearance >30 mL/min.

Tenofovir alafenamide is a substrate of P-glycoprotein, and levels of tenofovir can be affected by inhibitors or inducers of P-glycoprotein. Ritonavir and cobicistat can increase plasma concentrations of tenofovir, while darunavir can decrease tenofovir concentrations.

Adverse effects appear to be uncommon but may include gastrointestinal symptoms or headache. Tenofovir alafenamide is active against hepatitis B and has been approved for treatment of HBV infection.

ZIDOVUDINE

Zidovudine (azidothymidine; AZT) is a deoxythymidine analog that is well absorbed (63%) and distributed to most body tissues and fluids, including the cerebrospinal fluid, where drug levels are 60–65% of those in serum. Although the serum half-life averages 1 hour, the intracellular half-life of the phosphorylated compound is 3–4 hours, allowing twice-daily dosing. Zidovudine

is eliminated primarily by renal excretion following glucuronidation in the liver.

Zidovudine was the first antiretroviral agent to be approved and has been well studied. Studies evaluating the use of zidovudine during pregnancy, labor, and postpartum showed significant reductions in the rate of vertical transmission, and zidovudine remains one of the NRTI agents recommended for use in pregnant women (Table 49–5). Zidovudine is also recommended as an option for postexposure prophylaxis in individuals exposed to HIV.

The most common adverse effects of zidovudine are macrocytic anemia (1–4%) and neutropenia (2–8%). Gastrointestinal intolerance, headaches, and insomnia may occur but tend to resolve during therapy. A symptomatic myopathy may occur with prolonged use. Lipoatrophy appears to be more common in patients receiving zidovudine or other thymidine analogs. High doses can cause anxiety, confusion, and tremulousness.

Induction or inhibition of glucuronidation may alter serum levels of zidovudine when co-administered with atovaquone, lopinavir/ritonavir, probenecid, or valproic acid. Concurrent stavudine is contraindicated due to competitive inhibition of intracellular phosphorylation.

NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTIs)

The NNRTIs bind directly to HIV-1 reverse transcriptase (Figure 49–3), resulting in allosteric inhibition of RNA- and DNA-dependent DNA polymerase activity. The binding site of NNRTIs is near to but distinct from that of NRTIs. Unlike the NRTI agents, NNRTIs neither compete with nucleoside triphosphates nor require phosphorylation to be active.

The second-generation NNRTIs (etravirine, rilpivirine) have higher potency, longer half-lives and reduced side-effect profiles compared with older NNRTIs (delavirdine, efavirenz, nevirapine).

Baseline genotypic testing is recommended prior to initiating NNRTI treatment because primary resistance rates range from approximately 2% to 8%. NNRTI resistance occurs rapidly with monotherapy and can result from a single mutation. The K103N and Y181C mutations confer resistance to the first-generation NNRTIs, but not to etravirine or rilpivirine. Other mutations (eg, L100I, Y188C, G190A) may also confer cross-resistance among the NNRTI class. However, there is no cross-resistance between the NNRTIs and the NRTIs; in fact, some nucleoside-resistant viruses display hypersusceptibility to NNRTIs.

As a class, NNRTI agents tend to be associated with varying levels of gastrointestinal intolerance and skin rash, the latter of which may infrequently be serious (eg, Stevens-Johnson syndrome). A further limitation to use of NNRTI agents as a component of antiretroviral therapy is their metabolism by the CYP450 system, leading to innumerable potential drug-drug interactions (Tables 49–3 and 49–4). All NNRTI agents are substrates for CYP3A4 and can act as inducers (nevirapine), inhibitors (delavirdine), or mixed inducers and inhibitors (efavirenz, etravirine).

TABLE 49–4 Clinically significant drug-drug interactions pertaining to two-drug antiretroviral combinations.¹

Agent	Drugs That Increase Its Serum Levels	Drugs That Decrease Its Serum Levels
Atazanavir	Ritonavir	Didanosine, efavirenz, elvitegravir/cobicistat, etravirine, fosamprenavir, nevirapine, stavudine, tenofovir, tipranavir
Darunavir	Indinavir	Efavirenz, lopinavir/ritonavir, saquinavir
Delavirdine ²		Didanosine, fosamprenavir
Didanosine	Tenofovir	Atazanavir, ritonavir
Dolutegravir		Efavirenz, etravirine, nevirapine
Efavirenz ²	Darunavir	
Elvitegravir ³	Ritonavir	Efavirenz, nevirapine
Etravirine	Atazanavir, delavirdine, indinavir, lopinavir/ritonavir	Efavirenz, nevirapine, ritonavir, saquinavir, tipranavir
Fosamprenavir	Atazanavir, delavirdine, etravirine, ritonavir	Didanosine, efavirenz, lopinavir/ritonavir, maraviroc, nevirapine, tipranavir
Indinavir	Darunavir, delavirdine, nelfinavir, ritonavir	Didanosine, efavirenz, etravirine, nevirapine
Lopinavir/ritonavir	Darunavir	Didanosine, efavirenz, fosamprenavir, nelfinavir, nevirapine, tipranavir
Maraviroc	Atazanavir, darunavir, lopinavir/ritonavir, nevirapine, saquinavir, ritonavir	Efavirenz, etravirine, tipranavir
Nelfinavir	Delavirdine, indinavir, ritonavir, saquinavir	
Nevirapine ²	Fosamprenavir	
Raltegravir	Atazanavir	Etravirine, tipranavir
Rilpivirine ²	Darunavir, lopinavir/ritonavir	
Saquinavir	Atazanavir, delavirdine, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir	Efavirenz, etravirine, nevirapine, tipranavir
Tenofovir alafenamide	Ritonavir	Darunavir
Tenofovir disoproxil fumarate	Atazanavir	
Tipranavir		Efavirenz

¹Dose adjustment may be necessary if co-administered.

²NNRTI-NNRTI drug-drug interactions are not listed.

³Drug-drug interactions are rare with elvitegravir as a single agent but multiple if co-administered with either cobicistat or ritonavir.

Given the large number of non-HIV medications that are also metabolized by this pathway (see Chapter 4), drug-drug interactions must be expected and looked for; dosage adjustments are frequently required and some combinations are contraindicated.

DELAVIRDINE

Delavirdine has an oral bioavailability of about 85%, but this is reduced by antacids or H₂-blockers. It is extensively bound (~98%) to plasma proteins and has correspondingly low cerebrospinal fluid levels. Serum half-life is approximately 6 hours.

Skin rash occurs in up to 38% of patients receiving delavirdine; it typically occurs during the first 1–3 weeks of therapy and does not preclude rechallenge. However, severe rash such as erythema multiforme and Stevens-Johnson syndrome have rarely been reported. Other possible adverse effects are headache, fatigue, nausea, diarrhea, and increased serum aminotransferase levels. Delavirdine has been shown to be teratogenic in rats, causing ventricular septal defects and other malformations at dosages

not unlike those achieved in humans. Thus, pregnancy should be avoided when taking delavirdine.

Delavirdine is extensively metabolized by CYP3A and CYP2D6 enzymes. Therefore, there are numerous potential drug-drug interactions to consider (Tables 49–3 and 49–4). The concurrent use of delavirdine with fosamprenavir is not recommended because of bidirectional interactions. Co-administration of delavirdine with indinavir or saquinavir prolongs the elimination half-life of the latter agents, thus allowing them to be dosed twice rather than thrice daily.

EFAVIRENZ

Efavirenz can be given once daily because of its long half-life (40–55 hours). It is moderately well absorbed following oral administration (45%). Since toxicity may increase owing to increased bioavailability after a high-fat meal, efavirenz should be taken on an empty stomach. Efavirenz is principally metabolized by CYP3A4 and CYP2B6 to inactive hydroxylated metabolites;

the remainder is eliminated in the feces as unchanged drug. It is highly bound to albumin (~99%), and cerebrospinal fluid levels range from 0.3% to 1.2% of plasma levels.

The principal adverse effects of efavirenz involve the central nervous system. Dizziness, drowsiness, insomnia, nightmares, and headache tend to diminish with continued therapy; dosing at bedtime may also be helpful. Psychiatric symptoms such as depression, mania, and psychosis have been observed in the weeks following initiation and may necessitate discontinuation. Skin rash has been reported early in therapy in up to 28% of patients; the rash is usually mild to moderate in severity and typically resolves despite continuation. Rarely, rash has been severe or life-threatening. Other potential adverse reactions are nausea, vomiting, diarrhea, crystalluria, elevated liver enzymes, and an increase in total serum cholesterol by 10–20%. High rates of fetal abnormalities, such as neural tube defects, occurred in pregnant monkeys exposed to efavirenz in doses roughly equivalent to the human dosage; several cases of congenital anomalies have been reported in humans. Efavirenz is one of the NNRTI agents recommended for use in pregnancy (Table 49–5), but should be initiated after the first 8 weeks due to birth defects observed in a primate study.

As both an inducer and an inhibitor of CYP3A4, efavirenz induces its own metabolism and interacts with the metabolism of many other drugs (Tables 49–3 and 49–4). Co-administration with boceprevir, elvitegravir/cobicistat, etravirine, indinavir, itraconazole, ketoconazole, and simeprevir is contraindicated. Levels of efavirenz may be reduced by concomitant nevirapine. Levels of lopinavir/ritonavir, maraviroc, methadone, and telaprevir may be reduced when administered with efavirenz.

ETRAVIRINE

Etravirine, a diarylpyrimidine, was designed to be effective against strains of HIV that had developed resistance to first-generation NNRTIs due to mutations such as K103N and Y181C. Although etravirine has a higher genetic barrier to resistance than the other NNRTIs, mutations selected by etravirine usually are associated with resistance to efavirenz, nevirapine, and delavirdine.

Etravirine should be taken with a meal to increase systemic exposure. It is highly protein-bound and is primarily metabolized by the liver. Mean terminal half-life is ~41 hours.

The most common adverse effects of etravirine are rash, nausea, and diarrhea. The rash is typically mild and usually resolves after 1–2 weeks without discontinuation of therapy. Rarely, rash has been severe or life-threatening. Laboratory abnormalities include elevations in serum cholesterol, triglyceride, glucose, and hepatic aminotransferase levels. Aminotransferase elevations are more common in patients with HBV or HCV co-infection.

Etravirine is a substrate as well as an inducer of CYP3A4 and an inhibitor of CYP2C9 and CYP2C19 and thus has potential for numerous drug-drug interactions (Tables 49–3 and 49–4). Some of the interactions are difficult to predict. For example, etravirine may decrease itraconazole and ketoconazole concentrations but increase voriconazole concentrations. Etravirine should not be given with atazanavir, clopidogrel, efavirenz, elvitegravir/

cobicistat, fosamprenavir, indinavir, and tipranavir. In addition, co-administration with clarithromycin or with the antimalarial agent artemether/lumefantrine should be avoided if possible.

NEVIRAPINE

The oral bioavailability of nevirapine is excellent (>90%) and is not food-dependent. The drug is highly lipophilic and achieves cerebrospinal fluid levels that are 45% of those in plasma. Serum half-life is 25–30 hours. It is extensively metabolized by the CYP3A isoform to hydroxylated metabolites and then excreted, primarily in the urine.

A single dose of nevirapine (200 mg) is effective in the prevention of transmission of HIV from mother to newborn when administered at the onset of labor and followed by a 2-mg/kg dose to the neonate within 3 days of delivery. However, nevirapine is no longer recommended for use in pregnancy due to the potential for adverse events and low barrier to resistance.

Rash, usually a maculopapular eruption that spares the palms and soles, occurs in up to 20% of patients, usually in the first 4–6 weeks of therapy. Although typically mild and self-limited, rash is dose-limiting in about 7% of patients. Women appear to have an increased incidence of rash. When initiating therapy, gradual dose escalation over 14 days is recommended to decrease the incidence of rash. Severe and life-threatening skin rashes, including Stevens-Johnson syndrome and toxic epidermal necrolysis, are rare but are more common than with other NNRTIs. Nevirapine therapy should be immediately discontinued in patients with severe rash and in those with accompanying constitutional symptoms; since rash may accompany hepatotoxicity, liver tests should be assessed. Symptomatic liver toxicity may occur in up to 4% of patients, may be severe, and is more frequent in those with higher pretherapy CD4 cell counts (ie, >250 cells/mm³ in women and >400 cells/mm³ in men), in women, and in those with HBV or HCV co-infection. Fulminant, life-threatening hepatitis has been reported, typically within the first 18 weeks of therapy. Other adverse effects include fever, nausea, headache, and somnolence.

Nevirapine is a moderate inducer of CYP3A metabolism, resulting in numerous potential drug-drug interactions (see Tables 49–3 and 49–4). Co-administration of artemether/lumefantrine, atazanavir, dolutegravir, elvitegravir/cobicistat, fosamprenavir, ketoconazole, and rifampin should be avoided.

RILPIVIRINE

Rilpivirine, a diarylpyrimidine, must be administered with a meal (preferably high fat or >400 kcal). Its oral bioavailability is dependent on an acid gastric environment for optimal absorption; thus antacids and H₂-receptor antagonists should be separated in time and proton pump inhibitors are contraindicated. The drug is highly protein bound and the terminal elimination half-life is 50 hours.

Rilpivirine is one of the NNRTI agents recommended for use in pregnancy (Table 49–5). Rilpivirine is primarily metabolized by CYP3A4, and drugs that induce or inhibit CYP3A4 may thus

TABLE 49-5 The use of antiretroviral agents in pregnancy.

Recommended Agents	Alternate Agents
Nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs)	
Abacavir, emtricitabine, lamivudine, tenofovir disoproxil fumarate, zidovudine	
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	
Efavirenz	Rilpivirine
Protease inhibitors (PIs)	
Atazanavir/ritonavir, darunavir/ritonavir	Lopinavir/ritonavir
Integrase inhibitors	
Raltegravir	

affect the clearance of rilpivirine (see Table 49-3). However, clinically significant drug-drug interactions with other antiretroviral agents have not been identified to date.

The most common adverse effects associated with rilpivirine therapy are rash, depression, headache, insomnia, and increased serum aminotransferases. Increased serum cholesterol, and fat redistribution syndrome have also been reported. Higher doses have been associated with QT_c prolongation. Inhibition of renal tubular secretion of creatinine causes a reversible elevation in serum creatinine, but glomerular filtration rate is not affected.

PROTEASE INHIBITORS (PIs)

During the later stages of the HIV growth cycle, the *gag* and *gag-pol* gene products are translated into polypeptides, and these become immature budding particles. The HIV protease is responsible for cleaving these precursor molecules to produce the final structural proteins of the mature virion core. By preventing post-translational cleavage of the Gag-Pol polypeptide, protease inhibitors (PIs) prevent the processing of viral proteins into functional conformations, resulting in the production of immature, noninfectious viral particles (Figure 49-3). Unlike the NRTIs, PIs do not need intracellular activation.

Specific genotypic alterations that confer phenotypic resistance are fairly common with these agents, thus contraindicating monotherapy. Some of the most common mutations conferring broad resistance to PIs are substitutions at the 10, 46, 54, 82, 84, and 90 codons; the number of mutations may predict the level of phenotypic resistance. The I50L substitution emerging during atazanavir therapy has been associated with *increased* susceptibility to other PIs. Darunavir and tipranavir appear to have improved virologic activity in patients harboring HIV-1 resistant to other PIs.

As a class, PIs are associated with gastrointestinal intolerance, which may be dose-limiting, and lipodystrophy, which includes both metabolic (hyperglycemia, hyperlipidemia) and morphologic (lipoatrophy, fat deposition) derangements. A syndrome of redistribution and accumulation of body fat that results in central obesity, dorsocervical fat enlargement (buffalo hump), peripheral and facial wasting, breast enlargement, and a cushingoid appearance has been observed, least commonly with atazanavir. PIs may be

associated with cardiac conduction abnormalities, including PR and QT interval prolongation. A baseline electrocardiogram and avoidance of other agents causing prolonged PR or QT intervals should be considered. Abacavir, lopinavir/ritonavir, and fosamprenavir/ritonavir have been associated with an increased risk of cardiovascular disease in some, but not all, studies. Drug-induced hepatitis and rare severe hepatotoxicity have been reported to varying degrees with all PIs; the frequency of hepatic events is higher with tipranavir/ritonavir than with other PIs. Unconjugated hyperbilirubinemia may occur with atazanavir or indinavir. Whether PI agents are associated with bone loss and osteoporosis after long-term use is under investigation. PIs have been associated with increased spontaneous bleeding in patients with hemophilia A or B; an increased risk of intracranial hemorrhage has been reported in patients receiving tipranavir/ritonavir. Darunavir, amprenavir, fosamprenavir, and tipranavir are sulfonamides; caution should be used in patients with a history of sulfa allergy.

All of the antiretroviral PIs are extensively metabolized by CYP3A4, with ritonavir having the most pronounced inhibitory effect and saquinavir the least. Some PI agents, such as amprenavir and ritonavir, are also inducers of specific CYP isoforms. As a result, there is enormous potential for drug-drug interactions with other antiretroviral agents and other commonly used medications (Tables 49-3 and 49-4). Expert resources about drug-drug interactions should be consulted, as dosage adjustments are frequently required and some combinations are contraindicated. It is noteworthy that the potent CYP3A4 inhibitory properties of ritonavir are used to clinical advantage by having it “boost” the levels of other PI agents when given in combination, thus acting as a pharmacokinetic enhancer rather than an antiretroviral agent. Ritonavir boosting increases drug exposure, thereby prolonging the drug’s half-life and allowing reduction in frequency; in addition, the genetic barrier to resistance is raised.

ATAZANAVIR

Atazanavir is an azapeptide PI with a pharmacokinetic profile that allows once-daily dosing. Atazanavir requires an acidic medium for absorption and exhibits pH-dependent aqueous solubility; therefore, it should be taken with meals. Separation of ingestion from acid-reducing agents by at least 12 hours is recommended and concurrent proton pump inhibitors are contraindicated. Atazanavir is able to penetrate both the cerebrospinal and seminal fluids. The plasma half-life is 6–7 hours, which increases to approximately 11 hours when co-administered with ritonavir. The primary route of elimination is biliary; atazanavir should not be given to patients with severe hepatic insufficiency.

Boosted atazanavir is one of the recommended PI agents for use in pregnant women (Table 49-5).

The most common adverse effects in patients receiving atazanavir are diarrhea and nausea; vomiting, abdominal pain, headache, and peripheral neuropathy may also occur. Skin rash, reported in ~20% of patients, is generally mild; however severe rash and Stevens Johnson syndrome have been reported. As with indinavir, indirect hyperbilirubinemia with overt jaundice may

occur in approximately 10% of patients, owing to inhibition of the UGT1A1 glucuronidation enzyme. Elevation of serum aminotransferases has separately been observed, usually in patients with underlying HBV or HCV co-infection. Kidney stones, gallstones, PR prolongation, and decreased bone mineral density have also been reported. In contrast to the other PIs, atazanavir does not appear to be associated with dyslipidemia or hyperglycemia. The oral powder contains phenylalanine, which can be harmful to patients with phenylketonuria.

As an inhibitor of CYP3A4, CYP2C9, and UGT1A1, the potential for drug-drug interactions with atazanavir is great (Tables 49–3 and 49–4). Due to decreased atazanavir levels, atazanavir should not be administered with bosentan, elvitegravir/cobicistat, efavirenz, fosamprenavir, nevirapine, proton pump inhibitors, or tipranavir. Tenofovir and efavirenz should not be co-administered with atazanavir unless ritonavir is added to boost levels. In addition, co-administration of atazanavir with other drugs that inhibit UGT1A1, such as irinotecan, may increase its levels. Atovaquone and voriconazole levels may be decreased with coadministration, and levels of maraviroc and ranolazine may be increased.

DARUNAVIR

Darunavir must be co-administered with ritonavir or cobicistat. Darunavir should be taken with meals to improve bioavailability. It is highly protein-bound and primarily metabolized by the liver.

Boosted darunavir is one of the PI agents recommended for use in pregnancy (Table 49–5).

Adverse effects include diarrhea, nausea, headache, and increases in amylase and hepatic aminotransferase levels. Rash occurs in 2–7% of patients and may occasionally be severe. Liver toxicity, including severe hepatitis, has been reported, such that liver function tests should be monitored; the risk may be higher for persons with HBV, HCV, or other chronic liver disease. Darunavir contains a sulfonamide moiety and may cause a hypersensitivity reaction, particularly in patients with sulfa allergy.

Darunavir both inhibits and is metabolized by the CYP3A enzyme system, conferring many possible drug-drug interactions (Tables 49–3 and 49–4). In addition, the co-administered ritonavir is a potent inhibitor of CYP3A and CYP2D6, and an inducer of other hepatic enzyme systems. Co-administration with elvitegravir/cobicistat or simeprevir is contraindicated due to bidirectional drug-drug interactions. Levels of cyclophosphamide, digoxin, and simeprevir may be increased when administered with darunavir, and levels of paroxetine and sertraline may be decreased.

FOSAMPRENAVIR

Fosamprenavir is a prodrug of amprenavir that is rapidly hydrolyzed by enzymes in the intestinal epithelium. Because of its significantly lower daily pill burden, fosamprenavir tablets have replaced amprenavir capsules for adults. Fosamprenavir is most often administered in combination with low-dose ritonavir.

After hydrolysis of fosamprenavir, amprenavir is rapidly absorbed from the gastrointestinal tract, and its prodrug can be taken with or without food. However, high-fat meals decrease absorption and thus should be avoided. The plasma half-life is relatively long (7–11 hours). Amprenavir is metabolized in the liver and should be used with caution in the setting of hepatic insufficiency.

The most common adverse effects of fosamprenavir are headache, nausea, diarrhea, perioral paresthesias, depression. Fosamprenavir contains a sulfa moiety and may cause a rash in up to 19% of patients, sometimes severe enough to warrant drug discontinuation.

Amprenavir is both an inducer and an inhibitor of CYP3A4 (Tables 49–3 and 49–4). Co-administration of elvitegravir/cobicistat, efavirenz, lopinavir/ritonavir, nevirapine, posaconazole, or ranolazine is contraindicated. The oral suspension, which contains propylene glycol, is contraindicated in young children, pregnant women, patients with renal or hepatic failure, and those using metronidazole or disulfiram. Also, the oral solutions of amprenavir and ritonavir should not be co-administered because the propylene glycol in one and the ethanol in the other may compete for the same metabolic pathway, leading to accumulation of either. Because the oral solution contains vitamin E at several times the recommended daily dosage, supplemental vitamin E should be avoided.

INDINAVIR

Indinavir requires an acidic environment for optimum solubility and therefore must be consumed on an empty stomach or with a small, low-fat, low-protein meal for maximal absorption (60–65%). The serum half-life is 1.5–2 hours, protein binding is ~60%, and the drug has a high level of cerebrospinal fluid penetration (up to 76% of serum levels). Excretion is primarily fecal. An increase in AUC by 60% and in half-life to 2.8 hours in the setting of hepatic insufficiency necessitates dose reduction.

The most common adverse effects of indinavir are unconjugated hyperbilirubinemia and nephrolithiasis due to urinary crystallization of the drug. Nephrolithiasis can occur within days after initiating therapy, with an estimated incidence of approximately 10%. Acute renal failure and interstitial fibrosis have also been reported. Consumption of at least 48 ounces of water daily is important to maintain adequate hydration, and serum creatinine levels should be monitored. Nausea, diarrhea, sicca syndrome, headache, blurred vision, and elevations of serum aminotransferase levels have also been reported. Insulin resistance may be more common with indinavir than with the other PIs, occurring in 3–5% of patients. In some studies but not in others, indinavir has been associated with a higher risk of myocardial infarction. There have also been rare cases of acute hemolytic anemia.

Since indinavir is an inhibitor of CYP3A4, numerous and complex drug interactions can occur (Tables 49–3 and 49–4). Boosting with ritonavir allows for twice-daily rather than thrice-daily dosing and eliminates the food restriction associated with use of indinavir. However, there is potential for an increase in

nephrolithiasis with this combination compared with indinavir alone; thus, a high fluid intake (1.5–2 L/d) is advised. Indinavir should not be co-administered with astemizole, cerivastatin, efavirenz, ergotamine, etravirine, lovastatin, pimozone, rifampin, simvastatin, terfenadine, or triazolam. Levels of amlodipine, levodopa, and trazodone may be increased with concurrent administration of indinavir.

LOPINAVIR

Lopinavir is available only in combination with low-dose ritonavir as a pharmacologic “booster” via inhibition of its CYP3A-mediated metabolism, resulting in increased exposure and a reduced pill burden.

Lopinavir is highly protein bound (98–99%), and its half-life is 5–6 hours. It is extensively metabolized by CYP3A, which is inhibited by ritonavir. Lopinavir/ritonavir is one of the recommended antiretroviral agents for use in pregnant women (Table 49–5).

The most common adverse effects of lopinavir are diarrhea, nausea, vomiting, increased serum lipids, and increased serum aminotransferases (more common in patients with HBV or HCV co-infection). Prolongation of the PR and/or QT interval may occur. In some studies but not in others, lopinavir/ritonavir has been associated with a higher risk of myocardial infarction. Pancreatitis has rarely been reported. Ritonavir-boosted lopinavir may be more commonly associated with gastrointestinal adverse events than other PIs.

Potential drug-drug interactions are extensive (Tables 49–3 and 49–4). Levels of lamotrigine and methadone may be reduced with co-administration, and levels of bosentan may be increased. Concurrent use of darunavir, elvitegravir/cobicistat, fosamprenavir, and tipranavir is contraindicated. Since the oral solution of lopinavir/ritonavir contains alcohol, concurrent disulfiram and metronidazole are contraindicated. The oral solution also contains propylene glycol, contraindicating the co-administration of other drugs containing propylene glycol.

NELFINAVIR

Nelfinavir has high absorption in the fed state (70–80%), undergoes metabolism by CYP3A, and is excreted primarily in the feces. The plasma half-life in humans is 3.5–5 hours, and the drug is more than 98% protein-bound.

The most common adverse effects associated with nelfinavir (10–30%) are diarrhea and flatulence. Diarrhea responds to anti-diarrheal medications but may be dose-limiting. Nelfinavir is an inhibitor of the CYP3A system, and multiple drug interactions may occur (Tables 49–3 and 49–4). An increased dosage of nelfinavir is recommended when co-administered with rifabutin (with a decreased dose of rifabutin), whereas a decrease in saquinavir dose is suggested with concurrent nelfinavir. Do not co-administer with astemizole, cerivastatin, cisapride, ergotamine, lovastatin, omeprazole, pimozone, quinidine, rifampin, simvastatin, or terfenadine. The oral powder contains phenylalanine, which can be harmful to patients with phenylketonuria.

RITONAVIR

Ritonavir has a high bioavailability (~75%) that increases with food. It is 98% protein-bound and has a serum half-life of 3–5 hours. Metabolism to an active metabolite occurs via the CYP3A and CYP2D6 isoforms; excretion is primarily in the feces. Ritonavir as a pharmacologic “booster” is one of the recommended antiretroviral agents for use in pregnant women (Table 49–5).

Adverse effects of full-dose ritonavir include asthenia, gastrointestinal disturbances, and hepatitis; these are greatly reduced with the lower doses used for boosting. Dose escalation over 1–2 weeks decreases these side effects. Other potential adverse effects include altered taste, paresthesias (circumoral or peripheral), elevated serum aminotransferase and lipid levels, headache, elevations in serum creatine kinase, and pancreatitis. Inhibition of renal tubular secretion of creatinine causes a reversible elevation in serum creatinine, but glomerular filtration rate is not affected.

Ritonavir is a potent inhibitor of CYP3A4, resulting in many potential drug interactions (Tables 49–3 and 49–4). However, this characteristic has been used to great advantage when ritonavir is administered in low doses (100–200 mg twice daily) in combination with any of the other PI agents, to permit lower or less frequent dosing (or both) with greater tolerability as well as the potential for greater efficacy against resistant virus. Therapeutic levels of digoxin and theophylline should be monitored when co-administered with ritonavir. The concurrent use of saquinavir and ritonavir is contraindicated due to an increased risk of QT prolongation (with torsades de pointes arrhythmia) and PR interval prolongation. Concurrent simeprevir is also contraindicated.

SAQUINAVIR

In its original formulation as a hard gel capsule, oral saquinavir was poorly bioavailable (~4% after food). However, reformulation of saquinavir for once-daily dosing in combination with low-dose ritonavir has both improved antiviral efficacy and decreased gastrointestinal adverse effects. A previous formulation of saquinavir in soft gel capsules is no longer available.

Saquinavir should be taken within 2 hours after a fatty meal for enhanced absorption. Saquinavir is 97% protein-bound, and serum half-life is approximately 2 hours. Saquinavir has a large volume of distribution, but penetration into the cerebrospinal fluid is negligible. Excretion is primarily in the feces. Gastrointestinal discomfort (nausea, diarrhea, abdominal discomfort, dyspepsia) may occur. When administered in combination with low-dose ritonavir, there appears to be less dyslipidemia or gastrointestinal toxicity than with some of the other boosted PI regimens. Since prolongation of the QT interval and torsades de pointes have rarely been reported, saquinavir should not be used in patients with congenital long QT syndrome, AV block, refractory hypokalemia or hypomagnesemia, or in combination with drugs that both increase saquinavir plasma concentrations and prolong the QT interval. The concurrent use of saquinavir and ritonavir may confer an increased risk of QT or PR prolongation.

Saquinavir is subject to extensive first-pass metabolism by CYP3A4 and functions as a CYP3A4 inhibitor as well as a

substrate; thus, there are many potential drug-drug interactions (Tables 49–3 and 49–4). Increased saquinavir levels when co-administered with omeprazole necessitate close monitoring for toxicities. Digoxin levels should be monitored. Liver tests should be monitored if saquinavir is co-administered with delavirdine or rifampin. Concurrent darunavir or tipranavir is contraindicated.

TIPRANAVIR

Tipranavir is a newer PI indicated for use in treatment-experienced patients who harbor strains resistant to other PI agents. It is used in combination with ritonavir to achieve effective serum levels.

Bioavailability is poor but is increased when taken with a high-fat meal. The drug is metabolized by the liver microsomal system and is contraindicated in patients with hepatic insufficiency. Tipranavir contains a sulfonamide moiety and should not be administered to patients with known sulfa allergy.

The most common adverse effects of tipranavir are diarrhea, nausea, vomiting, and abdominal pain. An urticarial or maculopapular rash occurs in 10–14%, and may be more common with co-administered ethinyl estradiol. Liver toxicity, including life-threatening hepatic decompensation, has been observed and may be more common than with other PIs, particularly in patients with chronic HBV or HCV infection. Because of an increased risk for intracranial hemorrhage in patients receiving tipranavir/ritonavir, the drug should be avoided in patients with head trauma or bleeding diathesis. Other potential adverse effects include depression, elevation in serum amylase, increased serum lipids, and decreased white blood cell count.

Tipranavir both inhibits and induces the CYP3A4 system. When used in combination with ritonavir, its net effect is inhibition. Tipranavir also induces the P-glycoprotein transporter and thus may alter the disposition of many other drugs (Tables 49–3 and 49–4). Concurrent use with atazanavir, elvitegravir/cobicistat, etravirine, fosamprenavir, lopinavir/ritonavir and saquinavir should be avoided. Supplemental vitamin E is contraindicated in patients receiving the oral solution.

FUSION INHIBITORS

The process of HIV-1 entry into host cells is complex; each step presents a potential target for inhibition. Viral attachment to the host cell entails binding of the viral envelope glycoprotein complex gp160 (consisting of gp120 and gp41) to its cellular receptor CD4. This binding induces conformational changes in gp120 that enable access to the chemokine receptors CCR5 or CXCR4. Chemokine receptor binding induces further conformational changes in gp120, allowing exposure to gp41 and leading to fusion of the viral envelope with the host cell membrane and subsequent entry of the viral core into the cellular cytoplasm.

ENFUVIRTIDE

Enfuvirtide is a synthetic 36-amino-acid peptide fusion inhibitor that blocks HIV entry into the cell (Figure 49–3). Enfuvirtide binds to the gp41 subunit of the viral envelope glycoprotein,

preventing the conformational changes required for the fusion of the viral and cellular membranes.

Enfuvirtide, which must be administered by subcutaneous injection, is the only parenterally administered antiretroviral agent. Metabolism appears to be by proteolytic hydrolysis without involvement of the CYP450 system. Elimination half-life is 3.8 hours.

Resistance to enfuvirtide can result from mutations in gp41; the frequency and significance of this phenomenon are being investigated. However, enfuvirtide lacks cross-resistance with the other currently approved antiretroviral drug classes.

The most common adverse effects are local injection site reactions, consisting of painful erythematous nodules. Although frequent, these are typically mild-to-moderate in severity and rarely lead to discontinuation. Other potential side effects include insomnia, headache, dizziness, and nausea. Hypersensitivity reactions may rarely occur, are of varying severity, and may recur on rechallenge. Eosinophilia is the primary laboratory abnormality seen with enfuvirtide administration. In Phase 3 studies, bacterial pneumonia was seen at a higher rate in patients who received enfuvirtide than in those who did not receive enfuvirtide. No drug-drug interactions have been identified that would require the alteration of the dosage of concomitant antiretroviral or other drugs.

ENTRY INHIBITORS

MARAVIROC

Maraviroc is approved for use in combination with other antiretroviral agents in adult patients infected only with CCR5-tropic HIV-1. Maraviroc binds specifically and selectively to the host protein CCR5, one of two chemokine receptors necessary for entrance of HIV into CD4+ cells. Since maraviroc is active against HIV that uses the CCR5 co-receptor exclusively, and not against HIV strains with CXCR4, dual, or mixed tropism, co-receptor tropism should be determined by specific testing before maraviroc is started. Substantial proportions of patients, particularly those with advanced HIV infection, are likely to have virus that is not exclusively CCR5-tropic.

The absorption of maraviroc is rapid but variable, with the time to maximum absorption generally 1–4 hours after ingestion of the drug. Most of the drug ($\geq 75\%$) is excreted in the feces, whereas approximately 20% is excreted in urine. The recommended dose of maraviroc varies according to renal function and the concomitant use of CYP3A inducers or inhibitors (Table 49–3). Maraviroc is contraindicated in patients with severe or end-stage renal impairment and caution is advised when used in patients with preexisting hepatic impairment and in those co-infected with HBV or HCV. Maraviroc has excellent penetration into the cervicovaginal fluid, with levels almost four times higher than the corresponding concentrations in blood plasma.

Resistance to maraviroc is associated with one or more mutations in the V3 loop of gp120. However, emergence of CXCR4 virus (either previously undetected or newly developed) appears to be a more common cause of virologic failure than the development of resistance mutations. There appears to be no

cross-resistance with drugs from any other class, including the fusion inhibitor enfuvirtide.

Maraviroc is a substrate for CYP3A4 and therefore requires adjustment in the presence of drugs that interact with these enzymes (Tables 49–3 and 49–4). It is also a substrate for P-glycoprotein, which limits intracellular concentrations of the drug. The dosage of maraviroc must be decreased if it is co-administered with strong CYP3A inhibitors (eg, delavirdine, ketoconazole, itraconazole, clarithromycin, or any protease inhibitor other than tipranavir) and must be increased if co-administered with CYP3A inducers (eg, efavirenz, etravirine, carbamazepine, phenytoin, or St. John's wort). Concurrent use of rifampin is contraindicated.

Potential adverse effects of maraviroc include upper respiratory tract infection, cough, pyrexia, rash, dizziness, muscle and joint pain, diarrhea, sleep disturbance, and elevations in serum aminotransferases. Hepatotoxicity has been reported, which may be preceded by a systemic allergic reaction (ie, pruritic rash, eosinophilia, or elevated IgE); discontinuation of maraviroc should be prompt if this constellation occurs. Myocardial ischemia and infarction have been observed in patients receiving maraviroc; therefore caution is advised in patients at increased cardiovascular risk. There is an increased risk of postural hypotension in patients with severe renal impairment.

There has been concern that blockade of the chemokine CCR5 receptor—a human protein—may result in decreased immune surveillance, with a subsequent increased risk of malignancy or infection. To date, however, there has been no evidence of an increased risk of either malignancy or infection in patients receiving maraviroc.

INTEGRASE STRAND TRANSFER INHIBITORS (INSTIs)

This class of agents binds integrase, a viral enzyme essential to the replication of both HIV-1 and HIV-2. By doing so, it inhibits strand transfer, the third and final step of provirus integration, thus interfering with the integration of reverse-transcribed HIV DNA into the chromosomes of host cells (Figure 49–3). As a class, these agents tend to be well tolerated, with headache and gastrointestinal effects the most commonly reported adverse events. Their use in combination antiretroviral regimens or with cobicistat (ie, elvitegravir) means that additional adverse events and/or drug-drug interactions need to be considered as well. The available data suggest that effects upon lipid metabolism are favorable compared with efavirenz and PIs. Rare severe events include systemic hypersensitivity reactions and rhabdomyolysis.

DOLUTEGRAVIR

The frequency of dosing of dolutegravir depends on the presence or absence of integrase inhibitor-associated resistance mutations and the concurrent use of efavirenz, fosamprenavir/ritonavir, tipranavir/ritonavir, or rifampin. Dolutegravir should be taken 2 hours before or 6 hours after cation-containing antacids or laxatives, sucralfate, oral iron supplements, oral calcium supplements,

or buffered medications. Peak plasma concentrations occur within 2–3 hours of ingestion. Dolutegravir is highly protein bound (99%). The terminal half-life is ~14 hours. Serum levels may be reduced in patients with severe renal insufficiency.

Adverse effects of dolutegravir are infrequent but may include insomnia, headache, increased serum aminotransferase levels, and, rarely, rash. A hypersensitivity reaction, including rash and systemic symptoms, has been reported; the drug should be discontinued immediately if this occurs and not restarted. Dolutegravir increases serum creatinine by inhibiting tubular secretion of creatinine but has no effect on actual glomerular filtration rate.

Dolutegravir is primarily metabolized via UGT1A1 with some contribution from CYP3A. Therefore, multiple drug-drug interactions may occur (Table 49–3 and 49–4). Levels of dolutegravir may decrease when co-administered with efavirenz, etravirine, nevirapine, rifampin, or rifapentine, in some instances necessitating increased doses of dolutegravir or boosting or both. Co-administration with the metabolic inducers oxcarbazepine, phenytoin, phenobarbital, carbamazepine, and St. John's wort should be avoided. Dolutegravir inhibits the renal organic cation transporter OCT2, thereby increasing plasma concentrations of drugs eliminated via OCT2 such as dofetilide and metformin. For this reason, co-administration with dofetilide is contraindicated and close monitoring, with potential for dose adjustment, is recommended for co-administration with metformin.

ELVITEGRAVIR

Elvitegravir should be taken with food, and it should be taken 2 hours before or 6 hours after cation-containing antacids or laxatives, sucralfate, oral iron supplements, oral calcium supplements, or buffered medications. Peak levels occur within 4 hours of ingestion; elvitegravir is highly protein bound (>98%).

Elvitegravir requires boosting with an additional drug, such as cobicistat (a pharmacokinetic enhancer that inhibits CYP3A4 as well as certain intestinal transport proteins) or ritonavir. Cobicistat inhibits renal tubular secretion of creatinine; therefore, fixed-dose combinations need to be adjusted for renal function.

There appear to be few adverse effects associated with elvitegravir per se but may include diarrhea, rash, and elevation in hepatic aminotransferases.

Elvitegravir is primarily metabolized by CYP3A enzymes, so drugs that induce or inhibit the action of CYP3A may affect serum levels of elvitegravir (Table 49–3 and 49–4). In addition, cobicistat and ritonavir strongly inhibit CYP3A. Elvitegravir levels may be lowered by concurrent efavirenz or nevirapine, rifampin, rifabutin, carbamazepine, phenytoin, or St. John's wort. Concurrent use of azole antifungal drugs is contraindicated due to a potential increase in elvitegravir levels; rifabutin levels may also be increased by concurrent elvitegravir. Elvitegravir also induces CYP2D9 and may lower concentrations of substrates of this enzyme. With the fixed dose combination, concurrent alfuzosin or atazanavir, cisapride, darunavir, efavirenz, etravirine, fosamprenavir, ledipasvir, lopinavir/ritonavir, methylprednisolone, midazolam, nevirapine, pimozide, prednisolone, rifampin, rifabutin are contraindicated.

RALTEGRAVIR

Absolute bioavailability of the pyrimidinone analog raltegravir has not been established but does not appear to be food-dependent. Terminal half-life is ~ 9 hours. The drug does not interact with the cytochrome P450 system but is metabolized by glucuronidation, particularly UGT1A1. Therefore, concurrent use of inducers or inhibitors of UGT1A1 such as rifampin and rifapentine may necessitate dosage adjustment of raltegravir. The chewable tablets contain phenylalanine, which can be harmful to patients with phenylketonuria.

Raltegravir is one of the antiretroviral agents recommended for use in pregnancy (Table 49–5).

Adverse effects of raltegravir are uncommon but include nausea, headache, fatigue, muscle aches, and increased serum amylase and aminotransferase levels. Severe, potentially life-threatening and fatal skin reactions have been reported, including Stevens-Johnson syndrome, hypersensitivity reaction, and toxic epidermal necrolysis.

■ ANTIHEPATITIS AGENTS

The advantages of **nucleoside/nucleotide analogs (NA)** therapy of hepatitis over interferons (IFN) include fewer adverse effects and a one-pill-a-day oral administration. The main advantages of IFN over NAs are the absence of resistance, and achievement of higher rates of viral agglutinin reduction. However, the disadvantages of IFN are that less than 50% of persons treated will respond, its high cost, administration by injection, and common adverse effects, which preclude its use in many persons, particularly in resource-limited settings. A number of relative and absolute contraindications to IFN also exist, which include the

presence of decompensated cirrhosis and hypersplenism, thyroid disease, autoimmune diseases, severe coronary artery disease, renal transplant disease, pregnancy, seizures and psychiatric illness, concomitant use of certain drugs, retinopathy, thrombocytopenia and leucopenia. IFN also cannot be used in infants less than 1 year and in pregnant women.

INTERFERON ALFA

Interferons are host cytokines that exert complex antiviral, immunomodulatory, and antiproliferative actions (see Chapter 55). Interferon alfa appears to function by induction of intracellular signals following binding to specific cell membrane receptors, resulting in inhibition of viral penetration, translation, transcription, protein processing, maturation, and release, as well as increased host expression of major histocompatibility complex antigens, enhanced phagocytic activity of macrophages, and augmentation of the proliferation and survival of cytotoxic T cells.

Interferon alfa-2b is licensed for the treatment for chronic HBV infection; interferon alfa-2a, interferon alfa-2b, and interferon alfacon-1 are licensed for treatment of chronic HCV infection (Table 49–6). Interferon alfa-2a and interferon alfa-2b may be administered either subcutaneously or intramuscularly; half-life is 2–5 hours, depending on the route of administration. Alfa interferons are filtered at the glomerulus and undergo rapid proteolytic degradation during tubular reabsorption, such that detection in the systemic circulation is negligible. Liver metabolism and subsequent biliary excretion are considered minor pathways.

Pegylation (the attachment of polyethylene glycol to a protein) reduces the rate of absorption following subcutaneous injection, reduces renal and cellular clearance, and decreases

TABLE 49–6 Drugs used to treat chronic hepatitis B virus infection.

Agent	Recommended Adult Dosage	Potential Adverse Effects
Nucleoside/nucleotide analogs		
Entecavir ¹	500 or 1000 mg qd orally	Headache, fatigue, upper abdominal pain; lactic acidosis
Tenofovir alafenamide fumarate	25 mg qd orally	Nausea, abdominal pain, diarrhea, dizziness, fatigue, nephropathy, lactic acidosis
Tenofovir disoproxil ¹	300 mg qd orally	Nausea, abdominal pain, diarrhea, dizziness, fatigue, nephropathy, lactic acidosis
Adefovir dipivoxil ¹	10 mg qd orally	Renal dysfunction, lactic acidosis
Lamivudine ¹	100 mg qd orally	Headache, nausea, diarrhea, dizziness, myalgia, and malaise, lactic acidosis
Telbivudine ¹	600 mg qd orally	Fatigue, headache, cough, nausea, diarrhea, myopathy, peripheral neuropathy, lactic acidosis
Interferon alfa-2b	5 million IU/d or 10 million IU three times weekly subcutaneously or intramuscularly	Flu-like symptoms, fatigue, mood disturbances, cytopenias, autoimmune disorders
Pegylated interferon alfa-2a ¹	180 mcg once weekly subcutaneously	Flu-like symptoms, fatigue, mood disturbances, cytopenias, autoimmune disorders

¹Dose must be reduced in patients with renal insufficiency.

IU, international units.

TABLE 49-7 Direct-acting antiviral combination regimens for the treatment of chronic hepatitis C infection in adult patients without cirrhosis.¹

Regimen	Class of Agent(s)	HCV Genotype(s)
Velpatasvir 100 mg /sofosbuvir 400 mg once daily × 12 weeks	NS5A inhibitor/NS5B polymerase inhibitor	1, 2, 3, 4, 5, 6
Elbasvir 50 mg/grazoprevir 100 mg once daily × 12 weeks ²	NS5A inhibitor/NS 3/4A protease inhibitor	1a, 1b, 4
Ledipasvir 90 mg/sofosbuvir 400 mg once daily × 12 weeks	NS5A inhibitor/NS5B polymerase inhibitor	1a, 1b, 4, 5, 6
Paritaprevir 150 mg/ritonavir 100 mg/ombitasvir 25 mg once daily plus dasabuvir 250 mg bid plus weight-based ribavirin × 12 weeks	NS 3/4A protease inhibitor/ NS5A inhibitor plus NS5B polymerase inhibitor plus guanosine analog	1a, 1b
Paritaprevir 150 mg/ritonavir 100 mg/ombitasvir 25 mg once daily plus weight-based ribavirin × 12 weeks	NS 3/4A protease inhibitor/ NS5A inhibitor plus guanosine analog	4
Simeprevir 150 mg plus sofosbuvir 400 mg once daily × 12 weeks	NS3/4A protease inhibitor plus NS5B polymerase inhibitor	1a, 1b
Daclatasvir 60 mg ³ plus sofosbuvir 400 mg once daily × 12 weeks	NS5A inhibitor plus NS5B polymerase inhibitor	1a, 1b, 2, 3
Sofosbuvir 400 mg once daily plus weight-based ribavirin × 12 weeks	NS5B polymerase inhibitor plus guanosine analog	2, 3

¹ Regimens may differ in the presence of cirrhosis.

² As an alternative regimen, elbasvir 50 mg/grazoprevir 100 mg once daily may be given in combination with weight-based ribavirin for 16 weeks.

³ Dose adjustment may be required if co-administered with a CYP 3A substrate.

the immunogenicity of the protein, resulting in a longer half-life and steadier plasma concentrations. Renal elimination of pegylated interferon alfa-2a and pegylated interferon alfa-2b accounts for about 30% of clearance; dose must be adjusted in renal insufficiency due to impaired clearance. The polyethylene glycol moiety is a nontoxic polymer that is readily excreted in the urine.

Pegylated interferon alfa-2a is licensed to treat chronic HBV and HCV infection; pegylated interferon alfa-2b is licensed to treat chronic HCV infection. However, the availability of newer and highly effective antiviral agents for HCV infection has greatly diminished the use of the interferons for this indication.

The adverse effects of interferon alfa include a flu-like syndrome (ie, headache, fevers, chills, myalgias, and malaise) that occurs within 6 hours after dosing in more than 30% of patients; it tends to resolve upon continued administration. Transient hepatic enzyme elevations may occur in the first 8–12 weeks of therapy and appear to be more common in responders. Potential adverse effects during chronic therapy include neurotoxicities (mood disorders, depression, somnolence, confusion, seizures), myelosuppression, profound fatigue, weight loss, rash, cough, myalgia, alopecia, tinnitus, reversible hearing loss, retinopathy, pneumonitis, and possibly cardiotoxicity. Induction of autoantibodies may occur, causing exacerbation or unmasking of autoimmune disease (particularly thyroiditis).

Contraindications to interferon alfa therapy include hepatic decompensation, autoimmune disease, and history of cardiac arrhythmia. Caution is advised in the setting of psychiatric disease, epilepsy, thyroid disease, ischemic cardiac disease, severe renal insufficiency, and cytopenia. Alfa interferons are abortifacient in primates and should not be administered in pregnancy. Potential drug-drug interactions include increased theophylline and methadone levels. Co-administration with didanosine is not recommended because of a risk of hepatic failure, and co-administration with zidovudine may exacerbate cytopenias.

TREATMENT OF HEPATITIS B VIRUS INFECTION

No specific treatment is available for the treatment of acute hepatitis B infection, which most often resolves spontaneously.

The goals of chronic HBV therapy are the suppression of HBV DNA to undetectable levels, seroconversion of HBeAg (or more rarely, HBsAg) from positive to negative, and reduction in elevated serum aminotransferase levels. These endpoints are correlated with improvement in necroinflammatory disease, a decreased risk of hepatocellular carcinoma and cirrhosis, and a decreased need for liver transplantation. All of the currently licensed therapies achieve these goals. In contrast to the treatment of HCV infection (see below), cure is rare. In addition, because current therapies suppress HBV replication without eradicating the virus, initial responses may not be durable. The covalently closed circular (ccc) viral DNA exists in stable form indefinitely within the cell, serving as a reservoir for HBV throughout the life of the cell and resulting in the capacity to reactivate. Relapse is more common in patients co-infected with hepatitis D virus.

As of 2017 eight drugs were approved for treatment of chronic HBV infection in the United States: five oral nucleoside/nucleotide analogs (lamivudine, adefovir dipivoxil, tenofovir disoproxil, tenofovir alafenamide, entecavir, telbivudine) and two injectable interferon drugs (interferon alfa-2b, pegylated interferon alfa-2a) (Table 49-6). The use of standard interferon has been supplanted by long-acting pegylated interferon, allowing once-weekly rather than daily or thrice-weekly dosing. The advantages of interferon are its finite duration of treatment, the absence of selection of resistant variants, and a more durable response. However, adverse effects from interferon are more frequent, and may be severe. Furthermore, interferon cannot be used in patients with decompensated disease. In general, nucleoside/nucleotide analog therapies have better tolerability and produce a higher response rate than the interferons, and are now considered the first line of therapy.

Combination therapies may reduce the development of resistance. The optimal duration of therapy remains unknown.

Several anti-HBV agents have anti-HIV activity as well, including tenofovir disoproxil, tenofovir alafenamide, lamivudine, and adefovir dipivoxil. Emtricitabine, an NRTI used in HIV infection, has resulted in excellent biochemical, virologic, and histologic improvement in patients with chronic HBV infection, although it is not approved for this indication. Although agents with dual HBV and HIV activity are particularly useful as part of a first-line regimen in co-infected patients, it is important to note that acute exacerbation of hepatitis may occur upon discontinuation or interruption of these agents; this may be severe or even fatal.

ADEFOVIR DIPIVOXIL

Although initially and abortively developed for treatment of HIV infection, adefovir dipivoxil gained approval, at lower and less toxic doses, for treatment of HBV infection. Adefovir dipivoxil is the diester prodrug of adefovir, an acyclic phosphonated adenine nucleotide analog. It is phosphorylated by cellular kinases to the active diphosphate metabolite and then competitively inhibits HBV DNA polymerase and causes chain termination after incorporation into viral DNA. Adefovir is active *in vitro* against a wide range of DNA and RNA viruses, including HBV, HIV, and herpesviruses.

Oral bioavailability of adefovir dipivoxil is ~ 59% and is unaffected by meals; it is rapidly and completely hydrolyzed to the parent compound by intestinal and blood esterases. Protein binding is low (<5%). The intracellular half-life of the diphosphate is prolonged, ranging from 5 to 18 hours in various cells; this makes once-daily dosing feasible. Adefovir is excreted by both glomerular filtration and active tubular secretion and requires dose adjustment for renal dysfunction; however, it may be administered to patients with decompensated liver disease.

Of the oral agents, adefovir may be slower to suppress HBV DNA levels and the least likely to induce HBeAg seroconversion. Emergence of resistance is up to 29% after 5 years of use. However, there is no cross-resistance between adefovir and lamivudine or entecavir.

Adefovir is well tolerated at doses used to treat HBV infection. A reversible increase in serum creatinine has been reported in 3–9% of patients after 4–5 years of treatment. Other potential adverse effects are headache, diarrhea, asthenia, and abdominal pain. As with other NRTI agents, lactic acidosis and hepatic steatosis are a risk owing to mitochondrial dysfunction. Pivalic acid, a by-product of adefovir metabolism, can esterify free carnitine and result in decreased carnitine levels. However, it is not necessary to administer carnitine supplementation with the low doses used to treat patients with HBV (10 mg/d). Adefovir is embryotoxic in rats at high doses and is genotoxic in preclinical studies.

ENTECAVIR

Entecavir is an orally administered cyclopentyl guanosine nucleoside analog that competitively inhibits all three functions of HBV DNA polymerase, including base priming, reverse transcription of

the negative strand, and synthesis of the positive strand of HBV DNA. Oral bioavailability approaches 100% but is decreased by food; therefore, entecavir should be taken on an empty stomach. The intracellular half-life of the active phosphorylated compound is 15 hours and plasma half-life is prolonged at 128–149 hours, allowing once-daily dosing. It is excreted by the kidney, undergoing both glomerular filtration and net tubular secretion, and dosage should be adjusted in the setting of renal insufficiency.

Suppression of HBV DNA levels was greater with entecavir than with lamivudine or adefovir in comparative trials. Entecavir appears to have a higher barrier to the emergence of resistance than lamivudine. Although selection of resistant isolates with the S202G mutation has been documented during therapy, clinical resistance is rare (<1% at 5 years). However, resistance is more frequent in lamivudine-refractory patients (~ 50% at 5 years). Entecavir has weak anti-HIV activity and can induce development of the M184V variant in HBV/HIV co-infected patients, resulting in resistance to emtricitabine and lamivudine.

Entecavir is well tolerated. Potential adverse events are headache, fatigue, dizziness, nausea, and upper abdominal pain. Co-administration of entecavir with drugs that reduce renal function or compete for active tubular secretion may increase serum concentrations of either entecavir or the co-administered drug. Severe lactic acidosis was reported in a case series of entecavir; thus caution is advised for administration in the setting of severe hepatic decompensation. Lung adenomas and carcinomas in mice, hepatic adenomas and carcinomas in rats and mice, vascular tumors in mice, and brain gliomas and skin fibromas in rats have been observed at varying exposures, although clinical relevance is unknown.

LAMIVUDINE

The pharmacokinetics of lamivudine are described earlier in this chapter (see Nucleoside and Nucleotide Reverse Transcriptase Inhibitors). The more prolonged intracellular half-life in HBV-infected cell lines (17–19 hours) than in HIV-infected cell lines (10.5–15.5 hours) allows for lower doses and less frequent administration. Lamivudine can be safely administered to patients with decompensated liver disease. Prolonged treatment has been shown to decrease clinical progression of HBV, as well as development of hepatocellular cancer by approximately 50%. Also, lamivudine has been effective in preventing vertical transmission of HBV from mother to newborn when given in the last 4 weeks of gestation.

Lamivudine inhibits HBV DNA polymerase and HIV reverse transcriptase by competing with deoxycytidine triphosphate for incorporation into the viral DNA, resulting in chain termination. Although lamivudine results in rapid and potent virus suppression, chronic therapy is limited by the emergence of lamivudine-resistant HBV isolates (eg, L180M or M204I/V), estimated to occur in 15–30% of patients at 1 year and in up to 65% after 5 years of therapy. Resistance has been associated with flares of hepatitis and progressive liver disease. Cross-resistance between lamivudine and emtricitabine or entecavir may occur; however, adefovir and tenofovir maintain activity against lamivudine-resistant strains of HBV.

In the doses used for HBV infection, lamivudine has an excellent safety profile. Headache, nausea, diarrhea, dizziness, myalgia, and malaise are rare. Co-infection with HIV may increase the risk of pancreatitis.

TELIVUDINE

Telivudine is a thymidine nucleoside analog with activity against HBV DNA polymerase. It is phosphorylated by cellular kinases to the active triphosphate form, which has an intracellular half-life of 14 hours. The phosphorylated compound competitively inhibits HBV DNA polymerase, resulting in incorporation into viral DNA and chain termination. It is not active *in vitro* against HIV-1.

Oral bioavailability is unaffected by food. Plasma protein binding is low (3%) and distribution wide. The serum half-life is approximately 15 hours and excretion is renal. There are no known metabolites and no known interactions with the CYP450 system or other drugs.

Telivudine induced greater rates of virologic response than either lamivudine or adefovir in comparative trials. However, emergence of resistance, typically due to the M204I mutation, may occur in up to 22% of patients with durations of therapy exceeding 1 year, and may result in virologic rebound. Telivudine is not effective in patients with lamivudine-resistant HBV.

Adverse effects are mild; they include fatigue, headache, cough, nausea, and diarrhea. Both uncomplicated myalgia and myopathy with elevated creatinine kinase levels have been reported, as has peripheral neuropathy. As with other nucleoside analogs, lactic acidosis and severe hepatomegaly with steatosis may occur during therapy as well as flares of hepatitis after discontinuation.

TENOFOVIR DISOPROXIL

Tenofovir, a nucleotide analog of adenosine in use as an antiretroviral agent, has potent activity against HBV. The characteristics of tenofovir disoproxil are described earlier in this chapter. Tenofovir maintains activity against lamivudine- and entecavir-resistant hepatitis virus isolates. Although similar in structure to adefovir dipivoxil, comparative trials show a higher rate of virologic response and histologic improvement, and a lower rate of emergence of resistance in patients with chronic HBV infection. Resistance to tenofovir has not been documented in clinical trials, even among patients who have been treated with tenofovir for up to 8 years. However, efficacy is lower in patients who have resistance to adefovir and double mutations (A181T/V and N236T).

The most common adverse effects of tenofovir in patients with HBV infection are nausea, abdominal pain, diarrhea, dizziness, and fatigue. Chronic renal insufficiency secondary to a proximal tubulopathy may occur, and may progress to renal failure. Decreases in bone mineral density and Fanconi's syndrome, as observed in HIV-infected patients treated with tenofovir, have not been described in patients with HBV infection receiving tenofovir disoproxil. Tenofovir alafenamide fumarate (TAF) is an orally bioavailable prodrug of tenofovir that enables enhanced delivery

of the parent nucleotide and its active diphosphate metabolite into lymphoid cells and hepatocytes, so that the dose of tenofovir can be reduced and toxicities minimized.

EXPERIMENTAL AGENTS

The nucleoside analog **emtricitabine** (see HIV) is under clinical investigation for treatment of HBV infection. The entry inhibitors **Myrcludex B** and **cyclosporine**, as well as cccDNA inhibitors, are being evaluated. Research is also ongoing to develop and test new agents that can “cure” HBV by eliminating all replicative forms, including covalently closed circular DNA (cccDNA). Broadly curative antiviral strategies include agents that could directly target infected cells as well as novel immunotherapeutic strategies that boost HBV-specific adaptive immune responses or activate innate intrahepatic immunity. New molecules under investigation include entry inhibitors and short-interfering RNAs (siRNAs), and capsid inhibitors.

TREATMENT OF HEPATITIS C INFECTION

In contrast to the treatment of patients with chronic HBV infection, the primary goal of treatment in patients with HCV infection is viral eradication. In clinical trials, the primary efficacy end point is typically achievement of sustained viral response (SVR), defined as the absence of detectable viremia 24 weeks after completion of therapy. SVR is associated with improvement in liver histology, reduction in risk of end-stage liver disease and hepatocellular carcinoma, and, occasionally, with regression of cirrhosis as well. Late relapse occurs in less than 5% of patients who achieve SVR.

In acute hepatitis C, the rate of clearance of the virus without therapy is estimated at 20–35%. Therefore, most practitioners choose to delay therapy for a minimum of 6 months after the initial infection. If treatment is initiated thereafter due to persistent HCV RNA viremia, the regimens are the same as those administered for chronic HCV infection.

The advent of the first-generation direct-acting antiviral agents (DAAs) boceprevir and telaprevir dramatically altered the landscape for the optimal treatment of chronic HCV infection, which was previously treated with the combination of interferon- α (replaced by pegylated interferon- α) and ribavirin. Since interferon-containing regimens tend to be associated with higher rates of serious adverse events (including anemia and rash), longer treatment durations, more frequent dosing, and clinically significant drug-drug interactions, they are gradually being replaced by combination regimens of DAAs (see Table 49–7). Moreover, while the first-generation HCV protease inhibitors (ie, boceprevir, telaprevir) markedly improved the effectiveness of pegylated interferon plus ribavirin, they have been replaced by newer DAAs over the past 2 years, which can be administered in all-oral, interferon-free combinations—with or without ribavirin—with improved efficacy and tolerability, improved dosing schedules, lesser genotype specificity, and fewer potential drug-drug interactions. However, the DAA regimens are expensive.

There are four current classes of DAAs, which are defined by their mechanism of action and therapeutic target: nonstructural protein (NS) 3/4A protease inhibitors, NS5B nucleoside polymerase inhibitors, NS5B non-nucleoside polymerase inhibitors, and NS5A inhibitors. The main targets of the DAAs are the HCV-encoded proteins that are vital to the replication of the virus (Figure 49–1).

The safety profiles of all the combination regimens (see Table 49–7) are generally excellent, with adverse events of mild severity and very low rates of discontinuation due to adverse events in clinical trials in the absence of concurrent ribavirin use.

NS5A INHIBITORS

The NS5A protein plays a role in both viral replication and the assembly of HCV; however the exact mechanism of action of the HCV NS5A inhibitors remains unclear.

Daclatasvir

Daclatasvir is used in combination with sofosbuvir for treatment of HCV genotypes 1, 2, and 3. It may be taken with or without food and does not require adjustment for renal or hepatic impairment. Exposure of daclatasvir was similar between healthy and HCV-infected subjects. Protein binding is ~99%. It is metabolized via CYP3A and excreted primarily in the feces. Terminal elimination half-life is 12–15 hours.

Daclatasvir is generally well tolerated. The most common adverse effects in patients receiving daclatasvir/sofosbuvir were headache and fatigue, usually mild or moderate in severity. Serious symptomatic bradycardia has been reported in patients receiving daclatasvir with sofosbuvir and amiodarone.

Daclatasvir is primarily metabolized through CYP3A metabolism and should not be given with strong inducers of this enzyme. In addition, dose adjustment is required when co-administered with strong CYP3A inhibitors or moderate CYP3A inducers. Daclatasvir is an inhibitor of P-glycoprotein transporter (P-gp), organic anion transporting polypeptide (OATP) 1B1 and 1B3, and breast cancer resistance protein (BCRP).

Elbasvir

Elbasvir has in vitro activity against most major HCV genotypes, as well as some viral variants resistant to earlier NS5A inhibitors. It is only available as a fixed-dose combination with grazoprevir, recommended for treatment of HCV genotypes 1 and 4 (see Table 49–7).

The presence of baseline NS5A resistance-associated variants (RAVs) significantly reduced rates of SVR at 12 weeks using elbasvir/grazoprevir regimen in patients with genotype 1a. Since 10–15% of patients without prior exposure will have NS5A RAVs, baseline testing should be considered prior initiation of therapy.

Absorption is not food-dependent. Peak concentrations after ingestion occur at a median of 3 hours. Elbasvir is extensively bound to plasma proteins (>99.9%), partially eliminated by oxidative metabolism, and primarily excreted in the feces. Elbasvir/

grazoprevir should not be administered to patients with moderate or severe hepatic impairment or in conjunction with organic anion transporting polypeptides 1B1/3 (OATP1B1/3) inhibitors, strong inducers or inhibitors of CYP3A, or efavirenz.

The most commonly reported side effects during therapy with elbasvir/grazoprevir were fatigue, headache, and nausea. Elevations in serum aminotransferases may occur.

Ledipasvir

Ledipasvir was the first NS5A inhibitor to be available in the United States. It is available in a fixed-dose combination with sofosbuvir. Ledipasvir is not recommended for treatment of HCV genotype 2 infection (since potency is lost in the presence of the highly prevalent L31M polymorphism) or genotype 3 (due to the availability of more efficacious therapies (see Table 49–7).

Ledipasvir is not affected by food intake. Median peak plasma concentrations occur 4–4.5 hours after oral administration of ledipasvir/sofosbuvir. It is highly bound (>99.8%) to plasma proteins; unchanged ledipasvir is the major species present in feces. The median terminal half-life of ledipasvir following administration of ledipasvir/sofosbuvir is 47 hours. No dose adjustment is required in the setting of mild or moderate renal insufficiency or mild, moderate or severe hepatic insufficiency. The dose in patients with severe renal insufficiency has not yet been determined.

Ledipasvir is an inhibitor of the drug transporters P-gp and BCRP and may increase intestinal absorption of co-administered substrates for these transporters. Additionally, co-administration of P-gp inducers (e.g., rifampin or St. John's wort) with ledipasvir/sofosbuvir may decrease plasma concentrations of both of these agents.

The most common adverse reactions in patients receiving ledipasvir/sofosbuvir were fatigue, headache and asthenia. Serious symptomatic bradycardia has been reported in patients receiving ledipasvir with sofosbuvir and amiodarone.

Ombitasvir

Ombitasvir is available only as a fixed-dose combination with paritaprevir and ritonavir for the treatment of HCV genotype 4, and is given in combination with dasabuvir, paritaprevir, and ritonavir to treat genotype 1 (see Table 49–7). As in HIV infection, ritonavir is administered as a pharmacologic “booster” to increase plasma concentrations of paritaprevir via its effect on CYP3A, although it does not have activity against HCV.

The absolute bioavailability of ombitasvir is 48%. Peak plasma concentrations are reached 5 hours post-ingestion of the combination. It is 99.9% protein-bound; the route of metabolism is via biliary excretion. Ombitasvir/paritaprevir/ritonavir is contraindicated in patients with moderate or severe hepatic impairment.

Ombitasvir is an inhibitor of UGT1A1. Although ombitasvir is not metabolized by the CYP3A system, paritaprevir, ritonavir, and dasabuvir are, with the resulting potential for multiple drug-drug interactions. Co-administration of the combination with drugs that highly dependent on CYP3A for clearance, moderate or strong inducers of CYP3A, strong inducers of CYP2C8, or strong inhibitors of CYP2C8 is contraindicated.

The most commonly reported adverse reactions in patients receiving ombitasvir were nausea, pruritus and insomnia. Increased serum aminotransferases have also been reported, particularly in women using concomitant ethinyl estradiol-containing contraceptive medications.

Velpatasvir

Velpatasvir is available only in a fixed-dose combination with the sofosbuvir. It is the first once-daily single-tablet regimen with pangenotypic activity. No dose adjustment is required for patients with mild or moderate renal insufficiency, or any degree of hepatic impairment. Sofosbuvir exposure is increased in patients with severe renal impairment, including those on dialysis.

Velpatasvir is administered without regard to food; peak plasma concentrations are observed at 3 hours post-dose. It is >99% bound to plasma proteins. Metabolism is by CYP2B6, CYP2C8, and CYP3A4. Its median terminal half-life is 15 hours.

Velpatasvir and sofosbuvir are substrates of P-gp and BCRP; velpatasvir is also transported by OATP1B1 and OATP1B3. Inducers of P-gp and/or moderate or potent inducers of CYP2B6, CYP2C8, or CYP3A4 (e.g., rifampin, St. John's wort, carbamazepine) may decrease plasma concentrations of velpatasvir and/or sofosbuvir; co-administration with drugs that inhibit P-gp and/or BCRP may increase velpatasvir and/or sofosbuvir concentrations and drugs that inhibit CYP2B6, CYP2C8, or CYP3A4 may increase plasma concentration of velpatasvir.

The most common adverse events in patients receiving velpatasvir/sofosbuvir were headache and fatigue.

NS5B RNA POLYMERASE INHIBITORS

NS5B is an RNA-dependent RNA polymerase involved in post-translational processing that is necessary for replication of HCV. The enzyme has a catalytic site for nucleoside binding and at least four other sites at which a non-nucleoside compound can bind and cause allosteric alteration. The enzyme's structure is highly conserved across all HCV genotypes, giving agents that inhibit NS5B efficacy against all six genotypes.

There are two classes of polymerase inhibitors; these act at distinct stages of RNA synthesis. Nucleoside/nucleotide analogs (eg, sofosbuvir) target the catalytic site of NS5B, and are activated within the hepatocyte through phosphorylation to nucleoside triphosphate, which competes with nucleotides, resulting in chain termination. Non-nucleoside analogues (e.g., dasabuvir) act as allosteric inhibitors of NS5B.

Dasabuvir

Dasabuvir is a non-nucleoside NS5B polymerase inhibitor, available only as a fixed-dose combination with ombitasvir, paritaprevir, and ritonavir for treatment of HCV genotype 1. Ritonavir functions as a pharmacologic booster to increase paritaprevir plasma concentrations.

The absolute bioavailability of dasabuvir is 70%. Peak plasma concentrations are reached 4 hours post-ingestion of the

combination. It is >99.5% protein-bound. The primary route of metabolism is via CYP2C8, as well as CYP3A. This combination is contraindicated in patients with moderate or severe hepatic impairment.

The metabolism of paritaprevir, ritonavir, and dasabuvir by the CYP3A system incurs multiple potential drug-drug interactions. Co-administration of the combination with drugs that highly dependent on CYP3A for clearance, moderate or strong inducers of CYP3A, strong inducers of CYP2C8, or strong inhibitors of CYP2C8 is contraindicated.

The most commonly reported adverse reactions in patients receiving dasabuvir were nausea, pruritus and insomnia. Increased serum aminotransferases have also been reported, particularly in women using concomitant ethinyl estradiol-containing contraceptive medications.

Sofosbuvir

The nucleotide analog sofosbuvir is administered in combination with several other anti-HCV medications, including daclatasvir, simeprevir, peginterferon-alfa plus ribavirin, or ribavirin alone. It is also available in a fixed-dose combination with ledipasvir for treatment of HCV genotypes 1, 4, 5, and 6 (see Table 49–7).

Sofosbuvir is a prodrug that is rapidly converted after ingestion to GS-331007, which is efficiently taken up by hepatocytes and converted by cellular kinase to its pharmacologically active uridine analog 5'-triphosphate form GS-461203. The triphosphate is incorporated by the HCV RNA polymerase into the elongating RNA primer strand, resulting in chain termination.

Sofosbuvir is administered without regard to food; peak plasma concentrations are observed at 0.5–1 hour post-dose. It is 61–65% bound to plasma proteins and is metabolized in the liver. Renal clearance is the major elimination pathway for GS-331007. The median terminal half-lives of sofosbuvir and GS-331007 are 0.4 and 27 hours, respectively. No dose adjustment is required for patients with mild or moderate renal insufficiency, or any degree of hepatic impairment. Sofosbuvir exposure is increased in patients with severe renal impairment, including those on dialysis.

Sofosbuvir is a substrate of drug transporter P-gp; therefore, potent P-gp inducers in the intestine may decrease sofosbuvir concentrations and should not be co-administered.

Sofosbuvir is generally well tolerated. Drug-specific adverse effects are difficult to discern since it is always administered with other antiviral agents. In patients receiving sofosbuvir with ledipasvir, the most commonly reported adverse effects were fatigue, headache, and asthenia. Rare cases of symptomatic bradycardia have been reported patients taking sofosbuvir and amiodarone in combination with another DAAs, particularly in patients also receiving beta blockers, or in those with underlying cardiac comorbidities and/or advanced liver disease.

NS3/4A PROTEASE INHIBITORS

NS3/4A protease inhibitors are inhibitors of the NS3/4A serine protease, an enzyme involved in post-translational processing and replication of HCV (Figure 49–4).

FIGURE 49–4 HCV genome and potential targets of drug action. C, E1, E2, etc, protein products of specific genes; Nucs, nucleoside inhibitors; Non-Nucs, nonnucleoside inhibitors. (Adapted, with permission, from Asselah T, Marcellin P: Direct-acting antivirals for the treatment of chronic hepatitis C: One pill a day for tomorrow. *Liver Int* 2012;32 Suppl 1:88.)

Grazoprevir

Grazoprevir is a potent, pan-genotypic protease inhibitor, reversibly binding to HCV NS3/4A protease. It is distinct from earlier-generation protease inhibitors due to its pan-genotypic activity, as well as activity against some of the major resistance-associated variants (R155K and D168Y) resulting in failure with first-generation protease inhibitors. It is only available in combination with elbasvir for treatment of HCV genotypes 1 and 4.

Grazoprevir can be taken without regard to food. Oral exposures are ~2-fold greater in HCV-infected subjects than in healthy subjects. Peak plasma concentrations are reached at a median of 2 hours after ingestion. Grazoprevir is extensively bound to plasma proteins (98.8%), and distributes predominantly to the liver, likely facilitated by active transport through the OATP1B1/3 liver uptake transporter. It is partially eliminated by oxidative metabolism, primarily by CYP3A and is mostly eliminated in the feces. Its geometric mean terminal half-life is 31 hours.

Elbasvir/grazoprevir should not be administered to patients with moderate or severe hepatic impairment, or in conjunction with organic anion transporting polypeptides 1B1/3 (OATP1B1/3) inhibitors, strong inducers or inhibitors of CYP3A, or efavirenz.

The most commonly reported side effects during therapy with elbasvir/grazoprevir were fatigue, headache, and nausea. Elevations in serum aminotransferases may occur.

Paritaprevir

Paritaprevir is only available as a fixed-dose combination with ombitasvir and ritonavir for treatment of HCV genotype 4, and is administered in combination with dasabuvir for genotype 1 infection. Ritonavir functions as a pharmacologic booster of paritaprevir concentrations via its effect on CYP metabolism, although it does not have activity against HCV.

The absolute bioavailability of paritaprevir is 53%. Peak plasma concentrations are reached 4–5 hours post-ingestion of the combination. It is ~98% protein-bound. The primary route of metabolism is via CYP3A4, as well as CYP3A5. Ombitasvir/paritaprevir/ritonavir is contraindicated in patients with moderate or severe hepatic impairment.

The metabolism of paritaprevir, ritonavir, and dasabuvir by the CYP3A system incurs multiple potential drug-drug interactions. Co-administration of the combination with drugs highly dependent on CYP3A for clearance, moderate or strong inducers of CYP3A, strong inducers of CYP2C8, or strong inhibitors of CYP2C8 is contraindicated.

The most commonly reported adverse reactions in patients receiving paritaprevir were nausea, pruritus and insomnia. Increased serum aminotransferases have also been reported, particularly in women using concomitant ethinyl estradiol-containing contraceptive medications.

Simeprevir

Simeprevir was one of the earliest protease inhibitors available; however, it is considered a second-generation HCV protease inhibitor because of the enhanced binding affinity and specificity for NS3/4A. It is used in combination with sofosbuvir, with or without ribavirin, for treatment of HCV genotype 1, or it may be administered in combination with peg interferon-alfa and ribavirin. Simeprevir must be taken with food to maximize absorption. Mean absolute bioavailability is 62%. Peak plasma concentrations are reached 4–6 hours post-ingestion. It is extensively bound to plasma proteins (>99%), metabolized in the liver by CYP3A pathways, and undergoes biliary excretion. Simeprevir is not recommended in patients with moderate or severe hepatic impairment because of 2- to 5-fold increases in exposure. In addition, mean

simeprevir exposures are more than threefold higher in patients of East Asian ancestry compared with Caucasians, leading to potentially higher frequencies of adverse events.

Simeprevir is a substrate and mild inhibitor of CYP3A and a substrate and inhibitor of P-gp and OATP1B1/3. Co-administration with moderate or strong inhibitors or inducers of CYP3A may significantly increase or decrease the plasma concentration of simeprevir.

In patients with genotype 1a, the presence of a baseline NS3A polymorphism Q80K was associated with significantly reduced SVR at 12 weeks in patients treated with simeprevir plus peginterferon and ribavirin. Therefore, baseline screening for the Q80K mutation is recommended prior to initiation of therapy.

Simeprevir is generally well tolerated. Photosensitivity and rash have been reported, occasionally severe; pruritus or nausea may also occur. Transient, mild elevations in bilirubin have been observed with simeprevir due to decreased bilirubin elimination related to inhibition of the hepatic transporters OATP1B1 and MRP2, but no pattern to suggest liver toxicity has been observed. Since simeprevir contains a sulfa moiety, caution should be used in patients with a history of sulfa allergy.

RIBAVIRIN

Ribavirin is a guanosine analog that is phosphorylated intracellularly by host cell enzymes. Although its mechanism of action has not been fully elucidated, it appears to interfere with the synthesis of guanosine triphosphate, to inhibit capping of viral messenger RNA, and to inhibit the viral RNA-dependent polymerase of certain viruses. Ribavirin triphosphate inhibits the replication of a wide range of DNA and RNA viruses, including influenza A and B, parainfluenza, respiratory syncytial virus, paramyxoviruses, HCV, and HIV-1.

The absolute oral bioavailability of ribavirin is 45–64%, increases with high-fat meals, and decreases with co-administration of antacids. Plasma protein binding is negligible, volume of distribution is large, and cerebrospinal fluid levels are about 70% of those in plasma. Ribavirin elimination is primarily through the urine; therefore, clearance is decreased in patients with creatinine clearances <30 mL/min.

Higher doses of ribavirin (ie, 1000–1200 mg/d rather than 800 mg/d) and/or a longer duration of therapy may be more efficacious, but the risk of toxicity is also increased. A dose-dependent hemolytic anemia occurs in 10–20% of patients, usually within the first weeks of therapy. Other potential adverse effects are depression, fatigue, irritability, rash, cough, insomnia, nausea, and pruritus. Contraindications include anemia, end-stage renal failure, ischemic vascular disease, and pregnancy. Ribavirin is teratogenic and embryotoxic in animals as well as mutagenic in mammalian cells. Therefore, two effective forms of contraception should be used by both sexual partners during treatment and for several months thereafter.

The co-administration of ribavirin with didanosine causes significantly increased levels of didanosine; co-administration with azathioprine may result in myelotoxicity due to accumulation of azathioprine.

■ ANTI-INFLUENZA AGENTS

Influenza virus strains are classified by their core proteins (ie, A, B, or C), species of origin (eg, avian, swine), and geographic site of isolation. Influenza A, the only strain that causes pandemics, is classified into 16 H (hemagglutinin) and 9 N (neuraminidase) known subtypes based on surface proteins. Although influenza B viruses usually infect only people, influenza A viruses can infect a variety of animal hosts, including birds, providing an extensive reservoir. Current influenza A subtypes that are circulating among worldwide populations include H1N1, H1N2, and H3N2. Although avian influenza subtypes are typically highly species-specific, they have on rare occasions crossed the species barrier to infect humans and cats. Viruses of the H5 and H7 subtypes (eg, H5N1, H7N9) may rapidly mutate within poultry flocks from a low to high pathogenic form and have recently expanded their host range to cause both avian and human disease. However, person-to-person spread of these avian viruses to date has been rare, limited, and unsustainable.

There are 5 anti-influenza drugs approved for use: 3 are neuraminidase inhibitors (oral oseltamivir, inhaled zanamivir, IV peramivir) and 2 are adamantanes (amantadine, rimantadine). Treatment is recommended for individuals with severe infection or at high risk for complications. The neuraminidase inhibitors have activity against both influenza A and influenza B, and there is currently a low level of resistance. The adamantanes have activity against influenza A viruses only, and in recent past seasons there was a high level of resistance (>99%) among both influenza H3N2 and influenza A H1N1.

OSELTAMIVIR & ZANAMIVIR

The neuraminidase inhibitors oseltamivir and zanamivir, analogs of sialic acid, interfere with release of progeny influenza A and B virus from infected host cells, thus halting the spread of infection within the respiratory tract. These agents competitively and reversibly interact with the active enzyme site to inhibit viral neuraminidase activity at low nanomolar concentrations, resulting in clumping of newly released influenza virions to each other and to the membrane of the infected cell. Early administration is crucial because replication of influenza virus peaks at 24–72 hours after the onset of illness. Initiation of a 5-day course of therapy within 48 hours after the onset of illness (75 mg twice daily) modestly decreases the duration of symptoms, as well as duration of viral shedding and viral titer; some studies have also shown a decrease in the incidence of complications. Once-daily prophylaxis (75 mg once daily) is 70–90% effective in preventing disease after exposure.

Oseltamivir is an orally administered prodrug that is activated by hepatic esterases and widely distributed throughout the body. Oral bioavailability is ~80%, plasma protein binding is low, and concentrations in the middle ear and sinus fluid are similar to those in plasma. The half-life of oseltamivir is 6–10 hours, and excretion is by glomerular filtration and tubular secretion. Probenecid reduces renal clearance by 50%. Serum concentrations

of oseltamivir carboxylate, the active metabolite of oseltamivir, increase with declining renal function; therefore, dosage should be adjusted in patients with renal insufficiency. Potential adverse effects include nausea, vomiting, and headache. Taking oseltamivir with food does not interfere with absorption and may decrease nausea and vomiting. Fatigue and diarrhea have also been reported and appear to be more common with prophylactic use. Rash is rare. Neuropsychiatric events (self-injury or delirium) have been reported, particularly in adolescents and adults living in Japan.

Zanamivir is administered directly to the respiratory tract via inhalation. Of the active compound, 10–20% reaches the lungs; the remainder is deposited in the oropharynx. The concentration of the drug in the respiratory tract is estimated to be more than 1000 times the 50% inhibitory concentration for neuraminidase, and the pulmonary half-life is 2.8 hours. Of the total dose (10 mg twice daily for 5 days for treatment or 10 mg once daily for prevention), 5–15% is absorbed and excreted in the urine with minimal metabolism. Potential adverse effects include cough, bronchospasm (occasionally severe), reversible decrease in pulmonary function, and transient nasal and throat discomfort. Zanamivir administration is not recommended for patients with underlying airway disease.

Although resistance to oseltamivir and zanamivir may emerge during therapy and be transmissible, >98% of H1N1 and H3N2 strains as well as 100% of influenza B virus tested by the Centers for Disease Control in the 2014–2015 season retained susceptibility to both agents.

PERAMIVIR

The neuraminidase inhibitor peramivir, a cyclopentane analog, has activity against both influenza A and B viruses, and is approved as a single 600-mg IV dose for the treatment of acute uncomplicated influenza in adults. As with the other neuraminidase inhibitors, early treatment is optimal (ie, within 48 hours).

Less than 30% of peramivir is protein-bound. Peramivir is not significantly metabolized in humans and the major route of elimination is the kidney. Dose adjustment is required for renal insufficiency. The elimination half-life following IV administration is ~20 hours.

The main potential side effect is diarrhea, although serious skin or hypersensitivity reactions (e.g., Stevens-Johnson syndrome, erythema multiforme) have been rarely reported. In addition, as with the other neuraminidase inhibitors, an increased risk of hallucinations, delirium, and abnormal behavior in patients with influenza receiving peramivir has been reported.

AMANTADINE & RIMANTADINE

Amantadine (1-aminoadamantane hydrochloride) and its α -methyl derivative, rimantadine, are tricyclic amines of the adamantane family that block the M2 proton ion channel of the virus particle and inhibit uncoating of the viral RNA within infected host cells, thus preventing its replication. They are active against

influenza A only. Rimantadine is four to ten times more active than amantadine in vitro. Amantadine is well absorbed and 67% protein-bound, with a plasma half-life of 12–18 hours that varies by creatinine clearance. Rimantadine is about 40% protein-bound and has a half-life of 24–36 hours. Nasal mucus concentrations of rimantadine average 50% higher than those in plasma, and cerebrospinal fluid levels are 52–96% of those in the serum. Amantadine is excreted unchanged in the urine, whereas rimantadine undergoes extensive metabolism by hydroxylation, conjugation, and glucuronidation before urinary excretion. Dose reductions are required for both agents in the elderly and in patients with renal insufficiency, and for rimantadine in patients with severe hepatic insufficiency.

In the absence of resistance, both amantadine and rimantadine are 70–90% protective in the prevention of clinical illness when initiated before exposure and limit the duration of clinical illness by 1–2 days when administered as treatment. However, due to high rates of resistance in both H1N1 and H3N2 viruses, these agents are no longer recommended for the prevention or treatment of influenza.

The most common adverse effects are gastrointestinal (nausea, anorexia) and central nervous system (nervousness, difficulty in concentrating, insomnia, light-headedness). More serious side effects (eg, marked behavioral changes, delirium, hallucinations, agitation, and seizures) may be due to alteration of dopamine neurotransmission (see Chapter 28); are less frequent with rimantadine than with amantadine; are associated with high plasma concentrations; may occur more frequently in patients with renal insufficiency, seizure disorders, or advanced age; and may increase with concomitant antihistamines, anticholinergic drugs, hydrochlorothiazide, and trimethoprim-sulfamethoxazole. Clinical manifestations of anticholinergic activity tend to be present in acute amantadine overdose. Both agents are teratogenic and embryotoxic in rodents, and birth defects have been reported after exposure during pregnancy.

INVESTIGATIONAL AGENTS

An IV formulation of **zanamivir** is being evaluated in clinical trials and is available for compassionate use from the manufacturer. A long-acting neuraminidase inhibitor, **laninamivir octanoate**, may retain activity against oseltamivir-resistant virus. **DAS181** is a host-directed antiviral agent with activity against influenza and parainfluenza that acts by removing the virus receptor, sialic acid, from adjacent glycan structures.

OTHER ANTIVIRAL AGENTS

INTERFERONS

Interferons have been studied for numerous clinical indications. In addition to HBV and HCV infections (see Antihepatitis Agents), intralesional injection of interferon alfa-2b or alfa-n3 may be used for treatment of condylomata acuminata (see Chapter 61).

RIBAVIRIN

In addition to oral administration for HCV infection in combination with interferon alfa (see Antihepatitis Agents), aerosolized ribavirin is administered by nebulizer (20 mg/mL for 12–18 hours continuously per day) to children and infants with severe respiratory syncytial virus (RSV) bronchiolitis or pneumonia to reduce the severity and duration of illness. Systemic absorption is low (<1%). Aerosolized ribavirin may cause conjunctival or bronchial irritation and the aerosolized drug may precipitate on contact lenses. Ribavirin is teratogenic and embryotoxic. Health care workers and pregnant women should be protected against extended inhalation exposure.

Ribavirin has in vitro activity against a number of viruses, including Lassa, West Nile, measles, influenza, and parainfluenza. However, clinical data regarding effectiveness are lacking.

PALIVIZUMAB

Palivizumab is a humanized monoclonal antibody directed against an epitope in the A antigen site on the F surface protein of RSV. It is licensed for the prevention of RSV infection in high-risk infants and children, such as premature infants and those with bronchopulmonary dysplasia or congenital heart disease. A placebo-controlled trial using once-monthly intramuscular injections (15 mg/kg) for 5 months beginning at the start of the RSV season demonstrated a 55% reduction in the risk of hospitalization

for RSV in treated patients, as well as decreases in the need for supplemental oxygen, the illness severity score, and need for intensive care. Although resistant strains have been isolated in the laboratory, no resistant clinical isolates have yet been identified. Potential adverse effects include upper respiratory tract infection, fever, rhinitis, rash, diarrhea, vomiting, cough, otitis media, and elevation in serum aminotransferase levels.

Agents under investigation for the treatment or prophylaxis of patients with RSV infection include small molecule inhibitors that interfere with RSV fusion through interaction with the F protein of RSV (e.g., **GS-5806**) and the oral nucleoside analog **ALS-008176**.

IMIQUIMOD

Imiquimod is an immune response modifier shown to be effective in the topical treatment of external genital and perianal warts (ie, condyloma acuminatum; see Chapter 61). The 5% cream is applied three times weekly and washed off 6–10 hours after each application. Recurrences appear to be less common than after ablative therapies. Imiquimod may also be effective against molluscum contagiosum but is not licensed in the USA for this indication. Local skin reactions are the most common adverse effect; these tend to resolve within weeks after therapy. However, pigmentary skin changes may persist. Systemic adverse effects such as fatigue and influenza-like syndrome have occasionally been reported.

PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
Abacavir	Generic, Ziagen
Abacavir/lamivudine	Epzicom
Abacavir/lamivudine/zidovudine	Trizivir
Acyclovir	Generic, Zovirax
Adefovir	Generic, Hepsera
Amantadine	Generic, Symmetrel
Atazanavir	Reyataz
Boceprevir	Victrelis
Cidofovir	Generic, Vistide
Darunavir	Prezista (must be taken with ritonavir)
Delavirdine	Rescriptor
Didanosine (dideoxyinosine, ddl)	Generic, Videx, Videx-EC
Docosanol	Abreva (over-the-counter)
Efavirenz	Sustiva
Emtricitabine	Emtriva
Emtricitabine/tenofovir	Truvada
Emtricitabine/tenofovir/efavirenz	Atripla
Enfuvirtide	Fuzeon
Entecavir	Baraclude

GENERIC NAME	AVAILABLE AS
Etravirine	Intelence
Famciclovir	Generic, Famvir
Fosamprenavir	Lexiva
Foscarnet	Generic, Foscavir
Ganciclovir	Generic, Cytovene
Imiquimod	Generic, Aldara, others
Indinavir	Crixivan
Interferon alfa-2a	Roferon-A
Interferon alfa-2b	Intron-A
Interferon alfa-2b/ribavirin	Rebetron
Interferon alfa-n3	Alferon N
Interferon alfacon-1	Infergen
Lamivudine	Generic, Epivir, Epivir-HBV
Lamivudine/zidovudine	Combivir
Lamivudine/abacavir/zidovudine	Trizivir
Lopinavir/ritonavir	Kaletra
Maraviroc	Selzentry
Nelfinavir	Viracept
Nevirapine	Generic, Viramune
Oseltamivir	Tamiflu

(continued)

GENERIC NAME	AVAILABLE AS
Palivizumab	Synagis
Peginterferon alfa-2a (pegylated interferon alfa-2a)	Pegasys
Peginterferon alfa-2b (pegylated interferon alfa-2b)	PEG-Intron
Penciclovir	Denavir
Raltegravir	Isentress
Ribavirin	Generic, Rebetol
Ribavirin/interferon alfa-2b	Rebetron
Ribavirin Aerosol	Virazole
Rilpivirine	Edurant
Rilpivirine/emtricitabine/tenofovir	Complera
Rimantadine	Generic, Flumadine
Ritonavir	Norvir
Saquinavir	Invirase

GENERIC NAME	AVAILABLE AS
Sofosbuvir	Sovaldi
Stavudine	Generic, Zerit, Zerit XR
Telaprevir	Incivek
Telbivudine	Tyzeka
Tenofovir	Viread
Tipranavir	Aptivus
Trifluridine	Generic, Viroptic
Valacyclovir	Generic, Valtrex
Valganciclovir	Valcyte
Zalcitabine (dideoxycytidine, ddC)	Hivid (withdrawn)
Zanamivir	Relenza
Zidovudine (azidothymidine, AZT)	Generic, Retrovir
Zidovudine/lamivudine	Combivir
Zidovudine/lamivudine/abacavir	Trizivir

CASE STUDY ANSWER

Combination antiviral therapy against both HIV and hepatitis B virus (HBV) is indicated in this patient, given the high viral load and low CD4 cell count. However, the use of methadone and possibly excessive alcohol consumption necessitate caution. Tenofovir plus emtricitabine (two nucleoside/nucleotide reverse transcriptase inhibitors) would be excellent choices as the NRTI “backbone” of a fully suppressive regimen, since both are active against HIV-1 and HBV, do not interact with methadone, and are available in a once-daily, fixed-dose combination. A strand inhibitor such as raltegravir or dolutegravir, or the boosted combination of darunavir/ritonavir could be added. There are other

alternatives as well. Prior to initiation of this regimen, renal and liver function should be checked, HBV DNA level should be assessed, the patient should be screened for Hepatitis A and HCV infection, and a bone mineral density test should be considered. Pregnancy should be ruled out, and the patient should be counseled that efavirenz should not be taken during pregnancy. Avoidance of alcohol should be recommended. The potential for lowered methadone levels with darunavir, if used, necessitates close monitoring and possibly an increased dose of methadone. Finally, the patient should be made aware that abrupt cessation of these medications may precipitate an acute flare of hepatitis.

Miscellaneous Antimicrobial Agents; Disinfectants, Antiseptics, & Sterilants

Lisa G. Winston, MD*

CASE STUDY

A 56-year-old man is admitted to the intensive care unit of a hospital for treatment of community-acquired pneumonia. He receives ceftriaxone and azithromycin upon admission, rapidly improves, and is transferred to a semiprivate ward room. On day 7 of his hospitalization, he develops copious diarrhea with eight bowel movements but is otherwise

clinically stable. *Clostridium difficile* infection is confirmed by stool testing. What is an acceptable treatment for the patient's diarrhea? The patient is transferred to a single-bed room. The housekeeping staff asks what product should be used to clean the patient's old room.

■ METRONIDAZOLE, FIDAXOMYCIN, RIFAXIMIN, MUPIROCIN, POLYMYXINS, & URINARY ANTISEPTICS

METRONIDAZOLE

Metronidazole is a nitroimidazole antiprotozoal drug (see Chapter 52) that also has potent antibacterial activity against anaerobes, including *Bacteroides* and *Clostridium* species. Metronidazole is selectively absorbed by anaerobic bacteria and sensitive protozoa. Once taken up by anaerobes, it is nonenzymatically reduced by reacting with reduced ferredoxin. This reduction

results in products that accumulate in and are toxic to anaerobic cells. The metabolites of metronidazole are taken up into bacterial DNA, forming unstable molecules. This action occurs only when metronidazole is partially reduced, and, because this reduction usually happens only in anaerobic cells, it has relatively little effect on human cells or aerobic bacteria.

Metronidazole is well absorbed after oral administration, is widely distributed in tissues, and reaches serum levels of 4–6 mcg/mL after a 250-mg oral dose. It can also be given intravenously. The drug penetrates well into the cerebrospinal fluid and brain, reaching levels similar to those in serum. Metronidazole is metabolized in the liver and may accumulate in hepatic insufficiency.

Metronidazole is indicated for treatment of anaerobic or mixed intra-abdominal infections (in combination with other agents with activity against aerobic organisms), vaginitis (trichomonas infection, bacterial vaginosis), *Clostridium difficile* infection, and brain abscess. The typical dosage is 500 mg three times daily orally

*The authors thank Henry F. Chambers, MD and Daniel H. Deck, PharmD, for their contributions to previous editions of this chapter.

or intravenously (30 mg/kg/d). Vaginitis may respond to a single 2-g dose. A vaginal gel is available for topical use.

Adverse effects include nausea, diarrhea, stomatitis, and peripheral neuropathy with prolonged use. Metronidazole has a disulfiram-like effect, and patients should be instructed to avoid alcohol. Although teratogenic in some animals, metronidazole has not been associated with this effect in humans. Other properties of metronidazole are discussed in Chapter 52.

A structurally similar agent, **tinidazole**, is a once-daily drug approved for treatment of trichomonas infection, giardiasis, amebiasis, and bacterial vaginosis. It also is active against anaerobic bacteria, but is not approved in the USA for treatment of anaerobic infections.

FIDAXOMICIN

Fidaxomicin is a narrow-spectrum, macrocyclic antibiotic that is active against Gram-positive aerobes and anaerobes but lacks activity against Gram-negative bacteria. Fidaxomicin inhibits bacterial protein synthesis by binding to the sigma subunit of RNA polymerase. When administered orally, systemic absorption is negligible but fecal concentrations are high. Fidaxomicin has been approved by the U.S. Food and Drug Administration (FDA) for the treatment for *C difficile* infection in adults. It is as effective as oral vancomycin and may be associated with lower rates of relapsing disease. Fidaxomicin is administered orally as a 200 mg tablet twice daily for 10 days.

RIFAXIMIN

Rifaximin is a derivative of rifampin. It is active against Gram-positive and Gram-negative aerobes and anaerobes. Rifaximin inhibits bacterial protein synthesis by binding to the beta subunit of DNA-dependent RNA polymerase. When administered orally, systemic absorption is <0.5%, but fecal concentrations are high; following a three day course for travelers' diarrhea, the fecal concentrations were 8000 mcg/g. Rifaximin was originally approved by the FDA for the treatment of travelers' diarrhea, and it is now used in the management of hepatic encephalopathy, irritable bowel syndrome with diarrhea, and, occasionally, as an adjunct in cases of recurrent or refractory *C difficile* infection in adults. Typical doses of rifaximin range from 200 mg to 550 mg administered orally twice to three times daily depending on the indication. Unlike other rifamycins, rifaximin is not thought to be associated with cytochrome-P450-mediated drug interactions due to its limited absorption.

MUPIROCIN

Mupirocin (pseudomonic acid) is a natural substance produced by *Pseudomonas fluorescens*. It is rapidly inactivated after absorption, and systemic levels are undetectable. It is available as an ointment for topical application.

Mupirocin is active against Gram-positive cocci, including methicillin-susceptible and methicillin-resistant strains of

Staphylococcus aureus. Mupirocin inhibits staphylococcal isoleucyl tRNA synthetase. Low-level resistance, defined as a minimum inhibitory concentration (MIC) of up to 100 mcg/mL, is due to point mutation in the gene of the target enzyme. Low-level resistance has been observed after prolonged use. However, local concentrations achieved with topical application are well above this MIC, and this level of resistance does not lead to clinical failure. High-level resistance, with MICs exceeding 1000 mcg/mL, is due to the presence of a second isoleucyl tRNA synthetase gene, which is plasmid-encoded. High-level resistance results in complete loss of activity. Strains with high-level resistance have caused hospital-associated outbreaks of staphylococcal infection and colonization. Although higher rates of resistance are encountered with extensive use of mupirocin, most staphylococcal isolates are still susceptible.

Mupirocin is indicated for topical treatment of minor skin infections, such as impetigo (see Chapter 61). Topical application over large open areas, such as pressure ulcers or surgical wounds, is an important factor leading to emergence of mupirocin-resistant strains and is not recommended. Mupirocin temporarily eliminates *S aureus* nasal carriage by patients or health care workers, but results are mixed with respect to its ability to prevent subsequent staphylococcal infection. Patients most likely to benefit from decolonization are those undergoing orthopedic or cardiothoracic procedures.

POLYMYXINS

The polymyxins are a group of basic peptides active against Gram-negative bacteria and include **polymyxin B** and **polymyxin E (colistin)**. Polymyxins act as cationic detergents. They attach to and disrupt bacterial cell membranes. They also bind and inactivate endotoxin. Gram-positive organisms, *Proteus* sp, and *Neisseria* sp are resistant.

Owing to their significant toxicity with systemic administration (especially nephrotoxicity), polymyxins were, until recently, largely restricted to topical use. Ointments containing polymyxin B, 5000 units/g, in mixtures with bacitracin or neomycin (or both) are commonly applied to infected superficial skin lesions. Emergence of strains of *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and Enterobacteriaceae that are resistant to all other agents has renewed interest in polymyxins as parenteral agents for salvage therapy of infections caused by these organisms.

URINARY ANTISEPTICS

Urinary antiseptics are oral agents that exert antibacterial activity in the urine but have little or no systemic antibacterial effect. Their usefulness is limited to lower urinary tract infections.

Nitrofurantoin

At therapeutic doses, **nitrofurantoin** is bactericidal for many Gram-positive and Gram-negative bacteria; however, *P aeruginosa* and many strains of *Proteus* are inherently resistant. Nitrofurantoin has a complex mechanism of action that is not fully

understood. Antibacterial activity appears to correlate with rapid intracellular conversion of nitrofurantoin to highly reactive intermediates by bacterial reductases. These intermediates react non-specifically with many ribosomal proteins and disrupt metabolic processes and the synthesis of proteins, RNA, and DNA. It is not known which of the multiple actions of nitrofurantoin is primarily responsible for its bactericidal activity.

There is no cross-resistance between nitrofurantoin and other antimicrobial agents, and resistance emerges slowly. As resistance to trimethoprim-sulfamethoxazole and fluoroquinolones has become more common in *Escherichia coli*, nitrofurantoin has become an important alternative oral agent for treatment of uncomplicated urinary tract infection.

Nitrofurantoin is well absorbed after ingestion. It is metabolized and excreted so rapidly that no systemic antibacterial action is achieved. The drug is excreted into the urine by both glomerular filtration and tubular secretion. With average daily doses, concentrations of 200 mcg/mL are reached in urine. In renal failure, urine levels are insufficient for antibacterial action, but high blood levels may cause toxicity. Nitrofurantoin is contraindicated in patients with significant renal insufficiency. Traditional recommendations are to avoid use in patients with creatinine clearance <60 mL/min; however, some data suggest short-term nitrofurantoin treatment is acceptable in patients with creatinine clearance >30 mL/min.

The dosage for urinary tract infection in adults is 100 mg orally taken four times daily. A long-acting formulation (**Macrobid**) can be taken twice daily. Each long-acting capsule contains two forms of nitrofurantoin. Macrocrystalline nitrofurantoin, which has slower dissolution and absorption than nitrofurantoin monohydrate, constitutes 25%. The remaining 75% is nitrofurantoin monohydrate contained in a powder blend, which, upon exposure to gastric and intestinal fluids, forms a gel matrix that releases nitrofurantoin over time.

The drug should not be used to treat upper urinary tract infection. It is desirable to keep urinary pH below 5.5, which greatly enhances drug activity. A single daily dose of nitrofurantoin, 100 mg, can prevent recurrent urinary tract infections in some women.

Anorexia, nausea, and vomiting are the principal side effects of nitrofurantoin. Neuropathies and pulmonary toxicities may occur, particularly with prolonged use or in patients with renal impairment. Hemolytic anemia can occur in patients with glucose-6-phosphate dehydrogenase deficiency. Nitrofurantoin antagonizes the action of nalidixic acid. Rashes, pulmonary infiltration and fibrosis, and other hypersensitivity reactions have been reported.

Methenamine Mandelate & Methenamine Hippurate

Methenamine mandelate is the salt of mandelic acid and methenamine and possesses properties of both of these urinary antiseptics. Methenamine hippurate is the salt of hippuric acid and methenamine. Below pH 5.5, methenamine releases formaldehyde, which is antibacterial (see Aldehydes, below). Oral mandelic acid or hippuric acid is absorbed and excreted unchanged in the urine. These

drugs are bactericidal for some Gram-negative bacteria when urine pH is less than 5.5.

Methenamine mandelate, 1 g four times daily, or methenamine hippurate, 1 g twice daily by mouth (in children age 6 to 12 years, 500 mg four times daily or twice daily, respectively), is used only as a urinary antiseptic to prevent, not treat, symptomatic urinary tract infection. Acidifying agents (eg, ascorbic acid, 4–12 g/d) may be given to lower urinary pH below 5.5. Sulfonamides should not be given at the same time because they may form an insoluble compound with the formaldehyde released by methenamine. Persons taking methenamine mandelate may exhibit falsely elevated tests for catecholamine metabolites.

■ DISINFECTANTS, ANTISEPTICS, & STERILANTS

Disinfectants are chemical agents or physical procedures that inhibit or kill microorganisms (Table 50–1). Antiseptics are disinfecting chemical agents with sufficiently low toxicity for host cells that they can be used directly on skin, mucous membranes, or wounds. Sterilants kill both vegetative cells and spores when applied to materials for appropriate times and temperatures. Some of the terms used in this context are defined in Table 50–2.

Disinfection prevents infection by reducing the number of potentially infective organisms by killing, removing, or diluting them. Disinfection can be accomplished by application of chemical agents or use of physical agents such as ionizing radiation, dry or moist heat, or superheated steam (autoclave, 120°C) to kill microorganisms. Often a combination of agents is used, eg, water and moderate heat over time (pasteurization); ethylene oxide and moist heat (a sterilant); or addition of disinfectant to a detergent. Prevention of infection also can be achieved by washing, which dilutes the potentially infectious organism.

Hand hygiene is probably the most important means of preventing transmission of infectious agents from person to person or from regions of high microbial load, eg, mouth, nose, or gut, to potential sites of infection. Alcohol-based hand rubs and soap and warm water are used to remove bacteria. Skin disinfectants along with detergent and water are usually used preoperatively as a surgical scrub for surgeons' hands.

Evaluation of effectiveness of antiseptics, disinfectants, and sterilants, although seemingly simple in principle, is very complex. Factors in any evaluation include the intrinsic resistance of the microorganism, the number of microorganisms present, mixed populations of organisms, amount of organic material present (eg, blood, feces, tissue), concentration and stability of disinfectant or sterilant, time and temperature of exposure, pH, and hydration and binding of the agent to surfaces. Specific, standardized assays of activity are defined for each use. Toxicity for humans also must be evaluated. In the USA, the Environmental Protection Agency (EPA) regulates disinfectants and sterilants and the FDA regulates antiseptics.

Users of antiseptics, disinfectants, and sterilants need to consider their short-term and long-term toxicity because they may have general biocidal activity and may accumulate in the

TABLE 50–1 Activities of disinfectants.

	Bacteria			Viruses			Other

environment or in the body. Disinfectants and antiseptics may also become contaminated by resistant microorganisms—eg, spores, *P aeruginosa*, or *Serratia marcescens*—and actually transmit infection. Most topical antiseptics interfere with wound healing to some degree. Cleansing of wounds with soap and water may be less damaging than the application of antiseptics.

Some of the chemical classes of antiseptics, disinfectants, and sterilants are described briefly in the text that follows. The reader is referred to the general references for descriptions of physical disinfection and sterilization methods.

ALCOHOLS

The two alcohols most frequently used for antiseptics and disinfection are **ethanol** and **isopropyl alcohol (isopropanol)**. They are rapidly active, killing vegetative bacteria, *Mycobacterium*

tuberculosis, and many fungi, and inactivating lipophilic viruses. The optimum bactericidal concentration is 60–90% by volume in water. They probably act by denaturation of proteins. They are not used as sterilants because they are not sporicidal, do not penetrate protein-containing organic material, and may not be active against hydrophilic viruses. Their skin-drying effect can be alleviated by addition of emollients to the formulation. Use of alcohol-based hand rubs has been shown to reduce transmission of health care–associated bacterial pathogens and is recommended by the Centers for Disease Control and Prevention (CDC) as the preferred method of hand decontamination in health care settings. Alcohol-based hand rubs are ineffective against spores of *C difficile*, and handwashing with soap and water is required for decontamination after caring for a patient with infection from this organism.

Alcohols are flammable and must be stored in cool, well-ventilated areas. They must be allowed to evaporate before cautery, electrosurgery, or laser surgery. Alcohols may be damaging if applied directly to corneal tissue. Therefore, instruments such as tonometers that have been disinfected in alcohol should be rinsed with sterile water, or the alcohol should be allowed to evaporate before they are used.

CHLORHEXIDINE

Chlorhexidine is a cationic biguanide with very low water solubility. Water-soluble chlorhexidine digluconate is used in water-based formulations as an antiseptic. It is active against vegetative bacteria and mycobacteria and has variable activity against fungi and viruses. It strongly adsorbs to bacterial membranes, causing leakage of small molecules and precipitation of cytoplasmic proteins. It is active at pH 5.5–7.0. Chlorhexidine gluconate is slower in its action than alcohols, but, because of its persistence, it has residual activity, producing bactericidal action equivalent to alcohols. It is most effective against Gram-positive cocci and less active

TABLE 50–2 Commonly used terms related to chemical and physical killing of microorganisms.

Antisepsis	Application of an agent to living tissue for the purpose of preventing infection
Decontamination	Process that produces marked reduction in number or activity of microorganisms
Disinfection	Chemical or physical treatment that destroys most vegetative microbes and viruses, but not spores, in or on inanimate surfaces
Sanitization	Reduction of microbial load on an inanimate surface to a level considered acceptable for public health purposes
Sterilization	A process intended to kill or remove all types of microorganisms, including spores, and usually including viruses, with an acceptably low probability of their survival
Pasteurization	A process that kills nonsporulating microorganisms by hot water or steam at 65–100°C

against Gram-positive and Gram-negative rods. Spore germination is inhibited by chlorhexidine. Chlorhexidine digluconate is resistant to inhibition by blood and organic materials. However, anionic and nonionic agents in moisturizers, neutral soaps, and surfactants may neutralize its action. Chlorhexidine digluconate formulations of 4% concentration have slightly greater antibacterial activity than newer 2% formulations. The combination of chlorhexidine gluconate in 70% alcohol, available in some countries including the USA, is the preferred agent for skin antiseptics in many surgical and percutaneous procedures. The advantage of this combination over povidone-iodine may derive from its more rapid action after application, its retained activity after exposure to body fluids, and its persistent activity on the skin. Chlorhexidine has a very low skin-sensitizing or irritating capacity. Oral toxicity is low because it is poorly absorbed from the alimentary tract. Chlorhexidine must not be used during surgery on the middle ear because it causes sensorineural deafness. Similar neural toxicity may be encountered during neurosurgery.

HALOGENS

Iodine

Iodine in a 1:20,000 solution is bactericidal in 1 minute and kills spores in 15 minutes. Tincture of iodine USP contains 2% iodine and 2.4% sodium iodide in alcohol. It is the most active antiseptic for intact skin. It is not commonly used due to serious hypersensitivity reactions and staining of clothing and dressings.

Iodophors

Iodophors are complexes of iodine with a surface-active agent such as **polyvinyl pyrrolidone (PVP; povidone-iodine)**. Iodophors retain the activity of iodine. They kill vegetative bacteria, mycobacteria, fungi, and lipid-containing viruses. They may be sporicidal with prolonged exposure. Iodophors can be used as antiseptics or disinfectants, the latter containing more iodine. The amount of free iodine is low, but it is released as the solution is diluted. An iodophor solution must be diluted according to the manufacturer's directions to obtain full activity.

Iodophors are less irritating and less likely to produce skin hypersensitivity than tincture of iodine. They require drying time on skin before becoming active, which can be a disadvantage. Although iodophors have a somewhat broader spectrum of activity than chlorhexidine, including sporicidal action, they lack its persistent activity on skin.

Chlorine

Chlorine is a strong oxidizing agent and universal disinfectant that is commonly provided as a 5.25% **sodium hypochlorite** solution, a typical formulation for **household bleach**. Because formulations may vary, the exact concentration should be verified on the label. A 1:10 dilution of household bleach (producing a 0.525% concentration) provides 5000 ppm of available chlorine. The CDC recommends this concentration for disinfection of blood spills. Less than 5 ppm kills vegetative bacteria, whereas up to 5000 ppm is necessary

to kill bacterial spores. A concentration of 1000–10,000 ppm is tuberculocidal. One hundred ppm kills vegetative fungal cells in 1 hour, but fungal spores require 500 ppm. Viruses are inactivated by 200–500 ppm. Dilutions of sodium hypochlorite made up in pH 7.5–8.0 tap water retain their activity for months when kept in tightly closed, opaque containers. Frequent opening and closing of the container reduces the activity markedly.

Because chlorine is inactivated by blood, serum, feces, and protein-containing materials, surfaces should be cleaned before chlorine disinfectant is applied. Undissociated hypochlorous acid (HOCl) is the active biocidal agent. When pH is increased, the less active hypochlorite ion, OCl^- , is formed. When hypochlorite solutions contact formaldehyde, the carcinogen bischloromethyl is formed. Rapid evolution of irritating chlorine gas occurs when hypochlorite solutions are mixed with acid and urine. Solutions are corrosive to aluminum, silver, and stainless steel.

Alternative chlorine-releasing compounds include **chlorine dioxide** and **chloramine-T**. These agents have a prolonged bactericidal action.

PHENOLICS

Phenol itself (perhaps the oldest of the surgical antiseptics) is no longer used even as a disinfectant because of its corrosive effect on tissues, its toxicity when absorbed, and its carcinogenic effect. These adverse actions are diminished by forming derivatives in which a functional group replaces a hydrogen atom in the aromatic ring. The phenolic agents most commonly used are ***o*-phenylphenol**, ***o*-benzyl-*p*-chlorophenol**, and ***p*-tertiary amylphenol**. Mixtures of phenolic derivatives are often used. Some of these are derived from coal tar distillates, eg, cresols and xlenols. Skin absorption and skin irritation still occur with these derivatives, and appropriate care is necessary in their use. Detergents are often added to formulations to clean and remove organic material that may decrease the activity of a phenolic compound.

Phenolic compounds disrupt cell walls and membranes, precipitate proteins, and inactivate enzymes. They are bactericidal (including mycobacteria) and fungicidal and are capable of inactivating lipophilic viruses. They are not sporicidal. Dilution and time of exposure recommendations of the manufacturer must be followed.

Phenolic disinfectants are used for hard surface decontamination in hospitals and laboratories, eg, floors, beds, and counter or bench tops. They are not recommended for use in nurseries and especially near infants, where their use has been associated with hyperbilirubinemia. Use of **hexachlorophene** as a skin disinfectant has caused cerebral edema and seizures in premature infants and, occasionally, in adults. It is no longer available in the United States.

QUATERNARY AMMONIUM COMPOUNDS

The quaternary ammonium compounds ("quats") are cationic surface-active detergents. The active cation has at least one long water-repellent hydrocarbon chain, which causes the molecules to concentrate as an oriented layer on the surface of solutions and

colloidal or suspended particles. The charged nitrogen portion of the cation has high affinity for water and prevents separation out of solution. The bactericidal action of quaternary compounds has been attributed to inactivation of energy-producing enzymes, denaturation of proteins, and disruption of the cell membrane. These agents are fungistatic and sporistatic and also inhibit algae. They are bactericidal for Gram-positive bacteria and moderately active against Gram-negative bacteria. Lipophilic viruses are inactivated. They are not tuberculocidal or sporicidal, and they do not inactivate hydrophilic viruses. Quaternary ammonium compounds bind to the surface of colloidal protein in blood, serum, and milk and to the fibers in cotton, mops, cloths, and paper towels used to apply them, which can cause inactivation of the agent by removing it from solution. They are inactivated by anionic detergents (soaps), by many nonionic detergents, and by calcium, magnesium, ferric, and aluminum ions.

Quaternary compounds are used for sanitation of noncritical surfaces (floors, bench tops, etc). Their low toxicity has led to their use as sanitizers in food production facilities. The CDC recommends that quaternary ammonium compounds such as **benzalkonium chloride** not be used as antiseptics because several outbreaks of infections have occurred that were due to growth of *Pseudomonas* and other Gram-negative bacteria in quaternary ammonium antiseptic solutions.

ALDEHYDES

Formaldehyde and **glutaraldehyde** are used for disinfection or sterilization of instruments such as fiberoptic endoscopes, respiratory therapy equipment, hemodialyzers, and dental instruments that cannot withstand exposure to the high temperatures of steam sterilization. They are not corrosive for metal, plastic, or rubber. These agents have a broad spectrum of activity against microorganisms. They act by alkylation of chemical groups in proteins and nucleic acids. Failures of disinfection or sterilization can occur as a result of dilution below the known effective concentration, the presence of organic material, and the failure of liquid to penetrate into small channels in the instruments. Automatic circulating baths are available that increase penetration of aldehyde solution into the instrument while decreasing exposure of the operator to irritating fumes.

Formaldehyde is available as a 40% weight per volume solution in water (100% **formalin**). An 8% formaldehyde solution in water has a broad spectrum of activity against bacteria, fungi, and viruses. Sporicidal activity may take as long as 18 hours. Its rapidity of action is increased by solution in 70% isopropanol. Formaldehyde solutions are used for high-level disinfection of hemodialyzers, preparation of vaccines, and preservation and embalming of tissues. The 4% formaldehyde (10% formalin) solutions used for fixation of tissues and embalming may not be mycobactericidal.

Glutaraldehyde is a dialdehyde (1,5-pentanedial). Solutions of 2% weight per volume glutaraldehyde are most commonly used. The solution must be alkalinized to pH 7.4–8.5 for activation. Activated solutions are bactericidal, sporicidal, fungicidal, and

viricidal for both lipophilic and hydrophilic viruses. Glutaraldehyde has greater sporicidal activity than formaldehyde, but it may have less tuberculocidal activity. Lethal action against mycobacteria and spores may require prolonged exposure. Once activated, solutions have a shelf life of 14 days, after which polymerization reduces activity. Other means of activation and stabilization can increase the shelf life. Because glutaraldehyde solutions are frequently reused, the most common reason for loss of activity is dilution and exposure to organic material. Test strips to measure residual activity are recommended.

Formaldehyde has a characteristic pungent odor and is highly irritating to respiratory mucous membranes and eyes at concentrations of 2–5 ppm. The U.S. Occupational Safety and Health Administration (OSHA) has declared that formaldehyde is a potential carcinogen and has established an employee exposure standard that limits the 8-hour time-weighted average (TWA) exposure to 0.75 ppm. Protection of health care workers from exposure to glutaraldehyde concentrations greater than 0.2 ppm is advisable. Increased air exchange, enclosure in hoods with exhausts, tight-fitting lids on exposure devices, and use of protective personal equipment such as goggles, respirators, and gloves may be necessary to achieve these exposure limits.

Ortho-phthalaldehyde (OPA) is a phenolic dialdehyde chemical sterilant with a spectrum of activity comparable to glutaraldehyde, although it is several times more rapidly bactericidal. OPA solution typically contains 0.55% OPA. Its label claim is that high-level disinfection can be achieved in 12 minutes at room temperature compared with 45 minutes for 2.4% glutaraldehyde. Unlike glutaraldehyde, OPA requires no activation, is less irritating to mucous membranes, and does not require exposure monitoring. It has good materials compatibility and an acceptable environmental safety profile. OPA is useful for disinfection or sterilization of endoscopes, surgical instruments, and other medical devices.

SUPEROXIDIZED WATER

Electrolysis of saline yields a mixture of oxidants, primarily hypochlorous acid and chlorine, with potent disinfectant and sterilant properties. The solution generated by the process, which has been commercialized and marketed as **Sterilox** for disinfection of endoscopes and dental materials, is rapidly bactericidal, fungicidal, tuberculocidal, and sporicidal. High-level disinfection is achieved with a contact time of 10 minutes. The solution is nontoxic and nonirritating and requires no special disposal precautions.

PEROXYGEN COMPOUNDS

The peroxygen compounds, **hydrogen peroxide** and **peracetic acid**, have high killing activity and a broad spectrum against bacteria, spores, viruses, and fungi when used in appropriate concentration. They have the advantage that their decomposition products are not toxic and do not injure the environment. They are powerful oxidizers that are used primarily as disinfectants and sterilants.

Hydrogen peroxide is a very effective disinfectant when used for inanimate objects or materials with low organic content such

as water. Systems that produce hydrogen peroxide vapor or dry mist are now available for room decontamination in healthcare facilities. Organisms that produce the enzymes catalase and peroxidase rapidly degrade hydrogen peroxide. The innocuous degradation products are oxygen and water. Concentrated solutions containing 90% weight per volume H_2O_2 are prepared electrochemically. When diluted in high-quality deionized water to 6% and 3% and put into clean containers, the products remain stable. Concentrations of 10–25% hydrogen peroxide are sporicidal. Vapor phase hydrogen peroxide (VPH) is a cold gaseous sterilant that has the potential to replace the toxic or carcinogenic gases ethylene oxide and formaldehyde. VPH does not require a pressurized chamber and is active at temperatures as low as 4°C and concentrations as low as 4 mg/L. It is incompatible with liquids and cellulose products. It penetrates the surface of some plastics. Automated equipment using vaporized hydrogen peroxide or hydrogen peroxide mixed with formic acid is available for sterilizing endoscopes.

Peracetic acid (CH_3COOOH) is prepared commercially from hydrogen peroxide, acetic acid, and a catalyst such as sulfuric acid. It is explosive in the pure form. It is usually used in dilute solution and transported in containers with vented caps to prevent increased pressure as oxygen is released. Peracetic acid is more active than hydrogen peroxide as a bactericidal and sporicidal agent. Concentrations of 250–500 ppm are effective against a broad range of bacteria in 5 minutes at pH 7.0 at 20°C. Bacterial spores are inactivated by 500–30,000 ppm peracetic acid. Only slightly increased concentrations are necessary in the presence of organic matter. Viruses require variable exposures. Enteroviruses require 2000 ppm for 15–30 minutes for inactivation.

An automated machine that uses buffered peracetic acid liquid of 0.1–0.5% concentration has been developed for sterilization of medical, surgical, and dental instruments. Peracetic acid sterilization systems have also been adopted for hemodialyzers. The food processing and beverage industries use peracetic acid extensively because the breakdown products in high dilution do not produce objectionable odor, taste, or toxicity, and rinsing is not necessary.

Peracetic acid is a potent tumor promoter but a weak carcinogen. It is not mutagenic in the Ames test.

ULTRAVIOLET IRRADIATION

Ultraviolet irradiation is used in some health care facilities as an alternate mode of disinfection for patient care areas. It is typically employed via an automated system, allowing for less staff exposure to decontamination products. It has rapid cidal activity against numerous pathogens, providing effective decontamination for most vegetative bacteria in less than 25 minutes and against *C. difficile* in less than one hour.

HEAVY METALS

Heavy metals, principally mercury and silver, are now rarely used as disinfectants. Mercury is an environmental hazard, and some pathogenic bacteria have developed plasmid-mediated resistance

to mercurials. Hypersensitivity to thimerosal is common, possibly in up to 40% of the population. These compounds are absorbed from solution by rubber and plastic closures. **Thimerosal** 0.001–0.004% is still used safely as a preservative of vaccines, antitoxins, and immune sera. Although a causative link to autism has never been established and the original claim was found to be fraudulent, thimerosal-free vaccines are available for use in children and pregnant women.

Inorganic silver salts are strongly bactericidal. **Silver nitrate**, 1:1000, had been most commonly used, particularly as a preventive for gonococcal ophthalmitis in newborns. Antibiotic ointments have replaced silver nitrate for this indication. **Silver sulfadiazine** slowly releases silver and is used to suppress bacterial growth in burn wounds (see Chapter 46).

STERILANTS

For many years, pressurized **steam (autoclaving)** at 120°C for 30 minutes has been the basic method for sterilizing instruments and other heat-resistant materials. When autoclaving is not possible, as with lensed instruments and materials containing plastic and rubber, **ethylene oxide**—diluted with either fluorocarbon or carbon dioxide to diminish explosive hazard—has been used at 440–1200 mg/L at 45–60°C with 30–60% relative humidity. The higher concentrations have been used to increase penetration.

Ethylene oxide is classified as a mutagen and carcinogen. The OSHA permissible exposure limit (PEL) for ethylene oxide is 1 ppm calculated as a time-weighted average. Alternative sterilants now being used increasingly include vapor-phase hydrogen peroxide, peracetic acid, ozone, gas plasma, chlorine dioxide, formaldehyde, and propylene oxide. Each of these sterilants has potential advantages and problems. Automated peracetic acid systems are being used increasingly for high-level decontamination and sterilization of endoscopes and hemodialyzers because of their effectiveness, automated features, and the low toxicity of the residual products of sterilization.

PRESERVATIVES

Disinfectants are used as preservatives to prevent the overgrowth of bacteria and fungi in pharmaceutical products, laboratory sera and reagents, cosmetic products, and contact lenses. Multi-use vials of medication that may be reentered through a rubber diaphragm, eye drops, and nose drops require preservatives. Preservatives should not be irritating or toxic to tissues to which they will be applied, they must be effective in preventing growth of microorganisms likely to contaminate solutions, and they must have sufficient solubility and stability to remain active.

Commonly used preservative agents include organic acids such as **benzoic acid** and salts, the **parabens**, (alkyl esters of *p*-hydroxybenzoic acid), sorbic acid and salts, phenolic compounds, quaternary ammonium compounds, alcohols, and mercurials such as thimerosal in 0.001–0.004% concentration.

SUMMARY Miscellaneous Antimicrobials

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
NITROIMIDAZOLE				
• Metronidazole	Disruption of electron transport chain	Bactericidal activity against susceptible anaerobic bacteria and protozoa	Anaerobic infections • vaginitis • <i>C difficile</i> colitis	Oral or IV • hepatic clearance ($t_{1/2}$ 8 h) • disulfiram-like reaction when given with alcohol • Toxicity: Gastrointestinal upset • metallic taste • neuropathy • seizures
• Tinidazole: Oral; similar to metronidazole but dosed once daily; approved for trichomonas, giardiasis, and amebiasis				
MACROLIDE				
• Fidaxomicin	Inhibits bacterial RNA polymerase	Bactericidal in Gram-positive bacteria	<i>C difficile</i> colitis	Oral • blood levels negligible • Toxicity: Nonspecific gastrointestinal upset
RIFAMYCIN				
• Rifaximin	Inhibits bacterial RNA polymerase	Bactericidal activity in Gram-positive and Gram-negative bacteria	Travelers' diarrhea, hepatic encephalopathy, <i>C difficile</i> colitis, irritable bowel syndrome	Oral • blood levels negligible • Toxicity: Nausea
URINARY ANTISEPTICS				
• Nitrofurantoin	Not fully understood • disrupts protein synthesis and inhibits multiple bacterial enzyme systems	Bacteriostatic or bactericidal activity against susceptible bacteria	Uncomplicated urinary tract infections • long-term prophylaxis	Oral • rapid renal clearance ($t_{1/2}$ 0.5 h) • blood levels are negligible • contraindicated in renal failure • Toxicity: Gastrointestinal upset • neuropathies • hypersensitivity pneumonitis
• Methenamine hippurate and methenamine mandelate: Oral; release formaldehyde at acidic pH in the urine; used only for prophylaxis, not treatment, of urinary tract infections				

PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
MISCELLANEOUS ANTIMICROBIAL DRUGS	
Colistimethate sodium	Generic, Coly-Mycin M
Fidaxomicin	Dificid
Methenamine hippurate	Generic, Hiprex
Methenamine mandelate	Generic, Mandelamine
Metronidazole	Generic, Flagyl, Metro
Mupirocin	Generic, Bactroban, Centany
Nitrofurantoin	Generic, Macrochantin, Macrobid
Polymyxin B (Polymyxin B sulfate)	Generic
DISINFECTANTS, ANTISEPTICS, & STERILANTS	
Benzalkonium	Generic, Zephiran
Benzoyl peroxide	Generic
Chlorhexidine gluconate topical	Generic, Hibiclens, Betasept, others
Chlorhexidine gluconate, oral rinse: 0.12%	Peridex, Periogard
Glutaraldehyde	Cidex
Iodine aqueous	Generic, Lugol's Solution
Iodine tincture	Generic
Nitrofurazone	Generic, Furacin
Ortho-phthalaldehyde	Cidex OPA
Povidone-iodine	Generic, Betadine
Silver nitrate	Generic
Thimerosal	Generic, Mersol

CASE STUDY ANSWER

The patient may be treated with oral metronidazole, which is an appropriate drug for mild to moderate cases of *C. difficile* infection. Oral vancomycin is also a reasonable alternative and is the preferred treatment for severe cases and for older patients. Fidaxomicin is an effective

treatment for *C. difficile* infection, but it is more expensive than other first-line medications. The room should be cleaned with a bleach solution (5000 ppm) because it is sporicidal. Other sporicidal disinfectants also may be effective.

Clinical Use of
Antimicrobial Agents

Harry W. Lampiris, MD, &
Daniel S. Maddix, PharmD

CASE STUDY

A 65-year-old man undergoes cystoscopy because of the presence of microscopic hematuria in order to rule out urologic malignancy. The patient has mild dysuria and pyuria and empirically receives oral therapy with ciprofloxacin for presumed urinary tract infection prior to the procedure and tolerates the procedure well. Approximately 48 hours after the procedure, the patient presents to the emergency department with confusion, dysuria and chills. Physical exam reveals a blood pressure of

90/50, pulse of 120, temperature of 38.5° C and respiratory rate of 24. The patient is disoriented but the physical exam is otherwise unremarkable. Laboratory test shows WBC 24,000/mm³ and elevated serum lactate; urinalysis shows 300 WBC per high power field and 4+ bacteria. What possible organisms are likely to be responsible for the patient's symptoms? At this point, what antibiotic(s) would you choose for initial therapy of this potentially life-threatening infection?

The development of antimicrobial drugs represents one of the most important advances in therapeutics, both in the control or cure of serious infections and in the prevention and treatment of infectious complications of other therapeutic modalities such as cancer chemotherapy, immunosuppression, and surgery. However, evidence is overwhelming that antimicrobial agents are vastly overprescribed in outpatient settings in the USA, and the availability of antimicrobial agents without prescription in many developing countries has—by facilitating the development of resistance—already severely limited therapeutic options in the treatment of life-threatening infections. Therefore, the clinician should first determine whether antimicrobial therapy is warranted for a given patient. The specific questions one should ask include the following:

1. Is an antimicrobial agent indicated on the basis of clinical findings? Or is it prudent to wait until such clinical findings become apparent?
2. Have appropriate clinical specimens been obtained to establish a microbiologic diagnosis?

3. What are the likely etiologic agents for the patient's illness?
4. What measures should be taken to protect individuals exposed to the index case to prevent secondary cases, and what measures should be implemented to prevent further exposure?
5. Is there clinical evidence (eg, from well-executed clinical trials) that antimicrobial therapy will confer clinical benefit for the patient?

Once a specific cause is identified based on specific microbiologic tests, the following further questions should be considered:

1. If a specific microbial pathogen is identified, can a narrower-spectrum agent be substituted for the initial empiric drug?
2. Is one agent or a combination of agents necessary?
3. What are the optimal dose, route of administration, and duration of therapy?
4. What specific tests (eg, susceptibility testing) should be undertaken to identify patients who will not respond to treatment?
5. What adjunctive measures can be undertaken to eradicate the infection? For example, is surgery feasible for removal of devitalized tissue or foreign bodies—or drainage of an

abscess—into which antimicrobial agents may be unable to penetrate? Is it possible to decrease the dosage of immunosuppressive therapy in patients who have undergone organ transplantation? Is it possible to reduce morbidity or mortality due to the infection by reducing host immunologic response to the infection (eg, by the use of corticosteroids for the treatment of severe *Pneumocystis jiroveci* pneumonia or meningitis due to *Streptococcus pneumoniae*)?

■ EMPIRIC ANTIMICROBIAL THERAPY

Antimicrobial agents are frequently used before the pathogen responsible for a particular illness or the susceptibility to a particular antimicrobial agent is known. This use of antimicrobial agents is called empiric (or presumptive) therapy and is based on experience with a particular clinical entity. The usual justification for empiric therapy is the hope that early intervention will improve the outcome; in the best cases, this has been established by placebo-controlled, double-blind, prospective clinical trials. For example, treatment of febrile episodes in neutropenic cancer patients with empiric antimicrobial therapy has been demonstrated to have impressive morbidity and mortality benefits even though the specific bacterial agent responsible for fever is determined for only a minority of such episodes.

Finally, there are many clinical entities, such as certain episodes of community-acquired pneumonia, in which it is difficult to identify a specific pathogen. In such cases, a clinical response to empiric therapy may be an important clue to the likely pathogen.

Frequently, the signs and symptoms of infection diminish as a result of empiric therapy, and microbiologic test results become available to establish a specific microbiologic diagnosis. At the time that the pathogenic organism responsible for the illness is identified, empiric therapy is optimally modified to **definitive therapy**, which is typically narrower in coverage and is given for an appropriate duration based on the results of clinical trials, or experience when clinical trial data are not available.

Approach to Empiric Therapy

Initiation of empiric therapy should follow a specific and systematic approach.

A. Formulate a Clinical Diagnosis of Microbial Infection

Using all available data, the clinician should determine that there is a clinical syndrome compatible with infection (eg, pneumonia, cellulitis, sinusitis).

B. Obtain Specimens for Laboratory Examination

Examination of stained specimens by microscopy or simple examination of an uncentrifuged sample of urine for white blood cells and bacteria may provide important immediate etiologic clues. Cultures of selected anatomic sites (blood, sputum, urine, cerebrospinal fluid, and stool) and nonculture methods (antigen

testing, polymerase chain reaction, and serology) also may confirm specific etiologic agents.

C. Formulate a Microbiologic Diagnosis

The history, physical examination, and immediately available laboratory results (eg, Gram stain of urine or sputum) may provide highly specific information. For example, in a young man with urethritis and a Gram-stained smear from the urethral meatus demonstrating intracellular Gram-negative diplococci, the most likely pathogen is *Neisseria gonorrhoeae*. In the latter instance, however, the clinician should be aware that a significant number of patients with gonococcal urethritis have negative Gram stains for the organism and that a significant number of patients with gonococcal urethritis harbor concurrent chlamydial infection that is not demonstrated on the Gram-stained smear.

D. Determine the Necessity for Empiric Therapy

Whether to initiate empiric therapy is an important clinical decision based partly on experience and partly on data from clinical trials. Empiric therapy is indicated when there is a significant risk of serious morbidity or mortality if therapy is withheld until a specific pathogen is detected by the clinical laboratory.

In other settings, empiric therapy may be indicated for public health reasons rather than for demonstrated superior outcome of therapy in a specific patient. For example, urethritis in a young sexually active man usually requires treatment for *N gonorrhoeae* and *Chlamydia trachomatis* despite the absence of microbiologic confirmation at the time of diagnosis. Because the risk of noncompliance with follow-up visits in this patient population may lead to further transmission of these sexually transmitted pathogens, empiric therapy is warranted.

E. Institute Treatment

Selection of empiric therapy may be based on the microbiologic diagnosis or a clinical diagnosis without available microbiologic clues. If no microbiologic information is available, the antimicrobial spectrum of the agent or agents chosen must necessarily be broader, taking into account the most likely pathogens responsible for the patient's illness.

Choice of Antimicrobial Agent

Selection from among several drugs depends on **host factors** that include the following: (1) concomitant disease states (eg, AIDS, neutropenia due to the use of cytotoxic chemotherapy, organ transplantation, severe chronic liver or kidney disease) or the use of immunosuppressive medications; (2) prior adverse drug effects; (3) impaired elimination or detoxification of the drug (may be genetically predetermined but more frequently is associated with impaired renal or hepatic function due to underlying disease); (4) age of the patient; (5) pregnancy status; and (6) epidemiologic exposure (eg, exposure to a sick family member or pet, recent hospitalization, recent travel, occupational exposure, or new sexual partner).

Pharmacologic factors include (1) the kinetics of absorption, distribution, and elimination; (2) the ability of the drug to be delivered to the site of infection; (3) the potential toxicity of an

agent; and (4) pharmacokinetic or pharmacodynamic interactions with other drugs.

Knowledge of the **susceptibility** of an organism to a specific agent in a hospital or community setting is important in the selection of empiric therapy. Pharmacokinetic differences among agents with similar antimicrobial spectrums may be exploited to reduce the frequency of dosing (eg, ceftriaxone, ertapenem, or daptomycin may be conveniently given once every 24 hours). Finally, increasing consideration is being given to the cost of antimicrobial therapy, especially when multiple agents with comparable efficacy and toxicity are available for a specific infection. Changing from intravenous to oral antibiotics for prolonged administration can be particularly cost-effective.

Brief guides to empiric therapy based on presumptive microbial diagnosis and site of infection are given in Tables 51–1 and 51–2.

■ ANTIMICROBIAL THERAPY OF INFECTIONS WITH KNOWN ETIOLOGY

INTERPRETATION OF CULTURE RESULTS

Properly obtained and processed specimens for culture frequently yield reliable information about the cause of infection. The lack of a confirmatory microbiologic diagnosis may be due to the following:

1. Sample error, eg, obtaining cultures after antimicrobial agents have been administered, inadequate volume or quantity of specimen obtained, or contamination of specimens sent for culture
2. Noncultivable or slow-growing organisms (*Histoplasma capsulatum*, *Bartonella* or *Brucella* species), in which cultures are often discarded before sufficient growth has occurred for detection
3. Requesting *bacterial* cultures when infection is due to other organisms
4. Not recognizing the need for special media or isolation techniques (eg, charcoal yeast extract agar for isolation of *Legionella* species, shell-vial tissue culture system for rapid isolation of cytomegalovirus)

Even in the setting of a classic infectious disease for which isolation techniques have been established for decades (eg, pneumococcal pneumonia, pulmonary tuberculosis, streptococcal pharyngitis), the sensitivity of the culture technique may be inadequate to identify all cases of the disease.

GUIDING ANTIMICROBIAL THERAPY OF ESTABLISHED INFECTIONS

Susceptibility Testing

Testing bacterial pathogens in vitro for their susceptibility to antimicrobial agents is extremely valuable in confirming susceptibility, ideally to a narrow-spectrum nontoxic antimicrobial drug.

Tests measure the concentration of drug required to inhibit growth of the organism (**minimal inhibitory concentration [MIC]**) or to kill the organism (**minimal bactericidal concentration [MBC]**). The results of these tests can then be correlated with known drug concentrations in various body compartments. Only MICs are routinely measured in most infections, whereas in infections in which bactericidal therapy is required for eradication of infection (eg, meningitis, endocarditis, sepsis in the granulocytopenic host), MBC measurements occasionally may be useful.

Specialized Assay Methods

A. Beta-Lactamase Assay

For some bacteria (eg, *Haemophilus* species), the susceptibility patterns of strains are similar except for the production of β lactamase. In these cases, extensive susceptibility testing may not be required, and a direct test for β lactamase using a chromogenic β -lactam substrate (nitrocefin disk) may be substituted.

B. Synergy Studies

Synergy studies are in vitro tests that attempt to measure synergistic, additive, indifferent, or antagonistic drug interactions. In general, these tests have not been standardized and have not correlated well with clinical outcome. (See section on Antimicrobial Drug Combinations for details.)

MONITORING THERAPEUTIC RESPONSE: DURATION OF THERAPY

The therapeutic response may be monitored microbiologically or clinically. Cultures of specimens taken from infected sites should eventually become sterile or demonstrate eradication of the pathogen and are useful for documenting recurrence or relapse. Follow-up cultures may also be useful for detecting superinfections or the development of resistance. Clinically, the patient's systemic manifestations of infection (malaise, fever, leukocytosis) should abate, and the clinical findings should improve (eg, as shown by clearing of radiographic infiltrates or lessening hypoxemia in pneumonia).

The duration of definitive therapy required for cure depends on the pathogen, the site of infection, and host factors (immunocompromised patients generally require longer courses of treatment). Precise data on duration of therapy exist for some infections (eg, streptococcal pharyngitis, syphilis, gonorrhea, tuberculosis, and cryptococcal meningitis). In many other situations, duration of therapy is determined empirically. Minimizing duration of antimicrobial therapy for specific infections is an intervention that may help prevent the development of antimicrobial resistance. For many infections, a combined medical-surgical approach may be required for clinical cure.

Clinical Failure of Antimicrobial Therapy

When the patient has an inadequate clinical or microbiologic response to antimicrobial therapy selected by in vitro susceptibility testing, systematic investigation should be undertaken to

TABLE 51–1 Empiric antimicrobial therapy based on microbiologic etiology.

Suspected or Proven Disease or Pathogen	Drugs of First Choice	Alternative Drugs
Gram-negative cocci (aerobic)		
<i>Moraxella (Branhamella) catarrhalis</i>	TMP-SMZ, ¹ cephalosporin (second- or third-generation) ²	Quinolone, ³ macrolide ⁴
<i>Neisseria gonorrhoeae</i>	Ceftriaxone, cefixime	Spectinomycin, azithromycin
<i>Neisseria meningitidis</i>	Penicillin G	Chloramphenicol, ceftriaxone, cefotaxime
Gram-negative rods (aerobic)		
<i>E coli</i> , <i>Klebsiella</i> , <i>Proteus</i>	Cephalosporin (first- or second-generation), ² TMP-SMZ ¹	Quinolone, ³ aminoglycoside ⁵
<i>Enterobacter</i> , <i>Citrobacter</i> , <i>Serratia</i>	TMP-SMZ, ¹ quinolone, ³ carbapenem ⁶	Antipseudomonal penicillin, ⁷ aminoglycoside, ⁵ ceftazidime
<i>Shigella</i>	Quinolone ³	TMP-SMZ, ¹ ampicillin, azithromycin, ceftriaxone
<i>Salmonella</i>	Quinolone, ³ ceftriaxone	Chloramphenicol, ampicillin, TMP-SMZ ¹
<i>Campylobacter jejuni</i>	Erythromycin or azithromycin	Tetracycline, quinolone ³
<i>Brucella</i> species	Doxycycline + rifampin or aminoglycoside ⁵	Chloramphenicol + aminoglycoside ⁵ or TMP-SMZ ¹
<i>Helicobacter pylori</i>	Proton pump inhibitor + amoxicillin + clarithromycin	Bismuth + metronidazole + tetracycline + proton pump inhibitor
<i>Vibrio</i> species	Tetracycline	Quinolone, ³ TMP-SMZ ¹
<i>Pseudomonas aeruginosa</i>	Antipseudomonal penicillin + aminoglycoside ⁵	Antipseudomonal penicillin ± quinolone, ³ ceftazidime, antipseudomonal carbapenem, ⁶ or aztreonam ± aminoglycoside ⁵
<i>Burkholderia cepacia</i> (formerly <i>Pseudomonas cepacia</i>)	TMP-SMZ ¹	Ceftazidime, chloramphenicol
<i>Stenotrophomonas maltophilia</i> (formerly <i>Xanthomonas maltophilia</i>)	TMP-SMZ ¹	Minocycline, ticarcillin-clavulanate, tigecycline, ceftazidime, quinolone ³
<i>Legionella</i> species	Azithromycin or quinolone ³	Clarithromycin, erythromycin
Gram-positive cocci (aerobic)		
<i>Streptococcus pneumoniae</i>	Penicillin ⁸	Doxycycline, ceftriaxone, antipneumococcal quinolone, ³ macrolide, ⁴ linezolid
<i>Streptococcus pyogenes</i> (group A)	Penicillin, clindamycin	Erythromycin, cephalosporin (first-generation) ²
<i>Streptococcus agalactiae</i> (group B)	Penicillin (± aminoglycoside ⁵)	Vancomycin
<i>Viridans streptococci</i>	Penicillin	Cephalosporin (first- or third-generation), ² vancomycin
<i>Staphylococcus aureus</i>		
β-Lactamase negative	Penicillin	Cephalosporin (first-generation), ² vancomycin
β-Lactamase positive	Penicillinase-resistant penicillin ⁹	As above
Methicillin-resistant	Vancomycin	TMP-SMZ, ¹ minocycline, linezolid, daptomycin, tigecycline
<i>Enterococcus</i> species ¹⁰	Penicillin + aminoglycoside ⁵	Vancomycin + aminoglycoside ⁵
Gram-positive rods (aerobic)		
<i>Bacillus</i> species (non-anthraxis)	Vancomycin	Imipenem, quinolone, ³ clindamycin
<i>Listeria</i> species	Ampicillin (± aminoglycoside ⁵)	TMP-SMZ ¹
<i>Nocardia</i> species	Sulfadiazine, TMP-SMZ ¹	Minocycline, imipenem, amikacin, linezolid
Anaerobic bacteria		
Gram-positive (<i>Clostridia</i> , <i>Peptococcus</i> , <i>Actinomyces</i> , <i>Peptostreptococcus</i>)	Penicillin, clindamycin	Vancomycin, carbapenem, ⁶ chloramphenicol
<i>Clostridium difficile</i>	Metronidazole	Vancomycin, bacitracin
<i>Bacteroides fragilis</i>	Metronidazole	Chloramphenicol, carbapenem, ⁶ β-lactam—β-lactamase-inhibitor combinations, clindamycin
<i>Fusobacterium</i> , <i>Prevotella</i> , <i>Porphyromonas</i>	Metronidazole, clindamycin, penicillin	As for <i>B fragilis</i>

<i>Mucoraceae</i> (<i>Rhizopus</i> , <i>Absidia</i>)	Amphotericin B	Posaconazole, isavuconazole
<i>Sporothrix schenckii</i>	Amphotericin B	Itraconazole

¹Trimethoprim-sulfamethoxazole (TMP-SMZ) is a mixture of one part trimethoprim plus five parts sulfamethoxazole.²First-generation cephalosporins: cefazolin for parenteral administration; cefadroxil or cephalexin for oral administration. Second-generation cephalosporins: cefuroxime for parenteral administration; cefaclor, cefuroxime axetil, cefprozil for oral administration. Third-generation cephalosporins: ceftazidime, cefotaxime, ceftriaxone for parenteral administration; cefixime, cefpodoxime, ceftibuten, cefdinir, cefditoren for oral administration. Fourth-generation cephalosporin: cefepime for parenteral administration. Cephamycins: cefoxitin and cefotetan for parenteral administration.³Quinolones: ciprofloxacin, gemifloxacin, levofloxacin, moxifloxacin, norfloxacin, ofloxacin. Norfloxacin is not effective for the treatment of systemic infections. Gemifloxacin, levofloxacin, and moxifloxacin have excellent activity against pneumococci. Ciprofloxacin and levofloxacin have good activity against *Pseudomonas aeruginosa*.⁴Macrolides: azithromycin, clarithromycin, dirithromycin, erythromycin.⁵Generally, streptomycin and gentamicin are used to treat infections with Gram-positive organisms, whereas gentamicin, tobramycin, and amikacin are used to treat infections with Gram-negatives.⁶Carbapenems: doripenem, ertapenem, imipenem, meropenem. Ertapenem lacks activity against enterococci, *Acinetobacter*, and *P aeruginosa*.⁷Antipseudomonal penicillin: piperacillin, piperacillin/tazobactam, ticarcillin/clavulanic acid.⁸See footnote 3 in Table 51–2 for guidelines on the treatment of penicillin-resistant pneumococcal meningitis.⁹Parenteral nafcillin or oxacillin; oral dicloxacillin.¹⁰There is no regimen that is reliably bactericidal for vancomycin-resistant enterococcus for which there is extensive clinical experience; daptomycin has bactericidal activity in vitro. Regimens that have been reported to be efficacious include nitrofurantoin (for urinary tract infection); potential regimens for bacteremia include daptomycin, linezolid, and dalbapristin/quinupristin.¹¹Echinocandins: anidulafungin, caspofungin, micafungin.

TABLE 51-2 Empiric antimicrobial therapy based on site of infection.

Presumed Site of Infection	Common Pathogens	Drugs of First Choice	Alternative Drugs
Bacterial endocarditis			
Acute	<i>Staphylococcus aureus</i>	Vancomycin + ceftriaxone	Penicillinase-resistant penicillin ¹ + gentamicin
Subacute	<i>Viridans</i> streptococci, enterococci	Penicillin + gentamicin	Vancomycin + gentamicin
Septic arthritis			
Child	<i>Haemophilus influenzae</i> , <i>S aureus</i> , β -hemolytic streptococci	Vancomycin + ceftriaxone	Vancomycin + ampicillin-sulbactam or ertapenem
Adult	<i>S aureus</i> , Enterobacteriaceae, <i>Neisseria gonorrhoeae</i>	Vancomycin + ceftriaxone	Vancomycin + ertapenem, or quinolone
Acute otitis media, sinusitis	<i>H influenzae</i> , <i>Streptococcus pneumoniae</i> , <i>Moraxella catarrhalis</i>	Amoxicillin	Amoxicillin-clavulanate, cefuroxime axetil, TMP-SMZ
Cellulitis	<i>S aureus</i> , group A streptococcus	Penicillinase-resistant penicillin, cephalosporin (first-generation) ²	Vancomycin, clindamycin, linezolid, daptomycin
Meningitis			
Neonate	Group B streptococcus, <i>Escherichia coli</i> , <i>Listeria</i>	Ampicillin + cephalosporin (third-generation)	Ampicillin + aminoglycoside, chloramphenicol, meropenem
Child	<i>H influenzae</i> , pneumococcus, meningococcus	Ceftriaxone or cefotaxime \pm vancomycin ³	Chloramphenicol, meropenem
Adult	Pneumococcus, meningococcus	Ceftriaxone, cefotaxime	Vancomycin + ceftriaxone or cefotaxime ³
Peritonitis due to ruptured viscus	Coliforms, <i>Bacteroides fragilis</i>	Metronidazole + cephalosporin (third-generation), piperacillin/tazobactam	Carbapenem, tigecycline
Pneumonia			
Neonate	As in neonatal meningitis		
Child	Pneumococcus, <i>S aureus</i> , <i>H influenzae</i>	Ceftriaxone, cefuroxime, cefotaxime	Ampicillin-sulbactam
Adult (community-acquired)	Pneumococcus, <i>Mycoplasma</i> , <i>Legionella</i> , <i>H influenzae</i> , <i>S aureus</i> , <i>Chlamydia pneumoniae</i> , coliforms	Outpatient: Macrolide, ⁴ amoxicillin, tetracycline	Outpatient: Quinolone
		Inpatient: Macrolide ⁴ + cefotaxime, ceftriaxone, ertapenem, or ampicillin	Inpatient: Doxycycline + cefotaxime, ceftriaxone, ertapenem, or ampicillin; respiratory quinolone ⁵
Septicemia ⁶	Any	Vancomycin + cephalosporin (third-generation) or piperacillin/tazobactam or imipenem or meropenem	
Septicemia with granulocytopenia	Any	Antipseudomonal penicillin + aminoglycoside; ceftazidime; cefepime; imipenem or meropenem; consider addition of systemic antifungal therapy if fever persists beyond 5 days of empiric therapy	

¹See footnote 9, Table 51-1.²See footnote 2, Table 51-1.³When meningitis with penicillin-resistant pneumococcus is suspected, empiric therapy with this regimen is recommended.⁴Erythromycin, clarithromycin, or azithromycin (an azalide) may be used.⁵Quinolones used to treat pneumococcal infections include levofloxacin, moxifloxacin, and gemifloxacin.⁶Adjunctive immunomodulatory drugs such as drotrecogin- α can also be considered for patients with severe sepsis.

determine the cause of failure. Errors in susceptibility testing are rare, but the original results should be confirmed by repeat testing. Drug dosing and absorption should be scrutinized and tested directly using serum measurements, pill counting, or directly observed therapy.

The clinical data should be reviewed to determine whether the patient's immune function is adequate and, if not, what

can be done to maximize it. For example, are adequate numbers of granulocytes present and is undiagnosed immunodeficiency, malignancy, or malnutrition present? The presence of abscesses or foreign bodies should also be considered. Finally, culture and susceptibility testing should be repeated to determine whether superinfection has occurred with another organism or whether the original pathogen has developed drug resistance.

ANTIMICROBIAL PHARMACODYNAMICS

The time course of drug concentration is closely related to the antimicrobial effect at the site of infection and to any toxic effects. Pharmacodynamic factors include pathogen susceptibility testing, drug bactericidal versus bacteriostatic activity, drug synergism, antagonism, and postantibiotic effects. Together with pharmacokinetics, pharmacodynamic information permits the selection of optimal antimicrobial dosage regimens.

Bacteriostatic versus Bactericidal Activity

Antibacterial agents may be classified as bacteriostatic or bactericidal (Table 51–3). For agents that are primarily bacteriostatic, inhibitory drug concentrations are much lower than bactericidal drug concentrations. In general, cell wall-active agents are bactericidal, and drugs that inhibit protein synthesis are bacteriostatic.

The classification of antibacterial agents as bactericidal or bacteriostatic has limitations. Some agents that are considered to be bacteriostatic may be bactericidal against selected organisms. On the other hand, enterococci are inhibited but not killed by vancomycin, penicillin, or ampicillin used as single agents.

Bacteriostatic and bactericidal agents are equivalent for the treatment of most infectious diseases in immunocompetent hosts. Bactericidal agents should be selected over bacteriostatic ones in circumstances in which local or systemic host defenses are impaired. Bactericidal agents are required for treatment of endocarditis and other endovascular infections, meningitis, and infections in neutropenic cancer patients.

Bactericidal agents can be divided into two groups: agents that exhibit **concentration-dependent killing** (eg, aminoglycosides and quinolones) and agents that exhibit **time-dependent killing**

(eg, β -lactams and vancomycin). For drugs whose killing action is concentration-dependent, the rate and extent of killing increase with increasing drug concentrations. Concentration-dependent killing is one of the pharmacodynamic factors responsible for the efficacy of once-daily dosing of aminoglycosides. For drugs whose killing action is time-dependent, bactericidal activity continues as long as serum concentrations are greater than the MBC.

Postantibiotic Effect

Persistent suppression of bacterial growth after limited exposure to an antimicrobial agent is known as the postantibiotic effect (PAE). The PAE can be expressed mathematically as follows:

$$\text{PAE} = T - C$$

where T is the time required for the viable count in the test (in vitro) culture to increase tenfold above the count observed immediately before drug removal and C is the time required for the count in an untreated culture to increase tenfold above the count observed immediately after completion of the same procedure used on the test culture. The PAE reflects the time required for bacteria to return to logarithmic growth.

Proposed mechanisms include (1) slow recovery after reversible nonlethal damage to cell structures; (2) persistence of the drug at a binding site or within the periplasmic space; and (3) the need to synthesize new enzymes before growth can resume. Most antimicrobials possess significant in vitro PAEs (≥ 1.5 hours) against susceptible Gram-positive cocci (Table 51–4). Antimicrobials

TABLE 51–3 Bactericidal and bacteriostatic antibacterial agents.

Bactericidal Agents	Bacteriostatic Agents
Aminoglycosides	Chloramphenicol
Bacitracin	Clindamycin
β -Lactam antibiotics	Ethambutol
Daptomycin	Macrolides
Fosfomycin	Nitrofurantoin
Glycopeptide antibiotics	Novobiocin
Isoniazid	Oxazolidinones
Ketolides	Sulfonamides
Metronidazole	Tetracyclines
Polymyxins	Tigecycline
Pyrazinamide	Trimethoprim
Quinolones	
Rifampin	
Streptogramins	

TABLE 51–4 Antibacterial agents with in vitro postantibiotic effects ≥ 1.5 hours.

Against Gram-Positive Cocci	Against Gram-Negative Bacilli
Aminoglycosides	Aminoglycosides
Carbapenems	Carbapenems
Cephalosporins	Chloramphenicol
Chloramphenicol	Quinolones
Clindamycin	Rifampin
Daptomycin	Tetracyclines
Glycopeptide antibiotics	Tigecycline

with significant PAEs against susceptible Gram-negative bacilli are limited to carbapenems and agents that inhibit protein or DNA synthesis.

In vivo PAEs are usually much longer than in vitro PAEs. This is thought to be due to **postantibiotic leukocyte enhancement (PALE)** and exposure of bacteria to subinhibitory antibiotic concentrations. The efficacy of once-daily dosing regimens is in part due to the PAE. Aminoglycosides and quinolones possess concentration-dependent PAEs; thus, high doses of aminoglycosides given once daily result in enhanced bactericidal activity and extended PAEs. This combination of pharmacodynamic effects allows aminoglycoside serum concentrations that are below the MICs of target organisms to remain effective for extended periods of time.

PHARMACOKINETIC CONSIDERATIONS

Route of Administration

Many antimicrobial agents have similar pharmacokinetic properties when given orally or parenterally (ie, tetracyclines, trimethoprim-sulfamethoxazole, quinolones, metronidazole, clindamycin, rifampin, linezolid, and fluconazole). In most cases, oral therapy with these drugs is equally effective, is less costly, and results in fewer complications than parenteral therapy.

The intravenous route is preferred in the following situations: (1) for critically ill patients; (2) for patients with bacterial meningitis or endocarditis; (3) for patients with nausea, vomiting, gastrectomy, ileus, or diseases that may impair oral absorption; and (4) when giving antimicrobials that are poorly absorbed following oral administration.

Conditions That Alter Antimicrobial Pharmacokinetics

Various diseases and physiologic states alter the pharmacokinetics of antimicrobial agents. Impairment of renal or hepatic function

may result in decreased elimination. Table 51–5 lists drugs that require dosage reduction in patients with renal or hepatic insufficiency. Failure to reduce antimicrobial agent dosage in such patients may cause toxic effects. Conversely, patients with burns, cystic fibrosis, or trauma may have increased dosage requirements for selected agents. The pharmacokinetics of antimicrobials is also altered in the elderly (see Chapter 60), in neonates (see Chapter 59), and in pregnancy.

Drug Concentrations in Body Fluids

Most antimicrobial agents are well distributed to most body tissues and fluids. Penetration into the cerebrospinal fluid is an exception. Most do not penetrate uninfamed meninges to an appreciable extent. In the presence of meningitis, however, the cerebrospinal fluid concentrations of many antimicrobials increase (Table 51–6).

Monitoring Serum Concentrations of Antimicrobial Agents

For most antimicrobial agents, the relation between dose and therapeutic outcome is well established, and serum concentration monitoring is unnecessary for these drugs. To justify routine serum concentration monitoring, it should be established (1) that a direct relationship exists between drug concentrations and efficacy or toxicity; (2) that substantial interpatient variability exists in serum concentrations on standard doses; (3) that a small difference exists between therapeutic and toxic serum concentrations; (4) that the clinical efficacy or toxicity of the drug is delayed or difficult to measure; and (5) that an accurate assay is available.

In clinical practice, serum concentration monitoring is routinely performed on patients receiving aminoglycosides or vancomycin. Flucytosine serum concentration monitoring has been shown to reduce toxicity when doses are adjusted to maintain peak concentrations below 100 mcg/mL.

TABLE 51–5 Antimicrobial agents that require dosage adjustment or are contraindicated in patients with renal or hepatic impairment.

Dosage Adjustment Needed in Renal Impairment	Contraindicated in Renal Impairment	Dosage Adjustment Needed in Hepatic Impairment
Acyclovir, amantadine, aminoglycosides, aztreonam, carbapenems, cephalosporins, ¹ clarithromycin, colistin, cycloserine, dalbavancin, daptomycin, didanosine, emtricitabine, ethambutol, ethionamide, famciclovir, fluconazole, flucytosine, foscarnet, ganciclovir, lamivudine, oseltamivir, penicillins, ² peramivir, polymyxin B, pyrazinamide, quinolones, ³ ribavirin, rifabutin, rimantadine, stavudine, telavancin, telbivudine, telithromycin, tenofovir, terbinafine, trimethoprim-sulfamethoxazole, valacyclovir, vancomycin, zidovudine	Cidofovir, methenamine, nalidixic acid, nitrofurantoin, sulfonamides (long-acting), tetracyclines ⁴	Abacavir, atazanavir, caspofungin, chloramphenicol, clindamycin, erythromycin, fosamprenavir, indinavir, metronidazole, rimantadine, tigecycline

¹Except ceftriaxone.

²Except antistaphylococcal penicillins (eg, nafcillin and dicloxacillin).

³Except moxifloxacin.

⁴Except doxycycline and minocycline.

TABLE 51-6 Cerebrospinal fluid (CSF) penetration of selected antimicrobials.

Antimicrobial Agent	CSF Concentration (Uninflamed Meninges) as % of Serum Concentration	CSF Concentration (Inflamed Meninges) as % of Serum Concentration
Ampicillin	2–3	2–100
Aztreonam	2	5
Cefepime	0–2	4–12
Cefotaxime	22.5	27–36
Ceftazidime	0.7	20–40
Ceftriaxone	0.8–1.6	16
Cefuroxime	20	17–88

Imipenem	3.1	11–41
Meropenem	0–7	1–52
Nafcillin	2–15	5–27
Penicillin G	1–2	8–18
Sulfamethoxazole	40	12–47
Trimethoprim	<41	12–69
Vancomycin	0	1–53

■ MANAGEMENT OF ANTIMICROBIAL DRUG TOXICITY

Owing to the large number of antimicrobials available, it is usually possible to select an effective alternative in patients who develop serious drug toxicity (Table 51-1). However, for some infections there are no effective alternatives to the drug of choice. For example, in patients with neurosyphilis who have a history of anaphylaxis to penicillin, it is necessary to perform skin testing and desensitization to penicillin. It is important to obtain a clear history of drug allergy and other adverse drug reactions. A patient with a documented antimicrobial allergy should carry a card with the name of the drug and a description of the reaction. Cross-reactivity between penicillins and cephalosporins is less than 10%. Cephalosporins may be administered to patients with penicillin-induced maculopapular rashes but should be avoided in patients with a history of penicillin-induced immediate hypersensitivity reactions. On the other hand, aztreonam does not cross-react with penicillins and can be safely administered to patients with a history of penicillin-induced anaphylaxis. For mild reactions, it may be possible to continue therapy with use of adjunctive agents or dosage reduction.

Adverse reactions to antimicrobials occur with increased frequency in several groups, including neonates, geriatric patients, renal failure patients, and AIDS patients. Dosage adjustment of the drugs listed in Table 51-5 is essential for the prevention of adverse effects in patients with renal failure. In addition, several agents are contraindicated in patients with renal impairment because of increased rates of serious toxicity (Table 51-5). See the preceding chapters for discussions of specific drugs.

■ ANTIMICROBIAL DRUG COMBINATIONS

RATIONALE FOR COMBINATION ANTIMICROBIAL THERAPY

Most infections should be treated with a single antimicrobial agent. Although indications for combination therapy exist, antimicrobial combinations are often overused in clinical practice. The unnecessary use of antimicrobial combinations increases toxicity and costs and may occasionally result in reduced efficacy due to antagonism of one drug by another. Antimicrobial combinations should be selected for one or more of the following reasons:

1. To provide broad-spectrum empiric therapy in seriously ill patients.
2. To treat polymicrobial infections (such as intra-abdominal abscesses, which typically are due to a combination of anaerobic and aerobic Gram-negative organisms, and enterococci). The antimicrobial combination chosen should cover the most common known or suspected pathogens but need not cover all possible pathogens. The availability of antimicrobials with excellent polymicrobial coverage (eg, β -lactamase inhibitor combinations or carbapenems) may reduce the need for combination therapy in the setting of polymicrobial infections.
3. To decrease the emergence of resistant strains. The value of combination therapy in this setting has been clearly demonstrated for tuberculosis.
4. To decrease dose-related toxicity by using reduced doses of one or more components of the drug regimen. The use of flucytosine in combination with amphotericin B for the treatment of cryptococcal meningitis in non-HIV-infected patients allows for a reduction in amphotericin B dosage with decreased amphotericin B-induced nephrotoxicity.
5. To obtain enhanced inhibition or killing. This use of antimicrobial combinations is discussed in the paragraphs that follow.

SYNERGISM & ANTAGONISM

When the inhibitory or killing effects of two or more antimicrobials used together are significantly greater than expected from their effects when used individually, synergism is said to result. Synergism is marked by a fourfold or greater reduction in the MIC or MBC of each drug when used in combination versus when used alone. Antagonism occurs when the combined inhibitory or killing effects of two or more antimicrobial drugs are significantly less than observed when the drugs are used individually.

Mechanisms of Synergistic Action

The need for synergistic combinations of antimicrobials has been clearly established for the treatment of enterococcal endocarditis. Bactericidal activity is essential for the optimal management of bacterial endocarditis. Penicillin or ampicillin in combination with gentamicin or streptomycin is superior to monotherapy with

a penicillin or vancomycin. When tested alone, penicillins and vancomycin are only bacteriostatic against susceptible enterococcal isolates. When these agents are combined with an aminoglycoside, however, bactericidal activity results. The addition of gentamicin or streptomycin to penicillin allows for a reduction in the duration of therapy for selected patients with viridans streptococcal endocarditis.

Other synergistic antimicrobial combinations have been shown to be more effective than monotherapy with individual components. Trimethoprim-sulfamethoxazole has been successfully used in the treatment of bacterial infections and *P jiroveci* (carinii) pneumonia.* β -Lactamase inhibitors restore the activity of intrinsically active but hydrolyzable β lactams against organisms such as *Staphylococcus aureus* and *Bacteroides fragilis*. Three major mechanisms of antimicrobial synergism have been established:

1. **Blockade of sequential steps in a metabolic sequence:** Trimethoprim-sulfamethoxazole is the best-known example of this mechanism of synergy (see Chapter 46). Blockade of the two sequential steps in the folic acid pathway by trimethoprim-sulfamethoxazole results in a much more complete inhibition of growth than achieved by either component alone.
2. **Inhibition of enzymatic inactivation:** Enzymatic inactivation of β -lactam antibiotics is a major mechanism of antibiotic resistance. Inhibition of β lactamase by β -lactamase inhibitor drugs (eg, sulbactam) results in synergism.
3. **Enhancement of antimicrobial agent uptake:** Penicillins and other cell wall-active agents can increase the uptake of aminoglycosides by a number of bacteria, including staphylococci, enterococci, streptococci, and *P aeruginosa*. Enterococci are thought to be intrinsically resistant to aminoglycosides because of permeability barriers. Similarly, amphotericin B is thought to enhance the uptake of flucytosine by fungi.

Mechanisms of Antagonistic Action

There are few clinically relevant examples of antimicrobial antagonism. The most striking example was reported in a study of patients with pneumococcal meningitis. Patients who were treated with the combination of penicillin and chlortetracycline had a mortality rate of 79% compared with a mortality rate of 21% in patients who received penicillin monotherapy (illustrating the first mechanism set forth below).

The use of an antagonistic antimicrobial combination does not preclude other potential beneficial interactions. For example, rifampin may antagonize the action of anti-staphylococcal penicillins or vancomycin against staphylococci. However, the aforementioned antimicrobials may prevent the emergence of resistance to rifampin.

Two major mechanisms of antimicrobial antagonism have been established:

1. **Inhibition of cidal activity by static agents:** Bacteriostatic agents such as tetracyclines and chloramphenicol can

antagonize the action of bactericidal cell wall-active agents because cell wall-active agents require that the bacteria be actively growing and dividing.

2. **Induction of enzymatic inactivation:** Some Gram-negative bacilli, including *Enterobacter* species, *P aeruginosa*, *Serratia marcescens*, and *Citrobacter freundii*, possess inducible β -lactamases. β -Lactam antibiotics such as imipenem, cefoxitin, and ampicillin are potent inducers of β -lactamase production. If an inducing agent is combined with an intrinsically active but hydrolyzable β -lactam such as piperacillin, antagonism may result.

■ ANTIMICROBIAL PROPHYLAXIS

Antimicrobial agents are effective in preventing infections in many settings. Antimicrobial prophylaxis should be used in circumstances in which efficacy has been demonstrated and benefits outweigh the risks of prophylaxis. Antimicrobial prophylaxis may be divided into surgical prophylaxis and nonsurgical prophylaxis.

Surgical Prophylaxis

Surgical wound infections are a major category of nosocomial infections. The estimated annual cost of surgical wound infections in the USA is more than \$1.5 billion.

The National Research Council (NRC) Wound Classification Criteria have served as the basis for recommending antimicrobial prophylaxis. NRC criteria consist of four classes (see Box: National Research Council [NRC] Wound Classification Criteria).

The Study of the Efficacy of Nosocomial Infection Control (SENIC) identified four independent risk factors for postoperative wound infections: operations on the abdomen, operations lasting more than 2 hours, contaminated or dirty wound classification, and at least three medical diagnoses. Patients with at least two SENIC risk factors who undergo clean surgical procedures have an increased risk of developing surgical wound infections and should receive antimicrobial prophylaxis.

Surgical procedures that necessitate the use of antimicrobial prophylaxis include contaminated and clean-contaminated operations, selected operations in which postoperative infection may be catastrophic such as open heart surgery, clean procedures that involve placement of prosthetic materials, and any procedure in an immunocompromised host. The operation should carry a significant risk of postoperative site infection or cause significant bacterial contamination.

General principles of antimicrobial surgical prophylaxis include the following:

1. The antibiotic should be active against common surgical wound pathogens; unnecessarily broad coverage should be avoided.
2. The antibiotic should have proved efficacy in clinical trials.
3. The antibiotic must achieve concentrations greater than the MIC of suspected pathogens, and these concentrations must be present at the time of incision.

**Pneumocystis jiroveci* is a fungal organism found in humans (*P carinii* infects animals) that responds to antiprotozoal drugs. See Chapter 52.

National Research Council (NRC) Wound Classification Criteria

Clean: Elective, primarily closed procedure; respiratory, gastrointestinal, biliary, genitourinary, or oropharyngeal tract not entered; no acute inflammation and no break in technique; expected infection rate $\leq 2\%$.

Clean contaminated: Urgent or emergency case that is otherwise clean; elective, controlled opening of respiratory, gastrointestinal, biliary, or oropharyngeal tract; minimal spillage or minor break in technique; expected infection rate $\leq 10\%$.

Contaminated: Acute nonpurulent inflammation; major technique break or major spill from hollow organ; penetrating trauma less than 4 hours old; chronic open wounds to be grafted or covered; expected infection rate about 20%.

Dirty: Purulence or abscess; preoperative perforation of respiratory, gastrointestinal, biliary, or oropharyngeal tract; penetrating trauma more than 4 hours old; expected infection rate about 40%.

4. The shortest possible course—ideally a single dose—of the most effective and least toxic antibiotic should be used.
5. The newer broad-spectrum antibiotics should be reserved for therapy of resistant infections.
6. If all other factors are equal, the least expensive agent should be used.

The proper selection and administration of antimicrobial prophylaxis are of utmost importance. Common indications for surgical prophylaxis are shown in Table 51–7. Cefazolin is the prophylactic agent of choice for head and neck, gastroduodenal, biliary tract, gynecologic, and clean procedures. Local wound infection patterns should be considered when selecting antimicrobial prophylaxis. The selection of vancomycin over cefazolin may be necessary in hospitals with high rates of methicillin-resistant *S aureus* or *S epidermidis* infections. The antibiotic should be present in adequate concentrations at the operative site before incision and throughout the procedure; initial dosing is dependent on the volume of distribution, peak levels, clearance, protein binding, and bioavailability. Parenteral agents should be administered during the interval beginning 60 minutes before incision. In cesarean section, the antibiotic is administered after umbilical cord clamping. For many antimicrobial agents, doses should be repeated if the procedure exceeds 2–6 hours in duration. Single-dose prophylaxis is effective for most procedures and results in decreased toxicity and antimicrobial resistance.

Improper administration of antimicrobial prophylaxis leads to excessive surgical wound infection rates. Common errors in antibiotic prophylaxis include selection of the wrong antibiotic, administering the first dose too early or too late, failure to repeat doses during prolonged procedures, excessive duration of prophylaxis, and inappropriate use of broad-spectrum antibiotics.

Nonsurgical Prophylaxis

Nonsurgical prophylaxis includes the administration of antimicrobials to prevent colonization or asymptomatic infection as

TABLE 51–7 Recommendations for surgical antimicrobial prophylaxis.

Type of Operation	Common Pathogens	Drug of Choice
Cardiac (with median sternotomy)	Staphylococci, enteric Gram-negative rods	Cefazolin
Noncardiac, thoracic	Staphylococci, streptococci, enteric Gram-negative rods	Cefazolin
Vascular (abdominal and lower extremity)	Staphylococci, enteric Gram-negative rods	Cefazolin
Neurosurgical (craniotomy)	Staphylococci	Cefazolin
Orthopedic (with hardware insertion)	Staphylococci	Cefazolin
Head and neck (with entry into the oropharynx)	<i>Staphylococcus aureus</i> , oral flora	Cefazolin + metronidazole
Gastroduodenal	<i>S aureus</i> , oral flora, enteric Gram-negative rods	Cefazolin
Biliary tract	<i>S aureus</i> , enterococci, enteric Gram-negative rods	Cefazolin
Colorectal (elective surgery)	Enteric Gram-negative rods, anaerobes	Oral erythromycin + neomycin ¹
Colorectal (emergency surgery or obstruction)	Enteric Gram-negative rods, anaerobes	Cefoxitin, cefotetan, ertapenem, or cefazolin + metronidazole
Appendectomy, nonperforated	Enteric Gram-negative rods, anaerobes	Cefoxitin, cefotetan, or cefazolin + metronidazole
Hysterectomy	Enteric Gram-negative rods, anaerobes, enterococci, group B streptococci	Cefazolin, cefotetan, or cefoxitin
Cesarean section	Enteric Gram-negative rods, anaerobes, enterococci, group B streptococci	Cefazolin

¹In conjunction with mechanical bowel preparation.

TABLE 51–8 Recommendations for nonsurgical antimicrobial prophylaxis.

Infection to Be Prevented	Indication(s)	Drug of Choice	Efficacy
Anthrax	Suspected exposure	Ciprofloxacin or doxycycline	Proposed effective
Cholera	Close contacts of a case	Tetracycline	Proposed effective
Diphtheria	Unimmunized contacts	Penicillin or erythromycin	Proposed effective
Endocarditis	Dental, oral, or upper respiratory tract procedures ¹ in at-risk patients ²	Amoxicillin or clindamycin	Proposed effective
Genital herpes simplex	Recurrent infection (≥ 4 episodes per year)	Acyclovir	Excellent
Perinatal herpes simplex type 2 infection	Mothers with primary HSV or frequent recurrent genital HSV	Acyclovir	Proposed effective
Group B streptococcal (GBS) infection	Mothers with cervical or vaginal GBS colonization and their newborns with one or more of the following: (a) onset of labor or membrane rupture before 37 weeks' gestation, (b) prolonged rupture of membranes (>12 hours), (c) maternal intrapartum fever, (d) history of GBS bacteriuria during pregnancy, (e) mothers who have given birth to infants who had early GBS disease or with a history of streptococcal bacteriuria during pregnancy	Ampicillin or penicillin	Excellent
<i>Haemophilus influenzae</i> type B infection	Close contacts of a case in incompletely immunized children (>48 months old)	Rifampin	Excellent
HIV infection	Health care workers exposed to blood after needle-stick injury	Tenofovir/emtricitabine and raltegravir	Good
	Pregnant HIV-infected women who are at ≥ 14 weeks of gestation; newborns of HIV-infected women for the first 6 weeks of life, beginning 8–12 hours after birth	HAART ³	Excellent
Influenza A and B	Unvaccinated geriatric patients, immunocompromised hosts, and health care workers during outbreaks	Oseltamivir	Good
Malaria	Travelers to areas endemic for chloroquine-susceptible disease	Chloroquine	Excellent
	Travelers to areas endemic for chloroquine-resistant disease	Mefloquine, doxycycline, or atovaquone/proguanil	Excellent
Meningococcal infection	Close contacts of a case	Rifampin, ciprofloxacin, or ceftriaxone	Excellent
<i>Mycobacterium avium</i> complex	HIV-infected patients with CD4 count $<75/\mu\text{L}$	Azithromycin, clarithromycin, or rifabutin	Excellent
Otitis media	Recurrent infection	Amoxicillin	Good
Pertussis	Close contacts of a case	Azithromycin	Excellent
Plague	Close contacts of a case	Tetracycline	Proposed effective
Pneumococemia	Children with sickle cell disease or asplenia	Penicillin	Excellent
<i>Pneumocystis jiroveci</i> pneumonia (PCP)	High-risk patients (eg, AIDS, leukemia, transplant)	Trimethoprim-sulfamethoxazole, dapsone, or atovaquone	Excellent
Rheumatic fever	History of rheumatic fever or known rheumatic heart disease	Benzathine penicillin	Excellent
Toxoplasmosis	HIV-infected patients with IgG antibody to <i>Toxoplasma</i> and CD4 count $<100/\mu\text{L}$	Trimethoprim-sulfamethoxazole	Good
Tuberculosis	Persons with positive tuberculin skin tests and one or more of the following: (a) HIV infection, (b) close contacts with newly diagnosed disease, (c) recent skin test conversion, (d) medical conditions that increase the risk of developing tuberculosis, (e) age <35 y	Isoniazid or rifampin or isoniazid + rifapentine	Excellent
Urinary tract infections (UTI)	Recurrent infection	Trimethoprim-sulfamethoxazole	Excellent

¹Prophylaxis is recommended for the following: dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa, and invasive procedure of the respiratory tract that involves incision or biopsy of the respiratory mucosa, such as tonsillectomy and adenoidectomy.

²Prophylaxis should be targeted to those with the following risk factors: prosthetic heart valves, previous bacterial endocarditis, congenital cardiac malformations, cardiac transplantation patients who develop cardiac valvulopathy.

³Highly active antiretroviral therapy. See aidsinfo.nih.gov/ for updated guidelines.

well as the administration of drugs following colonization by or inoculation of pathogens but before the development of disease. Nonsurgical prophylaxis is indicated in individuals who are at high risk for temporary exposure to selected virulent pathogens and in patients who are at increased risk for developing infection

CASE STUDY ANSWER

This patient is experiencing a post-procedure urinary tract infection which may have been introduced into his bloodstream at the time of his cystoscopy. It is likely that the patient is experiencing a sepsis-like syndrome and has a systemic infection with a uropathogen that is resistant to the antibiotic that he has received. Possible bacteria that may be responsible for the patient's symptoms are methicillin-resistant *Staphylococcus aureus*, *Enterococcus sp.*, and enteric Gram-negative rods that are resistant to ciprofloxacin such as ESBL-positive *E coli* or *Klebsiella pneumoniae*, or other hospital-acquired Gram

negative organisms such as *Pseudomonas aeruginosa*. The patient was treated with vancomycin and meropenem, and blood and urine cultures were both positive for ESBL-positive *E coli* that was resistant to ciprofloxacin. The patient defervesced and hemodynamically stabilized over the subsequent 48 hours. ESBL-positive *E coli* is an emerging urinary tract pathogen that may be acquired in the outpatient setting, and oral antibiotic therapy may not reliably be effective; empiric therapy with a carbapenem (ertapenem, doripenem, meropenem, imipenem) is recommended for serious infections due to this organism.

Antiprotozoal Drugs

Philip J. Rosenthal, MD

CASE STUDY

A 5-year-old American girl presents with a 1-week history of intermittent chills, fever, and sweats. She had returned home 2 weeks earlier after leaving the USA for the first time to spend 3 weeks with her grandparents in Nigeria. She received all standard childhood immunizations, but no additional treatment before travel, since her parents have returned to their native Nigeria frequently without medical consequences. Three days ago, the child was seen in an outpatient clinic

and diagnosed with a viral syndrome. Examination reveals a lethargic child, with a temperature of 39.8°C (103.6°F) and splenomegaly. She has no skin rash or lymphadenopathy. Initial laboratory studies are remarkable for hematocrit 29.8%, platelets 45,000/mm³, creatinine 2.5 mg/dL (220 μmol/L), and mildly elevated bilirubin and transaminases. A blood smear shows ring forms of *Plasmodium falciparum* at 1.5% parasitemia. What treatment should be started?

■ MALARIA

Malaria is the most important parasitic disease of humans and causes hundreds of millions of illnesses per year. Four species of plasmodium typically cause human malaria: *Plasmodium falciparum*, *P vivax*, *P malariae*, and *P ovale*. A fifth species, *P knowlesi*, is primarily a pathogen of monkeys but has recently been recognized to cause illness, including severe disease, in humans in Asia. Although all of the latter species may cause significant illness, *P falciparum* is responsible for the majority of serious complications and deaths. Drug resistance is an important therapeutic problem, most notably with *P falciparum*.

PARASITE LIFE CYCLE

An anopheline mosquito inoculates plasmodium sporozoites to initiate human infection (Figure 52–1). Circulating sporozoites rapidly invade liver cells, and exoerythrocytic stage tissue schizonts mature in the liver. Merozoites are subsequently released from the liver and invade erythrocytes. Only erythrocytic parasites cause clinical illness. Repeated cycles of infection can lead to the

infection of many erythrocytes and serious disease. Sexual stage gametocytes also develop in erythrocytes before being taken up by mosquitoes, where they develop into infective sporozoites.

In *P falciparum* and *P malariae* infection, only one cycle of liver cell invasion and multiplication occurs, and liver infection ceases spontaneously in less than 4 weeks. Thus, treatment that eliminates erythrocytic parasites will cure these infections. In *P vivax* and *P ovale* infections, a dormant hepatic stage, the hypnozoite, is not eradicated by most drugs, and relapses can occur after therapy directed against erythrocytic parasites. Eradication of both erythrocytic and hepatic parasites is required to cure these infections.

DRUG CLASSIFICATION

Several classes of antimalarial drugs are available (Table 52–1 and Figure 52–2). Drugs that eliminate developing or dormant liver forms are called **tissue schizonticides**; those that act on erythrocytic parasites are **blood schizonticides**; and those that kill sexual stages and prevent transmission to mosquitoes are **gametocides**. No single available agent can reliably effect a **radical cure**, ie, eliminate both hepatic and erythrocytic stages. Few available

FIGURE 52-1 Life cycle of malaria parasites. Only the asexual erythrocytic stage of infection causes clinical malaria. All effective antimalarial treatments are blood schizonticides that kill this stage. (Reproduced from Baird JK: Effectiveness of antimalarial drugs. *N Engl J Med* 2005;352:1565.)

agents are **causal prophylactic drugs**, ie, capable of preventing erythrocytic infection. However, all effective chemoprophylactic agents kill erythrocytic parasites before they increase sufficiently in number to cause clinical disease.

CHEMOPROPHYLAXIS & TREATMENT

When patients are counseled on the prevention of malaria, it is imperative to emphasize measures to prevent mosquito bites (eg, with insect repellents, insecticides, and bed nets), because parasites are increasingly resistant to multiple drugs and no chemoprophylactic regimen is fully protective. Current recommendations from the U.S. Centers for Disease Control and Prevention (CDC) include the use of chloroquine for chemoprophylaxis in the few areas infested by only chloroquine-sensitive malaria parasites (principally Hispaniola and Central America west of the Panama Canal), and mefloquine, Malarone,^{*} or doxycycline for most other malarious areas, with doxycycline preferred for areas with a high prevalence of multidrug-resistant falciparum malaria (principally border areas of Thailand) (Table 52-2). CDC recommendations should be checked regularly (Phone: 770-488-7788; after hours 770-488-7100; Internet: www.cdc.gov/malaria), because these may change in response to changing resistance patterns and increasing experience with new drugs. In some circumstances, it

may be appropriate for travelers to carry supplies of drugs with them in case they develop a febrile illness when medical attention is unavailable. Regimens for self-treatment include new artemisinin-based combination therapies (see below), which are widely available internationally (and, in the case of Coartem[†], in the USA); Malarone; mefloquine; and quinine. Most authorities do not recommend routine terminal chemoprophylaxis with primaquine to eradicate dormant hepatic stages of *P vivax* and *P ovale* after travel, but this may be appropriate in some circumstances, especially for travelers with major exposure to these parasites.

Multiple drugs are available for the treatment of malaria that presents in the USA (Table 52-3). Most nonfalciparum infections and falciparum malaria from areas without known resistance should be treated with chloroquine. For vivax malaria from areas with suspected chloroquine resistance, including Indonesia and Papua New Guinea, other therapies effective against falciparum malaria may be used. Vivax and ovale malaria should subsequently be treated with primaquine to eradicate liver forms. Uncomplicated falciparum malaria from most areas is most often treated with Malarone, but new artemisinin-based combinations are increasingly the international standard of care, and one combination, Coartem, is now available in the USA. Other agents that are generally effective against resistant falciparum malaria include mefloquine, quinine, and halofantrine, all of which have toxicity concerns at treatment dosages. Severe falciparum malaria is treated with intravenous artesunate, quinidine, or quinine (intravenous quinine is not available in the USA).

CHLOROQUINE

Chloroquine has been a drug of choice for both treatment and chemoprophylaxis of malaria since the 1940s, but its usefulness against *P falciparum* has been seriously compromised by drug resistance. It remains the drug of choice in the treatment of sensitive *P falciparum* and other species of human malaria parasites.

Chemistry & Pharmacokinetics

Chloroquine is a synthetic 4-aminoquinoline (Figure 52-2) formulated as the phosphate salt for oral use. It is rapidly and almost completely absorbed from the gastrointestinal tract, reaches maximum plasma concentrations in about 3 hours, and is rapidly distributed to the tissues. It has a very large apparent volume of distribution of 100–1000 L/kg and is slowly released from tissues and metabolized. Chloroquine is principally excreted in the urine with an initial half-life of 3–5 days but a much longer terminal elimination half-life of 1–2 months.

Antimalarial Action & Resistance

When not limited by resistance, chloroquine is a highly effective blood schizonticide. Chloroquine is not reliably active against liver stage parasites or gametocytes. The drug probably acts by concentrating in parasite food vacuoles, preventing the biocrystallization

^{*}Malarone is a proprietary formulation of atovaquone plus proguanil.

[†]Coartem is a proprietary formulation of artemether and lumefantrine.

FIGURE 52-2 Structural formulas of some antimalarial drugs.

of the hemoglobin breakdown product, heme, into hemozoin, and thus eliciting parasite toxicity due to the buildup of free heme.

Resistance to chloroquine is now very common among strains of *P. falciparum* and uncommon but increasing for *P. vivax*. In *P. falciparum*, mutations in a putative transporter, PfCRT, are the primary mediators of resistance. Chloroquine resistance can be reversed by certain agents, including verapamil, desipramine, and chlorpheniramine, but the clinical value of resistance-reversing drugs is not established.

Clinical Uses

1. Treatment—Chloroquine is the drug of choice in the treatment of uncomplicated nonfalciparum and sensitive falciparum

malaria. It rapidly terminates fever (usually in 24–48 hours) and clears parasitemia (in 48–72 hours) caused by sensitive parasites. Chloroquine has been replaced by other drugs, principally artemisinin-based combination therapies, as the standard therapy to treat falciparum malaria in most endemic countries. Chloroquine does not eliminate dormant liver forms of *P. vivax* and *P. ovale*, and for that reason primaquine must be added for the radical cure of these species.

2. Chemoprophylaxis—Chloroquine is the preferred chemoprophylactic agent in malarious regions without resistant falciparum malaria. Eradication of *P. vivax* and *P. ovale* requires a course of primaquine to clear hepatic stages.

TABLE 52-1 Major antimalarial drugs.

Drug	Class	Use
Chloroquine	4-Aminoquinoline	Treatment and chemoprophylaxis of infection with sensitive parasites
Amodiaquine ¹	4-Aminoquinoline	Treatment of infection with some chloroquine-resistant <i>P falciparum</i> strains and in fixed combination with artesunate
Piperaquine ¹	Bisquinoline	Treatment of <i>P falciparum</i> infection in fixed combination with dihydroartemisinin
Quinine	Quinoline methanol	Oral and intravenous ¹ treatment of <i>P falciparum</i> infections
Quinidine	Quinoline methanol	Intravenous therapy of severe infections with <i>P falciparum</i>
Mefloquine	Quinoline methanol	Chemoprophylaxis and treatment of infections with <i>P falciparum</i>
Primaquine	8-Aminoquinoline	Radical cure and terminal prophylaxis of infections with <i>P vivax</i> and <i>P ovale</i> ; alternative chemoprophylaxis for all species
Sulfadoxine-pyrimethamine (Fansidar)	Folate antagonist combination	Treatment of infections with some chloroquine-resistant <i>P falciparum</i> , including combination with artesunate; intermittent preventive therapy in endemic areas
Atovaquone-proguanil (Malarone)	Quinone-folate antagonist combination	Treatment and chemoprophylaxis of <i>P falciparum</i> infection
Doxycycline	Tetracycline	Treatment (with quinine) of infections with <i>P falciparum</i> ; chemoprophylaxis
Halofantrine ¹	Phenanthrene methanol	Treatment of <i>P falciparum</i> infections
Lumefantrine ²	Amyl alcohol	Treatment of <i>P falciparum</i> malaria in fixed combination with artemether (Coartem)
Pyronaridine	Mannich base acridine	Treatment of <i>P falciparum</i> malaria in fixed combination with artesunate (Pyramax)
Artemisinins (artesunate, artemether, ² dihydroartemisinin ¹)	Sesquiterpene lactone endoperoxides	Treatment of <i>P falciparum</i> infections; oral combination therapies for uncomplicated disease; intravenous artesunate for severe disease

¹Not available in the USA.²Available in the USA only as the fixed combination Coartem.

3. Amebic liver abscess—Chloroquine reaches high liver concentrations and may be used for amebic abscesses that fail initial therapy with metronidazole (see below).

Adverse Effects

Chloroquine is usually very well tolerated, even with prolonged use. Pruritus is common, primarily in Africans. Nausea, vomiting, abdominal pain, headache, anorexia, malaise, blurring of vision,

and urticaria are uncommon. Dosing after meals may reduce some adverse effects. Rare reactions include hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient persons, impaired hearing, confusion, psychosis, seizures, agranulocytosis, exfoliative dermatitis, alopecia, bleaching of hair, hypotension, and electrocardiographic changes. The long-term administration of high doses of chloroquine for rheumatologic diseases (see Chapter 36) can result in irreversible ototoxicity, retinopathy, myopathy, and peripheral neuropathy, but these are rarely seen with standard-dose weekly

TABLE 52-2 Drugs for the prevention of malaria in travelers.¹

Drug	Use ²	Adult Dosage ³
Chloroquine	Areas without resistant <i>P falciparum</i>	500 mg weekly
Malarone	Areas with chloroquine-resistant <i>P falciparum</i>	1 tablet (250 mg atovaquone/100 mg proguanil) daily
Mefloquine	Areas with chloroquine-resistant <i>P falciparum</i>	250 mg weekly
Doxycycline	Areas with multidrug-resistant <i>P falciparum</i>	100 mg daily
Primaquine ⁴	Terminal prophylaxis of <i>P vivax</i> and <i>P ovale</i> infections; alternative for primary prevention	52.6 mg (30 mg base) daily for 14 days after travel; for primary prevention 52.6 mg (30 mg base) daily

¹Recommendations may change, as resistance to all available drugs is increasing. See text for additional information on toxicities and cautions. For additional details and pediatric dosing, see CDC guidelines (phone: 877-FYI-TRIP; www.cdc.gov). Travelers to remote areas should consider carrying effective therapy (see text) for use if they develop a febrile illness and cannot reach medical attention quickly.

²Areas without known chloroquine-resistant *P falciparum* are Central America west of the Panama Canal, Haiti, Dominican Republic, Egypt, and most malarious countries of the Middle East. Malarone or mefloquine are currently recommended for other malarious areas except for border areas of Thailand, where doxycycline is recommended.

³For drugs other than primaquine, begin 1–2 weeks before departure (except 2 days before for doxycycline and Malarone) and continue for 4 weeks after leaving the endemic area (except 1 week for Malarone). All dosages refer to salts.

⁴Screen for glucose-6-phosphate dehydrogenase (G6PD) deficiency before using primaquine.

TABLE 52–3 Treatment of malaria.

Clinical Setting	Drug Therapy ¹	Alternative Drugs
Chloroquine-sensitive <i>P falciparum</i> and <i>P malariae</i> infections	Chloroquine phosphate, 1 g, followed by 500 mg at 6, 24, and 48 hours or Chloroquine phosphate, 1 g at 0 and 24 hours, then 0.5 g at 48 hours	
<i>P vivax</i> and <i>P ovale</i> infections	Chloroquine (as above), then (if G6PD normal) primaquine, 52.6 mg (30 mg base) for 14 days	For infections from Indonesia, Papua New Guinea, and other areas with suspected resistance: therapies listed for uncomplicated chloroquine-resistant <i>P falciparum</i> plus primaquine
Uncomplicated infections with chloroquine-resistant <i>P falciparum</i>	Coartem (artemether, 20 mg, plus lumefantrine, 120 mg), four tablets twice daily for 3 days	Malarone, four tablets (total of 1 g atovaquone, 400 mg proguanil) daily for 3 days or Mefloquine, 15 mg/kg once or 750 mg, then 500 mg in 6–8 hours or Quinine sulfate, 650 mg 3 times daily for 3 days, plus doxycycline, 100 mg twice daily for 7 days, or clindamycin, 600 mg twice daily for 7 days or Other artemisinin-based combination regimens (see Table 52–4)
Severe or complicated infections with <i>P falciparum</i>	Artesunate, ² 2.4 mg/kg IV, every 12 hours for 1 day, then daily for 2 additional days; follow with 7-day oral course of doxycycline or clindamycin or full treatment course of Coartem, Malarone, or mefloquine or Quinidine gluconate, ^{4,5} 10 mg/kg IV over 1–2 hours, then 0.02 mg/kg IV/min or Quinidine gluconate ^{4,5} 15 mg/kg IV over 4 hours, then 7.5 mg/kg IV over 4 hours every 8 hours	Artemether, ³ 3.2 mg/kg IM, then 1.6 mg/kg/d IM; follow with oral therapy as for artesunate or Quinine dihydrochloride, ^{3–5} 20 mg/kg IV, then 10 mg/kg every 8 hours

¹All dosages are oral and refer to salts unless otherwise indicated. See text for additional information on all agents, including toxicities and cautions. See CDC guidelines (phone: 770-488-7788; www.cdc.gov) for additional information and pediatric dosing.

²Available in the United States only on an investigational basis through the CDC (phone: 770-488-7788).

³Not available in the USA.

⁴Cardiac monitoring should be in place during intravenous administration of quinidine or quinine. Change to an oral regimen as soon as the patient can tolerate it.

⁵Avoid loading doses in persons who have received quinine, quinidine, or mefloquine in the prior 24 hours.

G6PD, glucose-6-phosphate dehydrogenase.

chemoprophylaxis. Intramuscular injections or intravenous infusions of chloroquine hydrochloride can result in severe hypotension and respiratory and cardiac arrest, and should be avoided.

Contraindications & Cautions

Chloroquine is contraindicated in patients with psoriasis or porphyria. It should generally not be used in those with retinal or visual field abnormalities or myopathy, and should be used with caution in patients with liver, neurologic, or hematologic disorders. The antidiarrheal agent kaolin and calcium- and magnesium-containing antacids interfere with the absorption of chloroquine and should not be co-administered. Chloroquine is considered safe in pregnancy and for young children.

OTHER QUINOLINES

Amodiaquine is closely related to chloroquine, and it probably shares mechanisms of action and resistance. Amodiaquine was widely used to treat malaria because of its low cost, limited toxicity, and, in some areas, effectiveness against chloroquine-resistant strains of *P falciparum*, but toxicities, including agranulocytosis, aplastic anemia, and hepatotoxicity, have limited its use. However, recent reevaluation has shown that serious toxicity from amodiaquine is uncommon. The most important current use of amodiaquine is in combination therapy. The World Health Organization (WHO) lists artesunate plus amodiaquine as a recommended therapy for falciparum malaria (Table 52–4). This combination is now available as a single tablet (ASAQ, Arsucam, Coarsucam) and is the first-line

TABLE 52-4 WHO recommendations for the treatment of falciparum malaria.

Regimen	Notes
Artemether-lumefantrine (Coartem, Riamet)	Co-formulated; first-line therapy in many countries; approved in the USA
Artesunate-amodiaquine (ASAQ, Arsucam, Coarsucam)	Co-formulated; first-line therapy in many African countries
Artesunate-mefloquine	Co-formulated; first-line therapy in parts of Southeast Asia and South America
Dihydroartemisinin-piperaquine (Artekin, Duocotecxin)	Co-formulated; first-line therapy in some countries in Southeast Asia
Artesunate-sulfadoxine-pyrimethamine	First-line therapy in some countries, but efficacy lower than other regimens in most areas

Data from World Health Organization: Guidelines for the Treatment of Malaria, 3rd ed. World Health Organization. Geneva, 2015.

therapy for the treatment of uncomplicated falciparum malaria in many countries in Africa. Long-term chemoprophylaxis with amodiaquine is best avoided because of its apparent increased toxicity with long-term use, but short-term seasonal malaria chemoprevention with amodiaquine plus sulfadoxine-pyrimethamine (monthly treatment doses for 3–4 months during the transmission season) is now recommended by the WHO for the Sahel sub-region of Africa.

Piperaquine is a bisquinoline that was used widely to treat chloroquine-resistant falciparum malaria in China in the 1970s–1980s, but its use waned after resistance became widespread. More recently, piperaquine combined with dihydroartemisinin (Artekin, Duocotecxin) showed excellent efficacy and safety for the treatment of falciparum malaria, although very recently decreased efficacy has been seen in southeast Asia, linked to decreased activity of both components of the combination. Piperaquine has a longer half-life (~28 days) than amodiaquine (~14 days), mefloquine (~14 days), or lumefantrine (~4 days), leading to a longer period of post-treatment prophylaxis with dihydroartemisinin-piperaquine than with the other leading artemisinin-based combinations; this feature should be particularly advantageous in high-transmission areas. Dihydroartemisinin-piperaquine is now the first-line therapy for the treatment of uncomplicated falciparum malaria in some countries in Asia. As dihydroartemisinin-piperaquine offers extended protection against malaria, there is interest in chemoprevention with monthly dosing of the drug, which has shown excellent efficacy in children and pregnant women in Africa.

ARTEMISININ & ITS DERIVATIVES

Artemisinin (**qinghaosu**) is a sesquiterpene lactone endoperoxide (Figure 52-2), the active component of an herbal medicine that has been used as an antipyretic in China for more than 2000 years. Artemisinin is insoluble and can only be used orally. Analogs have been synthesized to increase solubility and improve antimalarial efficacy. The most important of these analogs are **artesunate** (water-soluble; oral, intravenous, intramuscular, and rectal administration),

artemether (lipid-soluble; oral, intramuscular, and rectal administration), and **dihydroartemisinin** (water-soluble; oral administration).

Chemistry & Pharmacokinetics

Artemisinin and its analogs are complex 3- and 4-ring structures (Figure 52-2). They are rapidly absorbed, with peak plasma levels occurring promptly. Half-lives after oral administration are 30–60 minutes for artesunate and dihydroartemisinin, and 2–3 hours for artemether. Artemisinin, artesunate, and artemether are rapidly metabolized to the active metabolite dihydroartemisinin. Drug levels appear to decrease after a number of days of therapy.

Antimalarial Action & Resistance

The artemisinins are now widely available, but monotherapy for the treatment of uncomplicated malaria is strongly *discouraged*. Rather, co-formulated artemisinin-based combination therapies are recommended to improve efficacy and prevent the selection of artemisinin-resistant parasites. The oral combination regimen Coartem (artemether-lumefantrine) was approved by the U.S. Food and Drug Administration (FDA) in 2009, and it may be considered the new first-line therapy in the USA for uncomplicated falciparum malaria, although it may not be widely available. Intravenous artesunate is available from the CDC; use is initiated by contacting the CDC, which will release it for appropriate indications (falciparum malaria with signs of severe disease or inability to take oral medications) from stocks stored around the USA.

Artemisinin and its analogs are very rapidly acting blood schizonticides against all human malaria parasites. Artemisinins have no effect on hepatic stages. They are active against young, but not mature gametocytes. The antimalarial activity of artemisinins appears to result from the production of free radicals that follows the iron-catalyzed cleavage of the artemisinin endoperoxide bridge. Artemisinin resistance is not yet a widespread problem, but delayed clearance of *P. falciparum* infections and decreased treatment efficacy in parts of Southeast Asia demonstrate a worrisome focus of resistance.

Clinical Uses

Artemisinin-based combination therapy is now the standard of care for treatment of uncomplicated falciparum malaria in nearly all endemic areas. The leading regimens are highly efficacious, safe, and well tolerated. These regimens were developed because the short plasma half-lives of the artemisinins led to unacceptably high recrudescence rates after short-course therapy, which were reversed by inclusion of longer-acting drugs. Combination therapy also helps to protect against the selection of artemisinin resistance. However, with completion of dosing after 3 days, the artemisinin components are rapidly eliminated, and so selection of resistance to partner drugs is of concern.

The WHO recommends five artemisinin-based combinations for the treatment of uncomplicated falciparum malaria (Table 52-4). One of these, artesunate-sulfadoxine-pyrimethamine is not recommended in many areas owing to unacceptable levels of resistance to sulfadoxine-pyrimethamine, but it is the first-line therapy in some countries. The other recommended regimens are

available as combination formulations, although manufacturing standards may vary. Artesunate-mefloquine is highly effective in Southeast Asia, where resistance to many antimalarials is common; it is the first-line therapy in some countries in Southeast Asia and South America. This regimen is less practical for other areas, particularly Africa, because of its relatively high cost and poor tolerability. Either artesunate-amodiaquine or artemether-lumefantrine is the standard treatment for uncomplicated falciparum malaria in most countries in Africa and some additional endemic countries on other continents. Dihydroartemisinin-piperaquine is a newer regimen that has shown excellent efficacy; it is a first-line therapy for falciparum malaria in parts of Southeast Asia. Artesunate-pyronaridine (Pyramax) was recently approved, and it appears to offer efficacy similar to that of other combinations, but data are limited, especially for young children. Of concern, increased failure rates for artesunate-mefloquine and dihydroartemisinin-piperaquine have been reported recently in parts of Southeast Asia, in the setting of decreased activity of both components of the regimens.

Artemisinins also have outstanding efficacy in the treatment of complicated falciparum malaria. Large randomized trials and meta-analyses have shown that intramuscular artemether has an efficacy equivalent to that of quinine and that intravenous artesunate is superior to intravenous quinine in terms of parasite clearance time and—most important—patient survival. Intravenous artesunate also has a superior side-effect profile when compared with intravenous quinine or quinidine. Thus, intravenous artesunate has replaced quinine as the standard of care for the treatment of severe falciparum malaria. Artesunate and artemether have also been effective in the treatment of severe malaria when administered rectally, offering a valuable treatment modality when parenteral therapy is not available.

Adverse Effects & Cautions

Artemisinins are generally very well tolerated. The most commonly reported adverse effects are nausea, vomiting, diarrhea, and dizziness, and these may often be due to underlying malaria rather than the medications. Rare serious toxicities include neutropenia, anemia, hemolysis, elevated liver enzymes, and allergic reactions. In addition, delayed hemolysis after artemisinins for severe malaria appears to be quite common (estimated in 13% of cases), typically beginning 2–3 weeks after therapy, with 73% of identified cases requiring transfusion. Irreversible neurotoxicity has been seen in animals, but only after doses much higher than those used to treat malaria. Artemisinins have been embryotoxic in animal studies, but rates of congenital abnormalities, stillbirths, and abortions were not elevated in women who received artemisinins during pregnancy, compared with those of controls. Based on this information and the significant risk of malaria during pregnancy, the WHO recommends artemisinin-based combination therapies for the treatment of uncomplicated falciparum malaria during the second and third trimesters of pregnancy (quinine plus clindamycin is recommended during the first trimester), and intravenous artesunate for the treatment of severe malaria during all stages of pregnancy.

QUININE & QUINIDINE

Quinine and quinidine remain important therapies for falciparum malaria—especially severe disease—although toxicity may complicate therapy.

Chemistry & Pharmacokinetics

Quinine is derived from the bark of the cinchona tree, a traditional remedy for intermittent fevers from South America. The alkaloid quinine was purified in 1820 and has been used in the treatment and prevention of malaria since that time. Quinidine, the dextrorotatory stereoisomer of quinine, is at least as effective as parenteral quinine in the treatment of severe falciparum malaria. After oral administration, quinine is rapidly absorbed, reaches peak plasma levels in 1–3 hours, and is widely distributed in body tissues. The use of a loading dose in severe malaria allows the achievement of peak levels within a few hours. Individuals with malaria develop higher plasma levels of quinine than healthy controls, but toxicity is not increased, apparently because of increased protein binding. The half-life of quinine also is longer in those with severe malaria (18 hours) than in healthy controls (11 hours). Quinidine has a shorter half-life than quinine, mostly as a result of decreased protein binding. Quinine is primarily metabolized in the liver and excreted in the urine.

Antimalarial Action & Resistance

Quinine is a rapid-acting, highly effective blood schizonticide against the four species of human malaria parasites. The drug is gametocidal against *P. vivax* and *P. ovale* but not *P. falciparum*. It is not active against liver stage parasites. The mechanism of action of quinine is unknown. Resistance to quinine is common in some areas of Southeast Asia, especially border areas of Thailand, where the drug may fail if used alone to treat falciparum malaria. However, quinine still provides at least a partial therapeutic effect in most patients.

Clinical Uses

1. Parenteral treatment of severe falciparum malaria—For many years quinine dihydrochloride or quinidine gluconate were the treatments of choice for severe falciparum malaria, although intravenous artesunate is now preferred. Quinine can be administered slowly intravenously or, in a dilute solution, intramuscularly, but parenteral preparations are not available in the USA. Quinidine is available (although not always readily accessible) in the USA for the parenteral treatment of severe falciparum malaria. Quinidine can be administered in divided doses or by continuous intravenous infusion; treatment should begin with a loading dose to achieve effective plasma concentrations promptly. Because of its cardiac toxicity (see Chapter 14) and the relative unpredictability of its pharmacokinetics, intravenous quinidine should be administered slowly with cardiac monitoring. Therapy should be changed to an effective oral agent as soon as the patient has improved sufficiently.

2. Oral treatment of falciparum malaria—Quinine sulfate is appropriate therapy for uncomplicated falciparum malaria except

when the infection was transmitted in an area without documented chloroquine resistance. Quinine is commonly used with a second drug (most often doxycycline or, in children, clindamycin) to shorten the duration of use (usually to 3 days) and limit toxicity. Quinine is not generally used to treat nonfalciparum malaria.

3. Malarial chemoprophylaxis—Quinine is not generally used in chemoprophylaxis owing to its toxicity, although a daily dose of 325 mg is effective.

4. Babesiosis—Quinine is first-line therapy, in combination with clindamycin, in the treatment of infection with *Babesia microti* or other human babesial infections.

Adverse Effects

Therapeutic dosages of quinine and quinidine commonly cause tinnitus, headache, nausea, dizziness, flushing, and visual disturbances, a constellation of symptoms termed **cinchonism**. Mild symptoms of cinchonism do not warrant the discontinuation of therapy. More severe findings, often after prolonged therapy, include more marked visual and auditory abnormalities, vomiting, diarrhea, and abdominal pain. Hypersensitivity reactions include skin rashes, urticaria, angioedema, and bronchospasm. Hematologic abnormalities include hemolysis (especially with G6PD deficiency), leukopenia, agranulocytosis, and thrombocytopenia. Therapeutic doses may cause hypoglycemia through stimulation of insulin release; this is a particular problem in severe infections and in pregnant patients, who may have increased sensitivity to insulin. Quinine can stimulate uterine contractions, especially in the third trimester. However, this effect is mild, and quinine and quinidine remain appropriate for treatment of severe falciparum malaria during pregnancy. Intravenous infusions of the drugs may cause thrombophlebitis.

Severe hypotension can follow too-rapid intravenous infusions of quinine or quinidine. Electrocardiographic abnormalities (QT interval prolongation) are fairly common with intravenous quinidine, but dangerous arrhythmias are uncommon when the drug is administered appropriately in a monitored setting.

Blackwater fever is a rare severe illness that includes marked hemolysis and hemoglobinuria in the setting of quinine therapy for malaria. It appears to be due to a hypersensitivity reaction to the drug, although its pathogenesis is uncertain.

Contraindications & Cautions

Quinine (or quinidine) should be discontinued if signs of severe cinchonism, hemolysis, or hypersensitivity occur. It should be avoided if possible in patients with underlying visual or auditory problems. It must be used with great caution in those with underlying cardiac abnormalities. Quinine should not be given concurrently with mefloquine and should be used with caution in a patient with malaria who has recently received mefloquine. Absorption may be blocked by aluminum-containing antacids. Quinine can raise plasma levels of warfarin and digoxin. Dosage must be reduced in renal insufficiency.

MEFLOQUINE

Mefloquine is effective therapy for many chloroquine-resistant strains of *P. falciparum* and against other species. Although toxicity is a concern, mefloquine is one of the recommended chemoprophylactic drugs for use in most malaria-endemic regions with chloroquine-resistant strains.

Chemistry & Pharmacokinetics

Mefloquine hydrochloride is a synthetic 4-quinoline methanol that is chemically related to quinine. It can only be given orally because severe local irritation occurs with parenteral use. It is well absorbed, and peak plasma concentrations are reached in about 18 hours. Mefloquine is highly protein-bound, extensively distributed in tissues, and eliminated slowly, allowing a single-dose treatment regimen. The terminal elimination half-life is about 20 days, allowing weekly dosing for chemoprophylaxis. With weekly dosing, steady-state drug levels are reached over a number of weeks. Mefloquine and its metabolites are slowly excreted, mainly in the feces.

Antimalarial Action & Resistance

Mefloquine has strong blood schizonticidal activity against *P. falciparum* and *P. vivax*, but it is not active against hepatic stages or gametocytes. The mechanism of action is unknown. Sporadic resistance to mefloquine has been reported from many areas, but resistance appears to be uncommon except in regions of Southeast Asia with high rates of multidrug resistance (especially border areas of Thailand). Mefloquine resistance does not appear to be associated with resistance to chloroquine.

Clinical Uses

1. Chemoprophylaxis—Mefloquine is effective in prophylaxis against most strains of *P. falciparum* and probably all other human malarial species. Mefloquine is therefore among the drugs recommended by the CDC for chemoprophylaxis in all malarious areas except those with no chloroquine resistance (where chloroquine is preferred) and some rural areas of Southeast Asia with a high prevalence of mefloquine resistance. As with chloroquine, eradication of *P. vivax* and *P. ovale* requires a course of primaquine.

2. Treatment—Mefloquine is effective in treating uncomplicated falciparum malaria. The drug is not appropriate for treating individuals with severe or complicated malaria, since quinine, quinidine, and artemisinins are more rapidly active, and since drug resistance is less likely with those agents. The combination of artesunate plus mefloquine showed excellent antimalarial efficacy in regions of Southeast Asia with some resistance to mefloquine, and this regimen is now one of the combination therapies recommended by the WHO for the treatment of uncomplicated falciparum malaria (Table 52–4). Artesunate-mefloquine is the first-line therapy for uncomplicated falciparum malaria in a number of countries in Asia and South America.

Adverse Effects

Weekly dosing with mefloquine for chemoprophylaxis may cause nausea, vomiting, dizziness, sleep and behavioral disturbances, epigastric pain, diarrhea, abdominal pain, headache, rash, and dizziness. Neuropsychiatric toxicities have received a good deal of publicity, but despite frequent anecdotal reports of seizures and psychosis, a number of controlled studies have found the frequency of serious adverse effects from mefloquine to be similar to that with other common antimalarial chemoprophylactic regimens. However, concern about reported long-term effects of short-term use of mefloquine led in 2013 to the FDA adding a black box warning regarding potential neurologic and psychiatric toxicities. Leukocytosis, thrombocytopenia, and aminotransferase elevations have also been reported.

Adverse effects are more common with the higher dosages of mefloquine required for treatment. These effects may be lessened by administering the drug in two doses separated by 6–8 hours. The incidence of neuropsychiatric symptoms appears to be about ten times greater than with chemoprophylactic dosing, with widely varying frequencies of up to about 50% reported. Serious neuropsychiatric toxicities (depression, confusion, acute psychosis, or seizures) have been reported in less than 1 in 1000 treatments, but some authorities believe that these toxicities are actually more common. Mefloquine can also alter cardiac conduction, and arrhythmias and bradycardia have been reported.

Contraindications & Cautions

Mefloquine is contraindicated in a patient with a history of epilepsy, psychiatric disorders, arrhythmia, cardiac conduction defects, or sensitivity to related drugs. It should not be co-administered with quinine, quinidine, or halofantrine, and caution is required if quinine or quinidine is used to treat malaria after mefloquine chemoprophylaxis. The CDC no longer advises against mefloquine use in patients receiving β -adrenoceptor antagonists. Mefloquine is also now considered safe in young children, and it is the only chemoprophylactic other than chloroquine approved for children weighing less than 5 kg and for pregnant women. Available data suggest that mefloquine is safe throughout pregnancy, although experience in the first trimester is limited. An older recommendation to avoid mefloquine use in those requiring fine motor skills (eg, airline pilots) is controversial. Mefloquine chemoprophylaxis should be discontinued if significant neuropsychiatric symptoms develop.

PRIMAQUINE

Primaquine is the drug of choice for the eradication of dormant liver forms of *P vivax* and *P ovale* and can also be used for chemoprophylaxis against all malarial species.

Chemistry & Pharmacokinetics

Primaquine phosphate is a synthetic 8-aminoquinoline (Figure 52–2). The drug is well absorbed orally, reaching peak plasma levels in 1–2 hours. The plasma half-life is 3–8 hours. Primaquine is widely distributed to the tissues, but only a small amount is bound there. It is rapidly metabolized and excreted in the urine.

Antimalarial Action & Resistance

Primaquine is active against hepatic stages of all human malaria parasites. It is the only available agent active against the dormant hypnozoite stages of *P vivax* and *P ovale*. The drug is also gametocidal against the four human malaria species and it has weak activity against erythrocytic stage parasites. The mechanism of antimalarial action is unknown.

Some strains of *P vivax* in New Guinea, Southeast Asia, Central and South America, and other areas are relatively resistant to primaquine. Liver forms of these strains may not be eradicated by a single standard treatment and may require repeated therapy.

Clinical Uses

1. Therapy (radical cure) of acute vivax and ovale malaria—Standard therapy for these infections includes chloroquine to eradicate erythrocytic forms and primaquine to eradicate liver hypnozoites and prevent a subsequent relapse. Chloroquine is given acutely, and therapy with primaquine is withheld until the G6PD status of the patient is known. If the G6PD level is normal, a 14-day course of primaquine is given. Prompt evaluation of the G6PD level is helpful, since primaquine appears to be most effective when instituted before completion of dosing with chloroquine.

2. Terminal prophylaxis of vivax and ovale malaria—Standard chemoprophylaxis does not prevent a relapse of vivax or ovale malaria, because the hypnozoite forms of these parasites are not eradicated by available blood schizonticides. To diminish the likelihood of relapse, some authorities advocate the use of primaquine after the completion of travel to an endemic area.

3. Chemoprophylaxis of malaria—Daily treatment with 30 mg (0.5 mg/kg) of primaquine base provided good protection against falciparum and vivax malaria, and the drug is now listed as an alternative chemoprophylactic regimen by the CDC.

4. Gametocidal action—Primaquine renders *P falciparum* gametocytes noninfective to mosquitoes. Including primaquine with treatment for falciparum malaria is used in some areas to decrease transmission, and routine inclusion of single low doses of primaquine (which may be safe without testing for G6PD deficiency) is under study.

5. Pneumocystis jiroveci infection—The combination of clindamycin and primaquine is an alternative regimen in the treatment of pneumocystosis, particularly mild to moderate disease. This regimen offers improved tolerance compared with high-dose trimethoprim-sulfamethoxazole or pentamidine, although its efficacy against severe pneumocystis pneumonia is not well studied.

Adverse Effects

Primaquine in recommended doses is generally well tolerated. It infrequently causes nausea, epigastric pain, abdominal cramps, and headache, and these symptoms are more common with higher dosages and when the drug is taken on an empty stomach. More serious but rare adverse effects are leukopenia, agranulocytosis,

leukocytosis, and cardiac arrhythmias. Standard doses of primaquine may cause hemolysis or methemoglobinemia (manifested by cyanosis), especially in persons with G6PD deficiency or other hereditary metabolic defects.

Contraindications & Cautions

Primaquine should be avoided in patients with a history of granulocytopenia or methemoglobinemia, in those receiving potentially myelosuppressive drugs (eg, quinidine), and in those with disorders that commonly include myelosuppression.

Patients should be tested for G6PD deficiency before primaquine is prescribed. When a patient is deficient in G6PD, treatment strategies may include withholding therapy and treating subsequent relapses, if they occur, with chloroquine; treating patients with standard dosing, paying close attention to their hematologic status; or treating with weekly primaquine (45 mg base) for 8 weeks. G6PD-deficient individuals of Mediterranean and Asian ancestry are most likely to have severe deficiency, whereas those of African ancestry usually have a milder biochemical defect. This difference can be taken into consideration in choosing a treatment strategy. In any event, primaquine should be discontinued if there is evidence of hemolysis or anemia. Primaquine should be avoided in pregnancy because the fetus is relatively G6PD-deficient and thus at risk of hemolysis.

ATOVAQUONE

Atovaquone, a hydroxynaphthoquinone (Figure 52–2), is a component of **Malarone**, which is recommended for the treatment and prevention of malaria. Atovaquone has also been approved by the FDA for the treatment of mild to moderate *P. jiroveci* pneumonia.

The drug is only administered orally. Its bioavailability is low and erratic, but absorption is increased by fatty food. The drug is heavily protein-bound, has a half-life of 2–3 days, and is mostly eliminated unchanged in the feces. Atovaquone acts against plasmodia by disrupting mitochondrial electron transport. It is active against tissue and erythrocytic schizonts, allowing chemoprophylaxis to be discontinued only 1 week after the end of exposure (compared with 4 weeks for mefloquine or doxycycline, which lack activity against tissue schizonts).

Initial use of atovaquone to treat malaria led to disappointing results, with frequent failures due to the selection of resistant parasites during therapy. In contrast, Malarone, a fixed combination of atovaquone (250 mg) and proguanil (100 mg), is highly effective for both the treatment and chemoprophylaxis of falciparum malaria, and it is now approved for both indications in the USA. For chemoprophylaxis, Malarone must be taken daily (Table 52–2). It has an advantage over mefloquine and doxycycline in requiring shorter periods of treatment before and after the period at risk for malaria transmission, but it is more expensive than the other agents. It should be taken with food.

Atovaquone is an alternative therapy for *P. jiroveci* infection, although its efficacy is lower than that of

trimethoprim-sulfamethoxazole. Standard dosing is 750 mg taken with food twice daily for 21 days. Atovaquone has also been effective in small numbers of immunocompromised patients with toxoplasmosis unresponsive to other agents.

Malarone is generally well tolerated. Adverse effects include abdominal pain, nausea, vomiting, diarrhea, headache, insomnia, and rash, and these are more common with the higher dosage required for treatment. Reversible elevations in liver enzymes have been reported. The safety of atovaquone in pregnancy is unknown, and its use is not advised in pregnant women. It is considered safe for use in children with body weight above 5 kg. Plasma concentrations of atovaquone are decreased about 50% by co-administration of tetracycline or rifampin.

INHIBITORS OF FOLATE SYNTHESIS

Inhibitors of enzymes involved in folate metabolism are used, generally in combination regimens, in the treatment and prevention of malaria.

Chemistry & Pharmacokinetics

Pyrimethamine is a 2,4-diaminopyrimidine related to trimethoprim (see Chapter 46). **Proguanil** is a biguanide derivative (Figure 52–2). Both drugs are slowly but adequately absorbed from the gastrointestinal tract. Pyrimethamine reaches peak plasma levels 2–6 hours after an oral dose, is bound to plasma proteins, and has an elimination half-life of about 3.5 days. Proguanil reaches peak plasma levels about 5 hours after an oral dose and has an elimination half-life of about 16 hours. Therefore, proguanil must be administered daily for chemoprophylaxis, whereas pyrimethamine can be given once a week. Pyrimethamine is extensively metabolized before excretion. Proguanil is a prodrug; its triazine metabolite, cycloguanil, is active. **Fansidar**, a fixed combination of the sulfonamide **sulfadoxine** (500 mg per tablet) and **pyrimethamine** (25 mg per tablet), is well absorbed. Its components display peak plasma levels within 2–8 hours and are excreted mainly by the kidneys. The average half-life of sulfadoxine is about 170 hours.

Antimalarial Action & Resistance

Pyrimethamine and proguanil act slowly against erythrocytic forms of susceptible strains of all four human malaria species. Proguanil also has activity against hepatic forms. Neither drug is adequately gametocidal or effective against hypnozoites of *P. vivax* or *P. ovale*. Sulfonamides and sulfones are weakly active against erythrocytic schizonts but not against liver stages or gametocytes.

Pyrimethamine and proguanil inhibit plasmodial dihydrofolate reductase, a key enzyme in the pathway for synthesis of folate. Sulfonamides and sulfones inhibit another enzyme in the folate pathway, dihydropteroate synthase. As described in Chapter 46, inhibitors of these two enzymes provide synergistic activity when used together (see Figure 46–2).

Resistance of *P falciparum* to folate antagonists and sulfonamides is common in many areas. Resistance is due primarily to mutations in dihydrofolate reductase and dihydropteroate synthase, with increasing numbers of mutations leading to increasing levels of resistance. Resistance seriously limits the efficacy of sulfadoxine-pyrimethamine for the treatment of malaria in most areas, but in Africa most parasites exhibit an intermediate level of resistance, such that antifolates may continue to offer some preventive efficacy.

Clinical Uses

1. Chemoprophylaxis—Chemoprophylaxis with single folate antagonists is no longer recommended because of frequent resistance and toxicity. However, the antifolate combination trimethoprim-sulfamethoxazole is commonly used as a daily prophylactic therapy for HIV-infected patients in developing countries, and this regimen offers partial preventive efficacy against malaria in Africa.

2. Intermittent preventive therapy—A new strategy for malaria control is intermittent preventive therapy, in which high-risk patients receive intermittent treatment for malaria, regardless of their infection status. This practice is most accepted in pregnancy, with the use of two or more doses of sulfadoxine-pyrimethamine after the first trimester now standard policy in Africa, although efficacy is limited. In children intermittent preventive therapy has not been widely accepted, but the WHO now recommends seasonal malaria chemoprevention with amodiaquine plus sulfadoxine-pyrimethamine in the Sahel sub-region of Africa, where malaria is highly seasonal and resistance to antifolates is relatively uncommon. In most other areas drug resistance seriously limits the preventive efficacy of antifolates.

3. Treatment of chloroquine-resistant falciparum malaria—Fansidar is no longer a recommended therapy for malaria, and in particular it should not be used for severe malaria, since it is slower-acting than other available agents. Fansidar is also not reliably effective in vivax malaria, and its usefulness against *P ovale* and *P malariae* has not been adequately studied. Artesunate plus sulfadoxine-pyrimethamine is listed by the WHO to treat falciparum malaria (Table 52–4), but other artemisinin-based combinations are generally preferred.

4. Toxoplasmosis—Pyrimethamine, in combination with sulfadiazine, is first-line therapy in the treatment of toxoplasmosis, including acute infection, congenital infection, and disease in immunocompromised patients. For immunocompromised patients, high-dose therapy is required followed by chronic suppressive therapy. Folinic acid is included to limit myelosuppression. The replacement of sulfadiazine with clindamycin provides an effective alternative regimen. Recent problems with pricing and availability of pyrimethamine in the USA made the use of this drug more difficult.

5. Pneumocystosis—*P jiroveci* is the cause of human pneumocystosis and is now recognized to be a fungus, but this organism

is discussed in this chapter because it responds to antiprotozoal drugs, not antifungals. First-line therapy of pneumocystosis is trimethoprim plus sulfamethoxazole (see also Chapter 46). Standard treatment includes high-dose intravenous or oral therapy (15 mg/kg trimethoprim and 75 mg/kg sulfamethoxazole per day in three or four divided doses) for 21 days. High-dose therapy entails significant toxicity, especially in patients with AIDS. Important toxicities include nausea, vomiting, fever, rash, leukopenia, hyponatremia, elevated hepatic enzymes, azotemia, anemia, and thrombocytopenia. Less common effects include severe skin reactions, mental status changes, pancreatitis, and hypocalcemia. Trimethoprim-sulfamethoxazole is also the standard chemoprophylactic drug for the prevention of *P jiroveci* infection in immunocompromised individuals. Dosing is one double-strength tablet daily or three times per week. The chemoprophylactic dosing schedule is much better tolerated than high-dose therapy, but rash, fever, leukopenia, or hepatitis may necessitate changing to another drug.

Adverse Effects & Cautions

Most patients tolerate pyrimethamine and proguanil well. Gastrointestinal symptoms, skin rashes, and itching are rare. Mouth ulcers and alopecia have been described with proguanil. Fansidar uncommonly causes severe cutaneous reactions, including erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Severe reactions appear to be much less common with single-dose or intermittent therapy, compared to regular chemoprophylaxis, and use of the drug has been justified by the risks associated with falciparum malaria.

Rare adverse effects with Fansidar are those associated with other sulfonamides, including hematologic, gastrointestinal, central nervous system, dermatologic, and renal toxicity. Folate antagonists should be used cautiously in the presence of renal or hepatic dysfunction. Although pyrimethamine is teratogenic in animals, Fansidar has been safely used in pregnancy. Proguanil is considered safe in pregnancy. In pregnant women receiving Fansidar preventive therapy, high-dose folate supplementation (eg, 5 mg daily) should be replaced by the standard recommended dosage (0.4–0.6 mg daily) to avoid potential loss of protective efficacy.

ANTIBIOTICS

A number of antibiotics are modestly active antimalarials. Bacterial protein synthesis inhibitors appear to act against malaria parasites by inhibiting protein synthesis in a plasmodial prokaryote-like organelle, the apicoplast. None of the antibiotics should be used as single agents in the treatment of malaria because their action is much slower than that of standard antimalarials.

Tetracycline and doxycycline (see Chapter 44) are active against erythrocytic schizonts of all human malaria parasites. They are not active against liver stages. Doxycycline is used in the treatment of falciparum malaria in conjunction with quinine, allowing a shorter and better-tolerated course of that drug. Doxycycline is also used to complete treatment courses after initial treatment of severe malaria with intravenous quinine, quinidine,

or artesunate. In all of these cases a 1-week treatment course of doxycycline is carried out. Doxycycline has also become a standard chemoprophylactic drug, especially for use in areas of Southeast Asia with high rates of resistance to other antimalarials, including mefloquine. Doxycycline adverse effects include gastrointestinal symptoms, esophagitis, candidal vaginitis, and photosensitivity. Clindamycin (see Chapter 44) is slowly active against erythrocytic schizonts and can be used after treatment courses of quinine, quinidine, or artesunate in those for whom doxycycline is not recommended, such as children and pregnant women. Antimalarial activity of azithromycin and fluoroquinolones has also been demonstrated, but efficacy for the therapy or chemoprophylaxis of malaria has been suboptimal.

Antibiotics are also active against other protozoans. Tetracycline and erythromycin are alternative therapies for the treatment of intestinal amebiasis. Clindamycin, in combination with other agents, is effective therapy for toxoplasmosis, pneumocystosis, and babesiosis. Spiramycin is a macrolide antibiotic that is used to treat primary toxoplasmosis acquired during pregnancy. Treatment lowers the risk of the development of congenital toxoplasmosis.

HALOFANTRINE, LUMEFANTRINE, & PYRONARIDINE

Halofantrine hydrochloride, a phenanthrene-methanol, is effective against erythrocytic (but not other) stages of all four human malaria species. Oral absorption is variable and enhanced by food. Because of toxicity concerns, it should not be taken with meals. The half-life is about 4 days and excretion is mainly in the feces. Halofantrine is not available in the USA (although it has been approved by the FDA), but it is available in malaria-endemic countries.

Halofantrine (three 500 mg doses at 6-hour intervals, repeated in 1 week for nonimmune individuals) is rapidly effective against *P. falciparum*, but its use is limited by cardiac toxicity. It is generally well tolerated. The most common adverse effects are abdominal pain, diarrhea, vomiting, cough, rash, headache, pruritus, and elevated liver enzymes. Of greater concern, the drug alters cardiac conduction, with dose-related prolongation of QT and PR intervals. Rare instances of dangerous arrhythmias and deaths have been reported. The drug is contraindicated in patients who have cardiac conduction defects or who have recently taken mefloquine. Halofantrine is embryotoxic in animals and therefore contraindicated in pregnancy.

Lumefantrine, an aryl alcohol, is available only as a fixed-dose combination with artemether (Coartem, Riamet), which is now the first-line therapy for uncomplicated falciparum malaria in many countries. In addition, Coartem is approved in many nonendemic countries, including the USA. The half-life of lumefantrine, when used in combination, is 3–4 days. Drug levels may be altered by interactions with other drugs, including those that affect CYP3A4 metabolism. Oral absorption is variable and improved when the drug is taken with food. Since lumefantrine is not associated with the toxicity concerns of halofantrine, Coartem should be administered with fatty food to maximize antimalarial efficacy. Coartem is highly effective in the treatment of falciparum malaria when administered twice daily for 3 days. Coartem can

cause minor prolongation of the QT interval, but this appears to be clinically insignificant, and the drug does not carry the risk of dangerous arrhythmias seen with halofantrine and quinidine. Coartem is very well tolerated. The most commonly reported adverse events have been gastrointestinal disturbances, headache, dizziness, rash, and pruritus, and in many cases these toxicities may have been due to underlying malaria or concomitant medications rather than to Coartem.

Pyronaridine, a Mannich base acridine, has been studied as an antimalarial for many years and used as monotherapy in China. It is now available in combination with artesunate as Pyramax. Pyronaridine is well absorbed orally without important food effects. It has a half life of about 8 days, with primarily renal elimination. Artesunate-pyronaridine has generally demonstrated excellent efficacy against falciparum and vivax malaria, although a recent report showed lower efficacy in Cambodia. It has generally been well tolerated. Adverse events have included eosinophilia and transaminitis. A general recommendation for use of artesunate-pyronaridine to treat malaria awaits further evaluation of efficacy in children and of potential hepatic toxicity.

■ AMEBIASIS

Amebiasis is infection with *Entamoeba histolytica*. This organism can cause asymptomatic intestinal infection, mild to moderate colitis, severe intestinal infection (dysentery), ameboma, liver abscess, and other extraintestinal infections. The choice of drugs for amebiasis depends on the clinical presentation (Table 52–5).

Treatment of Specific Forms of Amebiasis

1. Asymptomatic intestinal infection—Asymptomatic carriers generally are not treated in endemic areas, but in nonendemic areas they are treated with a luminal amebicide. A tissue amebicidal drug is unnecessary. Standard luminal amebicides are diloxanide furoate, iodoquinol, and paromomycin. Each drug eradicates carriage in about 80–90% of patients. Therapy with a luminal amebicide is also required in the treatment of all other forms of amebiasis.

2. Amebic Colitis—Metronidazole plus a luminal amebicide is the treatment of choice for amebic colitis and dysentery. Tetracyclines and erythromycin are alternative drugs for moderate colitis but are not effective against extraintestinal disease. Dehydroemetine or emetine can also be used, but are best avoided because of toxicity.

3. Extraintestinal Infections—The treatment of choice for extraintestinal infections is metronidazole plus a luminal amebicide. A 10-day course of metronidazole cures over 95% of uncomplicated liver abscesses. For unusual cases in which initial therapy with metronidazole has failed, aspiration of the abscess and the addition of chloroquine to a repeat course of metronidazole should be considered. Dehydroemetine and emetine are toxic alternative drugs.

TABLE 52–5 Treatment of amebiasis. Not all preparations are available in the USA.¹

Clinical Setting	Drugs of Choice and Adult Dosage	Alternative Drugs and Adult Dosage
Asymptomatic intestinal infection	Luminal agent: Diloxanide furoate, ² 500 mg 3 times daily for 10 days <i>or</i> Iodoquinol, 650 mg 3 times daily for 21 days <i>or</i> Paromomycin, 10 mg/kg 3 times daily for 7 days	
Mild to moderate intestinal infection	Metronidazole, 750 mg 3 times daily (or 500 mg IV every 6 hours) for 10 days <i>or</i> Tinidazole, 2 g daily for 3 days <i>plus</i> Luminal agent (see above)	Luminal agent (see above) <i>plus either</i> Tetracycline, 250 mg 3 times daily for 10 days <i>or</i> Erythromycin, 500 mg 4 times daily for 10 days
Severe intestinal infection	Metronidazole, 750 mg 3 times daily (or 500 mg IV every 6 hours) for 10 days <i>or</i> Tinidazole, 2 g daily for 3 days <i>plus</i> Luminal agent (see above)	Luminal agent (see above) <i>plus either</i> Tetracycline, 250 mg 3 times daily for 10 days <i>or</i> Dehydroemetine ² or emetine, ² 1 mg/kg SC or IM for 3–5 days
Hepatic abscess, ameboma, and other extraintestinal disease	Metronidazole, 750 mg 3 times daily (or 500 mg IV every 6 hours) for 10 days <i>or</i> Tinidazole, 2 g daily for 5 days <i>plus</i> Luminal agent (see above)	Dehydroemetine ² or emetine, ² 1 mg/kg SC or IM for 8–10 days, followed by (liver abscess only) chloroquine, 500 mg twice daily for 2 days, then 500 mg daily for 21 days <i>plus</i> Luminal agent (see above)

¹Route is oral unless otherwise indicated. See text for additional details and cautions.²Not available in the USA.

METRONIDAZOLE & TINIDAZOLE

Metronidazole, a nitroimidazole (Figure 52–3), is the drug of choice in the treatment of extraluminal amebiasis. It kills trophozoites but not cysts of *E histolytica* and effectively eradicates intestinal and extraintestinal tissue infections. Tinidazole, a related nitroimidazole, appears to have similar activity and a better toxicity profile. It offers simpler dosing regimens and can be substituted for the indications listed below.

Pharmacokinetics & Mechanism of Action

Oral metronidazole and tinidazole are readily absorbed and permeate all tissues by simple diffusion. Intracellular concentrations rapidly approach extracellular levels. Peak plasma concentrations are reached in 1–3 hours. Protein binding of both drugs is low (10–20%); the half-life of unchanged drug is 7.5 hours for metronidazole and 12–14 hours for tinidazole. Metronidazole and its metabolites are excreted mainly in the urine. Plasma clearance of metronidazole is decreased in patients with impaired liver function. The nitro group of metronidazole is chemically reduced in anaerobic bacteria and sensitive protozoans. Reactive reduction products appear to be responsible for antiprotozoal and antibacterial activity. The mechanism of tinidazole is assumed to be the same.

Clinical Uses

1. Amebiasis—Metronidazole or tinidazole is the drug of choice in the treatment of all tissue infections with *E histolytica*. Neither drug is reliably effective against luminal parasites and so must be used with a luminal amebicide to ensure eradication of the infection.

2. Giardiasis—Metronidazole is the treatment of choice for giardiasis. The dosage for giardiasis is much lower than that for amebiasis, and the drug is thus better tolerated. Efficacy after a single treatment is about 90%. Tinidazole is at least equally effective, and can be used as a single dose.

3. Trichomoniasis—Metronidazole is the treatment of choice. A single dose of 2 g is effective. Metronidazole-resistant organisms can lead to treatment failures. Tinidazole may be effective against some of these resistant organisms.

Adverse Effects & Cautions

Nausea, headache, dry mouth, and a metallic taste in the mouth occur commonly. Infrequent adverse effects include vomiting, diarrhea, insomnia, weakness, dizziness, thrush, rash, dysuria, dark urine, vertigo, paresthesias, encephalopathy, and neutropenia. Taking the drug with meals lessens gastrointestinal irritation.

FIGURE 52-3 Structural formulas of other antiprotozoal drugs.

Pancreatitis and severe central nervous system toxicity (ataxia, encephalopathy, seizures) are rare. Metronidazole has a disulfiram-like effect, so that nausea and vomiting can occur if alcohol is ingested during therapy. The drug should be used with caution in patients with central nervous system disease. Intravenous infusions have rarely caused seizures or peripheral neuropathy. The dosage should be adjusted for patients with severe liver or renal disease. Tinidazole has a similar adverse-effect profile, although it appears to be somewhat better tolerated than metronidazole.

Metronidazole has been reported to potentiate the anticoagulant effect of coumarin-type anticoagulants. Phenytoin and phenobarbital may accelerate elimination of the drug, whereas cimetidine may decrease plasma clearance. Lithium toxicity may occur when the drug is used with metronidazole. Metronidazole and its metabolites are mutagenic in bacteria and tumorigenic in mice. Data on teratogenicity are inconsistent. Metronidazole is thus best avoided in pregnant or nursing women, although congenital abnormalities have not clearly been associated with use in humans.

IDOQUINOL

Iodoquinol (diiodohydroxyquin), a halogenated hydroxyquinoline, is an effective luminal amebicide. Pharmacokinetic data are incomplete but 90% of the drug is retained in the intestine and

excreted in the feces. The remainder enters the circulation, has a half-life of 11–14 hours, and is excreted in the urine as glucuronides. Iodoquinol is effective against organisms in the bowel lumen but not against trophozoites.

Infrequent adverse effects include diarrhea—which usually stops after several days—anorexia, nausea, vomiting, abdominal pain, headache, rash, and pruritus. Some halogenated hydroxyquinolines can produce severe neurotoxicity with prolonged use. Iodoquinol is not known to produce these effects at its recommended dosage, and this dosage (Table 52-5) should never be exceeded. Iodoquinol should be taken with meals to limit gastrointestinal toxicity. It should be used with caution in patients with optic neuropathy, renal or thyroid disease, or nonamebic hepatic disease. The drug should be discontinued if it produces persistent diarrhea or signs of iodine toxicity (dermatitis, urticaria, pruritus, fever). It is contraindicated in patients with intolerance to iodine.

DILOXANIDE FUROATE

Diloxanide furoate is a dichloroacetamide derivative. It is an effective luminal amebicide but is not active against trophozoites. In the gut, diloxanide furoate is split into diloxanide and furoic acid; about 90% of the diloxanide is rapidly

absorbed and then conjugated to form the glucuronide, which is promptly excreted in the urine. The unabsorbed diloxanide is the active antiamebic substance. Diloxanide furoate is not available commercially in the USA but can be obtained from some compounding pharmacies. It does not produce serious adverse effects. Flatulence is common, but nausea and abdominal cramps are infrequent and rashes are rare. The drug is not recommended in pregnancy.

PAROMOMYCIN SULFATE

Paromomycin sulfate is an aminoglycoside antibiotic (see also Chapter 45) that is not significantly absorbed from the gastrointestinal tract. It is used as a luminal amebicide and has no effect against extraintestinal organisms. The small amount absorbed is slowly excreted unchanged, mainly by glomerular filtration. However, the drug may accumulate with renal insufficiency and contribute to renal toxicity. Paromomycin appears to have similar efficacy and less toxicity than other luminal agents; in one study it was superior to diloxanide furoate in clearing asymptomatic infections. As it is readily available, paromomycin can be considered the antiamebic luminal agent of choice in the USA. Adverse effects include occasional abdominal distress and diarrhea. Parenteral paromomycin is now used to treat visceral leishmaniasis and is discussed separately in the text that follows.

EMETINE & DEHYDROEMETINE

Emetine, an alkaloid derived from ipecac, and dehydroemetine, a synthetic analog, are effective against tissue trophozoites of *E. histolytica*, but because of major toxicity concerns their use is limited to unusual circumstances in which severe amebiasis requires effective therapy and metronidazole cannot be used. Dehydroemetine is preferred because of its somewhat better toxicity profile. The drugs should be used for the minimum period needed to relieve severe symptoms (usually 3–5 days) and administered subcutaneously (preferred) or intramuscularly in a supervised setting. Adverse effects, which are generally mild with use for 3–5 days but increase over time, include pain, tenderness, and sterile abscesses at the injection site; diarrhea, nausea, and vomiting; muscle weakness and discomfort; and minor electrocardiographic changes. Serious toxicities include cardiac arrhythmias, heart failure, and hypotension.

OTHER ANTIPROTOZOAL DRUGS

The primary drugs used to treat African trypanosomiasis are listed in Table 52–6, and those for other protozoal infections are listed in Table 52–7. Important antiprotozoal drugs that are not covered elsewhere are discussed below.

PENTAMIDINE

Pentamidine has activity against trypanosomatid protozoans and against *P. jiroveci*, but toxicity is significant.

Chemistry & Pharmacokinetics

Pentamidine is an aromatic diamidine (Figure 52–3) formulated as an isethionate salt. The drug is only administered parenterally. It leaves the circulation rapidly, with an initial half-life of about 6 hours, but is bound avidly by tissues. Pentamidine thus accumulates and is eliminated very slowly, with a terminal elimination half-life of about 12 days. Only trace amounts of pentamidine appear in the central nervous system, so it is not effective against CNS African trypanosomiasis. Pentamidine can also be inhaled as a nebulized powder for the prevention of pneumocystosis. Absorption into the systemic circulation after inhalation appears to be minimal. The mechanism of action of pentamidine is unknown.

Clinical Uses

1. Pneumocystosis—Pentamidine is a well-established alternative therapy for pulmonary and extrapulmonary disease caused by *P. jiroveci*. The drug has somewhat lower efficacy and greater toxicity than trimethoprim-sulfamethoxazole. The standard dosage is 3 mg/kg/d intravenously for 21 days. Significant adverse reactions are common, and with multiple regimens now available to treat *P. jiroveci* infection, pentamidine is best reserved for patients with severe disease who cannot tolerate or fail other drugs.

Pentamidine is also an alternative agent for primary or secondary prophylaxis against pneumocystosis in immunocompromised individuals, including patients with advanced AIDS. For this indication, pentamidine is administered as an inhaled aerosol (300 mg inhaled monthly). The drug is well tolerated in this form. Its efficacy is good but less than that of daily trimethoprim-sulfamethoxazole.

TABLE 52–6 Treatment of African trypanosomiasis.

Disease	Stage	First-Line Drugs	Alternative Drugs
West African	Early	Pentamidine	Suramin, eflornithine
	CNS involvement	Eflornithine	Melarsoprol, ¹ eflornithine-nifurtimox ¹
East African	Early	Suramin ¹	Pentamidine
	CNS involvement	Melarsoprol ¹

TABLE 52-7 Treatment of other protozoal infections. Not all preparations are available in the USA.¹

Organism or Clinical Setting	Drugs of Choice ²	Alternative Drugs
<i>Babesia species</i>	Clindamycin, 600 mg 3 times daily for 7 days <i>plus</i> Quinine, 650 mg for 7 days	Atovaquone or azithromycin
<i>Balantidium coli</i>	Tetracycline, 500 mg 4 times daily for 10 days	Metronidazole, 750 mg 3 times daily for 5 days
<i>Cryptosporidium species</i>	Paromomycin, 500–750 mg 3 or 4 times daily for 10 days	Azithromycin, 500 mg daily for 21 days
<i>Cyclospora cayetanensis</i>	Trimethoprim-sulfamethoxazole, one double-strength tablet 4 times daily for 7–14 days	
<i>Dientamoeba fragilis</i>	Iodoquinol, 650 mg 3 times daily for 20 days	Tetracycline, 500 mg 4 times daily for 10 days <i>or</i> Paromomycin, 500 mg 3 times daily for 7 days
<i>Giardia lamblia</i>	Metronidazole, 250 mg 3 times daily or 500 mg twice daily for 5 days <i>or</i> Tinidazole, 2 g once	Furazolidone, 100 mg 4 times daily for 7 days <i>or</i> Albendazole, 400 mg daily for 5 days
<i>Isospora belli</i>	Trimethoprim-sulfamethoxazole, one double-strength tablet 4 times daily for 10 days, then twice daily for 21 days	Pyrimethamine, 75 mg daily for 14 days <i>plus</i> Folinic acid, 10 mg daily for 14 days
<i>Microsporidia</i>	Albendazole, 400 mg twice daily for 20–30 days	
<i>Leishmaniasis</i> ³		
Visceral (<i>L. donovani</i> , <i>L. chagasi</i> , <i>L. infantum</i>) or mucosal (<i>L. braziliensis</i>)	Sodium stibogluconate, 20 mg/kg/d IV or IM for 28 days <i>or</i> Amphotericin (liposomal preparations preferred (3 mg/kg/d IV on days 1–5, 14, and 21)); various other dosing regimens, including single dose <i>or</i> Miltefosine, 2.5 mg/kg/d for 28 days <i>or</i> Paromomycin, 15 mg/kg for 21 days	Meglumine antimoniate <i>or</i> Pentamidine, 2–4 mg/kg IM daily or every other day for up to 15 doses <i>or</i> Combinations of listed drugs
Cutaneous (<i>L. major</i> , <i>L. tropica</i> , <i>L. mexicana</i> , <i>L. braziliensis</i>)	Sodium stibogluconate, 20 mg/kg/d IV or IM for 20 days	Meglumine antimoniate <i>or</i> Miltefosine <i>or</i> Topical or intralesional therapies
<i>Pneumocystis jiroveci</i> , <i>P. carinii</i> ⁴	Trimethoprim-sulfamethoxazole, 15–20 mg trimethoprim component/kg/d IV, or two double-strength tablets every 8 hours for 21 days	Pentamidine <i>or</i> Trimethoprim-dapsone <i>or</i> Clindamycin <i>plus</i> primaquine <i>or</i> Atovaquone
<i>Toxoplasma gondii</i>		
Acute, congenital, immunocompromised	Pyrimethamine <i>plus</i> clindamycin <i>plus</i> folinic acid	Pyrimethamine <i>plus</i> sulfadiazine <i>plus</i> folinic acid
Pregnancy	Spiramycin, 3 g daily until delivery

¹Additional information may be obtained from the Parasitic Disease Drug Service, Parasitic Diseases Branch, CDC, Atlanta, Georgia (phone: 404-639-3670; www.cdc.gov/laboratory/drugservice/).

²Established, relatively simple dosing regimens are provided. Route is oral unless otherwise indicated. See text for additional information, toxicities, cautions, and discussions of dosing for the more rarely used drugs, many of which are highly toxic.

³Specific recommendations for leishmaniasis vary geographically. Combination regimens are increasingly used.

⁴*P. jiroveci* (*carinii* in animals) has traditionally been considered a protozoan because of its morphology and drug sensitivity, but molecular analyses have shown it to be most closely related to fungi.

2. African trypanosomiasis (sleeping sickness)—Pentamidine has been used since 1940 and is the drug of choice to treat the early hemolympathic stage of disease caused by *Trypanosoma brucei gambiense* (West African sleeping sickness). The drug is inferior to suramin for the treatment of early East African sleeping sickness. Pentamidine should not be used to treat late trypanosomiasis with central nervous system involvement. A number of dosing regimens have been described, generally providing 2–4 mg/kg daily or on alternate days for a total of 10–15 doses. Pentamidine has also been used for chemoprophylaxis against African trypanosomiasis, with dosing of 4 mg/kg every 3–6 months.

3. Leishmaniasis—Pentamidine is an alternative to sodium stibogluconate and newer agents for the treatment of visceral leishmaniasis. The drug has been successful in some cases that have failed therapy with antimonials. The dosage is 2–4 mg/kg intramuscularly daily or every other day for up to 15 doses, and a second course may be necessary. Pentamidine has also shown success against cutaneous leishmaniasis, but it is not routinely used for this purpose.

Adverse Effects & Cautions

Pentamidine is a highly toxic drug, with adverse effects noted in about 50% of patients receiving 4 mg/kg/d. Rapid intravenous administration can lead to severe hypotension, tachycardia, dizziness, and dyspnea, so the drug should be administered slowly (over 2 hours), and patients should be recumbent and monitored closely during treatment. With intramuscular administration, pain at the injection site is common, and sterile abscesses may develop.

Pancreatic toxicity is common. Hypoglycemia due to inappropriate insulin release often appears 5–7 days after onset of treatment, can persist for days to several weeks, and may be followed by hyperglycemia. Reversible renal insufficiency is also common. Other adverse effects include rash, metallic taste, fever, gastrointestinal symptoms, abnormal liver function tests, acute pancreatitis, hypocalcemia, thrombocytopenia, hallucinations, and cardiac arrhythmias. Inhaled pentamidine is generally well tolerated but may cause cough, dyspnea, and bronchospasm.

SODIUM STIBOGLUCONATE

Pentavalent antimonials, including sodium stibogluconate (pentostam; Figure 52-3) and meglumine antimoniate, are first-line agents for cutaneous and visceral leishmaniasis except in parts of India, where the efficacy of these drugs has diminished greatly. The drugs are rapidly absorbed and distributed after intravenous (preferred) or intramuscular administration and eliminated in two phases, with a short initial (about 2-hour) half-life and a much longer terminal (>24-hour) half-life. Treatment is given at a dosage of 20 mg/kg once daily intravenously or intramuscularly for 20 days in cutaneous leishmaniasis and 28 days in visceral and mucocutaneous disease.

The mechanism of action of the antimonials is unknown. Their efficacy against different species may vary, possibly based on local drug resistance patterns. Cure rates are generally quite good, but resistance to sodium stibogluconate is increasing in some endemic areas, notably in India where other agents (eg, amphotericin or miltefosine) are generally recommended.

Few adverse effects occur initially, but the toxicity of stibogluconate increases over the course of therapy. Most common are gastrointestinal symptoms, fever, headache, myalgias, arthralgias, and rash. Intramuscular injections can be very painful and lead to sterile abscesses. Electrocardiographic changes may occur, most commonly T-wave changes and QT prolongation. These changes are generally reversible, but continued therapy may lead to dangerous arrhythmias. Thus, the electrocardiogram should be monitored during therapy. Hemolytic anemia and serious liver, renal, and cardiac effects are rare.

NITAZOXANIDE

Nitazoxanide is a nitrothiazolyl-salicylamide prodrug. It is approved in the USA for use against *Giardia lamblia* and *Cryptosporidium parvum*. It is rapidly absorbed and converted to tizoxanide and tizoxanide conjugates, which are subsequently excreted in both urine and feces. The active metabolite, tizoxanide, inhibits

the pyruvate-ferredoxin oxidoreductase pathway. Nitazoxanide appears to have activity against metronidazole-resistant protozoal strains and is well tolerated. Unlike metronidazole, nitazoxanide and its metabolites appear to be free of mutagenic effects. Other organisms that may be susceptible to nitazoxanide include *E histolytica*, *Helicobacter pylori*, *Ascaris lumbricoides*, several tape-worms, and *Fasciola hepatica*. The recommended adult dosage is 500 mg twice daily for 3 days.

OTHER DRUGS FOR TRYPANOSOMIASIS & LEISHMANIASIS

Current therapies for all forms of trypanosomiasis are seriously deficient in efficacy, safety, or both. Availability of these therapies is also a concern, since they are supplied mainly through donation or nonprofit production by pharmaceutical companies. For visceral leishmaniasis, liposomal amphotericin, miltefosine, and paromomycin are effective, and combinations of these agents have shown promising results.

Suramin

Suramin is a sulfated naphthylamine that was introduced in the 1920s. It is the first-line therapy for early hemolympathic East African trypanosomiasis (*T brucei rhodesiense* infection), but because it does not enter the central nervous system, it is not effective against advanced disease. Suramin is less effective than pentamidine for early West African trypanosomiasis. The drug's mechanism of action is unknown. It is administered intravenously and displays complex pharmacokinetics with very tight protein binding. Suramin has a short initial half-life but a terminal elimination half-life of about 50 days. The drug is slowly cleared by renal excretion.

Suramin is administered after a 200-mg intravenous test dose. Regimens that have been used include 1 g on days 1, 3, 7, 14, and 21 or 1 g each week for 5 weeks. Combination therapy with pentamidine may improve efficacy. Suramin can also be used for chemoprophylaxis against African trypanosomiasis. Adverse effects are common. Immediate reactions can include fatigue, nausea, vomiting, and, more rarely, seizures, shock, and death. Later reactions include fever, rash, headache, paresthesias, neuropathies, renal abnormalities including proteinuria, chronic diarrhea, hemolytic anemia, and agranulocytosis.

Melarsoprol

Melarsoprol is a trivalent arsenical that has been available since 1949 and is first-line therapy for advanced central nervous system East African trypanosomiasis, and second-line therapy (after eflornithine) for advanced West African trypanosomiasis. After intravenous administration it is excreted rapidly, but clinically relevant concentrations accumulate in the central nervous system within 4 days. Melarsoprol is administered in propylene glycol by slow intravenous infusion at a dosage of 3.6 mg/kg/d for 3–4 days, with repeated courses at weekly intervals, if needed. A new regimen of 2.2 mg/kg daily for 10 days had efficacy and toxicity similar to what was observed with three courses over 26 days. Melarsoprol is

extremely toxic. The use of such a toxic drug is justified only by the severity of advanced trypanosomiasis and the lack of available alternatives. Immediate adverse effects include fever, vomiting, abdominal pain, and arthralgias. The most important toxicity is a reactive encephalopathy that generally appears within the first week of therapy (in 5–10% of patients) and is probably due to disruption of trypanosomes in the central nervous system. Co-administration of corticosteroids may decrease the likelihood of encephalopathy. Common consequences of the encephalopathy include cerebral edema, seizures, coma, and death. Other serious toxicities include renal and cardiac disease and hypersensitivity reactions. Failure rates with melarsoprol appear to have increased recently in parts of Africa, suggesting drug resistance.

Eflornithine

Eflornithine (difluoromethylornithine), an inhibitor of ornithine decarboxylase, is the only new drug registered to treat African trypanosomiasis in the last half-century. It is now the first-line drug for advanced West African trypanosomiasis, but is not effective for East African disease. Eflornithine is administered intravenously, and good central nervous system drug levels are achieved. The elimination half-life is about 3 hours. The usual regimen is 100 mg/kg intravenously every 6 hours for 7–14 days (14 days was superior for a newly diagnosed infection). Eflornithine appears to be as effective as melarsoprol against advanced *T brucei gambiense* infection, but its efficacy against *T brucei rhodesiense* is limited by drug resistance. Combining eflornithine with a 10-day course of nifurtimox afforded efficacy against West African trypanosomiasis similar to a 14-day regimen of eflornithine alone, with simpler and shorter treatment (injections every 12 hours for 7 days). Toxicity from eflornithine is significant, but considerably less than that from melarsoprol. Adverse effects include diarrhea, vomiting, anemia, thrombocytopenia, leukopenia, and seizures. These effects are generally reversible. Increased experience with eflornithine and increased availability of the compound in endemic areas may lead to its replacement of suramin, pentamidine, and melarsoprol in the treatment of *T brucei gambiense* infection.

Benznidazole

Benznidazole is an orally administered nitroimidazole for the treatment of American trypanosomiasis (Chagas disease) that probably has improved efficacy and safety compared to nifurtimox. These drugs can eliminate parasites and prevent progression when used to treat acute infection, but activity against chronic Chagas disease is suboptimal. In a recent randomized trial, treatment of Chagas cardiomyopathy with benznidazole did not offer clinical benefit. Standard dosage is 5 mg/kg/d in two or three divided doses for 60 days, given with meals. Important toxicities, which are generally reversible, include rash (in 20–30% of those treated), peripheral neuropathy, gastrointestinal symptoms, and myelosuppression.

Nifurtimox

Nifurtimox, a nitrofurantoin, is a standard drug for Chagas disease. Nifurtimox is also used in the treatment of African

trypanosomiasis in combination with eflornithine. Nifurtimox is well absorbed after oral administration and eliminated with a plasma half-life of about 3 hours. The drug is administered at a dosage of 8–10 mg/kg/d in three divided doses with meals for 60–90 days. Toxicity related to nifurtimox is common. Adverse effects include nausea, vomiting, abdominal pain, fever, rash, headache, restlessness, insomnia, neuropathies, and seizures. These effects are generally reversible but often lead to cessation of therapy before completion of a standard course.

Amphotericin

This important antifungal drug (see Chapter 48) is an alternative therapy for visceral leishmaniasis, especially in parts of India with high-level resistance to sodium stibogluconate. Liposomal amphotericin has shown excellent efficacy at a dosage of 3 mg/kg/d intravenously on days 1–5, 14, and 21. Other regimens that have shown good efficacy in India include 4 doses of 5 mg/kg over 4–10 days and a single dose of 15 mg/kg. With single-dose therapy, an amphotericin lipid emulsion had similar efficacy to that of the liposomal formulation. Efficacy of amphotericin appears to be lower in Africa. Nonliposomal amphotericin (1 mg/kg intravenously every other day for 30 days) is more toxic, less expensive, also efficacious, and widely used in India. However, in an Indian trial a single infusion of liposomal amphotericin showed noninferior efficacy and decreased cost compared to a standard 30-day course of amphotericin. Amphotericin is also used for cutaneous leishmaniasis in some areas. The use of amphotericin, and especially liposomal preparations, is limited in developing countries by difficulty of administration, cost, and toxicity.

Miltefosine

Miltefosine is an alkylphosphocholine analog that is the first effective oral drug for visceral leishmaniasis. It has recently shown excellent efficacy in the treatment of visceral leishmaniasis in India, where it is administered orally (2.5 mg/kg/d with varied dosing schedules) for 28 days. It was also recently shown to be effective in regimens including a single dose of liposomal amphotericin followed by 7–14 days of miltefosine. A 28-day course of miltefosine (2.5 mg/kg/d) was also effective for the treatment of New World cutaneous leishmaniasis. Vomiting and diarrhea are common but generally short-lived toxicities. Transient elevations in liver enzymes and nephrotoxicity are also seen. The drug should

be avoided in pregnancy (or in women who may become pregnant within 2 months of treatment) because of its teratogenic effects. Miltefosine is registered for the treatment of visceral leishmaniasis in India and some other countries, and—considering the serious limitations of other drugs, including parenteral administration, toxicity, and resistance—it may become the treatment of choice for that disease. Miltefosine may also have a role in the treatment of cutaneous leishmaniasis; the drug was noninferior to meglumine antimoniate for this indication in South American children. Resistance to miltefosine develops readily *in vitro*.

Paromomycin

Paromomycin sulfate is an aminoglycoside antibiotic that until recently was used in parasitology only for oral therapy of intestinal parasitic infections (see previous text). It has recently been developed for the treatment of visceral leishmaniasis. It is much less expensive than amphotericin or miltefosine. A trial in India showed excellent efficacy, with a daily intramuscular dosage of 11 mg/kg for 21 days yielding a 95% cure rate, and noninferiority compared with amphotericin. However, a recent trial showed poorer efficacy in Africa, with the cure rate for paromomycin significantly inferior to that with sodium stibogluconate. In initial studies, paromomycin was well tolerated, with common mild injection pain, uncommon ototoxicity and reversible liver enzyme elevations, and no nephrotoxicity. Paromomycin has also shown good efficacy when topically applied, alone or with gentamicin, for the treatment of cutaneous leishmaniasis.

Drug Combinations Used in the Treatment of Visceral Leishmaniasis

The use of drug combinations to improve treatment efficacy, shorten treatment courses, and reduce the selection of resistant parasites has been an active area of research. In a recent trial in India, compared to a standard 30-day (treatment on alternate days) course of amphotericin, noninferior efficacy and decreased adverse events were seen with a single dose of liposomal amphotericin plus a 7-day course of miltefosine, a single dose of liposomal amphotericin plus a 10-day course of paromomycin, or a 10-day course of miltefosine plus paromomycin. In a trial in East Africa, compared to a standard 30-day course of sodium stibogluconate, similar efficacy was seen with a 17-day course of sodium stibogluconate plus paromomycin.

PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
Artemether/lumefantrine	Coartem, Riamet
Artesunate*	
Artesunate-pyronaridine	Pyramax
Atovaquone	Generic, Mepron
Atovaquone-proguanil	Malarone
Benznidazole*	
Chloroquine	Generic, Aralen
Clindamycin	Generic, Cleocin
Doxycycline	Generic, Vibramycin
Eflornithine	Vaniqa, Ornidyl
Iodoquinol	Diquinol, Yodoxin
Mefloquine	Generic, Lariam
Melarsoprol*	Mel B
Metronidazole	Generic, Flagyl
Nifurtimox*	
Nitazoxanide	Alinia
Paromomycin	Generic, Humatin
Pentamidine	Pentam 300, Pentacarinat, pentamidine isethionate, Nebupent (aerosol)
Primaquine	Generic
Pyrimethamine	Daraprim
Quinidine gluconate	Generic
Quinine	Generic
Sodium stibogluconate*	
Sulfadoxine-pyrimethamine	Fansidar
Suramin*	
Tinidazole	Generic, Tindamax

*Available in the USA only from the Drug Service, CDC, Atlanta, Georgia (phone: 404-639-3670; www.cdc.gov/laboratory/drugservice/).

CASE STUDY ANSWER

This child has acute falciparum malaria, and her lethargy and abnormal laboratory tests are consistent with progression to severe disease. She should be hospitalized and treated urgently with intravenous artesunate or, if this is unavailable, intravenous quinine or quinidine. She should be followed

closely for progression of severe malaria, in particular neurologic, renal, or pulmonary complications, and if treated with quinine or quinidine should have cardiac monitoring for potential toxicities.

53

Clinical Pharmacology of the Anthelmintic Drugs

Philip J. Rosenthal, MD

CASE STUDY

A 29-year-old Peruvian man presents with the incidental finding of a $10 \times 8 \times 8$ -cm liver cyst on an abdominal computed tomography (CT) scan. The patient had noted 2 days of abdominal pain and fever, and his clinical evaluation and CT scan were consistent with appendicitis. His clinical findings resolved after laparoscopic appendectomy. The patient

immigrated to the USA 10 years ago from a rural area of Peru where his family trades in sheepskins. His father and sister have undergone resection of abdominal masses, but details of their diagnoses are unavailable. What is your differential diagnosis? What are your diagnostic and therapeutic plans?

■ CHEMOTHERAPY OF HELMINTHIC INFECTIONS

Helminths (worms) are multicellular organisms that infect very large numbers of humans and cause a broad range of diseases. More than 1 billion people are infected with intestinal nematodes, and many millions are infected with filarial nematodes, flukes, and tapeworms in other organs. Many drugs, directed against a number of different targets, are available to treat helminthic infections. In many cases, especially in the developing world, the goal is control of infection, with elimination of most parasites, alleviating disease symptoms, and decreasing the transmission of infection. In other cases, complete elimination of parasites is the goal of therapy, although this goal can be challenging with certain helminthic infections, because of both limited efficacy of drugs and frequent reinfection after therapy in endemic areas.

Table 53-1 lists the major helminthic infections and provides a guide to the drug of choice and alternative drugs for each infection. In the text that follows, these drugs are arranged alphabetically. In general, parasites should be identified before treatment is started.

ALBENDAZOLE

Albendazole, a broad-spectrum oral anthelmintic, is the drug of choice and is approved in the USA for treatment of hydatid disease and cysticercosis. It is also used in the treatment of pinworm and hookworm infections, ascariasis, trichuriasis, and strongyloidiasis.

Basic Pharmacology

Albendazole is a benzimidazole carbamate. After oral administration, it is erratically absorbed (increased with a fatty meal) and then rapidly undergoes first-pass metabolism in the liver to the active metabolite albendazole sulfoxide. It reaches variable maximum plasma concentrations about 3 hours after a 400-mg oral dose, and its plasma half-life is 8–12 hours. The sulfoxide is mostly protein-bound, distributes well to tissues, and enters bile, cerebrospinal fluid, and hydatid cysts. Albendazole metabolites are excreted in the urine.

Benzimidazoles are thought to act against nematodes by inhibiting microtubule synthesis. Albendazole also has larvicidal effects in hydatid disease, cysticercosis, ascariasis, and hookworm infection and ovicidal effects in ascariasis, ancylostomiasis, and trichuriasis.

TABLE 53–1 Drugs for the treatment of helminthic infections.¹

Infesting Organism	Drug of Choice	Alternative Drugs
Roundworms (nematodes)		
<i>Ascaris lumbricoides</i> (roundworm)	Albendazole or pyrantel pamoate or mebendazole	Ivermectin, piperazine
<i>Trichuris trichiura</i> (whipworm)	Mebendazole or albendazole	Ivermectin, oxantel pamoate, drug combinations
<i>Necator americanus</i> (hookworm); <i>Ancylostoma duodenale</i> (hookworm)	Albendazole or mebendazole or pyrantel pamoate	
<i>Strongyloides stercoralis</i> (threadworm)	Ivermectin	Albendazole or thiabendazole
<i>Enterobius vermicularis</i> (pinworm)	Mebendazole or pyrantel pamoate	Albendazole
<i>Trichinella spiralis</i> (trichinosis)	Mebendazole or albendazole; add corticosteroids for severe infection	
<i>Trichostrongylus</i> species	Pyrantel pamoate or mebendazole	Albendazole
Cutaneous larva migrans (creeping eruption)	Albendazole or ivermectin	Thiabendazole (topical)
Visceral larva migrans	Albendazole	Mebendazole
<i>Angiostrongylus cantonensis</i>	Albendazole or mebendazole	
<i>Wuchereria bancrofti</i> (filariasis); <i>Brugia malayi</i> (filariasis); tropical eosinophilia; <i>Loa loa</i> (loiasis)	Diethylcarbamazine	Ivermectin
<i>Onchocerca volvulus</i> (onchocerciasis)	Ivermectin	
<i>Dracunculus medinensis</i> (guinea worm)	Metronidazole	Thiabendazole or mebendazole
<i>Capillaria philippinensis</i> (intestinal capillariasis)	Albendazole	Mebendazole
Flukes (trematodes)		
<i>Schistosoma haematobium</i> (bilharziasis)	Praziquantel	Metrifonate
<i>Schistosoma mansoni</i>	Praziquantel	Oxamniquine
<i>Schistosoma japonicum</i>	Praziquantel	
<i>Clonorchis sinensis</i> (liver fluke); <i>Opisthorchis</i> species	Praziquantel	Albendazole
<i>Paragonimus westermani</i> (lung fluke)	Praziquantel	Bithionol
<i>Fasciola hepatica</i> (sheep liver fluke)	Bithionol or triclabendazole	
<i>Fasciolopsis buski</i> (large intestinal fluke)	Praziquantel or niclosamide	
<i>Heterophyes heterophyes</i> ; <i>Metagonimus yokogawai</i> (small intestinal flukes)	Praziquantel or niclosamide	
Tapeworms (cestodes)		
<i>Taenia saginata</i> (beef tapeworm)	Praziquantel or niclosamide	Mebendazole
<i>Diphyllobothrium latum</i> (fish tapeworm)	Praziquantel or niclosamide	
<i>Taenia solium</i> (pork tapeworm)	Praziquantel or niclosamide	
Cysticercosis (pork tapeworm larval stage)	Albendazole	Praziquantel
<i>Hymenolepis nana</i> (dwarf tapeworm)	Praziquantel	Niclosamide, nitazoxanide
<i>Echinococcus granulosus</i> (hydatid disease); <i>Echinococcus multilocularis</i>	Albendazole	

¹Additional information may be obtained from the Parasitic Disease Drug Service, Parasitic Diseases Branch, Centers for Disease Control and Prevention, Atlanta, Georgia, 30333. Telephone: (404) 639-3670. Some of the drugs listed are not generally available in the USA.

Clinical Uses

Albendazole is administered on an empty stomach when used against intraluminal parasites but with a fatty meal when used against tissue parasites.

1. Ascariasis, trichuriasis, and hookworm and pinworm infections—For adults and children older than 2 years with ascariasis and pinworm infections, the treatment for ascariasis

is a single dose of 400 mg orally (repeated daily for 2–3 days for heavy infections and in 2 weeks for pinworm infections). These treatments typically achieve good cure rates and marked reduction in egg counts in those not cured. For hookworm infections and trichuriasis, albendazole at 400 mg orally once daily for 3 days is now recommended, with albendazole showing improved efficacy over mebendazole. For trichuriasis, combination of either mebendazole or albendazole with ivermectin and

combination of albendazole with oxantel pamoate markedly improved treatment outcomes.

2. Hydatid disease—Albendazole is the treatment of choice for medical therapy and is a useful adjunct to surgical removal or aspiration of cysts. It is more active against *Echinococcus granulosus* than against *Echinococcus multilocularis*. Dosing is 400 mg twice daily with meals for 1 month or longer. Daily therapy for up to 6 months has been well tolerated. One reported therapeutic strategy is to treat with albendazole and praziquantel, to assess response after 1 month or more, and, depending on the response, to then manage the patient with continued chemotherapy or combined surgical and drug therapy.

3. Neurocysticercosis—Indications for medical therapy for neurocysticercosis are controversial, since antihelminthic therapy is not clearly superior to therapy with corticosteroids alone and may exacerbate neurologic disease. Therapy is probably most appropriate for symptomatic parenchymal or intraventricular cysts. Corticosteroids are usually given with the antihelminthic drug to decrease inflammation caused by dying organisms. Albendazole is now generally considered the drug of choice over praziquantel because of its shorter course, lower cost, improved penetration into the subarachnoid space, and increased drug levels (as opposed to decreased levels of praziquantel) when administered with corticosteroids. Albendazole is given in a dosage of 400 mg twice daily for up to 21 days. Albendazole combined with praziquantel improves efficacy in patients with multiple brain cysts.

4. Other infections—Albendazole is the drug of choice in the treatment of cutaneous larva migrans (400 mg daily for 3 days), visceral larva migrans (400 mg twice daily for 5 days), intestinal capillariasis (400 mg daily for 10 days), microsporidial infections (400 mg twice daily for 2 weeks or longer), and gnathostomiasis (400 mg twice daily for 3 weeks). It also has activity against taeniasis (400 mg daily for 3 days), trichinosis (400 mg twice daily for 1–2 weeks), and clonorchiasis (400 mg twice daily for 1 week). There have been reports of effectiveness in treatment of opisthorchiasis, toxocariasis, and loiasis. Albendazole is included in programs to control lymphatic filariasis. It appears to be less active than diethylcarbamazine or ivermectin for this purpose, but it is included in combination with either of those drugs in control programs. Albendazole has been recommended as empiric therapy to treat those who return from the tropics with persistent unexplained eosinophilia. Albendazole has activity against giardiasis, but with decreased efficacy compared to tinidazole.

Adverse Reactions, Contraindications, & Cautions

When used for 1–3 days, albendazole is nearly free of significant adverse effects. Mild and transient epigastric distress, diarrhea, headache, nausea, dizziness, lassitude, and insomnia can occur. In long-term use for hydatid disease, albendazole is well tolerated, but it can cause abdominal distress, headaches, fever, fatigue, alopecia, increases in liver enzymes, and pancytopenia.

Blood counts and liver function should be monitored during long-term therapy. The drug should not be given to patients with known hypersensitivity to other benzimidazole drugs or to those with cirrhosis. The safety of albendazole in pregnancy and in children younger than 2 years has not been established. Exposure to albendazole is increased by dexamethasone, praziquantel, and cimetidine, and decreased by phenytoin, phenobarbital, carbamazepine, and ritonavir.

BITHIONOL

Bithionol is an alternative to triclabendazole for the treatment of fascioliasis (sheep liver fluke) and an alternative to praziquantel for the treatment of paragonimiasis.

Basic Pharmacology & Clinical Uses

After ingestion, bithionol reaches peak blood levels in 4–8 hours. Excretion appears to be mainly via the kidney.

For treatment of paragonimiasis and fascioliasis, the dosage of bithionol is 30–50 mg/kg in two or three divided doses, given orally after meals on alternate days for 10–15 doses. For pulmonary paragonimiasis, cure rates are over 90%. For cerebral paragonimiasis, repeat courses may be necessary.

Adverse Reactions, Contraindications, & Cautions

Adverse effects, which occur in up to 40% of patients, are generally mild and transient, but occasionally their severity requires interruption of therapy. These problems include diarrhea, abdominal cramps, anorexia, nausea, vomiting, dizziness, and headache. Skin rashes may occur after a week or more of therapy, suggesting a reaction to antigens released from dying worms. Bithionol should be used with caution in children younger than 8 years because there has been limited experience in this age group.

DIETHYLCARBAMAZINE CITRATE

Diethylcarbamazine is a drug of choice in the treatment of filariasis, loiasis, and tropical eosinophilia. It has been replaced by ivermectin for the treatment of onchocerciasis.

Basic Pharmacology

Diethylcarbamazine, a synthetic piperazine derivative, is rapidly absorbed from the gastrointestinal tract; after a dose of 0.5 mg/kg, peak plasma levels are reached within 1–2 hours. The plasma half-life is 2–3 hours in the presence of acidic urine but about 10 hours if the urine is alkaline, a Henderson-Hasselbalch trapping effect (see Chapter 1). The drug rapidly equilibrates with all tissues except fat. It is excreted, principally in the urine, as unchanged drug and the *N*-oxide metabolite. Dosage should be reduced in patients with renal impairment.

Diethylcarbamazine immobilizes microfilariae and alters their surface structure, displacing them from tissues and making them

more susceptible to destruction by host defense mechanisms. The mode of action against adult worms is unknown.

Clinical Uses

The drug should be taken after meals.

1. *Wuchereria bancrofti*, *Brugia malayi*, *Brugia timori*, and *Loa loa*—Diethylcarbamazine is the drug of choice for treatment of infections with these parasites because of its efficacy and lack of serious toxicity. Microfilariae of all species are rapidly killed; adult parasites are killed more slowly, often requiring several courses of treatment. The drug is highly effective against adult *L. loa*. The extent to which *W. bancrofti* and *B. malayi* adults are killed is not known, but after appropriate therapy microfilariae do not reappear in the majority of patients. Lymphatic filariasis is treated with 2 mg/kg three times a day for 12 days, and loiasis is treated with the same regimen for 2–3 weeks. Antihistamines may be given for the first few days of therapy to limit allergic reactions, and corticosteroids should be started and doses of diethylcarbamazine lowered or interrupted if severe reactions occur. Cures may require several courses of treatment. For patients with high *L. loa* worm burdens (more than 2500 circulating parasites/mL), strategies to decrease risks of severe toxicity include (a) apheresis, if available, to remove microfilariae before treatment with diethylcarbamazine, or (b) therapy with albendazole, which is slower acting and better tolerated, followed by therapy with diethylcarbamazine or ivermectin. Diethylcarbamazine may also be used for chemoprophylaxis against filarial infections (300 mg weekly or 300 mg on 3 successive days each month for loiasis; 50 mg monthly for bancroftian and Malayan filariasis).

2. Other uses—For tropical eosinophilia, diethylcarbamazine is given orally at a dosage of 2 mg/kg three times daily for 2–3 weeks. Diethylcarbamazine is effective in *Mansonella streptocerca* infections, since it kills both adults and microfilariae. Limited information suggests that the drug is not effective, however, against adult *Mansonella ozzardi* or *Mansonella perstans* and that it has limited activity against microfilariae of these parasites. An important application of diethylcarbamazine has been mass treatment to reduce the prevalence of *W. bancrofti* infection, generally in combination with ivermectin or albendazole. This strategy has led to excellent progress in disease control in a number of countries.

Adverse Reactions, Contraindications, & Cautions

Reactions to diethylcarbamazine, which are generally mild and transient, include headache, malaise, anorexia, weakness, nausea, vomiting, and dizziness. Adverse effects also occur as a result of the release of proteins from dying microfilariae or adult worms. Reactions can be particularly severe with onchocerciasis, but diethylcarbamazine is no longer commonly used for this infection because ivermectin is equally efficacious and less toxic. Reactions to dying microfilariae are usually mild in *W. bancrofti*, more intense in *B. malayi*, and occasionally severe in *L. loa* infections. Reactions include fever, malaise, papular rash, headache, gastrointestinal symptoms, cough, chest pain, and muscle or joint

pain. Leukocytosis is common and eosinophilia may increase with treatment. Proteinuria also may occur. Symptoms are most likely to occur in patients with heavy loads of microfilariae. Retinal hemorrhages and, rarely, encephalopathy have been described. Local reactions may occur in the vicinity of dying adult or immature worms. These include lymphangitis with localized swellings in *W. bancrofti* and *B. malayi*, small wheals in the skin in *L. loa*, and flat papules in *M. streptocerca* infections. Patients with attacks of lymphangitis due to *W. bancrofti* or *B. malayi* should be treated during a quiescent period between attacks. Caution is advised when using diethylcarbamazine in patients with hypertension or renal disease.

DOXYCYCLINE

This tetracycline antibiotic is described in more detail in Chapter 44. Doxycycline has recently been shown to have significant macrofilaricidal activity against *W. bancrofti*, suggesting better activity than any other available drug against adult worms. Activity is also seen against onchocerciasis. Doxycycline acts indirectly, by killing *Wolbachia*, an intracellular bacterial symbiont of filarial parasites. It may prove to be an important drug for filariasis and onchocerciasis, both for treatment of active disease and in mass chemotherapy campaigns.

IVERMECTIN

Ivermectin is the drug of choice in strongyloidiasis and onchocerciasis. It is also an alternative drug for a number of other helminthic infections (Table 53–1).

Basic Pharmacology

Ivermectin, a semisynthetic macrocyclic lactone derived from the soil actinomycete *Streptomyces avermitilis*, is a mixture of avermectin B_{1a} and B_{1b}. Ivermectin is available only for oral administration in humans. The drug is rapidly absorbed, reaching maximum plasma concentrations 4 hours after a 12-mg dose. Ivermectin has a wide tissue distribution and a volume of distribution of about 50 L. Its half-life is about 16 hours. Excretion of the drug and its metabolites is almost exclusively in the feces.

Ivermectin appears to paralyze nematodes and arthropods by intensifying γ -aminobutyric acid (GABA)-mediated transmission of signals in peripheral nerves. In onchocerciasis, ivermectin is microfilaricidal. It does not effectively kill adult worms but blocks the release of microfilariae for some months after therapy. After a single standard dose, microfilariae in the skin diminish rapidly within 2–3 days, remain low for months, and then gradually increase; microfilariae in the anterior chamber of the eye decrease slowly over months, eventually clear, and then gradually return. With repeated doses of ivermectin, the drug appears to have a low-level macrofilaricidal action and to permanently reduce microfilarial production.

Clinical Uses

1. Onchocerciasis—Treatment is with a single oral dose of ivermectin, 150 mcg/kg, with water on an empty stomach.

Doses are repeated; regimens vary from monthly to less frequent (every 6–12 months) dosing schedules. After acute therapy, treatment is repeated at 12-month intervals until the adult worms die, which may take 10 years or longer. With the first treatment only, patients with microfilariae in the cornea or anterior chamber may be treated with corticosteroids to avoid inflammatory eye reactions.

Ivermectin also now plays a key role in onchocerciasis control. Annual mass treatments have led to major reductions in disease transmission. However, evidence of diminished responsiveness after mass administration of ivermectin has raised concern regarding selection of drug-resistant parasites.

2. Strongyloidiasis—Treatment consists of 200 mcg/kg once daily for 2 days. In immunosuppressed patients with disseminated infection, repeated treatment is often needed, and cure may not be possible. In this case, suppressive therapy—ie, once monthly—may be helpful.

3. Other parasites—Ivermectin reduces microfilariae in *B malayi* and *M ozzardi* infections but not in *M perstans* infections. It has been used with diethylcarbamazine and albendazole for the control of *W bancrofti*, but it does not kill adult worms. In loiasis, although the drug reduces microfilaria concentrations, it can occasionally induce severe reactions and appears to be more dangerous in this regard than diethylcarbamazine. Ivermectin is also effective in controlling scabies, lice, and cutaneous larva migrans and in eliminating a large proportion of ascarid worms.

Adverse Reactions, Contraindications, & Cautions

In strongyloidiasis treatment, infrequent adverse effects of ivermectin include fatigue, dizziness, nausea, vomiting, abdominal pain, and rashes. In onchocerciasis treatment, adverse effects are principally from the killing of microfilariae and can include fever, headache, dizziness, somnolence, weakness, rash, increased pruritus, diarrhea, joint and muscle pains, hypotension, tachycardia, lymphadenitis, lymphangitis, and peripheral edema. This reaction starts on the first day and peaks on the second day after treatment. It occurs in 5–30% of persons and is generally mild, but it may be more frequent and more severe in individuals who are not long-term residents of onchocerciasis-endemic areas. A more intense reaction occurs in 1–3% of persons and a severe reaction in 0.1%, including high fever, hypotension, and bronchospasm. Corticosteroids are indicated in these cases, at times for several days. Toxicity diminishes with repeated dosing. Swellings and abscesses occasionally occur at 1–3 weeks, presumably at sites of adult worms. Some patients develop corneal opacities and other eye lesions several days after treatment. These are rarely severe and generally resolve without corticosteroid treatment. It is best to avoid concomitant use of ivermectin with other drugs that enhance GABA activity, eg, barbiturates, benzodiazepines, and valproic acid. Ivermectin should not be used during pregnancy. Safety in children younger than 5 years has not been established.

MEBENDAZOLE

Mebendazole is a synthetic benzimidazole that has a wide spectrum of antihelminthic activity and a low incidence of adverse effects.

Basic Pharmacology

Less than 10% of orally administered mebendazole is absorbed. The absorbed drug is protein-bound (>90%), is rapidly converted to inactive metabolites (primarily during its first pass in the liver), and has a half-life of 2–6 hours. It is excreted mostly in the urine, principally as decarboxylated derivatives, as well as in the bile. Absorption is increased if the drug is ingested with a fatty meal.

Mebendazole probably acts by inhibiting microtubule synthesis; the parent drug appears to be the active form. Efficacy of the drug varies with gastrointestinal transit time, with intensity of infection, and perhaps with the strain of parasite. The drug kills hookworm, *Ascaris*, and *Trichuris* eggs.

Clinical Uses

Mebendazole is indicated for use in ascariasis, trichuriasis, hookworm and pinworm infections, and certain other helminthic infections. It can be taken before or after meals; the tablets should be chewed before swallowing. For pinworm infection, the dose is 100 mg once, repeated at 2 weeks. For ascariasis, trichuriasis, hookworm, and *Trichostrongylus* infections, a dosage of 100 mg twice daily for 3 days is used for adults and for children older than 2 years. Cure rates are good for pinworm infections and ascariasis but have been disappointing in recent studies of trichuriasis, although efficacy for trichuriasis is better than that of albendazole. Cure rates are also low for hookworm infections, but a marked reduction in the worm burden occurs in those not cured. For intestinal capillariasis, mebendazole is used at a dosage of 200 mg twice daily for 21 or more days. In trichinosis, limited reports suggest efficacy against adult worms in the intestinal tract and tissue larvae. Treatment is three times daily, with fatty foods, at 200–400 mg per dose for 3 days and then 400–500 mg per dose for 10 days; corticosteroids should be co-administered for severe infections.

Adverse Reactions, Contraindications, & Cautions

Short-term mebendazole therapy for intestinal nematodes is nearly free of adverse effects. Mild nausea, vomiting, diarrhea, and abdominal pain have been reported infrequently. Rare side effects, usually with high-dose therapy, are hypersensitivity reactions (rash, urticaria), agranulocytosis, alopecia, and elevation of liver enzymes.

Mebendazole is teratogenic in animals and therefore contraindicated in pregnancy. It should be used with caution in children younger than 2 years because of limited experience and rare reports of convulsions in this age group. Plasma levels may be decreased by concomitant use of carbamazepine, phenytoin, or ritonavir, and increased by cimetidine. Mebendazole should be used with caution in patients with cirrhosis.

METRIFONATE (TRICHLORFON)

Metrifonate is a safe, low-cost alternative drug for the treatment of *Schistosoma haematobium* infections. It is not active against *Schistosoma mansoni* or *Schistosoma japonicum*. It is not available in the USA.

Basic Pharmacology

Metrifonate, an organophosphate, is rapidly absorbed after oral administration. After the standard oral dose, peak blood levels are reached in 1–2 hours; the half-life is about 1.5 hours. Clearance appears to be through nonenzymatic transformation to dichlorvos, its active metabolite. Metrifonate and dichlorvos are well distributed to the tissues and are completely eliminated in 24–48 hours.

The mode of action is thought to be cholinesterase inhibition, temporarily paralyzing adult worms, resulting in their transit from bladder vasculature to small arterioles in the lungs, where they are killed. The drug is not effective against *S. haematobium* eggs; live eggs continue to pass in the urine for several months after all adult worms have been killed.

Clinical Uses

In the treatment of *S. haematobium*, an oral dose of 7.5–10 mg/kg is given three times at 14-day intervals. Cure rates on this schedule are 44–93%, with marked reductions in egg counts in those not cured. Metrifonate was also effective as a prophylactic agent when given monthly to children in a highly endemic area, and it has been used in mass treatment programs. In mixed infections with *S. haematobium* and *S. mansoni*, metrifonate has been successfully combined with oxamniquine.

Adverse Reactions, Contraindications, & Cautions

Some studies note mild and transient cholinergic symptoms, including nausea and vomiting, diarrhea, abdominal pain, bronchospasm, headache, sweating, fatigue, weakness, dizziness, and vertigo. Metrifonate should not be used after recent exposure to insecticides or drugs that might potentiate cholinesterase inhibition. It is contraindicated in pregnancy.

NICLOSAMIDE

Niclosamide is a second-line drug for the treatment of most tapeworm infections, but it is not available in the USA.

Basic Pharmacology

Niclosamide is a salicylamide derivative. It appears to be minimally absorbed from the gastrointestinal tract—neither the drug nor its metabolites have been recovered from the blood or urine. Adult worms (but not ova) are rapidly killed, presumably due to inhibition of oxidative phosphorylation or stimulation of ATPase activity.

Clinical Uses

The adult dose of niclosamide is 2 g once, given in the morning on an empty stomach. The tablets must be chewed thoroughly and then swallowed with water.

1. *Taenia saginata* (beef tapeworm), *Taenia solium* (pork tapeworm), and *Diphyllobothrium latum* (fish tapeworm)—A single 2-g dose of niclosamide results in cure rates of over 85% for *D. latum* and about 95% for *T. saginata*. It is probably equally effective against *T. solium*. Cysticercosis can theoretically occur after treatment of *T. solium* infections, because viable ova are released into the gut lumen after digestion of segments, but no such cases have been reported.

2. Other tapeworms—Most patients treated with niclosamide for *Hymenolepis diminuta* and *Dipylidium caninum* infections are cured with a 7-day course of treatment; a few require a second course. Praziquantel is superior for *Hymenolepis nana* (dwarf tapeworm) infection. Niclosamide is not effective against cysticercosis or hydatid disease.

3. Intestinal fluke infections—Niclosamide can be used as an alternative drug in the treatment of *Fasciolopsis buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai* infections. The standard dose is given every other day for three doses.

Adverse Reactions, Contraindications, & Cautions

Infrequent, mild, and transitory adverse events include nausea, vomiting, diarrhea, and abdominal discomfort. Alcohol should not be consumed during or for 1 day after treatment. Safety has not been established in pregnancy or for children younger than 2 years.

OXAMNIQUINE

Oxamniquine is an alternative to praziquantel for the treatment of *S. mansoni* infections. It has also been used extensively for mass treatment. It is not effective against *S. haematobium* or *S. japonicum*. It is not available in the USA.

Basic Pharmacology

Oxamniquine, a semisynthetic tetrahydroquinoline, is readily absorbed orally; it should be taken with food. Its plasma half-life is about 2.5 hours. The drug is extensively metabolized to inactive metabolites and excreted in the urine—up to 75% in the first 24 hours. Intersubject variations in serum concentration have been noted, which may explain some treatment failures.

Oxamniquine is active against both mature and immature stages of *S. mansoni* but does not appear to be cercaricidal. The mechanism of action is unknown. Contraction and paralysis of the worms results in detachment from terminal venules in the mesentery and transit to the liver, where many die; surviving females return to the mesenteric vessels but cease to lay eggs. Strains of *S. mansoni* in

different parts of the world vary in susceptibility. Oxamniquine has been effective in instances of praziquantel resistance.

Clinical Uses

Oxamniquine is safe and effective in all stages of *S. mansoni* disease, including advanced hepatosplenomegaly. The drug is generally less effective in children, who require higher doses than adults. It is better tolerated with food.

Optimal dosage schedules vary for different regions of the world. In the western hemisphere and western Africa, the adult oxamniquine dosage is 12–15 mg/kg given once. In northern and southern Africa, standard schedules are 15 mg/kg twice daily for 2 days. In eastern Africa and the Arabian peninsula, standard dosage is 15–20 mg/kg twice in 1 day. Cure rates are 70–95%, with marked reduction in egg excretion in those not cured. In mixed schistosome infections, oxamniquine has been successfully used in combination with metrifonate.

Adverse Reactions, Contraindications, & Cautions

Mild symptoms occur in more than one-third of patients receiving oxamniquine. Central nervous system symptoms (dizziness, headache, drowsiness) are most common; nausea and vomiting, diarrhea, colic, pruritus, and urticaria also occur. Infrequent adverse effects are low-grade fever, an orange to red discoloration of the urine, proteinuria, microscopic hematuria, and transient leukopenia. Seizures have been reported rarely.

Since the drug makes many patients dizzy or drowsy, it should be used with caution in patients whose work or activity requires mental alertness (eg, no driving for 24 hours). It should be used with caution in those with a history of epilepsy. Oxamniquine is contraindicated in pregnancy.

PIPERAZINE

Piperazine is an alternative for the treatment of ascariasis, with cure rates over 90% when taken for 2 days, but it is not recommended for other helminth infections. Piperazine is available as the hexahydrate and as a variety of salts. It is readily absorbed, and maximum plasma levels are reached in 2–4 hours. Most of the drug is excreted unchanged in the urine in 2–6 hours, and excretion is complete within 24 hours. Piperazine causes paralysis of ascaris by blocking acetylcholine at the myoneural junction; live worms are expelled by peristalsis.

For ascariasis, the dosage of piperazine (as the hexahydrate) is 75 mg/kg (maximum dose, 3.5 g) orally once daily for 2 days. For heavy infections, treatment should be continued for 3–4 days or repeated after 1 week.

Occasional mild adverse effects include nausea, vomiting, diarrhea, abdominal pain, dizziness, and headache. Neurotoxicity and allergic reactions are rare. Piperazine should not be given to pregnant women, patients with impaired renal or hepatic function, or those with a history of epilepsy or chronic neurologic disease.

PRAZIQUANTEL

Praziquantel is effective in the treatment of schistosome infections of all species and most other trematode and cestode infections, including cysticercosis. The drug's safety and effectiveness as a single oral dose have also made it useful in mass treatment of several infections.

Basic Pharmacology

Praziquantel is a synthetic isoquinoline-pyrazine derivative. It is rapidly absorbed, with a bioavailability of about 80% after oral administration. Peak serum concentrations are reached 1–3 hours after a therapeutic dose. Cerebrospinal fluid concentrations of praziquantel reach 14–20% of the drug's plasma concentration. About 80% of the drug is bound to plasma proteins. Most of the drug is rapidly metabolized to inactive mono- and polyhydroxylated products after a first pass in the liver. The half-life is 0.8–1.5 hours. Excretion is mainly via the kidneys (60–80%) and bile (15–35%). Plasma concentrations of praziquantel increase when the drug is taken with a high-carbohydrate meal or with cimetidine; bioavailability is markedly reduced by phenytoin, carbamazepine, or corticosteroids.

Praziquantel appears to increase the permeability of trematode and cestode cell membranes to calcium, resulting in paralysis, dislodgement, and death. In schistosome infections of experimental animals, praziquantel is effective against adult worms and immature stages, and it has a prophylactic effect against cercarial infection.

Clinical Uses

Praziquantel tablets are taken with liquid after a meal; they should be swallowed without chewing because their bitter taste can induce retching and vomiting.

1. Schistosomiasis—Praziquantel is the drug of choice for all forms of schistosomiasis. The dosage is 20 mg/kg per dose for two (*S. mansoni* and *S. haematobium*) or three (*S. japonicum* and *S. mekongi*) doses at intervals of 4–6 hours. High cure rates (75–95%) are achieved when patients are evaluated at 3–6 months; there is marked reduction in egg counts in those not cured. The drug is effective in adults and children and is generally well tolerated by patients in the hepatosplenic stage of advanced disease. There is no standard regimen for acute schistosomiasis (Katayama syndrome), but standard doses as described above, often with corticosteroids to limit inflammation from the acute immune response and dying worms, are recommended. Increasing evidence indicates rare *S. mansoni* drug resistance, which may be countered with extended courses of therapy (eg, 3–6 days at standard dosing) or treatment with oxamniquine. Effectiveness of praziquantel for chemoprophylaxis has not been established.

2. Clonorchiasis, opisthorchiasis, and paragonimiasis—Standard dosing is 25 mg/kg three times daily for 2 days for each of these fluke infections.

3. Taeniasis and diphyllbothriasis—A single dose of praziquantel, 5–10 mg/kg, results in nearly 100% cure rates for

T. saginata, *T. solium*, and *D. latum* infections. Because praziquantel does not kill eggs, it is theoretically possible that larvae of *T. solium* released from eggs in the large bowel could penetrate the intestinal wall and give rise to cysticercosis, but this hazard is probably minimal.

4. Neurocysticercosis—Albendazole is now the preferred drug, but when it is not appropriate or available, praziquantel has similar efficacy. Indications for praziquantel are similar to those for albendazole. The praziquantel dosage is 100 mg/kg/d in three divided doses for 1 day, then 50 mg/kg/d to complete a 2- to 4-week course. Clinical responses to therapy vary from dramatic improvements of seizures and other neurologic findings to no response and even progression of the disease. Praziquantel—but not albendazole—has diminished bioavailability when taken concurrently with a corticosteroid. Recommendations on use of both antihelminthics and corticosteroids in neurocysticercosis vary.

5. Hymenolepis nana—Praziquantel is the drug of choice for *H. nana* infections and the first drug to be highly effective. A single dose of 25 mg/kg is taken initially and repeated in 1 week.

6. Hydatid disease—In hydatid disease, praziquantel kills protoscoleces but does not affect the germinal membrane. Praziquantel may be used as an adjunct with albendazole pre- and post-surgery. In addition to its direct action, praziquantel enhances the plasma concentration of albendazole.

7. Other parasites—Limited trials showed effectiveness of praziquantel at a dosage of 25 mg/kg three times daily for 1–2 days against fasciolopsiasis, metagonimiasis, and other forms of heterophyiasis. Praziquantel was not effective for fascioliasis, however, even at dosages as high as 25 mg/kg three times daily for 3–7 days.

Adverse Reactions, Contraindications, & Cautions

Mild and transient adverse effects are common. They begin within hours after ingestion of praziquantel and may persist for about 1 day. Most common are headache, dizziness, drowsiness, and lassitude; others include nausea, vomiting, abdominal pain, loose stools, pruritus, urticaria, arthralgia, myalgia, and low-grade fever. Mild and transient elevations of liver enzymes have been reported. Several days after starting praziquantel, low-grade fever, pruritus, and skin rashes (macular and urticarial), sometimes associated with worsened eosinophilia, may occur, probably due to the release of proteins from dying worms rather than direct drug toxicity. The intensity and frequency of adverse effects increase with dosage such that they occur in up to 50% of patients who receive 25 mg/kg three times daily.

In neurocysticercosis, neurologic abnormalities may be exacerbated by inflammatory reactions around dying parasites. Common findings in patients who do not receive corticosteroids, usually presenting during or shortly after therapy, are headache, meningismus, nausea, vomiting, mental changes, and

seizures (often accompanied by increased cerebrospinal fluid pleocytosis). More serious reactions, including arachnoiditis, hyperthermia, and intracranial hypertension, may also occur. Corticosteroids are commonly used with praziquantel in the treatment of neurocysticercosis to decrease the inflammatory response, but this is controversial and complicated by knowledge that corticosteroids decrease the plasma level of praziquantel up to 50%. Praziquantel is contraindicated in ocular cysticercosis, because parasite destruction in the eye may cause irreparable damage. Some workers also caution against use of the drug in spinal neurocysticercosis.

Praziquantel is safe and well tolerated in children. Recent data suggest that the drug can be given safely during pregnancy. Because praziquantel induces dizziness and drowsiness, patients should not drive during therapy and should be warned regarding activities requiring particular physical coordination or alertness.

PYRANTEL PAMOATE

Pyrantel pamoate is a broad-spectrum antihelminthic highly effective for the treatment of pinworm, ascaris, and *Trichostrongylus orientalis* infections. It is moderately effective against both species of hookworm. It is not effective in trichuriasis or strongyloidiasis. Oxantel pamoate, an analog of pyrantel not available in the USA, has shown better efficacy against trichuriasis than any other single agent and promising activity in combination with albendazole or ivermectin for this indication. Pyrantel/oxantel pamoate combinations are widely used in veterinary medicine and have been studied for some human indications.

Basic Pharmacology

Pyrantel pamoate is a tetrahydropyrimidine derivative. It is poorly absorbed from the gastrointestinal tract and active mainly against luminal organisms. Peak plasma levels are reached in 1–3 hours. Over half of the administered dose is recovered unchanged in the feces. Pyrantel is effective against mature and immature forms of susceptible helminths within the intestinal tract but not against migratory stages in the tissues or against ova. The drug is a neuromuscular blocking agent that causes release of acetylcholine and inhibition of cholinesterase; this results in paralysis of worms, followed by expulsion.

Clinical Uses

The standard dose is 11 mg (base)/kg (maximum, 1 g), given orally once with or without food. For pinworm, the dose is repeated in 2 weeks, and cure rates are greater than 95%. The drug is available in the USA without prescription for this indication.

For ascariasis, a single dose yields cure rates of 85–100%. Treatment should be repeated if eggs are found 2 weeks after treatment. For hookworm infections, a single dose is effective against light infections; but for heavy infections, especially with *Necator americanus*, a 3-day course is necessary to achieve 90% cure rates. A course of treatment can be repeated in 2 weeks.

Adverse Reactions, Contraindications, & Cautions

Pyrantel's adverse effects are infrequent, mild, and transient. They may include nausea, vomiting, diarrhea, abdominal cramps, dizziness, drowsiness, headache, insomnia, rash, fever, and weakness. Pyrantel should be used with caution in patients with liver dysfunction, as transient aminotransferase elevations have been noted. Experience with the drug in pregnant women and children younger than 2 years is limited.

THIABENDAZOLE

Thiabendazole is an alternative to ivermectin or albendazole for the treatment of strongyloidiasis and cutaneous larva migrans.

Basic Pharmacology

Thiabendazole is a benzimidazole compound. Although it is a chelating agent that forms stable complexes with a number of metals, including iron, it does not bind calcium. Thiabendazole is rapidly absorbed after ingestion. With a standard dose, drug concentrations in plasma peak within 1–2 hours; the half-life is 1.2 hours. The drug is almost completely metabolized in the liver to the 5-hydroxy form; 90% is excreted in the urine in 48 hours, largely as the glucuronide or sulfonate conjugate. Thiabendazole can also be absorbed from the skin. The mechanism of action of thiabendazole is probably the same as that of other benzimidazoles (inhibition of microtubule synthesis). The drug has ovicidal effects against some parasites.

Clinical Uses

The standard dosage, 25 mg/kg (maximum 1.5 g) twice daily, should be given after meals. Tablets should be chewed. For *Strongyloides* infection, treatment is for 2 days. Cure rates are reportedly 93%. A course can be repeated in 1 week if indicated. In patients with hyperinfection syndrome, the standard dose is continued twice daily for 5–7 days. For cutaneous larva migrans, thiabendazole cream can be applied topically, or the oral drug can be given for 2 days (although albendazole is less toxic and therefore preferred).

Adverse Reactions, Contraindications, & Cautions

Thiabendazole is much more toxic than other benzimidazoles and more toxic than ivermectin, so other agents are now preferred for most indications. Common adverse effects include dizziness, anorexia, nausea, and vomiting. Less common problems are epigastric pain, abdominal cramps, diarrhea, pruritus, headache, drowsiness, and neuropsychiatric symptoms. Irreversible liver failure and fatal Stevens-Johnson syndrome have been reported. Experience with thiabendazole is limited in children weighing less than 15 kg. The drug should not be used in pregnancy or in the presence of hepatic or renal disease.

PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
Albendazole	Albenza
Bithionol	Bitin
Diethylcarbamazine	Hetrazan
Ivermectin	Mectizan, Stromectol
Mebendazole	Generic, Vermox
Metrifonate	Trichlorfon, Bilarcil
Niclosamide	Niclocide
Oxamniquine	Vansil, Mansil
Oxantel pamoate	Quantrel
Oxantel/pyrantel pamoate	Telopar
Piperazine	Generic, Vermizine
Praziquantel	Biltricide; others outside the USA
Pyrantel pamoate	Ascarel, Pamix, Pin Rid, Pin-X
Thiabendazole	Mintezol

CASE STUDY ANSWER

The presentation is highly suggestive of cystic hydatid disease (infection with *Echinococcus granulosus*), which is transmitted by eggs from the feces of dogs in contact with livestock. Other causes of liver fluid collections include amebic and pyogenic abscesses, but these are usually not cystic in appearance. For echinococcosis, a typical cystic lesion

and positive serology support the diagnosis, and treatment generally entails albendazole in conjunction with cautious surgery or percutaneous aspiration. One approach entails treatment with albendazole followed by aspiration to confirm the diagnosis and, if it is confirmed, to remove most of the infecting worms.

Cancer Chemotherapy

Edward Chu, MD

CASE STUDY

A 55-year-old man presents with increasing fatigue, 15-pound weight loss, and a microcytic anemia. Colonoscopy identifies a mass in the ascending colon, and biopsy specimens reveal well-differentiated colorectal cancer (CRC). He undergoes surgical resection and is found to have high-risk stage III CRC with five positive lymph nodes. After surgery, he feels entirely well with no symptoms. Of note, he has no other illnesses. What is this patient's overall prognosis? Based on his prognosis, what

are the possible benefits of adjuvant chemotherapy? The patient receives a combination of 5-fluorouracil (5-FU), leucovorin, and oxaliplatin (FOLFOX) as adjuvant therapy. One week after receiving the first cycle of therapy, he experiences significant toxicity in the form of myelosuppression, diarrhea, and altered mental status. What is the most likely explanation for this increased toxicity? Is there any role for genetic testing to determine the etiology of the increased toxicity?

In 2016, approximately 1.68 million new cancer cases were diagnosed in the USA, and nearly 600,000 individuals are expected to die from this disease. Cancer is the second most common cause of death in the United States, accounting for 1 in 4 deaths. It is a disease characterized by a defect in the normal control mechanisms that govern cell survival, proliferation, and differentiation. Cells that have undergone neoplastic transformation usually express cell surface antigens that may be of normal fetal type, and they may display other signs of apparent immaturity. They may exhibit qualitative or quantitative chromosomal abnormalities, including various translocations and the appearance of amplified gene sequences. It is now well established that a small subpopulation of cells, referred to as *tumor stem cells*, reside within a tumor mass. They retain the ability to undergo repeated cycles of proliferation as well as to migrate to distant sites in the body to colonize various organs in the process called *metastasis*. Such tumor stem cells thus can express clonogenic (colony-forming) capability, and they are characterized by chromosome abnormalities reflecting their genetic instability, which leads to progressive selection of subclones that can survive more readily in the multicellular environment of the host. This genetic instability also allows them to

become resistant to chemotherapy and radiotherapy. The invasive and metastatic processes as well as a series of metabolic abnormalities associated with the cancer result in tumor-related symptoms and eventual death of the patient unless the neoplasm can be eradicated with treatment.

CAUSES OF CANCER

The incidence, geographic distribution, and behavior of specific types of cancer are related to multiple factors, including sex, age, race, genetic predisposition, and exposure to environmental carcinogens. Of these factors, **environmental exposure** is probably most important. Exposure to ionizing radiation has been well documented as a significant risk factor for a number of cancers, including acute leukemias, thyroid cancer, breast cancer, lung cancer, soft tissue sarcoma, and basal cell and squamous cell skin cancers. Chemical carcinogens (particularly those in tobacco smoke) as well as azo dyes, aflatoxins, asbestos, benzene, and radon all have been well documented as leading to a wide range of human cancers.

ACRONYMS

ABVD	Doxorubicin (Adriamycin, hydroxydaunorubicin), bleomycin, vinblastine, dacarbazine
BCNU	Carmustine
CCNU	Lomustine
CHOP	Cyclophosphamide, doxorubicin (Adriamycin, hydroxydaunorubicin), vincristine (Oncovin), prednisone
CMF	Cyclophosphamide, methotrexate, fluorouracil
COP	Cyclophosphamide, vincristine (Oncovin), prednisone
CRC	Colorectal cancer
FAC	5-Fluorouracil, doxorubicin (Adriamycin, hydroxydaunorubicin), cyclophosphamide
FEC	5-Fluorouracil, epirubicin, cyclophosphamide
5-FU	5-Fluorouracil
FOLFIRI	5-Fluorouracil, leucovorin, irinotecan
FOLFOX	5-Fluorouracil, leucovorin, oxaliplatin
MP	Melphalan, prednisone
6-MP	6-Mercaptopurine
MOPP	Mechlorethamine, vincristine (Oncovin), procarbazine, prednisone
MTX	Methotrexate
NSCLC	Non-small cell lung cancer
PCV	Procarbazine, lomustine, vincristine
PEB	Cisplatin (platinum), etoposide, bleomycin
6-TG	6-Thioguanine
VAD	Vincristine, doxorubicin (Adriamycin, hydroxydaunorubicin), dexamethasone
XELOX	Capecitabine, oxaliplatin

Several **viruses** have been implicated in the etiology of various human cancers. For example, hepatitis B (HBV) and hepatitis C (HCV) are associated with the development of hepatocellular cancer; HIV is associated with Hodgkin's and non-Hodgkin's lymphomas; human papillomavirus (HPV) is associated with cervical cancer, anal and penile cancers, and oropharyngeal head and neck cancer; Epstein-Barr virus (EBV), also known as human herpesvirus 4 (HHV-4), is associated with nasopharyngeal cancer, Burkitt's lymphoma, and Hodgkin's lymphoma; and Merkel cell polyomavirus (MCV) causes Merkel cell cancer, a rare but aggressive form of skin cancer. Expression of virus-induced neoplasia may also depend on additional host and environmental factors that modulate the transformation process. Cellular genes are known that are homologous to the transforming genes of the retroviruses, a family of RNA viruses, and induce oncogenic transformation. These mammalian cellular genes, known as **oncogenes**, have been shown to code for specific growth factors and their corresponding receptors. These genes may be amplified (increased number of gene copies) or mutated, both of which can lead to constitutive overexpression in malignant cells. The *bcl-2* family of genes represents a series of pro-survival genes that promotes survival by directly inhibiting apoptosis, a key pathway of programmed cell death.

Another class of genes, known as **tumor suppressor genes**, may be deleted or mutated, which gives rise to the neoplastic phenotype. The *p53* gene is the best-established tumor suppressor gene identified to date, and the normal wild-type gene appears to play an important role in suppressing malignant transformation. Of note, *p53* is mutated in up to 50% of all human solid tumors, including liver, breast, colon, lung, cervix, bladder, prostate, and skin.

CANCER TREATMENT MODALITIES

With present methods of treatment, when the tumor remains localized at the time of diagnosis, about one-third of patients are cured with local treatment strategies, such as surgery or radiotherapy. Earlier diagnosis might lead to increased cure rates with such local treatment. In the remaining cases, however, early micrometastasis is a characteristic feature, indicating that a systemic approach with chemotherapy is required for effective cancer management. In patients with locally advanced disease, chemotherapy is often combined with radiotherapy to allow for subsequent surgical resection to take place, and such a combined modality approach has led to improved clinical outcomes. At present, about 50% of patients who are initially diagnosed with cancer can be cured. In contrast, chemotherapy alone is able to cure less than 10% of all cancer patients when the tumor is diagnosed at an advanced stage.

Chemotherapy is presently used in three main clinical settings: (1) primary induction treatment for advanced disease or for cancers for which there are no other effective treatment approaches, (2) neoadjuvant treatment for patients who present with localized disease, for whom local forms of therapy such as surgery or radiation, or both, are inadequate by themselves, (3) adjuvant treatment to local methods of treatment, including surgery, radiation therapy, or both.

Primary chemotherapy refers to chemotherapy administered as the primary treatment in patients who present with advanced cancer for which no alternative treatment exists. This has been the main approach in treating patients with advanced metastatic disease, and in most cases, the goals of therapy are to relieve tumor-related symptoms, improve overall quality of life, and prolong time to tumor progression. Studies in a wide range of solid tumors have shown that chemotherapy in patients with advanced disease confers survival benefit when compared with supportive care, providing sound rationale for the early initiation of drug treatment. However, cancer chemotherapy can be curative in only a small subset of patients who present with advanced disease. In adults, these curable cancers include Hodgkin's and non-Hodgkin's lymphoma, acute myelogenous leukemia, germ cell cancer, and choriocarcinoma, while the curable childhood cancers include acute lymphoblastic leukemia, Burkitt's lymphoma, Wilms' tumor, and embryonal rhabdomyosarcoma.

Neoadjuvant chemotherapy refers to the use of chemotherapy in patients who present with localized cancer for which alternative local therapies, such as surgery, exist but which have been shown to be less than completely effective. At present, neoadjuvant therapy

is most often administered in the treatment of anal cancer, bladder cancer, breast cancer, gastroesophageal cancer, laryngeal cancer, locally advanced non-small cell lung cancer (NSCLC), osteogenic sarcoma, and locally advanced rectal cancer. For diseases such as anal cancer, gastroesophageal cancer, laryngeal cancer, NSCLC, and rectal cancer, optimal clinical benefit is derived when chemotherapy is administered with radiation therapy either concurrently or sequentially. The goal of the neoadjuvant approach is to reduce the size of the primary tumor so that surgical resection can be made easier and more effective. In addition, with rectal cancer and laryngeal cancer, the administration of combined modality therapy prior to surgery can result in sparing of vital normal organs, such as the rectum or larynx. In general, additional chemotherapy is given for a defined period of time, usually 3–4 months, after surgery has been performed.

One of the most important roles for cancer chemotherapy is as an adjuvant to local treatment modalities such as surgery, and this has been termed **adjuvant chemotherapy**. In this setting, chemotherapy is administered after surgery has been performed, and the goal of chemotherapy is to reduce the incidence of both local and systemic recurrence and to improve the overall survival of patients. In general, chemotherapy regimens with clinical activity against advanced disease may have curative potential following surgical resection of the primary tumor, provided the appropriate dose and schedule are administered. Adjuvant chemotherapy is effective in prolonging both disease-free survival (DFS) and overall survival (OS) in patients with breast cancer, colon cancer, gastric cancer, NSCLC, Wilms' tumor, anaplastic astrocytoma, and osteogenic sarcoma. Patients with primary malignant melanoma at high risk of local or systemic recurrence derive clinical benefit from adjuvant treatment with the biologic agent interferon α (IFN- α), although this treatment must be given for 1 year's duration for maximal clinical efficacy. Finally, the antihormonal agents tamoxifen, anastrozole, and letrozole are effective in the adjuvant therapy of postmenopausal women with early-stage breast cancer whose breast tumors express the estrogen receptor (see Chapter 40 for additional details). However, because these agents are cytostatic rather than cytotoxic, they must be administered on a long-term basis, with the standard recommendation being 5 years' duration.

ROLE OF CELL CYCLE KINETICS & ANTI-CANCER EFFECT

The key principles of cell cycle kinetics were initially developed using the murine L1210 leukemia as the experimental model system (Figure 54–1). However, drug treatment of human cancers requires a clear understanding of the differences between the characteristics of this rodent leukemia and of human cancers, as well as an understanding of the differences in growth rates of normal target tissues between mice and humans. For example, L1210 is a rapidly growing leukemia with a high percentage of cells synthesizing DNA, as measured by the uptake of tritiated thymidine (the labeling index). Because L1210 leukemia has a growth fraction of 100% (ie, all its cells are actively progressing through the cell cycle), its life cycle is consistent and predictable.

FIGURE 54–1 Log-kill hypothesis: relationship of tumor cell number to time of diagnosis, symptoms, treatment, and survival. Three alternative approaches to drug treatment are shown for comparison with the course of tumor growth when no treatment is given (*dashed line*). In the protocol diagrammed at top, treatment (indicated by the arrows) is given infrequently, and the result is manifested as prolongation of survival but with recurrence of symptoms between courses of treatment and eventual death of the patient. The combination chemotherapy treatment diagrammed in the middle section is begun earlier and is more intensive. Tumor cell kill exceeds regrowth, drug resistance does not develop, and “cure” results. In this example, treatment has been continued long after all clinical evidence of cancer has disappeared (1–3 years). This approach has been established as effective in the treatment of childhood acute leukemia, testicular cancers, and Hodgkin’s lymphoma. In the treatment diagrammed near the bottom of the graph, early surgery has been employed to remove the primary tumor and intensive adjuvant chemotherapy has been administered long enough (up to 1 year) to eradicate the remaining tumor cells that comprise the occult micrometastases.

Based on the murine L1210 model, the cytotoxic effects of anti-cancer drugs follow log cell-kill kinetics. As such, a given agent would be predicted to kill a constant fraction of cells as opposed to a constant number.

Thus, if a particular dose of an individual drug leads to a 3-log kill of cancer cells and reduces the tumor burden from 10^{10} to 10^7 cells, the same dose used at a tumor burden of 10^5 cells reduces the tumor mass to 10^2 cells. Cell kill is, therefore, proportional, regardless of tumor burden. The cardinal rule of chemotherapy—the invariable inverse relation between cell number and curability—was established with the murine L1210 leukemia model, and this relationship is clearly applicable to hematologic malignancies, such as acute leukemias and lymphomas.

Although growth of murine leukemias simulates exponential cell kinetics, mathematical modeling data suggest that most

human solid tumors do not grow in such an exponential manner. Rather, the experimental data in human solid cancers support a Gompertzian model of tumor growth and regression. The critical distinction between Gompertzian and exponential growth is that the growth fraction of the tumor is not constant with Gompertzian kinetics but instead decreases exponentially with time (exponential growth is matched by exponential retardation of growth, due to blood supply limitations and other factors). The growth fraction peaks when the tumor is approximately one-third its maximum size. According to the Gompertzian model, when a patient with advanced cancer is treated, the tumor mass is larger, its growth fraction is low, and the fraction of cells killed is, therefore, small. An important feature of Gompertzian growth is that response to chemotherapy in drug-sensitive tumors depends, in large measure, on where the tumor is in its particular growth curve.

Information on cell and population kinetics of cancer cells explains, in part, the limited effectiveness of most available anticancer drugs. A schematic summary of cell cycle kinetics is presented in Figure 54–2. This information is relevant to the mode of action, indications, and scheduling of cell cycle-specific (CCS) and cell cycle-nonspecific (CCNS) drugs. Agents falling into these two major classes are summarized in Table 54–1.

The Role of Drug Combinations

With rare exceptions (eg, choriocarcinoma and Burkitt's lymphoma), single drugs are unable to cure cancers when they are in an advanced stage. In the 1960s and early 1970s, drug

FIGURE 54–2 Cell cycle and cancer. A conceptual depiction of the cell cycle phases that all cells—normal and neoplastic—must traverse before and during cell division. The percentages given represent the approximate percentage of time spent in each phase by a typical malignant cell; the duration of G_1 , however, can vary markedly. Many of the effective anti-cancer drugs exert their action on cells traversing the cell cycle and are called cell cycle-specific (CCS) drugs (see Table 54–1). A second group of agents called cell cycle-nonspecific (CCNS) drugs can sterilize tumor cells whether they are cycling or resting in the G_0 compartment. CCNS drugs can kill both G_0 and cycling cells (although cycling cells are more sensitive).

TABLE 54–1 Cell cycle effects of major classes of anti-cancer drugs.

Cell Cycle-Specific (CCS) Agents	Cell Cycle-Nonspecific (CCNS) Agents
Antimetabolites (S phase)	Alkylating agents
Capecitabine	Altretamine
Cladribine	Bendamustine
Clofarabine	Busulfan
Cytarabine (ara-C)	Carmustine
Fludarabine	Chlorambucil
5-Fluorouracil (5-FU)	Cyclophosphamide
Gemcitabine	Dacarbazine
6-Mercaptopurine (6-MP)	Lomustine
Methotrexate (MTX)	Mechlorethamine
Nelarabine	Melphalan
Pralatrexate	Temozolomide
6-Thioguanine (6-TG)	Thiotepa
Topoisomerase II inhibitor (G_1-S phase)	Antitumor antibiotics
Etoposide	Dactinomycin
	Mitomycin
Topoisomerase I inhibitors (Camptothecins, G_2-M)	Platinum analogs
Irinotecan	Carboplatin
Topotecan	Cisplatin
	Oxaliplatin
Taxanes (M phase)	Anthracyclines
Albumin-bound paclitaxel	Daunorubicin
Cabazitaxel	Doxorubicin
Docetaxel	Epirubicin
Paclitaxel	Idarubicin
Vinca alkaloids (M phase)	Mitoxantrone
Vinblastine	
Vincristine	
Vinorelbine	
Antimicrotubule inhibitor (M phase)	
Ixabepilone	
Eribulin	
Antitumor antibiotics (G_2-M phase)	
Bleomycin	

combination regimens were developed based on the known biochemical actions of available anti-cancer drugs rather than on their clinical efficacy. Such regimens were, however, largely ineffective. The era of effective combination chemotherapy began when a number of active drugs from different classes became available for use in combination in the treatment of the acute leukemias and lymphomas. Following this initial success with hematologic malignancies, combination chemotherapy was extended to the treatment of solid tumors.

The use of combination chemotherapy is important for several reasons. First, it provides maximal cell kill within the range of toxicity tolerated by the host for each drug as long as dosing is not compromised. Second, it provides a broader range of interaction between drugs and tumor cells with different genetic abnormalities in a heterogeneous tumor population. Finally, it may prevent and/or slow the subsequent development of cellular drug resistance. Of note, these same concepts apply to the therapy of chronic infections, such as HIV and tuberculosis.

Certain principles have guided the selection of drugs in the most effective drug combinations, and they provide a paradigm for the development of new drug therapeutic programs.

1. **Efficacy:** Only drugs known to have some level of clinical efficacy when used alone against a given tumor should be selected for use in combination. If available, drugs that produce complete remission in some fraction of patients are preferred to those that produce only partial responses.
2. **Toxicity:** When several drugs of a given class are available and are equally effective, a drug should be selected on the basis of toxicity that does not overlap with the toxicity of other drugs in the combination. Although such selection leads to a wider range of adverse effects, it minimizes the risk of a lethal effect caused by multiple insults to the same organ system by different drugs and allows dose intensity to be maximized.
3. **Optimum scheduling:** Drugs should be used in their optimal dose and schedule, and drug combinations should be given at consistent intervals. Because long intervals between cycles negatively affect dose intensity, the treatment-free interval between cycles should be the shortest time necessary for recovery of the most sensitive normal target tissue, which is usually the bone marrow.
4. **Mechanism of interaction:** There should be a clear understanding of the biochemical, molecular, and pharmacokinetic mechanisms of interaction between the individual drugs in a given combination, to allow for maximal antitumor effect. Omission of a drug from a combination may allow overgrowth by a tumor clone sensitive to that drug alone and resistant to other drugs in the combination.
5. **Avoidance of arbitrary dose changes:** An arbitrary reduction in the dose of an effective drug in order to add other less effective drugs may reduce the dose of the most effective agent below the threshold of effectiveness and destroy the ability of the combination to cure disease in a given patient.

Dosage Factors

Dose intensity is one of the main factors limiting the ability of chemotherapy or radiation therapy to achieve cure. As described in Chapter 2, the dose-response curve in biologic systems is usually sigmoidal in shape, with a threshold, a linear phase, and a plateau phase. For chemotherapy, therapeutic selectivity is dependent on the difference between the dose-response curves of normal and tumor tissues. In experimental animal models, the dose-response curve is usually steep in the linear phase, and a reduction in dose when the tumor is in the linear phase of the dose-response curve

almost always results in a loss in the capacity to cure the tumor effectively before a reduction in the antitumor activity is observed. Although complete remissions may continue to be observed with dose reductions down to as low as 20% of the optimal dose, residual tumor cells may not be entirely eliminated, thereby allowing for eventual relapse. Because toxicities are usually associated with anticancer drugs, it is often appealing for clinicians to avoid acute toxicity by simply reducing the dose and/or by increasing the time interval between each cycle of treatment. However, such empiric modifications in dose represent a major cause of treatment failure, especially in patients with drug-sensitive tumors.

A positive relationship between dose intensity and clinical efficacy has been documented in several solid tumors, including advanced ovarian, breast, lung, and colon cancers, as well as in hematologic malignancies, such as the lymphomas. At present, there are three main approaches to dose-intense delivery of chemotherapy. The first approach, **dose escalation**, involves increasing the doses of the respective anti-cancer agents. The second strategy is administration of anti-cancer agents in a dose-intense manner by **reducing the interval** between treatment cycles, while the third approach involves **sequential scheduling** of either single agents or combination regimens. Each of these strategies is presently being applied to the treatment of a wide range of solid cancers, including breast, colorectal, and NSCLC, and in general, such dose-intense regimens have significantly improved clinical outcomes.

DRUG RESISTANCE

A fundamental problem in cancer chemotherapy is the development of cellular drug resistance. *Primary* or *inherent resistance* refers to drug resistance in the absence of prior exposure to available standard agents. The presence of inherent drug resistance was first proposed by Goldie and Coleman in the early 1980s and was thought to result from the genomic instability associated with the development of most cancers. For example, mutations in the *p53* tumor suppressor gene occur in up to 50% of all human tumors. Preclinical and clinical studies have shown that loss of *p53* function leads to resistance to radiation therapy as well as resistance to a wide range of anti-cancer agents. Defects in the mismatch repair enzyme family, which are tightly linked to the development of familial and sporadic colorectal cancer, are associated with resistance to several unrelated anti-cancer agents, including fluoropyrimidines, thiopurines, and cisplatin/carboplatin. In contrast to primary resistance, *acquired resistance* develops in response to exposure to a given anti-cancer agent. Experimentally, drug resistance can be highly specific to a single drug and is usually based on a specific change in the genetic machinery of a given tumor cell with amplification or increased expression of one or more genes. In other instances, a multidrug-resistant phenotype occurs, associated with increased expression of the *MDR1* gene, which encodes a cell surface transporter glycoprotein (P-glycoprotein, see Chapter 5). This form of drug resistance leads to enhanced drug efflux and reduced intracellular accumulation of a broad range of structurally unrelated anti-cancer agents, including

the anthracyclines, vinca alkaloids, taxanes, camptothecins, epipodophyllotoxins, and even small molecule inhibitors, such as imatinib.

■ BASIC PHARMACOLOGY OF CANCER CHEMOTHERAPEUTIC DRUGS

ALKYLATING AGENTS

The major clinically useful alkylating agents (Figure 54–3) have a structure containing a bis(chloroethyl)amine, ethyleneimine, or nitrosourea moiety, and they are classified in several different groups. Among the bis(chloroethyl)amines, cyclophosphamide, mechlorethamine, melphalan, and chlorambucil are the most useful. Ifosfamide is closely related to cyclophosphamide but has a somewhat different spectrum of activity and toxicity. Thiotepa and busulfan are used to treat breast and ovarian cancer, and chronic myeloid leukemia, respectively. The major nitrosoureas are carmustine (BCNU) and lomustine (CCNU).

Mechanism of Action

As a class, the alkylating agents exert their cytotoxic effects via transfer of their alkyl groups to various cellular constituents. Alkylation of DNA within the nucleus probably represents the major interaction leading to cell death. However, these drugs react chemically with sulfhydryl, amino, hydroxyl, carboxyl, and phosphate groups of other cellular nucleophiles as well. The general mechanism of action of these drugs involves intramolecular cyclization to form an ethyleneiminonium ion that may directly or through formation of a carbonium ion transfer an alkyl group to a cellular constituent. In addition to alkylation, a secondary mechanism that occurs with nitrosoureas involves carbamoylation of lysine residues of proteins through formation of isocyanates.

The major site of alkylation within DNA is the N7 position of guanine; however, other bases are also alkylated albeit to lesser degrees, including N1 and N3 of adenine, N3 of cytosine, and O6 of guanine, as well as phosphate atoms and proteins associated with DNA. These interactions can occur on a single strand or on both strands of DNA through cross-linking, as most major alkylating agents are bifunctional, with two reactive groups. Alkylation of guanine can result in miscoding through abnormal base pairing with thymine or in depurination by excision of guanine residues.

FIGURE 54–3 Structures of major classes of alkylating agents.

The latter effect leads to DNA strand breakage through scission of the sugar-phosphate backbone of DNA. Cross-linking of DNA appears to be of major importance to the cytotoxic action of alkylating agents, and replicating cells are most susceptible to these drugs. Thus, although alkylating agents are not cell cycle-specific, cancer cells are most susceptible to this class of drugs in late G₁ and S phases of the cell cycle.

Resistance

The mechanism of acquired resistance to alkylating agents may involve increased capability to repair DNA lesions through increased expression and activity of DNA repair enzymes, decreased cellular transport of the alkylating drug, and increased expression or activity of glutathione and glutathione-associated proteins, which are needed to conjugate the alkylating agent, or increased glutathione *S*-transferase activity, which catalyzes the conjugation.

Adverse Effects

The adverse effects associated with alkylating agents are generally dose-related and occur primarily in rapidly growing tissues such as bone marrow (myelosuppression), gastrointestinal tract (diarrhea), and reproductive system. Nausea and vomiting also can be a serious issue with a number of these agents. In addition, they are potent vesicants and can damage tissues at the site of administration as well as produce systemic toxicity. As a class, alkylating agents are carcinogenic in nature, and there is an increased risk of secondary malignancies, especially acute myelogenous leukemia.

Cyclophosphamide is one of the most widely used alkylating agents. One significant advantage of this compound relates to its high oral bioavailability. As a result, it can be administered via the oral and intravenous routes with equal clinical efficacy. It is inactive in its parent form and must be activated to cytotoxic metabolites by liver microsomal enzymes (Figure 54–4). The cytochrome P450 mixed-function oxidase system converts cyclophosphamide to 4-hydroxycyclophosphamide, which is in equilibrium with aldophosphamide. These active metabolites are delivered to both tumor and normal tissue, where nonenzymatic cleavage of aldophosphamide to the cytotoxic forms—phosphoramidate mustard and acrolein—occurs. The liver appears to be protected through the enzymatic formation of the inactive metabolites 4-ketocyclophosphamide and carboxyphosphamide.

The major toxicities of the individual alkylating agents are outlined in Table 54–2 and discussed below.

NITROSOUREAS

These drugs appear to be non-cross-resistant with other alkylating agents; all require biotransformation, which occurs by nonenzymatic decomposition, to metabolites with both alkylating and carbamoylating activities. The nitrosoureas are highly lipid-soluble and are able to readily cross the blood-brain barrier, making them effective in the treatment of brain tumors. Although the majority of alkylations by the nitrosoureas are on the N7 position of guanine in DNA, the critical alkylation responsible for cytotoxicity appears to be on the O6 position of guanine, which leads to

FIGURE 54–4 Cyclophosphamide metabolism.

TABLE 54–2 Alkylating agents and platinum analogs: Clinical activity and toxicities.

Alkylating Agent	Mechanism of Action	Clinical Applications	Acute Toxicity	Delayed Toxicity
Mechlorethamine	Forms DNA cross-links, resulting in inhibition of DNA synthesis and function	Hodgkin's and non-Hodgkin's lymphoma	Nausea and vomiting	Moderate depression of peripheral blood count; excessive doses produce severe bone marrow depression with leukopenia, thrombocytopenia, and bleeding; alopecia and hemorrhagic cystitis occasionally occur with cyclophosphamide; cystitis can be prevented with adequate hydration; busulfan is associated with skin pigmentation, pulmonary fibrosis, and adrenal insufficiency
Chlorambucil	Same as above	CLL and non-Hodgkin's lymphoma	Nausea and vomiting	
Cyclophosphamide	Same as above	Breast cancer, ovarian cancer, non-Hodgkin's lymphoma, CLL, soft tissue sarcoma, neuroblastoma, Wilms' tumor, rhabdomyosarcoma	Nausea and vomiting	
Bendamustine	Same as above	CLL and non-Hodgkin's lymphoma	Nausea and vomiting	
Melphalan	Same as above	Multiple myeloma, breast cancer, ovarian cancer	Nausea and vomiting	
Thiotepa	Same as above	Breast cancer, ovarian cancer, superficial bladder cancer	Nausea and vomiting	
Busulfan	Same as above	CML	Nausea and vomiting	
Carmustine	Same as above	Brain cancer, Hodgkin's and non-Hodgkin's lymphoma	Nausea and vomiting	Myelosuppression; rarely interstitial lung disease and interstitial nephritis
Lomustine	Same as above	Brain cancer	Nausea and vomiting	
Altretamine	Same as above	Ovarian cancer	Nausea and vomiting	Myelosuppression, peripheral neuropathy, flu-like syndrome
Temozolomide	Methylates DNA and inhibits DNA synthesis and function	Brain cancer, melanoma	Nausea and vomiting, headache and fatigue	Myelosuppression, mild elevation in liver function tests, photosensitivity
Procarbazine	Methylates DNA and inhibits DNA synthesis and function	Hodgkin's and non-Hodgkin's lymphoma, brain tumors	Central nervous system depression	Myelosuppression, hypersensitivity reactions
Dacarbazine	Methylates DNA and inhibits DNA synthesis and function	Hodgkin's lymphoma, melanoma, soft tissue sarcoma	Nausea and vomiting	Myelosuppression, central nervous system toxicity with neuropathy, ataxia, lethargy, and confusion
Cisplatin	Forms intrastrand and interstrand DNA cross-links; binding to nuclear and cytoplasmic proteins	Non-small cell and small cell lung cancer, breast cancer, bladder cancer, cholangiocarcinoma, gastroesophageal cancer, head and neck cancer, ovarian cancer, germ cell cancer	Nausea and vomiting	Nephrotoxicity, peripheral sensory neuropathy, ototoxicity, nerve dysfunction
Carboplatin	Same as cisplatin	Non-small cell and small cell lung cancer, breast cancer, bladder cancer, head and neck cancer, ovarian cancer	Nausea and vomiting	Myelosuppression; rarely peripheral neuropathy, renal toxicity, hepatic dysfunction
Oxaliplatin	Same as cisplatin	Colorectal cancer, gastroesophageal cancer, pancreatic cancer	Nausea and vomiting, laryngopharyngeal dysesthesias	Myelosuppression, peripheral sensory neuropathy, diarrhea

CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia.

G-C crosslinks in DNA. After oral administration of lomustine, peak plasma levels of metabolites appear within 1–4 hours; central nervous system concentrations reach 30–40% of the activity present in the plasma. Urinary excretion appears to be the major route of elimination from the body. One naturally occurring sugar-containing nitrosourea, streptozocin, is interesting because it has minimal bone marrow toxicity. This agent has activity in the treatment of insulin-secreting islet cell carcinoma of the pancreas.

NONCLASSIC ALKYLATING AGENTS

Several other compounds have mechanisms of action that involve DNA alkylation as their cytotoxic mechanism of action. These agents include procarbazine, dacarbazine, and bendamustine. Their clinical activities and toxicities are listed in Table 54–2.

Procarbazine

Procarbazine is an orally active methylhydrazine derivative, and in the clinical setting, it is used in combination regimens for Hodgkin's and non-Hodgkin's lymphoma as well as for brain tumors.

The precise mechanism of action of procarbazine is uncertain; however, it inhibits DNA, RNA, and protein biosynthesis; prolongs interphase; and produces chromosome breaks. Oxidative metabolism of this drug by microsomal enzymes generates azoprocarbazine and H_2O_2 , which may be responsible for DNA strand scission. A variety of other drug metabolites are formed that may be cytotoxic. One metabolite is a weak monoamine oxidase (MAO) inhibitor, and adverse events can occur when procarbazine is given with other MAO inhibitors as well as with sympathomimetic agents, tricyclic antidepressants, antihistamines, central nervous system depressants, antidiabetic agents, alcohol, and tyramine-containing foods.

There is an increased risk of secondary cancers in the form of acute leukemia, and its carcinogenic potential is thought to be higher than that of other alkylating agents.

Dacarbazine

Dacarbazine is a synthetic compound that functions as an alkylating agent following metabolic activation in the liver by oxidative *N*-demethylation to the monomethyl derivative. This metabolite spontaneously decomposes to diazomethane, which generates a methyl carbonium ion that is believed to be the key cytotoxic species. Dacarbazine is administered parenterally and is used in the treatment of malignant melanoma, Hodgkin's lymphoma, soft tissue sarcomas, and neuroblastoma. The main dose-limiting toxicity is myelosuppression, but nausea and vomiting can be severe in some cases. This agent is a potent vesicant, and care must be taken to avoid extravasation during drug administration.

Bendamustine

Bendamustine is a bifunctional alkylating agent consisting of a purine benzimidazole ring and a nitrogen mustard moiety. As with other alkylating agents, it forms cross-links with DNA resulting in

single- and double-stranded breaks, leading to inhibition of DNA synthesis and function. This molecule also inhibits mitotic checkpoints and induces mitotic catastrophe, which leads to cell death. Of note, the cross-resistance between bendamustine and other alkylating agents is only partial, thereby providing a rationale for its clinical activity despite the development of resistance to other alkylating agents. This agent is approved for use in chronic lymphocytic leukemia, with activity also observed in Hodgkin's and non-Hodgkin's lymphoma, multiple myeloma, and breast cancer. The main dose-limiting toxicities include myelosuppression and mild nausea and vomiting. Hypersensitivity infusion reactions, skin rash, and other skin reactions occur rarely.

PLATINUM ANALOGS

Three platinum analogs are currently used in clinical practice: cisplatin, carboplatin, and oxaliplatin. Cisplatin (cis-diamminedichloroplatinum [II]) is an inorganic metal complex that was initially discovered through a serendipitous observation that neutral platinum complexes inhibited division and filamentous growth of *Escherichia coli*. Several platinum analogs were subsequently synthesized. Although the precise mechanism of action of the platinum analogs is unclear, they exert their cytotoxic effects in the same manner as alkylating agents. As such, they kill tumor cells in all stages of the cell cycle and bind DNA through the formation of intrastrand and interstrand cross-links, thereby leading to inhibition of DNA synthesis and function. The primary binding site is the N7 position of guanine, but covalent interaction with the N3 position of adenine and O6 position of cytosine also can occur. In addition to targeting DNA, the platinum analogs have been shown to bind to both cytoplasmic and nuclear proteins, which may also contribute to their cytotoxic and antitumor effects. The platinum complexes appear to synergize with certain other anticancer drugs, including alkylating agents, fluoropyrimidines, and taxanes. The major toxicities of the individual platinum analogs are outlined in Table 54–2.

Cisplatin has major antitumor activity in a broad range of solid tumors, including non-small cell and small cell lung cancer, esophageal and gastric cancer, cholangiocarcinoma, head and neck cancer, and genitourinary cancers, particularly testicular, ovarian, and bladder cancer. When used in combination regimens, cisplatin-based therapy has led to the cure of nonseminomatous testicular cancer. Cisplatin and the other platinum analogs are cleared by the kidneys and excreted in the urine. As a result, dose modification is required in patients with renal dysfunction.

Carboplatin is a second-generation platinum analog whose mechanisms of cytotoxic action, mechanisms of resistance, and clinical pharmacology are identical to those described for cisplatin. As with cisplatin, carboplatin has broad-spectrum activity against

a wide range of solid tumors. However, in contrast to cisplatin, it exhibits significantly less renal and gastrointestinal toxicity. Its main dose-limiting toxicity is myelosuppression. It has, therefore, been widely used in transplant regimens to treat refractory hematologic malignancies. Moreover, since vigorous intravenous hydration is not required for carboplatin therapy, carboplatin is viewed as an easier agent to administer to patients, and as such, it has replaced cisplatin in various combination chemotherapy regimens.

Oxaliplatin is a third-generation diaminocyclohexane platinum analog. Its mechanism of action and clinical pharmacology are identical to those of cisplatin and carboplatin. However, tumors that are resistant to cisplatin or carboplatin on the basis of mismatch repair defects are not cross-resistant to oxaliplatin, and this finding may explain the clinical activity of this platinum compound in colorectal cancer. Oxaliplatin was initially approved for use as second-line therapy in combination with the fluoropyrimidine 5-fluorouracil (5-FU) and leucovorin, termed the FOLFOX regimen, for metastatic colorectal cancer. There are various iterations of the FOLFOX regimen, which have now become the most widely used combinations in the first-line treatment of advanced colorectal cancer. This regimen also plays a major role in the adjuvant therapy of stage III colon cancer and high-risk stage II colon cancer. Clinical activity has also been observed in other gastrointestinal cancers, such as pancreatic, gastroesophageal, and hepatocellular cancer. Neurotoxicity is the main dose-limiting toxicity, and it is manifested by a peripheral sensory neuropathy. There are two forms of neurotoxicity, an acute form that is often triggered and worsened by exposure to cold, and a chronic form that is dose-dependent. Although the chronic form of oxaliplatin toxicity is dependent on the cumulative dose of drug administered, it tends to be more readily reversible than that observed with cisplatin-induced neurotoxicity.

ANTIMETABOLITES

The antimetabolites represent an important class of agents that have been rationally designed and synthesized based on knowledge of critical cellular processes involved in DNA biosynthesis. The individual antimetabolites and their respective clinical spectrum and toxicities are presented in Table 54-3 and are discussed below.

ANTIFOLATES

Methotrexate

Methotrexate (MTX) is a folic acid analog that binds with high affinity to the active catalytic site of dihydrofolate reductase (DHFR). This results in inhibition of synthesis of tetrahydrofolate (THF), the key one-carbon carrier for enzymatic processes involved in de novo synthesis of thymidylate, purine nucleotides, and the amino acids serine and methionine. Inhibition of these metabolic processes interferes with the formation of DNA, RNA, and key cellular proteins (see Figure 33-3). Intracellular formation of polyglutamate metabolites, with the addition of up to

5–7 glutamate residues, is critically important for the therapeutic action of MTX, and this process is catalyzed by the enzyme folypolyglutamate synthase (FPGS). MTX polyglutamates are selectively retained within cancer cells, and they display increased inhibitory effects on enzymes involved in de novo purine nucleotide and thymidylate biosynthesis, making them important determinants of MTX's cytotoxic action.

Folic acid

Methotrexate

Several resistance mechanisms to MTX have been identified, and they include (1) decreased drug transport via the reduced folate carrier or folate receptor protein, (2) decreased formation of cytotoxic MTX polyglutamates, (3) increased levels of the target enzyme DHFR through gene amplification and other genetic mechanisms, and (4) altered DHFR protein with reduced affinity for MTX. Recent studies have suggested that decreased accumulation of drug through activation of the multidrug resistance transporter P170 glycoprotein also may result in drug resistance.

MTX is administered by the intravenous, intrathecal, or oral route. However, oral bioavailability is saturable and erratic at doses greater than 25 mg/m². Renal excretion is the main route of elimination and is mediated by glomerular filtration and tubular secretion. As a result, dose modification is required in the setting of renal dysfunction. Care must also be taken when MTX is used in the presence of drugs such as aspirin, nonsteroidal anti-inflammatory agents, penicillin, and cephalosporins, as these agents inhibit the renal excretion of MTX. The biologic effects of MTX can be reversed by administration of the reduced folate leucovorin (5-formyltetrahydrofolate) or by L-leucovorin, which is the active enantiomer. Leucovorin rescue is used in conjunction with high-dose MTX therapy to rescue normal cells from undue toxicity, and it has also been used in cases of accidental drug overdose. The main adverse effects are listed in Table 54-3.

Pemetrexed

Pemetrexed is a pyrrolopyrimidine antifolate analog with activity in the S phase of the cell cycle. As in the case of MTX, it is

TABLE 54-3 Antimetabolites: Clinical activity and toxicities.

Drug	Mechanism of Action	Clinical Applications	Toxicity
Capecitabine	Inhibits TS; incorporation of FUTP into RNA resulting in alteration in RNA processing; incorporation of FdUTP into DNA resulting in inhibition of DNA synthesis and function	Breast cancer, colorectal cancer, gastroesophageal cancer, hepatocellular cancer, pancreatic cancer	Diarrhea, hand-foot syndrome, myelosuppression, nausea and vomiting
5-Fluorouracil	Inhibits TS; incorporation of FUTP into RNA resulting in alteration in RNA processing; incorporation of FdUTP into DNA resulting in inhibition of DNA synthesis and function	Colorectal cancer, anal cancer, breast cancer, gastroesophageal cancer, head and neck cancer, hepatocellular cancer	Nausea, mucositis, diarrhea, bone marrow depression, neurotoxicity
Methotrexate	Inhibits DHFR; inhibits TS; inhibits de novo purine nucleotide synthesis	Breast cancer, head and neck cancer, osteogenic sarcoma, primary central nervous system lymphoma, non-Hodgkin's lymphoma, bladder cancer, choriocarcinoma	Mucositis, diarrhea, myelosuppression with neutropenia and thrombocytopenia
Pemetrexed	Inhibits TS, DHFR, and purine nucleotide synthesis	Mesothelioma, non-small cell lung cancer	Myelosuppression, skin rash, mucositis, diarrhea, fatigue, hand-foot syndrome
Cytarabine	Inhibits DNA chain elongation, DNA synthesis and repair; inhibits ribonucleotide reductase with reduced formation of dNTPs; incorporation of cytarabine triphosphate into DNA	AML, ALL, CML in blast crisis	Nausea and vomiting, myelosuppression with neutropenia and thrombocytopenia, cerebellar ataxia
Gemcitabine	Inhibits DNA synthesis and repair; inhibits ribonucleotide reductase with reduced formation of dNTPs; incorporation of gemcitabine triphosphate into DNA resulting in inhibition of DNA synthesis and function	Pancreatic cancer, bladder cancer, breast cancer, non-small cell lung cancer, ovarian cancer, non-Hodgkin's lymphoma, soft tissue sarcoma	Nausea, vomiting, diarrhea, myelosuppression
Fludarabine	Inhibits DNA synthesis and repair; inhibits ribonucleotide reductase; incorporation of fludarabine triphosphate into DNA; induction of apoptosis	Non-Hodgkin's lymphoma, CLL	Myelosuppression, immunosuppression, nausea and vomiting, fever, myalgias, arthralgias
Cladribine	Inhibits DNA synthesis and repair; inhibits ribonucleotide reductase; incorporation of cladribine triphosphate into DNA; induction of apoptosis	Hairy cell leukemia, CLL, non-Hodgkin's lymphoma	Myelosuppression, nausea and vomiting, and immunosuppression
6-Mercaptopurine (6-MP)	Inhibits de novo purine nucleotide synthesis; incorporation of triphosphate into RNA; incorporation of triphosphate into DNA	AML	Myelosuppression, immunosuppression, and hepatotoxicity
6-Thioguanine	Same as 6-MP	ALL, AML	Same as 6-MP

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; DHFR, dihydrofolate reductase; dNTP, deoxyribonucleotide triphosphate; FdUTP, 5-fluorodeoxyuridine-5'-triphosphate; FUTP, 5-fluorouridine-5'-triphosphate; TS, thymidylate synthase.

transported into the cell via the reduced folate carrier and requires activation by FPGS to yield higher polyglutamate forms. While this agent targets DHFR and enzymes involved in de novo purine nucleotide biosynthesis, its main mechanism of action is inhibition of thymidylate synthase (TS). Pemetrexed is currently approved for use in combination with cisplatin in the treatment of mesothelioma, as a single agent in the second-line therapy of NSCLC, in combination with cisplatin for the first-line treatment of NSCLC, and most recently, as maintenance therapy in patients with NSCLC whose disease has not progressed after four cycles of platinum-based chemotherapy. As with MTX, pemetrexed is mainly excreted in urine, and dose modification is required in patients with renal dysfunction. The main adverse effects include

myelosuppression, skin rash, mucositis, diarrhea, fatigue, and hand-foot syndrome. Of note, vitamin supplementation with folic acid and vitamin B₁₂ has been shown to significantly reduce the toxicities associated with pemetrexed, while not interfering with clinical efficacy. The hand-foot syndrome is manifested by painful erythema and swelling of the hands and feet, and treatment with the steroid dexamethasone is effective in reducing the incidence and severity of this skin toxicity.

Pralatrexate

Pralatrexate is a 10-deaza-aminopterin antifolate analog, and as in the case of MTX, it is transported into the cell via the

reduced folate carrier (RFC) and requires activation by FPGS to yield higher polyglutamate forms. This molecule was originally designed to be a more potent substrate for the RFC-1 carrier protein and to serve as an improved substrate for FPGS. This agent inhibits DHFR, inhibits enzymes involved in de novo purine nucleotide biosynthesis, and also inhibits TS. Pralatrexate is presently approved for use in the treatment of relapsed or refractory peripheral T-cell lymphoma. Consistent with other antifolate analogs, pralatrexate is mainly excreted in the urine, and dose modification is required in renal dysfunction. The main adverse effects include myelosuppression, skin rash, mucositis, diarrhea, and fatigue. As with pemetrexed, vitamin supplementation with folic acid and vitamin B₁₂ appears to reduce the toxicities associated with pralatrexate, without interfering with clinical efficacy.

FLUOROPYRIMIDINES

5-Fluorouracil

5-Fluorouracil (5-FU) is inactive in its parent form and requires activation via a complex series of enzymatic reactions to ribosyl and deoxyribosyl nucleotide metabolites. One of these metabolites, 5-fluoro-2'-deoxyuridine-5'-monophosphate (FdUMP), forms a covalently bound ternary complex with the enzyme TS and the reduced folate 5,10-methylenetetrahydrofolate, a reaction critical for the de novo synthesis of thymidylate. Formation of this ternary complex results in inhibition of DNA synthesis through "thymineless death." 5-FU is converted to 5-fluorouridine-5'-triphosphate (FUTP), which is then incorporated into RNA, where it interferes with RNA processing and mRNA translation. 5-FU is also converted to 5-fluorodeoxyuridine-5'-triphosphate (FdUTP), which is subsequently incorporated into cellular DNA, resulting in inhibition of DNA synthesis and function. Thus, the cytotoxicity of 5-FU is thought to be mediated by the combined effects of both DNA- and RNA-mediated events.

5-FU is administered intravenously, and the clinical activity of this drug is highly schedule-dependent. Because of its extremely short half-life, approximately 10–15 minutes, infusion administration schedules have been generally favored over bolus schedules. Up to 80–85% of an administered dose of 5-FU is catabolized by the enzyme dihydropyrimidine dehydrogenase (DPD). There is an autosomal recessive pharmacogenetic syndrome involving partial or complete deficiency of the DPD enzyme that is seen in up to 5% of cancer patients. In this particular setting, severe, excessive toxicity is observed with the classic triad of myelosuppression, GI toxicity in the form of diarrhea and/or mucositis, and neurotoxicity.

5-FU remains the most widely used agent in the treatment of colorectal cancer, both as adjuvant therapy and for advanced disease. It also has activity against a wide range of solid tumors, including cancers of the breast, stomach, pancreas, esophagus, liver, head and neck, and anus. Major toxicities include myelosuppression, gastrointestinal toxicity in the form of mucositis and diarrhea, skin toxicity manifested by the hand-foot syndrome, and neurotoxicity.

Capecitabine

Capecitabine is a fluoropyrimidine carbamate prodrug with 70–80% oral bioavailability. As with 5-FU, capecitabine is inactive in its parent form and undergoes extensive metabolism in the liver by the enzyme carboxylesterase to an intermediate, 5'-deoxy-5-fluorocytidine. This metabolite is then converted to 5'-deoxy-5-fluorouridine by the enzyme cytidine deaminase. These two initial steps occur mainly in the liver. The 5'-deoxy-5-fluorouridine metabolite is finally hydrolyzed by thymidine phosphorylase to 5-FU directly in the tumor. The expression of thymidine phosphorylase has been shown to be significantly higher in a broad range of solid tumors than in corresponding normal tissue, particularly in breast cancer and colorectal cancer (CRC).

Capecitabine is used in the treatment of metastatic breast cancer either as a single agent or in combination with other anti-cancer agents, including docetaxel, paclitaxel, lapatinib, ixabepilone, and trastuzumab. It is also approved for use in the adjuvant therapy of stage III and high-risk stage II colon cancer, and used in the treatment of metastatic CRC as monotherapy or in combination with other active cytotoxic agents, including irinotecan and oxaliplatin. The capecitabine/oxaliplatin (XELOX) regimen is now widely used for the first-line treatment of metastatic CRC as well as in the adjuvant setting for patients with stage III and high-risk stage II colon cancer. The main toxicities of capecitabine include diarrhea and the hand-foot syndrome. While myelosuppression, nausea and vomiting, mucositis, and alopecia are also observed with capecitabine, their incidence is significantly less than that observed with intravenous 5-FU.

TAS-102

TAS-102 is an oral fluoropyrimidine analog approved in 2015 by the U.S. Food and Drug Administration (FDA) for the treatment of progressive, refractory metastatic CRC. As with 5-FU, TAS-102 is inactive in its parent form. It is made up of trifluridine, a fluorinated pyrimidine nucleoside analog, and tipiracil, a thymidine phosphorylase (TP) inhibitor, in a 1/0.5 ratio. Trifluridine is metabolized to the monophosphate form, which inhibits TS, albeit a much weaker TS inhibitor than FdUMP, and also to the triphosphate form, which is directly incorporated into DNA, leading to inhibition of DNA synthesis and function. The role of tipiracil is to inhibit TP, a key enzyme that degrades trifluridine to inactive forms. Thus, tipiracil allows for higher levels of

trifluridine, which can then be activated to the active metabolite forms. The advantages of TAS-102 are that it retains clinical activity in 5-FU resistant tumors and it displays similar clinical activity in the setting of wild-type and mutant *RAS* colorectal cancer. The main dose-limiting toxicity is myelosuppression, with neutropenia more commonly observed than anemia and thrombocytopenia. The other adverse effects commonly observed with this oral fluoropyrimidine are GI toxicity with diarrhea and nausea/vomiting, fatigue, and anorexia.

DEOXYCYTIDINE ANALOGS

Cytarabine

Cytarabine (ara-C) is an S phase-specific antimetabolite that is converted by deoxycytidine kinase to the 5'-mononucleotide (ara-CMP). Ara-CMP is further metabolized to the diphosphate and triphosphate metabolites, and the ara-CTP triphosphate is thought to be the main cytotoxic metabolite. Ara-CTP competitively inhibits DNA polymerase- α and DNA polymerase- β , thereby resulting in blockade of DNA synthesis and DNA repair, respectively. This metabolite is also incorporated into RNA and DNA. Incorporation into DNA leads to interference with chain elongation and defective ligation of fragments of newly synthesized DNA. The cellular retention of ara-CTP appears to correlate with its lethality to malignant cells.

After intravenous administration, the drug is cleared rapidly, with most of an administered dose being deaminated to inactive forms. The stoichiometric balance between the level of activation and catabolism of cytarabine is important in determining its eventual cytotoxicity. The clinical activity of cytarabine is highly schedule-dependent and, because of its rapid degradation, it is usually administered via continuous infusion over a 5- to 7-day period. Its activity is limited exclusively to hematologic malignancies, including acute myelogenous leukemia and non-Hodgkin's lymphoma. This agent has absolutely no activity in solid tumors. The main adverse effects associated with cytarabine therapy include myelosuppression, mucositis, nausea and vomiting, and neurotoxicity when high-dose therapy is administered.

Gemcitabine

Gemcitabine is a fluorine-substituted deoxycytidine analog that is phosphorylated initially by the enzyme deoxycytidine kinase to the monophosphate form and then by other nucleoside kinases to the diphosphate and triphosphate nucleotide forms. The antitumor effect is considered to result from several mechanisms: inhibition of ribonucleotide reductase by gemcitabine diphosphate, which reduces the level of deoxyribonucleoside triphosphates required for DNA synthesis; inhibition by gemcitabine triphosphate of DNA polymerase- α and DNA polymerase- β , thereby resulting in blockade of DNA synthesis and DNA repair; and incorporation of gemcitabine triphosphate into DNA, leading to inhibition of DNA synthesis and function.

In contrast to cytarabine, which has no activity in solid tumors, gemcitabine has broad-spectrum activity against both solid tumors and hematologic malignancies. In fact, this nucleoside analog was initially approved for use in advanced pancreatic cancer and is now widely used to treat a broad range of malignancies, including NSCLC, bladder cancer, ovarian cancer, soft tissue sarcoma, and non-Hodgkin's lymphoma. Myelosuppression in the form of neutropenia is the principal dose-limiting toxicity. Nausea and vomiting occur in 70% of patients, and a flu-like syndrome has also been observed. In rare cases, renal microangiopathy syndromes, including hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP), have been reported.

PURINE ANTAGONISTS

6-Thiopurines

6-Mercaptopurine (6-MP) was the first of the thiopurine analogs found to have clinical efficacy in cancer therapy. This agent is used primarily in the treatment of childhood acute leukemia, and a closely related analog, azathioprine, is used as an immunosuppressive agent (see Chapter 55). As with other thiopurines, 6-MP is inactive in its parent form and must be metabolized by hypoxanthine-guanine phosphoribosyl transferase (HGPRT) to form the monophosphate nucleotide 6-thioinosinic acid, which in turn, inhibits several enzymes of de novo purine nucleotide synthesis (Figure 54-6). The monophosphate form is eventually metabolized to the triphosphate form, which can then be incorporated into both RNA and DNA. Significant levels of thioguanilic acid and

6-methylmercaptopurine ribotide (MMPR) also are formed from 6-MP. These metabolites may contribute to its cytotoxic action.

6-Thioguanine (6-TG) also inhibits several enzymes in the de novo purine nucleotide biosynthetic pathway. Various metabolic lesions result, including inhibition of purine nucleotide interconversion; decrease in intracellular levels of guanine nucleotides, which leads to inhibition of glycoprotein synthesis; interference with the formation of DNA and RNA; and incorporation of thiopurine nucleotides into both DNA and RNA. 6-TG has a synergistic action when used together with cytarabine in the treatment of adult acute leukemia.

6-MP is converted to an inactive metabolite (6-thiouric acid) by an oxidation reaction catalyzed by xanthine oxidase, whereas 6-TG undergoes deamination. This is an important difference because the purine analog allopurinol, a potent xanthine oxidase inhibitor, is frequently used as a supportive care measure in the treatment of acute leukemias to prevent the development of hyperuricemia that often occurs with tumor cell lysis. Because allopurinol inhibits xanthine oxidase, simultaneous therapy with allopurinol and 6-MP would result in increased levels of 6-MP, thereby leading to excessive toxicity. In this setting, the dose of mercaptopurine must be reduced by 50–75%. In contrast, such an interaction does not occur with 6-TG, which can be used in full doses with allopurinol.

The thiopurines are also metabolized by the enzyme thiopurine methyltransferase (TPMT), in which a methyl group is attached to the thiopurine ring. Patients who have a pharmacogenetic syndrome involving partial or complete deficiency of this enzyme are at increased risk for developing severe toxicities in the form of myelosuppression and gastrointestinal toxicity with mucositis and diarrhea.

Fludarabine

Fludarabine phosphate is rapidly dephosphorylated to 2-fluoroarabinofuranosyladenosine and then phosphorylated intracellularly by deoxycytidine kinase to the monophosphate, which is eventually converted to the triphosphate. Fludarabine

triphosphate interferes with the processes of DNA synthesis and DNA repair through inhibition of DNA polymerase- α and DNA polymerase- β . The triphosphate form can also be directly incorporated into DNA, resulting in inhibition of DNA synthesis and function. The diphosphate metabolite of fludarabine inhibits ribonucleotide reductase, leading to inhibition of essential deoxyribonucleotide triphosphates. Finally, fludarabine induces apoptosis in susceptible cells through as yet undetermined mechanisms. This purine nucleotide analog is used mainly in the treatment of low-grade non-Hodgkin's lymphoma and chronic lymphocytic leukemia (CLL). It is given parenterally, and up to 25–30% of parent drug is excreted in the urine. The main dose-limiting toxicity is myelosuppression. This agent is a potent immunosuppressant with inhibitory effects on CD4 and CD8 T cells. Patients are at increased risk for opportunistic infections, including fungi, herpes, and *Pneumocystis jiroveci* pneumonia (PCP). Patients should receive PCP prophylaxis with trimethoprim-sulfamethoxazole (double strength) at least three times a week, and this should continue for up to 1 year after stopping fludarabine therapy.

Cladribine

Cladribine (2-chlorodeoxyadenosine) is a purine nucleoside analog with high specificity for lymphoid cells. Inactive in its parent form, it is initially phosphorylated by deoxycytidine kinase to the monophosphate form and eventually metabolized to the triphosphate form, which can then be incorporated into DNA. The triphosphate metabolite can also interfere with DNA synthesis and DNA repair by inhibiting DNA polymerase- α and DNA polymerase- β , respectively. Cladribine is indicated for the treatment of hairy cell leukemia, with activity in other low-grade lymphoid malignancies such as CLL and low-grade non-Hodgkin's lymphoma. It is normally administered as a single continuous 7-day infusion; under these conditions, it has a very manageable safety profile with the main toxicity consisting of transient myelosuppression. As with other purine nucleoside analogs, it has immunosuppressive effects, and a decrease in CD4 and CD8 T cells, lasting for over 1 year, is observed in patients.

NATURAL PRODUCT CANCER CHEMOTHERAPY DRUGS

VINCA ALKALOIDS

The vinca alkaloids inhibit the process of tubulin polymerization, which disrupts assembly of microtubules, especially those involved in the mitotic spindle apparatus. This inhibitory effect results in mitotic arrest in metaphase, bringing cell division to a halt, which then leads to cell death. Thus, the vinca alkaloids work in the M phase of the cell cycle. Microtubules also play an important role in maintaining cell shape and cellular motility, and they facilitate the intracellular transport of cellular proteins. As such, inhibition of microtubule formation has important consequences that can lead to cell death.

Vinblastine

Vinblastine is an alkaloid derived from the periwinkle plant *Vinca rosea*. Vinblastine and other vinca alkaloids are metabolized by the liver P450 system, and the majority of the drug is excreted in feces via the hepatobiliary system. As such, dose modification is required in the setting of liver dysfunction.

The main adverse effects are outlined in Table 54–4, and they include nausea and vomiting, bone marrow suppression, and alopecia. This agent is also a potent vesicant, and care must be taken in its administration. It has clinical activity in the treatment of Hodgkin's and non-Hodgkin's lymphomas, breast cancer, and germ cell cancer.

TABLE 54–4 Natural product cancer chemotherapy drugs: Clinical activity and toxicities.

Drug	Mechanism of Action	Clinical Applications	Acute Toxicity	Delayed Toxicity
Bleomycin	Oxygen free radicals bind to DNA causing single- and double-strand DNA breaks	Hodgkin's and non-Hodgkin's lymphoma, germ cell cancer, head and neck cancer	Allergic reactions, fever, hypotension	Skin toxicity, pulmonary fibrosis, mucositis, alopecia
Daunorubicin	Oxygen free radicals bind to DNA causing single- and double-strand DNA breaks; inhibits topoisomerase II; intercalates into DNA	AML, ALL	Nausea and vomiting, fever, red urine (not hematuria)	Cardiotoxicity (see text), alopecia, myelosuppression
Docetaxel	Inhibits mitosis	Breast cancer, non-small cell lung cancer, prostate cancer, gastric cancer, head and neck cancer, ovarian cancer, bladder cancer	Hypersensitivity	Neurotoxicity, fluid retention, myelosuppression with neutropenia
Doxorubicin	Oxygen free radicals bind to DNA causing single- and double-strand DNA breaks; inhibits topoisomerase II; intercalates into DNA	Breast cancer, Hodgkin's and non-Hodgkin's lymphoma, soft tissue sarcoma, ovarian cancer, non-small cell and small cell lung cancer, thyroid cancer, Wilms' tumor, neuroblastoma	Nausea, red urine (not hematuria)	Cardiotoxicity (see text), alopecia, myelosuppression, stomatitis
Etoposide	Inhibits topoisomerase II	Non-small cell and small cell lung cancer; non-Hodgkin's lymphoma, gastric cancer	Nausea, vomiting, hypotension	Alopecia, myelosuppression
Idarubicin	Oxygen free radicals bind to DNA causing single- and double-strand DNA breaks; inhibits topoisomerase II; intercalates into DNA	AML, ALL, CML in blast crisis	Nausea and vomiting	Myelosuppression, mucositis, cardiotoxicity
Irinotecan	Inhibits topoisomerase I	Colorectal cancer, gastroesophageal cancer, non-small cell and small cell lung cancer	Diarrhea, nausea, vomiting	Diarrhea, myelosuppression, nausea and vomiting
Mitomycin	Acts as an alkylating agent and forms cross-links with DNA; formation of oxygen free radicals, which target DNA	Superficial bladder cancer, gastric cancer, breast cancer, non-small cell lung cancer, head and neck cancer (in combination with radiotherapy)	Nausea and vomiting	Myelosuppression, mucositis, anorexia and fatigue, hemolytic-uremic syndrome
Paclitaxel	Inhibits mitosis	Breast cancer, non-small cell and small cell lung cancer, ovarian cancer, gastroesophageal cancer, prostate cancer, bladder cancer, head and neck cancer	Nausea, vomiting, hypotension, arrhythmias, hypersensitivity	Myelosuppression, peripheral sensory neuropathy
Topotecan	Inhibits topoisomerase I	Small cell lung cancer, ovarian cancer	Nausea and vomiting	Myelosuppression
Vinblastine	Inhibits mitosis	Hodgkin's and non-Hodgkin's lymphoma, germ cell cancer, breast cancer, Kaposi's sarcoma	Nausea and vomiting	Myelosuppression, mucositis, alopecia, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), vascular events
Vincristine	Inhibits mitosis	ALL, Hodgkin's and non-Hodgkin's lymphoma, rhabdomyosarcoma, neuroblastoma, Wilms' tumor	None	Neurotoxicity with peripheral neuropathy, paralytic ileus, myelosuppression, alopecia, SIADH
Vinorelbine	Inhibits mitosis	Non-small cell lung cancer, breast cancer, ovarian cancer	Nausea and vomiting	Myelosuppression, constipation, SIADH

ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CML, chronic myelogenous leukemia.

Vincristine

Vincristine is another alkaloid derivative of *Vinca rosea* and is closely related in structure to vinblastine. Its mechanism of action, mechanism of resistance, and clinical pharmacology are identical to those of vinblastine. Despite these similarities to vinblastine, vincristine has a strikingly different spectrum of clinical activity and safety profile, which results, in large part, from its higher affinity for axonal microtubules.

Vincristine has been effectively combined with prednisone for remission induction in acute lymphoblastic leukemia in children. It is also active in various hematologic malignancies such as Hodgkin's and non-Hodgkin's lymphomas, and multiple myeloma, and in several pediatric tumors including rhabdomyosarcoma, neuroblastoma, Ewing's sarcoma, and Wilms' tumor.

The main dose-limiting toxicity is neurotoxicity, usually expressed as a peripheral sensory neuropathy, although autonomic nervous system dysfunction with orthostatic hypotension, urinary retention, and paralytic ileus or constipation, cranial nerve palsies, ataxia, seizures, and coma have been observed. While myelosuppression occurs, it is generally milder and much less significant than with vinblastine. The other adverse effect that may develop is the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Vinorelbine

Vinorelbine is a semisynthetic derivative of vinblastine whose mechanism of action is identical to that of vinblastine and vincristine, ie, inhibition of mitosis of cells in the M phase through inhibition of tubulin polymerization. This agent has activity in NSCLC, breast cancer, and ovarian cancer. Myelosuppression with neutropenia is the dose-limiting toxicity, but other adverse effects include nausea and vomiting, transient elevations in liver function tests, neurotoxicity, and SIADH.

TAXANES & OTHER ANTI-MICROTUBULE DRUGS

Paclitaxel is an alkaloid ester derived from the Pacific yew (*Taxus brevifolia*) and the European yew (*Taxus baccata*). The drug functions as a mitotic spindle poison through high-affinity binding to

microtubules with enhancement of tubulin polymerization. This promotion of microtubule assembly by paclitaxel results in inhibition of mitosis and cell division. As such, paclitaxel and the other taxanes work in the M phase of the cell cycle.

Paclitaxel has significant activity in a broad range of solid tumors, including ovarian, advanced breast, NSCLC and small cell lung cancer (SCLC), head and neck, esophageal, prostate, and bladder cancers, as well as AIDS-related Kaposi's sarcoma. It is metabolized extensively by the liver P450 system, and nearly 80% of the drug is excreted in feces via the hepatobiliary route. Dose reduction is required in patients with liver dysfunction. The primary dose-limiting toxicities are listed in Table 54-4. Hypersensitivity reactions may be observed in up to 5% of patients, but the incidence is significantly reduced by premedication with dexamethasone, diphenhydramine, and an H₂ blocker.

An **albumin-bound paclitaxel nanoparticle formulation (Abraxane)** is approved for several solid tumors, including breast cancer, pancreatic cancer, and non-small cell lung cancer. In contrast to paclitaxel, this nanoparticle formulation is not associated with hypersensitivity reactions, and premedication to prevent such reactions is not required. Moreover, this agent has significantly reduced myelosuppressive effects compared with paclitaxel, and the neurotoxicity that results appears to be more readily reversible than is typically observed with paclitaxel.

Docetaxel is a semisynthetic taxane derived from the European yew tree. Its mechanism of action, metabolism, and elimination are identical to those of paclitaxel. It is approved for use as second-line therapy in advanced breast cancer and NSCLC, and it also has major activity in head and neck cancer, small cell lung cancer, gastric cancer, advanced platinum-refractory ovarian cancer, and bladder cancer. Its major toxicities are listed in Table 54-4.

Cabazitaxel is a semisynthetic taxane and its mechanism of action, metabolism, and elimination are identical to those of the other taxanes. However, unlike other taxanes, cabazitaxel is a poor substrate for the multidrug resistance P-glycoprotein efflux pump and may, therefore, be useful for treating multidrug-resistant tumors. It is approved for use in combination with prednisone in the second-line therapy of hormone-refractory metastatic prostate cancer previously treated with a docetaxel-containing regimen. Its major toxicities include myelosuppression, neurotoxicity, and allergic reactions.

Ixabepilone is a semisynthetic epothilone B analog, not a taxane, that functions as a microtubule inhibitor and binds directly to β -tubulin subunits on microtubules, leading to inhibition of normal microtubule dynamics. As such, it is active in the M phase of the cell cycle. This agent is presently approved for metastatic breast cancer in combination with the oral fluoropyrimidine capecitabine or as monotherapy. Of note, this agent continues to have activity in drug-resistant tumors that overexpress P-glycoprotein or tubulin mutations. The main adverse effects include myelosuppression, hypersensitivity reactions, and neurotoxicity in the form of peripheral sensory neuropathy.

Eribulin is a synthetic analog of halichondrin B, and it inhibits microtubule function, leading to a block in the G₂-M phase of the cell cycle. This agent appears to be less sensitive to the multidrug resistance-mediated P-glycoprotein efflux pump, and one of the

advantages of this agent is that it has activity in drug-resistant tumors that overexpress P-glycoprotein. It is presently approved for the treatment of patients with metastatic breast cancer.

EPIPODOPHYLLOTOXINS

Etoposide is a semisynthetic derivative of podophyllotoxin, which is extracted from the mayapple root (*Podophyllum peltatum*). Intravenous and oral formulations of etoposide are approved for clinical use in the USA. Oral bioavailability is about 50%, requiring oral dosage to be twice that of intravenous dosage. Up to 30–50% of an administered dose of drug is excreted in the urine, and dose reduction is required in patients with renal dysfunction. Etoposide forms a complex with topoisomerase II, the enzyme responsible for cutting and religating double stranded DNA, and DNA, leading to inhibition of the functional activity of topoisomerase II with inhibition of DNA synthesis and function. Etoposide has clinical activity in germ cell cancer, small cell and NSCLC, Hodgkin's and non-Hodgkin's lymphomas, and gastric cancer. Major toxicities are listed in Table 54–4.

CAMPTOTHECINS

The camptothecins are natural products derived from the *Camptotheca acuminata* tree originally found in China; they inhibit the activity of topoisomerase I, the key enzyme responsible for cutting and religating single DNA strands. Inhibition of this enzyme results in DNA damage. **Topotecan** and **irinotecan** are the two camptothecin analogs used in clinical practice in the USA. Although they both inhibit the same molecular target, their spectrum of clinical activity is quite different.

Topotecan is indicated in the treatment of advanced ovarian cancer as second-line therapy following initial treatment with platinum-based chemotherapy. It is also approved as second-line therapy of small cell lung cancer. The main route of elimination is renal excretion, and dosage must be adjusted in patients with renal impairment. Irinotecan is a prodrug that is converted mainly in the liver by the carboxylesterase enzyme to the **SN-38** metabolite, which is 1000-fold more potent as an inhibitor of topoisomerase I than the parent compound. In contrast to topotecan, irinotecan and SN-38 are mainly eliminated in bile and feces, and dose reduction is required in the setting of liver dysfunction. Irinotecan was originally approved as second-line monotherapy in patients with metastatic colorectal cancer who had failed fluorouracil-based therapy. It is now approved as first-line therapy when used in combination with 5-FU and leucovorin, and this combination is known as FOLFIRI. Myelosuppression and diarrhea are the two most common adverse events (Table 54–4). There are two forms of diarrhea: an early form that occurs within 24 hours after administration and is thought to be a cholinergic event effectively treated with atropine, and a late form that usually occurs 2–10 days after treatment. The late diarrhea can be severe, leading to significant electrolyte imbalance and dehydration in some cases.

Liposomal irinotecan is approved in combination with 5-FU and leucovorin for the treatment of metastatic adenocarcinoma of the pancreas after disease progression following gemcitabine-based

therapy. The main adverse effects associated with the liposomal formulation are myelosuppression and GI toxicity with diarrhea and nausea and vomiting. Relatively little is known about the clinical pharmacology and metabolism of this liposomal formulation of irinotecan.

ANTITUMOR ANTIBIOTICS

Screening of microbial products led to the discovery of a number of growth-inhibiting compounds that have proved to be clinically useful in cancer chemotherapy. Many of these antibiotics bind to DNA through intercalation between specific bases and block the synthesis of RNA, DNA, or both; cause DNA strand scission; and interfere with cell replication. All of the anti-cancer antibiotics now being used in clinical practice are products of various strains of the soil microbe *Streptomyces*. These include the anthracyclines, bleomycin, and mitomycin.

ANTHRACYCLINES

The anthracycline antibiotics, isolated from *Streptomyces peucetius* var *caesius*, are among the most widely used cytotoxic anti-cancer drugs. The structures of the two original anthracyclines, doxorubicin and daunorubicin, are shown below. Several other anthracycline analogs have entered clinical practice, including idarubicin, epirubicin, and mitoxantrone. The anthracyclines exert their cytotoxic action through four major mechanisms: (1) inhibition of topoisomerase II; (2) generation of semiquinone free radicals and oxygen free radicals through an iron-dependent, enzyme-mediated reductive process; (3) high-affinity binding to DNA through intercalation, with consequent blockade of the synthesis of DNA and RNA, and DNA strand scission; and (4) binding to cellular membranes to alter fluidity and ion transport. While the precise mechanisms by which the anthracyclines exert their cytotoxic effects remain to be defined in particular tumors, the free radical mechanism is well-established to be the cause of the cardiotoxicity associated with the anthracyclines (Table 54–4).

Anthracyclines are administered via the intravenous route. They are metabolized extensively in the liver, with reduction and hydrolysis of the ring substituents. The hydroxylated metabolite is an active species, whereas the aglycone is inactive. Up to 50%

of drug is eliminated in the feces via biliary excretion, and dose reduction is required in patients with liver dysfunction. Although anthracyclines are usually administered on an every-3-week schedule, alternative schedules such as low-dose weekly or 72- to 96-hour continuous infusions have been shown to yield equivalent clinical efficacy with reduced toxicity.

Doxorubicin is one of the most important anti-cancer drugs in clinical practice, with major clinical activity in cancers of the breast, endometrium, ovary, testicle, thyroid, stomach, bladder, liver, and lung; in soft tissue sarcomas; and in several childhood cancers, including neuroblastoma, Ewing's sarcoma, osteosarcoma, and rhabdomyosarcoma. It also has clinical activity in hematologic malignancies, including acute lymphoblastic leukemia, multiple myeloma, and Hodgkin's and non-Hodgkin's lymphomas. It is generally used in combination with other anti-cancer agents (eg, cyclophosphamide, cisplatin, and 5-FU), and clinical activity is improved with combination regimens as opposed to single-agent therapy.

Daunorubicin was the first agent in this class to be isolated, and it is still used in the treatment of acute myeloid leukemia. In contrast to doxorubicin, its efficacy in solid tumors is limited.

Idarubicin is a semisynthetic anthracycline glycoside analog of daunorubicin, and it is approved for use in combination with cytarabine for induction therapy of acute myeloid leukemia. When combined with cytarabine, idarubicin appears to be more active than daunorubicin in producing complete remissions and in improving survival in patients with acute myelogenous leukemia.

Epirubicin is an anthracycline analog whose mechanism of action and clinical pharmacology are identical to those of all other anthracyclines. It was initially approved for use as a component of adjuvant therapy in early-stage, node-positive breast cancer but is also used in the treatment of metastatic breast cancer and gastroesophageal cancer.

Mitoxantrone (dihydroxyanthracenedione) is an anthracene compound whose structure resembles the anthracycline ring. It binds to DNA to produce strand breakage and inhibits both DNA and RNA synthesis. It is currently used in the treatment of advanced, hormone-refractory prostate cancer and low-grade non-Hodgkin's lymphoma. It is also indicated in breast cancer and in pediatric and adult acute myeloid leukemias. Myelosuppression with leukopenia is the dose-limiting toxicity, and mild nausea and vomiting, mucositis, and alopecia also occur. Although the drug is thought to be less cardiotoxic than doxorubicin, both acute and chronic cardiac toxicities are observed. A blue discoloration of the fingernails, sclera, and urine is observed 1–2 days after drug administration.

The main dose-limiting toxicity of all anthracyclines is myelosuppression, with neutropenia more commonly observed than thrombocytopenia. In some cases, mucositis is dose-limiting. Two forms of cardiotoxicity are observed. The acute form occurs within the first 2–3 days and presents as arrhythmias and conduction abnormalities, other electrocardiographic changes, pericarditis, and myocarditis. This form is usually transient and in most cases is asymptomatic. The chronic form is a dose-dependent, dilated cardiomyopathy associated with heart failure. The chronic cardiac toxicity appears to result from increased production of oxygen free

radicals within the myocardium. This effect is rarely seen at total doxorubicin dosages below 400–450 mg/m². Use of lower weekly doses or continuous infusions of doxorubicin appear to reduce the incidence of cardiac toxicity. In addition, treatment with the iron-chelating agent **dexrazoxane** (ICRF-187) is currently approved to prevent or reduce anthracycline-induced cardiotoxicity in women with metastatic breast cancer who have received a total cumulative dose of doxorubicin of 300 mg/m². The anthracyclines can also produce a “radiation recall reaction,” with erythema and desquamation of the skin observed at sites of prior radiation therapy.

MITOMYCIN

Mitomycin (mitomycin C) is an antibiotic isolated from *Streptomyces caespitosus*. It undergoes metabolic activation through an enzyme-mediated reduction to generate an alkylating agent that cross-links DNA. Hypoxic tumor stem cells of solid tumors exist in an environment conducive to reductive reactions and are more sensitive to the cytotoxic effects of mitomycin than normal cells and oxygenated tumor cells. This agent is active in all phases of the cell cycle and is the best available drug for use in combination with radiation therapy to attack hypoxic tumor cells. Its clinical use is mainly limited to the treatment of squamous cell cancer of the anus in combination with 5-FU and radiation therapy. One special application of mitomycin has been in the intravesical treatment of superficial bladder cancer. Because virtually none of the agent is absorbed, there is little to no systemic toxicity when used in this way.

The common adverse events of mitomycin are outlined in Table 54–4. Hemolytic-uremic syndrome, manifested as microangiopathic hemolytic anemia, thrombocytopenia, and renal failure, as well as occasional instances of interstitial pneumonitis have been reported.

BLEOMYCIN

Bleomycin is a small peptide that contains a DNA-binding region and an iron-binding domain at opposite ends of the molecule. It acts by binding to DNA, which results in single- and double-strand breaks following free radical formation, and inhibition of DNA biosynthesis. The fragmentation of DNA is due to oxidation of a DNA-bleomycin-Fe(II) complex and leads to chromosomal aberrations. Bleomycin is a cell cycle-specific drug that causes accumulation of cells in the G₂ phase of the cell cycle.

Bleomycin is indicated for the treatment of Hodgkin's and non-Hodgkin's lymphomas, germ cell tumor, head and neck cancer, and squamous cell cancer of the skin, cervix, and vulva. One advantage of this agent is that it can be administered subcutaneously, intramuscularly, or intravenously. Elimination of bleomycin is mainly via renal excretion, and dose modification is recommended in patients with renal dysfunction.

Pulmonary toxicity is dose-limiting for bleomycin and usually presents as pneumonitis with cough, dyspnea, dry inspiratory crackles on physical examination, and infiltrates on chest x-ray.

The incidence of pulmonary toxicity is increased in patients older than 70 years of age, in those who receive cumulative doses greater than 400 units, in those with underlying pulmonary disease, and in those who have received prior mediastinal or chest irradiation. In rare cases, pulmonary toxicity can be fatal. Other toxicities are listed in Table 54–4.

MISCELLANEOUS ANTI-CANCER DRUGS

A large number of anti-cancer drugs that do not fit traditional categories have been approved for clinical use; they are listed in Table 54–5.

TABLE 54–5 Miscellaneous anti-cancer drugs: Clinical activity and toxicities.

Drug	Mechanism of Action ¹	Clinical Applications ¹	Acute Toxicity	Delayed Toxicity
Bortezomib	Inhibitor of the 26S proteasome; results in down-regulation of the NF-κB signaling pathway	Multiple myeloma, mantle cell lymphoma	Nausea and vomiting, fever	Peripheral sensory neuropathy, diarrhea, orthostatic hypotension, fever, pulmonary toxicity, reversible posterior leukoencephalopathy (RPLS), congestive heart failure (CHF), rare cases of QT prolongation
Carfilzomib	Inhibitor of the 26S proteasome; results in down-regulation of the NF-κB signaling pathway; maintains activity in bortezomib-resistant tumors	Multiple myeloma	Fever	Fatigue, cardiac toxicity with CHF and myocardial infarction, myelosuppression, pulmonary toxicity, hepatotoxicity, orthostatic hypotension
Erlotinib	Inhibits EGFR tyrosine kinase leading to inhibition of EGFR signaling	Non-small cell lung cancer, pancreatic cancer	Diarrhea	Skin rash, diarrhea, anorexia, interstitial lung disease
Imatinib	Inhibits Bcr-Abl tyrosine kinase and other receptor tyrosine kinases, including PDGFR, and c-kit	CML, gastrointestinal stromal tumor (GIST), Philadelphia chromosome-positive ALL	Nausea and vomiting	Fluid retention with ankle and periorbital edema, diarrhea, myalgias, congestive heart failure
Bosutinib	Inhibits Bcr-Abl tyrosine kinase and retains activity in imatinib-resistant Bcr-Abl mutations except for the T315I and V299L mutations. Inhibits Src family tyrosine kinases.	CML	Nausea and vomiting	Diarrhea, fluid retention, myelosuppression, skin rash hepatotoxicity
Cetuximab	Binds to EGFR and inhibits downstream EGFR signaling; enhances response to chemotherapy and radiotherapy	Colorectal cancer, head and neck cancer (used in combination with radiotherapy), non-small cell lung cancer	Infusion reaction	Skin rash, hypomagnesemia, fatigue, interstitial lung disease
Panitumumab	Binds to EGFR and inhibits downstream EGFR signaling; enhances response to chemotherapy and radiotherapy	Colorectal cancer	Infusion reaction (rarely)	Skin rash, hypomagnesemia, fatigue, interstitial lung disease
Bevacizumab	Inhibits binding of VEGF-A to VEGFR leading to inhibition of VEGF signaling; inhibits tumor vascular permeability; enhances tumor blood flow and drug delivery	Colorectal cancer, breast cancer, non-small cell lung cancer, renal cell cancer, glioblastoma multiformae	Hypertension, infusion reaction	Arterial thromboembolic events, gastrointestinal perforations, wound healing complications, bleeding complications, proteinuria
Ziv-aflibercept	Inhibits binding of VEGF-A, VEGF-B, and PlGF to VEGFR leading to inhibition of VEGF signaling; inhibits tumor vascular permeability; enhances tumor blood flow and drug delivery	Colorectal cancer	Hypertension	Arterial thromboembolic events, gastrointestinal perforations, wound healing complications, bleeding complications, diarrhea, mucositis, proteinuria
Sorafenib	Inhibits multiple RTKs, including raf kinase, VEGF-R2, VEGF-R3, and PDGFR-β leading to inhibition of angiogenesis, invasion, and metastasis	Renal cell cancer, hepatocellular cancer	Nausea, hypertension	Skin rash, fatigue and asthenia, bleeding complications, hypophosphatemia
Sunitinib, pazopanib	Inhibits multiple RTKs, including VEGF-R1, VEGF-R2, VEGF-R3, PDGFR-α and PDGFR-β leading to inhibition of angiogenesis, invasion, and metastasis	Renal cell cancer, GIST	Hypertension	Skin rash, fatigue and asthenia, bleeding complications, cardiac toxicity leading to congestive heart failure in rare cases

¹See text for acronyms.

IMATINIB & OTHER TYROSINE KINASE INHIBITORS (TKIs)

Imatinib is an inhibitor of the tyrosine kinase domain of the Bcr-Abl oncoprotein and prevents phosphorylation of the kinase substrate by ATP. It is indicated for the treatment of chronic myelogenous leukemia (CML), a pluripotent hematopoietic stem cell disorder characterized by the t(9;22) Philadelphia chromosomal translocation. This translocation results in the Bcr-Abl fusion protein, the causative agent in CML, and is present in up to 95% of patients with this disease. This agent also inhibits other receptor tyrosine kinases for platelet-derived growth factor receptor (PDGFR), and c-kit.

Imatinib is well absorbed orally, and it is metabolized in the liver, with elimination of metabolites occurring mainly in feces via biliary excretion. This agent is approved for use as first-line therapy in chronic phase CML, in blast crisis, and as second-line therapy for chronic phase CML that has progressed on prior IFN- α therapy. Imatinib is also effective in the treatment of gastrointestinal stromal tumors (GIST) expressing the c-kit tyrosine kinase. The main adverse effects are listed in Table 54–5.

Dasatinib is an oral inhibitor of several tyrosine kinases, including Bcr-Abl, Src, c-kit, and PDGFR- α . It differs from imatinib in that it binds to the active and inactive conformations of the Abl kinase domain and overcomes imatinib resistance resulting from mutations in the Bcr-Abl kinase. It is approved for use in CML and Philadelphia chromosome-positive (Ph+) acute lymphoblastic leukemia (ALL) with resistance or intolerance to imatinib therapy.

Nilotinib is a second-generation phenylamino-pyrimidine molecule that inhibits Bcr-Abl, c-kit, and PDGFR- β tyrosine kinases. It has a higher binding affinity (up to 20- to 50-fold) for the Abl kinase when compared with imatinib, and it overcomes imatinib resistance resulting from Bcr-Abl mutations. It was originally approved for chronic phase and accelerated phase CML with resistance or intolerance to prior therapy that included imatinib and was recently approved as first-line therapy of chronic phase CML.

Bosutinib is a potent inhibitor of the Bcr-Abl tyrosine kinase, and it retains activity in 16 of 18 imatinib-resistant Bcr-Abl mutations. However, it is not effective against T315I and V299L mutations, which reside within the ATP-binding domain of the Abl tyrosine kinase. It is currently approved for the treatment of adult patients with chronic, accelerated, or blast phase Ph chromosome-positive CML with resistance or intolerance to prior therapy.

Ponatinib is a potent inhibitor of the Bcr-Abl tyrosine kinase, and it inhibits all known mutant forms of BCR-ABL, including the gatekeeper mutation T315I. It inhibits other kinases, including members of VEGF-R, PDGF, FGF, Flt3, TIE-2, Src family kinases, Kit, TET, and EPH. This agent is currently FDA-approved for adult patients with chronic, accelerated, or blast phase CML that is resistant or intolerant to prior TKI therapy and also approved for Ph+ ALL that is resistant or intolerant to prior TKI therapy.

Imatinib and the other TKIs are metabolized in the liver, mainly by the CYP3A4 liver microsomal enzymes and then

eliminated in feces via the hepatobiliary route. It is also important to review the patient's current list of prescription and nonprescription drugs because these agents have potential drug-drug interactions, especially with those that are also metabolized by the CYP3A4 system. In addition, patients should avoid grapefruit products, starfruit, and pomelos, as they may inhibit the metabolism of these small molecule inhibitors, leading to increased drug levels and toxicity (see Chapter 4).

GROWTH FACTOR RECEPTOR INHIBITORS

Cetuximab, Panitumumab, & Nectinumab

The epidermal growth factor receptor (EGFR) is a member of the erb-B family of growth factor receptors, and it is overexpressed in a number of solid tumors, including colorectal cancer, head and neck cancer, NSCLC, and pancreatic cancer. Activation of the EGFR signaling pathway results in downstream activation of several key cellular events involved in cellular growth and proliferation, invasion and metastasis, and angiogenesis. In addition, this pathway inhibits the cytotoxic activity of various anti-cancer agents and radiation therapy, presumably through suppression of key apoptotic mechanisms, thereby leading to the development of cellular drug resistance.

Cetuximab is a chimeric monoclonal antibody directed against the extracellular domain of the EGFR, and it is presently approved for use in combination with irinotecan for metastatic colon cancer in the refractory setting or as monotherapy in patients who are deemed to be irinotecan-refractory. Because cetuximab is of the G₁ isotype, its antitumor activity may also be mediated, in part, by immunologic-mediated mechanisms. There is growing evidence that cetuximab can be effectively and safely combined with irinotecan- and oxaliplatin-based chemotherapy in the first-line treatment of metastatic colorectal cancer as well. Of note, the efficacy of cetuximab is restricted to only those patients whose tumors express the wild-type *RAS* gene, which includes both *KRAS* and *NRAS*. Combination regimens of cetuximab with cytotoxic chemotherapy may be of particular benefit in the neoadjuvant therapy of patients with liver-limited disease. Although this antibody was initially approved to be administered on a weekly schedule, pharmacokinetic studies have shown that an every-2-week schedule provides the same level of clinical activity as the weekly schedule. This agent is also approved for use in combination with radiation therapy in patients with locally advanced head and neck cancer. Cetuximab is well tolerated, with the main adverse effects being an acneiform skin rash, hypersensitivity infusion reaction, and hypomagnesemia. However, when cetuximab is combined with radiation therapy for head and neck cancer, there is a very low but real increased risk (1%) of sudden death, which has resulted in a black-box warning for the drug.

Panitumumab is a fully human monoclonal antibody directed against the EGFR and works through inhibition of the EGFR signaling pathway. In contrast to cetuximab, this antibody is

of the G₂ isotype and, as such, would not be expected to exert any immunologic-mediated effects. Panitumumab was originally approved for patients with refractory metastatic CRC who have been treated with all other active agents. However, it is now also approved for use in combination with FOLFOX chemotherapy in the front-line treatment of metastatic CRC. As with cetuximab, this antibody is only effective in patients whose tumors express wild-type *RAS*. Recent clinical studies have shown that this antibody can also be effectively and safely combined with irinotecan-based chemotherapy in the second-line treatment of metastatic CRC. Acneiform skin rash and hypomagnesemia are the two main adverse effects associated with its use. Despite being a fully human antibody, infusion-related reactions can still be observed, although much less commonly than cetuximab.

Necitumumab is a fully human IgG1 monoclonal antibody directed against EGFR. Like cetuximab and panitumumab, it works through inhibition of the EGFR signaling pathway. However, as with cetuximab, necitumumab is of the G₁ isotype, and as such, its antitumor activity may also be mediated, at least in part, through immunologically mediated mechanisms. It is approved for use in combination with gemcitabine and cisplatin chemotherapy for the treatment of squamous NSCLC. The main adverse effects are what have been previously described for other anti-EGFR antibodies, and both venothrombotic and arterioembolic events have also been described.

Erlotinib

Erlotinib is a small molecule inhibitor of the tyrosine kinase domain associated with the EGFR. It is now approved as first-line treatment of metastatic NSCLC in patients whose tumors have EGFR exon 19 deletions or exon 21 (L858R) mutations and are refractory to at least one prior chemotherapy regimen. It is also approved for maintenance therapy of patients with metastatic NSCLC whose disease has not progressed after four cycles of platinum-based chemotherapy. Patients who are nonsmokers and who have a bronchoalveolar histologic subtype appear to be more responsive to these agents. In addition, erlotinib has been approved for use in combination with gemcitabine for the treatment of advanced pancreatic cancer. It is metabolized in the liver by the CYP3A4 enzyme system, and elimination is mainly hepatic with excretion in feces. Caution must be taken when using these agents with drugs that also are metabolized by the liver CYP3A4 system, such as phenytoin and warfarin, and the use of grapefruit products should be avoided. An acneiform skin rash, diarrhea, and anorexia and fatigue are the most common adverse effects observed with these small molecules (Table 54–5).

Afatinib is a small molecule inhibitor of the tyrosine kinase domains associated with EGFR, HER2 and HER4, and causes inhibition of downstream ErbB signaling. It is approved for the first-line treatment of metastatic NSCLC with EGFR exon 19 deletions or exon 21 substitution mutations. The toxicities associated with this agent are similar to those seen with erlotinib.

Osimertinib is a small molecule inhibitor approved in 2015 for the treatment of metastatic EGFR T790M mutant NSCLC following progression on or after EGFR tyrosine kinase inhibitor therapy. In addition to targeting the T790M mutant, this agent

targets the L858R and exon 19 EGFR mutations. The adverse effect profile is similar to erlotinib and afatinib, but unique cardiac toxicities are associated with this agent, including QT_c prolongation and cardiomyopathy.

Bevacizumab, Ziv-Aflibercept, Ramucirumab, Sorafenib, Sunitinib, & Pazopanib

Vascular endothelial growth factor (VEGF) is one of the most important angiogenic growth factors. The growth of both primary and metastatic solid tumors requires an intact vasculature; thus the VEGF signaling pathway represents an attractive target for chemotherapy. Several approaches have been taken to inhibit VEGF signaling; they include inhibition of VEGF interactions with its receptor by targeting either the VEGF ligand with antibodies or soluble chimeric decoy receptors, or by direct inhibition of VEGF receptor-associated tyrosine kinase activity by small molecule inhibitors.

Bevacizumab is a recombinant humanized monoclonal antibody that targets all forms of VEGF-A. This antibody binds to and prevents VEGF-A from interacting with the target VEGF receptors. Bevacizumab can be safely and effectively combined with 5-FU-, irinotecan-, and oxaliplatin-based chemotherapy in the treatment of metastatic colorectal cancer. Bevacizumab is FDA approved as a first-line treatment for metastatic colorectal cancer in combination with any intravenous fluoropyrimidine-containing regimen and is now also approved in combination with chemotherapy for metastatic NSCLC and breast cancer. One potential advantage of this antibody is that it does not appear to exacerbate the toxicities typically observed with cytotoxic chemotherapy. The main safety concerns associated with bevacizumab include hypertension, an increased incidence of arterial thromboembolic events (transient ischemic attack, stroke, angina, and myocardial infarction), wound healing complications, gastrointestinal perforations, and proteinuria.

Ziv-aflibercept is a recombinant fusion protein made up of portions of the extracellular domains of human VEGF receptors (VEGFR) 1 and 2 fused to the Fc portion of the human IgG1 molecule. This molecule serves as a soluble receptor to VEGF-A, VEGF-B, and placental growth factor (PlGF), and it binds with significantly higher affinity to VEGF-A than bevacizumab. Presumably, binding of the VEGF ligands prevents their subsequent interactions with the target VEGF receptors, which then results in inhibition of downstream VEGFR signaling. This agent is FDA-approved in combination with the FOLFIRI regimen for patients with metastatic colorectal cancer that has progressed on oxaliplatin-based chemotherapy. The main adverse effects are similar to what has been observed with bevacizumab.

Ramucirumab is an IgG1 antibody that targets the VEGFR2 receptor. This agent inhibits binding of the VEGF ligands, VEGF-A, VEGF-C, and VEGF-D, to the target VEGFR2 receptor, which then results in inhibition of downstream VEGFR signaling. This agent is now FDA-approved for advanced gastric or gastroesophageal junction adenocarcinoma, metastatic NSCLC, and metastatic CRC. The main adverse events are similar to those observed with bevacizumab and other anti-VEGF inhibitors.

Sorafenib is a small molecule that inhibits multiple receptor tyrosine kinases (RTKs), especially VEGF-R2 and VEGF-R3, platelet-derived growth factor- β (PDGFR- β), and raf kinase. It was initially approved for advanced renal cell cancer and is also approved for advanced hepatocellular cancer.

Sunitinib is similar to sorafenib in that it inhibits multiple RTKs, although the specific types are somewhat different. They include PDGFR- α and PDGFR- β , VEGF-R1, VEGF-R2, VEGF-R3, and c-kit. It is approved for the treatment of advanced renal cell cancer and for the treatment of gastrointestinal stromal tumors after disease progression on or with intolerance to imatinib.

Pazopanib is a small molecule that inhibits multiple RTKs, especially VEGF-R2 and VEGF-R3, PDGFR- β , and raf kinase. This oral agent is approved for the treatment of advanced renal cell cancer.

Sorafenib, sunitinib, and pazopanib are metabolized in the liver by the CYP3A4 system, and elimination is primarily hepatic with excretion in feces. Therefore, each of these agents has potential interactions with drugs that are also metabolized by the CYP3A4 system, especially warfarin. In addition, patients should avoid grapefruit products, starfruit, pomelos, and St. John's Wort, as they may alter the metabolism of these agents. Hypertension, bleeding complications, and fatigue are the most common adverse effects seen with these drugs. With respect to sorafenib, skin rash and the hand-foot syndrome are observed in up to 30–50% of patients. For sunitinib, there is also an increased risk of cardiac dysfunction, which in some cases can lead to congestive heart failure.

■ CLINICAL PHARMACOLOGY OF CANCER CHEMOTHERAPEUTIC DRUGS

The use of specific cytotoxic and biologic agents for each of the main cancers is discussed in the following sections.

THE LEUKEMIAS

ACUTE LEUKEMIA

Childhood Leukemia

Acute lymphoblastic leukemia (ALL) is the main form of leukemia in childhood, and it is the most common form of cancer in children. Children with this disease now have a relatively good prognosis. A subset of patients with neoplastic lymphocytes expressing surface antigenic features of T lymphocytes has a poor prognosis (see Chapter 55). A cytoplasmic enzyme expressed by normal thymocytes, terminal deoxycytidyl transferase (terminal transferase), is also expressed in many cases of ALL. T-cell ALL also expresses high levels of the enzyme adenosine deaminase (ADA). This led to interest in the use of the ADA inhibitor pentostatin (deoxycoformycin) for treatment of such T-cell cases. Until 1948, the median length of survival in ALL was 3 months. With the advent of methotrexate, the length of survival was greatly increased. Subsequently, corticosteroids, 6-mercaptopurine, cyclophosphamide, vincristine, daunorubicin, and asparaginase all

have been found to be active against this disease. A combination of vincristine and prednisone plus other agents is currently used to induce remission. More than 90% of children enter complete remission with this therapy with only minimal toxicity. However, circulating leukemic cells often migrate to sanctuary sites located in the brain and testes. The value of prophylactic intrathecal methotrexate therapy for prevention of central nervous system leukemia (a major mechanism of relapse) has been clearly demonstrated. Intrathecal therapy with methotrexate should therefore be considered as a standard component of the induction regimen for children with ALL.

Adult Leukemia

Acute myelogenous leukemia (AML) is the most common leukemia in adults. The single most active agent for AML is cytarabine; however, it is best used in combination with an anthracycline, which leads to complete remissions in about 70% of patients. While there are several anthracyclines that can be effectively combined with cytarabine, idarubicin is preferred.

Patients often require intensive supportive care during the period of induction chemotherapy. Such care includes platelet transfusions to prevent bleeding, the granulocyte colony-stimulating factor filgrastim to shorten periods of neutropenia, and antibiotics to combat infections. Younger patients (eg, age < 55) who are in complete remission and have an HLA-matched donor are candidates for allogeneic bone marrow transplantation. The transplant procedure is preceded by high-dose chemotherapy and total body irradiation followed by immunosuppression. This approach may cure up to 35–40% of eligible patients. Patients over age 60 respond less well to chemotherapy, primarily because their tolerance for aggressive therapy and resistance to infection are lower.

Once remission of AML is achieved, consolidation chemotherapy is required to maintain a durable remission and to induce cure.

CHRONIC MYELOGENOUS LEUKEMIA

Chronic myelogenous leukemia (CML) arises from a chromosomally abnormal hematopoietic stem cell in which a balanced translocation between the long arms of chromosomes 9 and 22, t(9;22), is observed in 90–95% of cases. This translocation results in constitutive expression of the Bcr-Abl fusion oncoprotein with a molecular weight of 210 kDa. The clinical symptoms and course are related to the white blood cell count and its rate of increase. Most patients with white cell counts greater than 50,000/ μ L should be treated. The goals of treatment are to reduce the granulocytes to normal levels, to raise the hemoglobin concentration to normal, and to relieve disease-related symptoms. The tyrosine kinase inhibitor imatinib is considered as standard first-line therapy in previously untreated patients with chronic phase CML. Nearly all patients treated with imatinib exhibit a complete hematologic response, and up to 40–50% of patients show a complete cytogenetic response. As described previously, this drug is generally well tolerated and is associated with relatively minor adverse effects. Initially, dasatinib and nilotinib were approved for patients

who were intolerant or resistant to imatinib; each shows clinical activity, and both are now also indicated as first-line treatment of chronic phase CML. In addition to these tyrosine kinase inhibitors, other treatment options include IFN- α , busulfan, other oral alkylating agents, and hydroxyurea.

CHRONIC LYMPHOCYTIC LEUKEMIA

Patients with early-stage chronic lymphocytic leukemia (CLL) have a relatively good prognosis, and therapy has not changed the course of the disease. However, in the setting of high-risk disease or in the presence of disease-related symptoms, treatment is indicated.

Chlorambucil and cyclophosphamide are the two most widely used alkylating agents for this disease. Chlorambucil is frequently combined with prednisone, although there is no clear evidence that the combination yields better response rates or survival compared with chlorambucil alone. In most cases, cyclophosphamide is combined with vincristine and prednisone (COP), or it can also be given with these same drugs along with doxorubicin (CHOP). Bendamustine is the newest alkylating agent to be approved for use in this disease, either as monotherapy or in combination with prednisone. The purine nucleoside analog fludarabine also is effective in treating CLL. This agent can be given alone, in combination with cyclophosphamide and with mitoxantrone and dexamethasone, or combined with **rituximab**. Monoclonal antibody targeted therapies are being widely used in CLL, especially in relapsed or refractory disease. Rituximab is an anti-CD20 antibody that has documented clinical activity in this setting. This chimeric antibody appears to enhance the antitumor effects of cytotoxic chemotherapy and is also effective in settings in which resistance to chemotherapy has developed. **Ofatumumab** is a fully human IgG1 antibody that binds to a different CD20 epitope than rituximab. Of note, it maintains activity in rituximab-resistant tumors, and it is presently approved for CLL that is refractory to fludarabine and alemtuzumab therapy.

HODGKIN'S & NON-HODGKIN'S LYMPHOMAS

HODGKIN'S LYMPHOMA

The treatment of Hodgkin's lymphoma has undergone dramatic evolution over the last 40 years. This lymphoma is now widely recognized as a B-cell neoplasm in which the malignant Reed-Sternberg cells have rearranged *VH* genes. In addition, the Epstein-Barr virus genome has been identified in up to 80% of tumor specimens.

Complete staging evaluation is required before a definitive treatment plan can be made. For patients with stage I and stage IIA disease, there has been a significant change in the treatment approach. Initially, these patients were treated with extended-field radiation therapy. However, given the well-documented late effects of radiation therapy, which include hypothyroidism, an increased risk of secondary cancers, and coronary artery disease, combined-modality therapy with a brief course of combination

chemotherapy and involved field radiation therapy is now the recommended approach. The main advance for patients with advanced stage III and IV Hodgkin's lymphoma came with the development of MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) chemotherapy in the 1960s. This regimen resulted initially in high complete response rates, on the order of 80–90%, with cures in up to 60% of patients. More recently, the anthracycline-containing regimen termed ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) has been shown to be more effective and less toxic than MOPP, especially with regard to the incidence of infertility and secondary malignancies. In general, four cycles of ABVD are given to patients. An alternative regimen, termed Stanford V, utilizes a 12-week course of combination chemotherapy (doxorubicin, vinblastine, mechlorethamine, vincristine, bleomycin, etoposide, and prednisone), followed by involved radiation therapy.

With all of these regimens, over 80% of previously untreated patients with advanced Hodgkin's lymphoma (stages III and IV) are expected to go into complete remission, with disappearance of all disease-related symptoms and objective evidence of disease. In general, approximately 50–60% of all patients with Hodgkin's lymphoma are cured of their disease.

NON-HODGKIN'S LYMPHOMA

Non-Hodgkin's lymphoma is a heterogeneous disease, and the clinical characteristics of non-Hodgkin's lymphoma subsets are related to the underlying histopathologic features and the extent of disease involvement. In general, the nodular (or follicular) lymphomas have a far better prognosis, with a median survival up to 7 years, compared with the diffuse lymphomas, which have a median survival of about 1–2 years.

Combination chemotherapy is the treatment standard for patients with diffuse non-Hodgkin's lymphoma. The anthracycline-containing regimen CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) has been considered the best treatment in terms of initial therapy. Randomized phase III clinical studies now have shown that the combination of CHOP with rituximab results in improved response rates, disease-free survival, and overall survival compared with CHOP chemotherapy alone.

The nodular follicular lymphomas are low-grade, relatively slow-growing tumors that tend to present in an advanced stage and are usually confined to lymph nodes, bone marrow, and spleen. This form of non-Hodgkin's lymphoma, when presenting at an advanced stage, is considered incurable, and treatment is generally palliative. To date, there is no evidence that immediate treatment with combination chemotherapy offers clinical benefit over close observation and “watchful waiting” with initiation of chemotherapy at the onset of disease symptoms.

MULTIPLE MYELOMA

This plasma cell malignancy is one of the models of neoplastic disease in humans, as it arises from a single tumor stem cell. Moreover, the tumor cells produce a marker protein (myeloma

immunoglobulin) that allows the total body burden of tumor cells to be quantified. Multiple myeloma principally involves the bone marrow and bone, causing bone pain, lytic lesions, bone fractures, and anemia as well as an increased susceptibility to infection.

Most patients with multiple myeloma are symptomatic at the time of initial diagnosis and require treatment with cytotoxic chemotherapy. Treatment with the combination of the alkylating agent melphalan and prednisone (MP protocol) has been a standard regimen for nearly 30 years. About 40% of patients respond to the MP combination, and the median duration of remission is 2–2.5 years.

In patients who are considered candidates for high-dose therapy with stem cell transplantation, melphalan and other alkylating agents are to be avoided, as they can affect the success of stem cell harvesting.

Thalidomide is a well-established agent for treating refractory or relapsed disease, and about 30% of patients will achieve a response to this therapy. More recently, thalidomide has been used in combination with dexamethasone, and response rates approaching 65% have been observed. Studies are now under way to directly compare the combination of vincristine, doxorubicin, and dexamethasone (VAD protocol) with the combination of thalidomide and dexamethasone. In some patients, especially those with poor performance status, single-agent pulse dexamethasone administered on a weekly basis can be effective in palliating symptoms. **Lenalidomide** and **pomalidomide** are two immunomodulatory analogs (IMiDs) of thalidomide. Lenalidomide is approved in combination with dexamethasone for multiple myeloma patients who have received at least one prior therapy, and clinical data show that this combination is effective as first-line therapy. Pomalidomide is the most recent IMiD to receive approval, and this drug may be able to overcome resistance to thalidomide and lenalidomide. The side-effect profiles of these IMiDs appear to be similar, although neurotoxicity is observed more commonly with thalidomide, somewhat less often with pomalidomide, and rarely with lenalidomide.

Bortezomib was first approved for use in relapsing or refractory multiple myeloma and is now widely used as first-line therapy. This agent is thought to exert its main cytotoxic effects through inhibition of the 26S proteasome, resulting in downregulation of the nuclear factor kappa B (NF- κ B) signaling pathway, which is thought to be a major signaling pathway for this disease. Of note, inhibition of NF- κ B has also been shown to restore chemosensitivity. One potential advantage of bortezomib is that it can be administered by the intravenous or subcutaneous route. **Carfilzomib** is an epoxyketone 26S proteasome inhibitor that is approved for patients with multiple myeloma who have received at least two prior therapies, including bortezomib and an immunomodulatory agent. This agent is important as it is able to overcome resistance to bortezomib, and preclinical and clinical studies suggest that it has broad-spectrum activity in hematologic malignancies and solid tumors. **Ixazomib** is the newest proteasome inhibitor to be approved in multiple myeloma, and in contrast to the other proteasome inhibitors, it is orally administered with good oral bioavailability. This agent can cause peripheral sensory neuropathy, but it is also associated with GI toxicity in the form of diarrhea and nausea and vomiting, thrombocytopenia, and hepatotoxicity.

BREAST CANCER

STAGE I & STAGE II DISEASE

The management of primary breast cancer has undergone a remarkable evolution as a result of major efforts at early diagnosis (through encouragement of self-examination as well as through the use of cancer detection centers) and the implementation of combined modality approaches incorporating systemic chemotherapy as an adjuvant to surgery and radiation therapy. Women with stage I disease (small primary tumors and negative axillary lymph node dissections) are currently treated with surgery alone, and they have an 80% chance of cure.

Women with node-positive disease have a high risk of both local and systemic recurrence. Thus, lymph node status directly indicates the risk of occult distant micrometastasis. In this situation, postoperative use of systemic adjuvant chemotherapy with six cycles of cyclophosphamide, methotrexate, and fluorouracil (CMF protocol) or of fluorouracil, doxorubicin, and cyclophosphamide (FAC) has been shown to significantly reduce the relapse rate and prolong survival. Alternative regimens with equivalent clinical benefit include four cycles of doxorubicin and cyclophosphamide and six cycles of fluorouracil, epirubicin, and cyclophosphamide (FEC). Each of these chemotherapy regimens has benefited women with stage II breast cancer with one to three involved lymph nodes. Women with four or more involved nodes have had limited benefit thus far from adjuvant chemotherapy. Long-term analysis has clearly shown improved survival rates in node-positive premenopausal women who have been treated aggressively with multiagent combination chemotherapy. The results from three randomized clinical trials clearly show that the addition of **trastuzumab**, a monoclonal antibody directed against the HER-2/*neu* receptor, to anthracycline- and taxane-containing adjuvant chemotherapy benefits women with HER-2-overexpressing breast cancer with respect to disease-free and overall survival.

Breast cancer was the first neoplasm shown to be responsive to hormonal manipulation. **Tamoxifen** is beneficial in postmenopausal women when used alone or in combination with cytotoxic chemotherapy. The present recommendation is to administer tamoxifen for 5 years of continuous therapy after surgical resection. Longer durations of tamoxifen therapy do not appear to offer additional clinical benefit. Postmenopausal women who complete 5 years of tamoxifen therapy should be placed on an aromatase inhibitor such as **anastrozole** for at least 2.5 years, although the optimal duration is unknown. In women who have completed 2–3 years of tamoxifen therapy, treatment with an aromatase inhibitor for a total of 5 years of hormonal therapy is now recommended (see Chapter 40).

Results from several randomized trials for breast cancer have established that adjuvant chemotherapy for premenopausal women and adjuvant tamoxifen for postmenopausal women are of benefit to women with stage I (node-negative) breast cancer. While this group of patients has the lowest overall risk of recurrence after surgery alone (about 35–50% over 15 years), this risk can be further reduced with adjuvant therapy.

STAGE III & STAGE IV DISEASE

The approach to women with advanced breast cancer remains a major challenge, as current treatment options are only palliative. Combination chemotherapy, endocrine therapy, or a combination of both results in overall response rates of 40–50%, but only a 10–20% complete response rate. Breast cancers expressing estrogen receptors (ER) or progesterone receptors (PR) retain the intrinsic hormonal sensitivities of the normal breast—including the growth-stimulatory response to ovarian, adrenal, and pituitary hormones. Patients who show improvement with hormonal ablative procedures also respond to the addition of tamoxifen. The aromatase inhibitors anastrozole and letrozole are now approved as first-line therapy in women with advanced breast cancer whose tumors are hormone receptor–positive. In addition, these agents and exemestane are approved as second-line therapy following treatment with tamoxifen.

Patients with significant involvement of the lung, liver, or brain and those with rapidly progressive disease rarely benefit from hormonal maneuvers, and initial systemic chemotherapy is indicated in such cases. For the 25–30% of breast cancer patients whose tumors express the HER-2/*neu* cell surface receptor, trastuzumab, is available for therapeutic use alone or in combination with cytotoxic chemotherapy. Other agents that target HER-2/*neu* signaling include pertuzumab, ado-trastuzumab emtansine, and the small molecule lapatinib. **Pertuzumab** is a humanized IgG1 antibody that targets a different epitope on the HER-2/*neu* receptor than trastuzumab, and this antibody inhibits heterodimerization of HER2 with other HER family members, including EGFR, HER3, and HER4. This drug is used in combination with trastuzumab and docetaxel for HER2-positive metastatic breast cancer in patients who have not previously received anti-HER chemotherapy for metastatic disease. **Ado-trastuzumab emtansine** is an antibody-drug conjugate composed of trastuzumab and the small molecule microtubule inhibitor DM1; it is approved for women with HER2-positive metastatic breast cancer who have received prior therapy with trastuzumab and taxane-based chemotherapy. Finally, **lapatinib** is a small molecule inhibitor of the tyrosine kinases associated with EGFR (ErbB1) and HER2 (ErbB2), resulting in inhibition of downstream signaling. This agent is used in combination with the oral fluoropyrimidine capecitabine for metastatic breast cancer whose tumors overexpress HER2 and who have received prior therapy with an anthracycline, a taxane, and trastuzumab.

About 50–60% of patients with metastatic disease respond to initial chemotherapy. A broad range of anti-cancer agents have activity in this disease, including the anthracyclines (doxorubicin, mitoxantrone, and epirubicin) and the taxanes (docetaxel, paclitaxel, and albumin-bound paclitaxel), along with the microtubule inhibitor ixabepilone, navelbine, capecitabine, gemcitabine, cyclophosphamide, methotrexate, and cisplatin. The anthracyclines and the taxanes are two of the most active classes of cytotoxic drugs. Combination chemotherapy has been found to induce higher and more durable remissions in up to 50–80% of patients, and anthracycline-containing regimens are now considered the standard of care in first-line therapy. With most combination

regimens, partial remissions have a median duration of about 10 months and complete remissions have a duration of about 15 months. Unfortunately, only 10–20% of patients achieve complete remissions with any of these regimens, and as noted, complete remissions are usually not long-lasting.

PROSTATE CANCER

Prostate cancer was the second cancer shown to be responsive to hormonal manipulation. The treatment of choice for patients with metastatic prostate cancer is elimination of testosterone production by the testes through either surgical or chemical castration. Bilateral orchiectomy or estrogen therapy in the form of diethylstilbestrol was previously used as first-line therapy. Presently, the use of luteinizing hormone-releasing hormone (LHRH) agonists—including **leuprolide** and **goserelin** agonists, alone or in combination with an antiandrogen (eg, **flutamide**, **bicalutamide**, or **nilutamide**)—is the preferred approach (see Chapter 40). There appears to be no survival advantage of total androgen blockade using a combination of LHRH agonist and antiandrogen agent compared with single-agent therapy. **Abiraterone**, an inhibitor of steroid synthesis (see Chapter 39), has recently been approved. Hormonal treatment reduces symptoms—especially bone pain—in 70–80% of patients and may cause a significant reduction in the prostate-specific antigen (PSA) level, which is now widely accepted as a surrogate marker for response to treatment in prostate cancer. Although initial hormonal manipulation is able to control symptoms for up to 2 years, patients usually develop progressive disease. Second-line hormonal therapies include aminoglutethimide plus hydrocortisone, the antifungal agent ketoconazole plus hydrocortisone, or hydrocortisone alone.

Unfortunately, nearly all patients with advanced prostate cancer eventually become refractory to hormone therapy. A regimen of mitoxantrone and prednisone is approved in patients with hormone-refractory prostate cancer because it provides effective palliation in those who experience significant bone pain. **Estramustine** is an antimicrotubule agent that produces an almost 20% response rate as a single agent. However, when used in combination with either etoposide or a taxane such as docetaxel or paclitaxel, response rates are more than doubled to 40–50%. The combination of docetaxel and prednisone was recently shown to confer survival advantage when compared with the mitoxantrone-prednisone regimen, and this combination has now become the standard of care for hormone-refractory prostate cancer.

GASTROINTESTINAL CANCERS

Colorectal cancer (CRC) is the most common type of gastrointestinal malignancy. Nearly 150,000 new cases are diagnosed each year in the USA; worldwide, nearly 1.2 million cases are diagnosed annually. At the time of initial presentation, only about 40–45% of patients are potentially curable with surgery. Patients presenting with high-risk stage II disease and stage III disease are candidates for adjuvant chemotherapy with an oxaliplatin-based regimen in combination with 5-FU plus leucovorin (FOLFOX) or with oral

capecitabine (XELOX) and are generally treated for 6 months following surgical resection. Treatment with this combination regimen reduces the recurrence rate after surgery by 35% and clearly improves overall patient survival compared with surgery alone.

Significant advances have been made over the past 10 years with respect to treatment of metastatic CRC. Five active cytotoxic agents have been approved during this time period—5-FU, the oral fluoropyrimidine analogs capecitabine and TAS-102, oxaliplatin, and irinotecan. In addition, 5 novel biologic agents and one small molecule inhibitor have been approved, including the anti-VEGF antibody bevacizumab; the recombinant fusion protein ziv-aflibercept, which targets VEGF-A, VEGF-B, and PlGF; the anti-VEGF-R2 antibody ramucirumab, which inhibits binding of the VEGF ligands VEGF-A, VEGF-C, and VEGF-D; the two anti-EGFR antibodies cetuximab and panitumumab; and the small molecule TKI inhibitor regorafenib. In general, a fluoropyrimidine—either intravenous 5-FU or oral capecitabine—serves as the main foundation of cytotoxic chemotherapy regimens. Recent clinical studies have shown that in tumors with wild-type *KRAS* and *NRAS*, FOLFOX/FOLFIRI regimens in combination with the anti-VEGF antibody bevacizumab or with the anti-EGFR antibody cetuximab or panitumumab result in significantly improved clinical efficacy with no worsening of the toxicities normally observed with chemotherapy. In order for patients to derive maximal benefit, they should be treated with each of these active agents in a continuum of care approach. Regorafenib and TAS-102 are approved for the chemo-refractory disease setting, but unfortunately, each drug is associated with significant toxicities and only limited clinical efficacy with very low overall response rates; median progression-free survival is about 2-months. Given all of the available treatment regimens, median overall survival for metastatic CRC is now in the 28- to 30-month range and, in some cases, approaches or even exceeds 3 years.

The incidence of gastric cancer, esophageal cancer, and pancreatic cancer is much lower than for CRC, but these malignancies tend to be more aggressive and result in greater tumor-related symptoms. In most cases, they cannot be completely resected surgically, as most patients present with either locally advanced or metastatic disease at the time of their initial diagnosis. 5-FU-based chemotherapy, using either intravenous 5-FU or oral capecitabine, is generally considered the main backbone for regimens targeting gastroesophageal cancers. In addition, cisplatin-based regimens in combination with either irinotecan or one of the taxanes (paclitaxel or docetaxel) also exhibit clinical activity. Response rates in the 40–50% range are now being reported. The addition of the biologic agent trastuzumab to cisplatin-containing chemotherapy regimens provides significant clinical benefit in metastatic gastric cancer patients whose tumors overexpress the HER-2/*neu* receptor. At present, the optimal fluoropyrimidine backbone has not been established, and either infused 5-FU or oral capecitabine can be combined with cisplatin plus trastuzumab. For second-line therapy, the combination of ramucirumab plus paclitaxel is recommended for patients with a good performance status and favorable comorbidity profile. In patients who are unable to tolerate more intensive therapy, single-agent ramucirumab or paclitaxel monotherapy are more appropriate treatment options.

Although gemcitabine is approved for use as a single agent in metastatic pancreatic cancer, the overall response rate is low at less than 10%, with complete responses being exceedingly rare. Intense efforts have focused on incorporating gemcitabine into various combination regimens, and currently, the most commonly used regimen for the first-line treatment of metastatic pancreatic cancer is gemcitabine plus nanoparticle albumin-bound paclitaxel (nab-paclitaxel [Abraxane]). In patients who are able to tolerate a more aggressive approach, the FOLFIRINOX regimen, which includes intravenous 5-FU, irinotecan, and oxaliplatin, has become a widely used therapy. Single-agent irinotecan or liposomal irinotecan in combination with intravenous 5-FU are appropriate treatment options in the second-line setting. In patients with early-stage pancreatic cancer who have undergone successful surgical resection, adjuvant chemotherapy with either single-agent gemcitabine or 5-FU/leucovorin is recommended.

Hepatocellular cancer (HCC) has been a relatively difficult tumor to treat as it frequently occurs in the context of chronic liver disease and cirrhosis. It is usually diagnosed late in the course of chronic liver disease, and a large majority of patients have underlying poor liver function and only limited hepatic reserve. In general, HCC is considered to be a chemotherapy-resistant disease, and palliative chemotherapy is usually not recommended as first-line therapy in patients with unresectable or advanced HCC. Single-agent sorafenib therapy is currently approved for advanced or unresectable HCC, and in patients who have progressed on front-line sorafenib therapy, the small molecule tyrosine kinase inhibitor regorafenib is recommended.

LUNG CANCERS

Lung cancer is divided into two main histopathologic subtypes, non-small cell and small cell. Non-small cell lung cancer (NSCLC) makes up about 75–80% of all cases of lung cancer, and this group includes adenocarcinoma, squamous cell cancer, and large cell cancer, while small cell lung cancer (SCLC) makes up the remaining 20–25%. When NSCLC is diagnosed in an advanced stage with metastatic disease, the prognosis is extremely poor, with a median survival of about 8 months. It is clear that prevention (primarily through avoidance of cigarette smoking) and early detection remain the most important means of control. When diagnosed at an early stage, surgical resection results in patient cure. Moreover, recent studies have shown that adjuvant platinum-based chemotherapy provides a survival benefit in patients with pathologic stage IB, II, and IIIA disease. However, in most cases, distant metastases have occurred at the time of diagnosis. In certain instances, radiation therapy can be offered for palliation of pain, airway obstruction, or bleeding and to treat patients whose performance status would not allow for more aggressive treatments.

In patients with advanced disease, systemic chemotherapy is generally recommended. Combination regimens that include a platinum agent (“platinum doublets”) appear superior to non-platinum doublets, and either cisplatin or carboplatin are appropriate platinum agents for such regimens. For the second drug, paclitaxel and vinorelbine appear to have activity

independent of histology, while the antifolate pemetrexed should be used for non-squamous cell cancer, and gemcitabine for squamous cell cancer. For patients with good performance status and those with non-squamous histology, the combination of the anti-VEGF antibody bevacizumab with carboplatin and paclitaxel is a standard treatment option. In patients deemed not to be appropriate candidates for bevacizumab therapy and those with squamous cell histology, a platinum-based chemotherapy regimen in combination with the anti-EGFR antibody cetuximab is a reasonable treatment strategy. Maintenance chemotherapy with pemetrexed is now used in patients with non-squamous NSCLC whose disease has remained stable after four cycles of platinum-based first-line chemotherapy.

Patients with advanced NSCLC should have molecular testing of their tumor. Patients whose tumors contain an actionable mutation should then receive a targeted therapy. For example, first-line therapy with erlotinib significantly improves outcomes in advanced NSCLC patients with sensitizing EGFR mutations, which include exon 19 deletions or exon 21 (L858R) substitution mutations. Afatinib is a small molecule inhibitor of EGFR, HER2, and HER4, and it is approved for the first-line treatment of metastatic NSCLC whose tumors have EGFR exon 19 deletions or exon 21 mutations. Osimertinib is approved for the treatment of metastatic EGFR T790M-mutant NSCLC following progression on or after EGFR TKI therapy. This small molecule is important as it is able to overcome the resistance that arises from the emergence of the T790M gatekeeper mutation either de novo or following previous EGFR TKI therapy. In NSCLC that is ALK-positive, three new small molecules have been developed: crizotinib, ceritinib, and alectinib. Crizotinib is the first-generation ALK inhibitor, while ceritinib and alectinib have clinical efficacy in patients whose disease has progressed on or who have become intolerant to crizotinib.

Squamous cell NSCLC makes up approximately 30% of NSCLC. This form of NSCLC is responsive to platinum-based chemotherapy with either cisplatin or carboplatin in combination with gemcitabine. Recent studies have shown superior clinical activity when cisplatin and gemcitabine are combined with the anti-EGFR antibody necitumumab when compared to the cisplatin-gemcitabine combination in the first-line treatment of metastatic disease. In 2015, the immune checkpoint inhibitor nivolumab was approved to treat metastatic squamous cell NSCLC whose cancer has progressed during or after standard platinum-based chemotherapy. This agent binds to the PD-1 receptor and inhibits the PD-1 immune signaling pathway, which then leads to activation and proliferation of T cells as well as inhibition of T-regulatory cells.

Small cell lung cancer is the most aggressive form of lung cancer. It is usually exquisitely sensitive, at least initially, to platinum-based combination regimens, including cisplatin and etoposide or cisplatin and irinotecan. Unfortunately, drug resistance eventually develops in nearly all patients with extensive disease. When diagnosed at an early stage, this disease is potentially curable using combined chemotherapy and radiation therapy. Topotecan is used as second-line monotherapy in patients who have failed a platinum-based regimen.

OVARIAN CANCER

In the majority of patients, ovarian cancer remains occult and becomes symptomatic only after it has already metastasized to the peritoneal cavity. At this stage, it usually presents with malignant ascites. It is important to accurately stage this cancer with laparoscopy, ultrasound, and CT scanning. Patients with stage I disease appear to benefit from whole-abdomen radiotherapy and may receive additional benefit from combination chemotherapy with cisplatin and cyclophosphamide.

Combination chemotherapy is the standard approach to stage III and stage IV disease. Randomized clinical studies have shown that the combination of paclitaxel and cisplatin provides survival benefit compared with the previous standard combination of cisplatin plus cyclophosphamide. More recently, carboplatin plus paclitaxel has become the treatment of choice. In patients who present with recurrent disease, topotecan, altretamine, or liposomal doxorubicin are used as single-agent monotherapy.

TESTICULAR CANCER

The introduction of platinum-based combination chemotherapy has made an impressive change in the treatment of patients with advanced testicular cancer. Presently, chemotherapy is recommended for patients with stage IIC or stage III seminomas and nonseminomatous disease. Over 90% of patients respond to chemotherapy and, depending upon the extent and severity of disease, complete remissions are observed in 70–80% of patients. More than 50% of patients achieving complete remission are cured with chemotherapy. In patients with good risk features, three cycles of cisplatin, etoposide, and bleomycin (PEB protocol) or four cycles of cisplatin and etoposide yield virtually identical results. In patients with high-risk disease, the combination of cisplatin, etoposide, and ifosfamide can be used as well as etoposide and bleomycin with high-dose cisplatin.

MALIGNANT MELANOMA

Malignant melanoma is curable with surgical resection when it presents locally (see also Chapter 61). However, once metastasis has occurred, it is one of the most difficult cancers to treat because of drug resistance. While dacarbazine, temozolomide, and cisplatin are the most active cytotoxic agents for this disease, the overall response rates to these agents remain low. Biologic agents, including IFN- α and interleukin 2 (IL-2), have greater activity than traditional cytotoxic agents, and treatment with high-dose IL-2 has led to cures, albeit in a relatively small subset of patients. **Ipilimumab** binds to cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4), which is expressed on the surface of activated CD4 and CD8 T-cells. CTLA-4 normally acts as a brake on T-cell antitumor activity. Binding of ipilimumab results in inhibition of the interaction between CTLA-4 and its target ligands CD80/CD86 and thus enhances T-cell immune responses, which include T-cell activation and proliferation. This agent is approved for the treatment of metastatic melanoma. More recently, ipilimumab is recommended as adjuvant therapy for cutaneous melanoma following complete surgical resection, with treatment for up to 3 years.

Nivolumab and **pembrolizumab** are IgG4 antibodies that bind to the programmed death (PD)-1 receptor, which is expressed on T cells, and they inhibit the interaction between the programmed death ligand 1 (PD-L1) and ligand 2 (PD-L2) and the PD-1 receptor. The PD-1 signaling pathway mediates an immune escape mechanism, and inhibition of this pathway enhances T-cell immune response, leading to T cell activation and proliferation. Each of these agents is approved for unresectable or metastatic melanoma as monotherapy. In addition, nivolumab is also approved in combination with ipilimumab for BRAF V600 mutation–positive unresectable or metastatic melanoma.

The BRAF V600E mutation has been identified in the large majority of melanomas. This mutation results in constitutive activation of BRAF kinase, which then leads to activation of downstream signaling pathways involved in cell growth and proliferation. Two oral and highly selective small molecule inhibitors of BRAF V600E are approved for metastatic melanoma: **vemurafenib** and **dabrafenib**. Studies are ongoing to determine their activity in combination with other cytotoxic and biologic agents for metastatic melanoma as well as their potential role in the adjuvant and neoadjuvant therapy of early stage melanoma.

Trametinib and **cobimetinib** are reversible inhibitors of mitogen-activated extracellular signal-regulated kinase 1 (MEK1) and kinase 2 (MEK2), and in combination with a BRAF inhibitor molecule, they are approved for patients with metastatic melanoma whose tumors express the BRAF V600E or V600K mutation. While these agents have clinical activity as monotherapies, clinical studies suggest that the most promising clinical activity is seen when they are used in combination with a BRAF inhibitor.

BRAIN CANCER

In general, chemotherapy has had only limited efficacy in the treatment of malignant gliomas. Because of their ability to cross the blood-brain barrier, the nitrosoureas have historically been the most active agents in this disease. Carmustine (BCNU) has been used as a single agent, or lomustine (CCNU) can be used in

combination with procarbazine and vincristine (PCV regimen). In addition, the alkylating agent **temozolomide** is active when combined with radiotherapy and is also used in patients with newly diagnosed glioblastoma multiforme (GBM) as well as in those with recurrent disease. The histopathologic subtype oligodendroglioma has been shown to be especially chemosensitive, and the PCV combination regimen is the treatment of choice for this disease. It is now well-established that the anti-VEGF antibody bevacizumab alone or in combination with chemotherapy has documented clinical activity in adult GBM. Bevacizumab is presently approved as a single agent for adult GBM in the setting of progressive disease following first-line chemotherapy.

SECONDARY MALIGNANCIES & CANCER CHEMOTHERAPY

The development of secondary malignancies is a late complication of the alkylating agents and the epipodophyllotoxin etoposide. For both drug classes, the most frequent secondary malignancy is acute myelogenous leukemia (AML). AML develops in up to 15% of patients with Hodgkin's lymphoma who have received radiotherapy plus MOPP chemotherapy and in patients with multiple myeloma, ovarian carcinoma, or breast carcinoma treated with melphalan. The increased risk of AML is observed as early as 2–4 years after the initiation of chemotherapy and typically peaks at 5 and 9 years. With improvements in the clinical efficacy of various combination chemotherapy regimens resulting in prolonged survival and in some cases actual cure of cancer, the issue of how second cancers may affect long-term survival assumes greater importance. Certain alkylating agents (eg, cyclophosphamide) may be less carcinogenic than others (eg, melphalan). In addition to AML, other secondary malignancies have been well-described, including non-Hodgkin's lymphoma and bladder cancer, the latter most typically associated with cyclophosphamide therapy. Etoposide can give rise to an 11:23 translocation, which has been associated with the development of the M4 and M5 AML histologic subtypes.

SUMMARY Anti-cancer Drugs

See Tables 54–2, –3, –4, and –5.

CASE STUDY ANSWER

The 5-year survival rate for patients with high-risk stage III CRC is on the order of 25–30%. Because the patient has no symptoms after surgery and has no comorbid illnesses, he would be an appropriate candidate to receive aggressive adjuvant chemotherapy. Adjuvant chemotherapy is usually begun 4–6 weeks after surgery to allow sufficient time for the surgical wound to heal. The usual recommendation would be to administer 6 months of oxaliplatin-based chemotherapy using either intravenous 5-FU or oral capecitabine as the fluoropyrimidine base in combination with oxaliplatin.

Patients with partial or complete deficiency in the enzyme dihydropyrimidine dehydrogenase (DPD) experience an increased incidence of severe toxicity to fluoropyrimidines in the form of myelosuppression, gastrointestinal

toxicity in the form of mucositis and diarrhea, and neurotoxicity. This is an autosomal recessive pharmacogenetic syndrome that is present in up to 10% of the North American population (see Chapter 5). Although mutations in DPD can be identified in peripheral blood mononuclear cells, nearly 50% of patients who exhibit severe 5-FU toxicity do not have a defined mutation in the *DPD* gene. In addition, such mutations may not result in reduced expression of the DPD protein or in altered enzymatic activity. For this reason, genetic testing is not recommended at this time as part of routine clinical practice. There is now an immunoassay that can measure 5-FU drug levels in the peripheral blood that can help guide 5-FU dosing even in patients with DPD deficiency.

Immunopharmacology

Douglas F. Lake, PhD & Adrienne D. Briggs, MD

CASE STUDY

A 45-year-old man with high-risk acute myelogenous leukemia undergoes high-dose chemotherapy followed by an allogeneic stem cell transplant from an unrelated donor. He receives tacrolimus and low-dose methotrexate as prophylaxis for graft-vs-host disease. One month after blood count

recovery, he develops a skin rash despite ongoing tacrolimus therapy. A skin biopsy confirms grade II acute graft-vs-host disease. How should this case be pharmacologically managed at this point?

Agents that suppress the immune system play an important role in preventing the rejection of organ or tissue grafts and in the treatment of certain diseases that arise from dysregulation of the immune response. While precise details of the mechanisms of action of a number of these agents are still obscure, knowledge of the elements of the immune system is useful in understanding their effects. Agents that augment the immune response or selectively alter the balance of various components of the immune system are also becoming important in the management of certain diseases such as cancer, AIDS, and autoimmune or inflammatory diseases. A growing number of other conditions (infections, cardiovascular diseases, organ transplantation) are also areas for immune manipulation.

■ ELEMENTS OF THE IMMUNE SYSTEM

NORMAL IMMUNE RESPONSES

The immune system has evolved to protect the host from invading pathogens and to eliminate disease. When functioning at its best, the immune system is exquisitely responsive to invading pathogens while retaining the capacity to recognize self tissues and antigens to which it is tolerant. Protection from infection and disease is provided by the collaborative efforts of the innate and adaptive immune systems.

The Innate Immune System

The innate immune system is the first line of defense against invading pathogens (eg, bacteria, viruses, fungi, parasites) and consists of mechanical, biochemical, and cellular components. Mechanical components include skin/epidermis and mucus; biochemical components include antimicrobial peptides and proteins (eg, defensins), complement, enzymes (eg, lysozyme, acid hydrolases), interferons, acidic pH, and free radicals (eg, hydrogen peroxide, superoxide anions); cellular components include neutrophils, monocytes, macrophages, natural killer (NK) cells, and natural killer-T (NKT) cells. Unlike adaptive immunity, the innate immune response exists prior to infection, is not enhanced by repeated infection, and is generally not antigen-specific. An intact skin or mucosa is the first barrier to infection. When this barrier is breached, an immediate innate immune response, referred to as “inflammation,” is provoked and ultimately leads to destruction of the pathogen. The process of pathogen destruction can be accomplished, for example, by biochemical components such as lysozyme (which breaks down bacterial peptidoglycan cell walls) and complement activation. Complement components (Figure 55–1) enhance macrophage and neutrophil phagocytosis by acting as opsonins (C3b) and chemoattractants (C3a, C5a), which recruit immune cells from the bloodstream to the site of infection. The activation of complement eventually leads to pathogen lysis via the generation of a membrane attack complex that creates holes in the pathogen membrane, killing it. Although the complement cascade helps

FIGURE 55-1 Role of complement in innate immunity. Complement is made up of nine proteins (C1–C9), which are split into fragments during activation. **A:** Complement components (C3a, C5a) attract phagocytes (1) to inflammatory sites (2), where they ingest and degrade pathogens (3). **B:** Complement components C5b, C6, C7, C8, and C9 associate to form a membrane attack complex (MAC) that lyses bacteria, causing their destruction. Eculizumab is a monoclonal antibody that blocks cleavage of C5. **C:** Complement component C3b is an opsonin that coats bacteria (1) and facilitates their ingestion (2) and digestion (3) by phagocytes.

eliminate invading pathogens from the host, in some individuals with complement inhibitor deficiency, complement may lyse host red blood cells and cause a disease called paroxysmal nocturnal hemoglobinuria (PNH). These patients can be treated with a **monoclonal antibody (Mab)** that binds the C5 component of complement (see Mab section below), disrupting the lytic cascade. Patients taking a C5 inhibitor are at risk of life-threatening meningococcal infections.

During the inflammatory response triggered by infection, neutrophils and monocytes enter the tissue sites from the peripheral circulation. This cellular influx is mediated by the action of **chemoattractant cytokines (chemokines)** (eg, interleukin-8 [IL-8; CXCL8], macrophage chemotactic protein-1 [MCP-1; CCL2], and macrophage inflammatory protein-1 α [MIP-1 α ; CCL3]) released from activated endothelial cells and immune cells (mostly tissue macrophages) at the inflammatory site. Egress of the immune cells from blood vessels into the inflammatory site is mediated by adhesive interactions between cell surface receptors (eg, L-selectin, integrins) on the immune cells and ligands (eg, sialyl-Lewis x, intercellular

adhesion molecule-1 [ICAM-1]) on the activated endothelial cell surface. The tissue macrophages as well as dendritic cells express pattern recognition receptors (PRRs) that include Toll-like receptors (TLRs), nucleotide-binding oligomerization domain-like receptors (NLRs), scavenger receptors, mannose receptors, and lipopolysaccharide (LPS)-binding protein, which recognize key evolutionarily conserved pathogen components referred to as pathogen-associated molecular patterns (PAMPs). Examples of PAMPs include microbe-derived unmethylated CpG DNA, flagellin, double-stranded RNA, peptidoglycan, and LPS. The PRRs recognize PAMPs in various components of pathogens and stimulate the release of pro-inflammatory cytokines, chemokines, and interferons. If the innate immune response is successfully executed, the invading pathogen is ingested, degraded, and eliminated, and disease is either prevented or is of short duration.

In addition to monocytes and neutrophils, **natural killer (NK)**, **natural killer-T (NKT)**, and **gamma-delta T ($\gamma\delta$ T)** cells recruited to the inflammatory site contribute to the innate response by secreting interferon-gamma (IFN- γ) and

ACRONYMS

ADA	Adenosine deaminase
ADC	Antibody-drug conjugate
ALG	Antilymphocyte globulin
APC	Antigen-presenting cell
ATG	Antithymocyte globulin
CD	Cluster of differentiation
CSF	Colony-stimulating factor
CTL	Cytotoxic T lymphocyte
DC	Dendritic cell
DTH	Delayed-type hypersensitivity
FKBP	FK-binding protein
GVHD	Graft-versus-host disease
HAMA	Human antimouse antibody
HLA	Human leukocyte antigen
IFN	Interferon
IGIV	Immune globulin intravenous
IL	Interleukin
LFA	Leukocyte function-associated antigen
Mab	Monoclonal antibody
MHC	Major histocompatibility complex
NK cell	Natural killer cell
SCID	Severe combined immunodeficiency disease
TCR	T-cell receptor
TGF- β	Transforming growth factor- β
Th1, Th2	T helper cell types 1 and 2
TNF	Tumor necrosis factor

interleukin-17 (IL-17),* which activate resident tissue macrophages and dendritic cells and recruit neutrophils, respectively, to successfully eliminate invading pathogens. NK cells are so called because they are able to recognize and destroy virus-infected normal cells as well as tumor cells without prior stimulation. This activity is regulated by “killer cell immunoglobulin-like receptors” (KIRs) on the NK cell surface that are specific for major histocompatibility complex (MHC) class I molecules. When NK cells bind self MHC class I proteins (expressed on all nucleated cells), these receptors deliver inhibitory signals, preventing them from killing normal host cells. Tumor cells or virus-infected cells that have downregulated MHC class I expression do not engage these KIRs, resulting in activation of NK cells and subsequent destruction of the target cell. NK cells kill target cells by releasing cytotoxic granules such as perforins and granzymes that induce programmed cell death.

NKT cells express T-cell receptors as well as receptors commonly found on NK cells. NKT cells recognize microbial lipid antigens presented by a unique class of MHC-like molecules

known as CD1 and have been implicated in host defense against microbial agents, autoimmune diseases, and tumors.

The Adaptive Immune System

The adaptive immune system is mobilized by cues from the innate response when the innate processes are incapable of coping with an infection. The adaptive immune system has a number of characteristics that contribute to its success in eliminating pathogens. These include the ability to (1) respond to a variety of antigens, each in a specific manner; (2) discriminate between foreign (“non-self”) antigens (pathogens) and self antigens of the host; and (3) respond to a previously encountered antigen in a learned way by initiating a vigorous memory response. This adaptive response culminates in the production of **antibodies**, which are the effectors of **humoral immunity**; and the activation of **T lymphocytes**, which are the effectors of **cell-mediated immunity**.

The induction of specific adaptive immunity requires the participation of professional **antigen-presenting cells (APCs)**, which include dendritic cells (DCs), macrophages, and B lymphocytes. These cells play pivotal roles in the induction of an adaptive immune response because of their capacity to phagocytize particulate antigens (eg, pathogens) or endocytose protein antigens, and enzymatically digest them to generate peptides, which are then loaded onto class I or class II MHC proteins and “presented” to the cell surface T-cell receptor (TCR) (Figure 55–2). CD8 T cells recognize class I–MHC peptide complexes while CD4 T cells recognize class II–MHC peptide complexes. At least two signals are necessary for the activation of T cells. The first signal is delivered following engagement of the TCR with peptide-bound MHC molecules. In the absence of a second signal, the T cells become

FIGURE 55–2 T-cell activation by an antigen-presenting cell requires engagement of the T-cell receptor by the MHC-peptide complex (signal 1) and binding of the costimulatory molecules (CD80, CD86) on the dendritic cell to CD28 on the T cell (signal 2). The activation signals are strengthened by CD40/CD40L and ICAM-1/LFA-1 interactions. In a normal immune response, T-cell activation is regulated by T-cell–derived CTLA-4 and PD-1. CTLA-4 binds to CD80 or CD86 with higher affinity than CD28 and sends inhibitory signals to the nucleus of the T cell, while ligation of PD-1 by PD-L1 or -L2 also inhibits T cell proliferation.

*Interferons and interleukins are cytokines, which are discussed later in this chapter.

unresponsive (anergic) or undergo apoptosis. The second signal involves binding of costimulatory molecules (CD40, CD80 [also known as B7-1], and CD86 [also known as B7-2]) on the APC to their respective ligands (CD40L for CD40, CD28 for CD80 or CD86). Activation of T cells is regulated via a negative feedback loop involving another molecule known as T-lymphocyte-associated antigen 4 (CTLA-4). Following engagement of CD28 with CD80 or CD86, CTLA-4 in the cytoplasm is mobilized to the cell surface where, because of its higher affinity of binding to CD80 and CD86, it outcompetes or displaces CD28 resulting in suppression of T-cell activation and proliferation. This property of CTLA-4 has been exploited as a strategy for sustaining a desirable immune response such as that directed against cancer. A recombinant humanized antibody (ipilimumab) that binds CTLA-4 prevents its association with CD80/CD86. In so doing, the activated state of T cells is sustained. Programmed cell death protein-1 (PD-1) is another negative regulator of T cells. Ligation of PD-1 with its ligands (PD-L1 or PD-L2) suppresses T-cell activity. Like CTLA-4, Mabs have been developed to block the interaction of PD-1 with PD-L1, having the effect of sustained T cell activation. Mabs to CTLA-4 and PD-1/PD-L1 are immune checkpoint inhibitors. They have been associated in some patients with the development of autoimmune toxicity that subsides upon discontinuation of Mab therapy.

T lymphocytes develop and learn to recognize self and non-self antigens in the thymus; those T cells that bind with high affinity to self antigens in the thymus undergo apoptosis (negative selection), while those that are capable of recognizing foreign antigens in the presence of self MHC molecules are retained and expanded (positive selection) for export to the periphery (lymph nodes, spleen, mucosa-associated lymphoid tissue, peripheral blood), where they become activated after encountering MHC-presented peptides (Figures 55–2 and 55–3).

Studies using murine T-cell clones have demonstrated the presence of two subsets of T helper lymphocytes (Th1 and Th2) based on the cytokines they secrete after activation. The Th1 subset characteristically produces IFN- γ , IL-2, and IL-12 and induces cell-mediated immunity by activation of macrophages, cytotoxic T cells (CTLs), and NK cells. The Th2 subset produces IL-4, IL-5, IL-6, and IL-10 (and sometimes IL-13), which induce B-cell proliferation and differentiation into antibody-secreting plasma cells. IL-10 produced by Th2 cells inhibits cytokine production by Th1 cells via the downregulation of MHC expression by APCs. Conversely, IFN- γ produced by Th1 cells inhibits the proliferation of Th2 cells (Figure 55–3). Although these subsets have been well described in vitro, the nature of the antigenic challenge that elicits a Th1 or Th2 phenotype is less clear. Extracellular bacteria typically cause the elaboration of Th2 cytokines, culminating in the production of neutralizing or opsonic antibodies. In contrast, intracellular organisms (eg, mycobacteria) elicit the production of Th1 cytokines, which lead to the activation of effector cells such as macrophages.

Another subset of CD4 T cells that secrete IL-17 (Th17) is important in leukocyte recruitment to sites of bacterial and fungal pathogens. Th17 cells also contribute to the pathogenesis of autoimmune diseases such as psoriasis, inflammatory bowel

disease, rheumatoid arthritis, and multiple sclerosis. In fact, new Mabs for some of these diseases that neutralize IL-17 by binding to the cytokine itself or to its receptor (see Mab section below) have recently been FDA-approved.

Regulatory T (Treg) cells constitute a population of CD4 T cells that is essential for preventing autoimmunity and allergy as well as maintaining homeostasis and tolerance to self antigens. This cell population exists as natural Treg (nTreg), derived directly from the thymus, and induced (adaptive) Treg (iTreg), generated from naïve CD4 T cells in the periphery. Both populations have also been shown to inhibit antitumor immune responses and are implicated in fostering tumor growth and progression. Recent attempts to distinguish both populations have resulted in the discovery of a transcription factor, Helios, in nTreg but not in iTreg cells.

CD8 T lymphocytes recognize endogenously processed peptides presented by virus-infected cells or tumor cells. These peptides are usually nine-amino-acid fragments derived from virus or protein tumor antigens in the cytoplasm and are loaded onto MHC class I molecules (Figure 55–2) in the endoplasmic reticulum. In contrast, class II MHC molecules present peptides (usually 11–22 amino acids) derived from extracellular (exogenous) pathogens to CD4 T helper cells. In some instances, exogenous antigens, upon ingestion by APCs, can be presented on class I MHC molecules to CD8 T cells. This phenomenon, referred to as “cross-presentation,” involves retro-translocation of antigens from the endosome to the cytosol for peptide generation in the proteasome and is thought to be useful in generating effective immune responses against infected host cells that are incapable of priming T lymphocytes. Upon activation, CD8 T cells induce target cell death via lytic granule enzymes (“granzymes”), perforin, and the Fas-Fas ligand (Fas-FasL) apoptosis pathways.

B lymphocytes undergo selection in the bone marrow, during which self-reactive B lymphocytes are clonally deleted while B-cell clones specific for foreign antigens are retained and expanded. The repertoire of antigen specificities by T cells is genetically determined and arises from *T-cell receptor* gene rearrangement while the specificities of B cells arise from *immunoglobulin* gene rearrangement; for both types of cells, these determinations occur prior to encounters with antigen. Upon an encounter with antigen, a mature B cell binds the antigen, internalizes and processes it, and presents its peptide—bound to class II MHC—to CD4 helper cells, which in turn secrete IL-4 and IL-5. These interleukins stimulate B-cell proliferation and differentiation into memory B cells and antibody-secreting plasma cells. The primary antibody response consists mostly of IgM-class immunoglobulins. Subsequent antigenic stimulation results in a vigorous “booster” response accompanied by class (isotype) switching to produce IgG, IgA, and IgE antibodies with diverse effector functions (Figure 55–3). These antibodies also undergo affinity maturation, which allows them to bind more efficiently to the antigen. With the passage of time, this results in accelerated elimination of microorganisms in subsequent infections. Antibodies mediate their functions by acting as opsonins to enhance phagocytosis and cellular cytotoxicity and by activating complement to elicit an inflammatory response and induce bacterial lysis (Figure 55–4).

FIGURE 55-3 Scheme of cellular interactions during the generation of cell-mediated and humoral immune responses (see text).

The cell-mediated arm of the immune response involves the ingestion and digestion of antigen by antigen-presenting cells such as macrophages. Activated Th cells secrete IL-2, which causes proliferation and activation of cytotoxic T lymphocytes as well as Th1 and Th2 cell subsets. Th1 cells also produce IFN- γ and TNF- β , which can directly activate macrophages and NK cells. Th17 cells may be induced by IL-1, -6, -23 or TGF- β secretion by antigen-presenting cells; Th17 cells are inflammatory and secrete IL-17 and -22. The humoral response is triggered when B lymphocytes bind antigen via their surface immunoglobulin. They are then induced by Th2-derived IL-4 and IL-5 to proliferate and differentiate into memory cells and antibody-secreting plasma cells. Regulatory cytokines such as IFN- γ and IL-10 down-regulate Th2 and Th1 responses, respectively (dashed arrows).

ABNORMAL IMMUNE RESPONSES

Whereas the normally functioning immune response can successfully neutralize toxins, inactivate viruses, destroy transformed cells, and eliminate pathogens, inappropriate responses can lead to extensive tissue damage (hypersensitivity) or reactivity against self antigens (autoimmunity); conversely, impaired reactivity to appropriate targets (immunodeficiency) may occur and abrogate essential defense mechanisms.

Hypersensitivity

Hypersensitivity can be classified as antibody-mediated or cell-mediated. Three types of hypersensitivity are antibody-mediated (types I–III), while the fourth is cell-mediated (type IV). Hypersensitivity occurs in two phases: the sensitization phase and the effector phase. Sensitization occurs upon initial encounter with an antigen; the effector phase involves immunologic memory and results in tissue pathology upon a subsequent encounter with that antigen.

FIGURE 55-4 Antibody has multiple functions. The prototypical antibody consists of two heavy (H) and two light (L) chains, each subdivided into constant (C_L , C_H) and variable (V_L , V_H) domains. The structure is held together by intra- and interchain disulfide bridges. **A:** The complementarity-determining region (CDR) of the antigen-binding portion of the antibody engages the antigenic determinant (epitope) in a lock-and-key fashion. **B:** Antigen-antibody complexes activate complement to produce split complement components that cause bacterial lysis. **C:** The Fc portion of antibodies binds to Fc receptors on phagocytes (eg, macrophages, neutrophils) and facilitates uptake of bacteria (opsonization).

1. Type I—Immediate, or type I, hypersensitivity is IgE-mediated, with symptoms usually occurring within minutes following the patient's reenounter with antigen. Type I hypersensitivity results from cross-linking of membrane-bound IgE on blood basophils or tissue mast cells by antigen. This cross-linking causes cells to degranulate, releasing substances such as histamine, leukotrienes, and eosinophil chemotactic factor, which induce anaphylaxis, asthma, hay fever, or urticaria (hives) in affected individuals (Figure 55-5). A severe type I hypersensitivity reaction such as systemic anaphylaxis (eg, from insect envenomation, ingestion of certain foods, or drug hypersensitivity) requires immediate medical intervention.

2. Type II—Type II hypersensitivity results from the formation of antigen-antibody complexes between foreign antigen and IgM or

IgG immunoglobulins. One example of this type of hypersensitivity is a blood transfusion reaction that can occur if blood is not cross-matched properly. Preformed antibodies bind to red blood cell membrane antigens that activate the complement cascade, generating a membrane attack complex that lyses the transfused red blood cells. In hemolytic disease of the newborn, anti-Rh IgG antibodies produced by an Rh-negative mother cross the placenta, bind to red blood cells of an Rh-positive fetus, and damage them. The disease is prevented in subsequent pregnancies by the administration of anti-Rh antibodies to the mother 24–48 hours after delivery (see Immunosuppressive Antibodies, below). Type II hypersensitivity can also be drug-induced and may occur during the administration of penicillin (for example) to allergic patients. In these patients, penicillin binds to red blood cells or other host

FIGURE 55–5 Mechanism of type I hypersensitivity. Initial exposure to allergen (**sensitization phase**) leads to production of IgE by plasma cells differentiated from allergen-specific B cells (not shown). The secreted IgE binds IgE-specific receptors (FcεR) on blood basophils and tissue mast cells. Re-exposure to allergen leads to cross-linking of membrane-bound IgE (**effector phase**). This cross-linking causes degranulation of cytoplasmic granules and release of mediators that induce vasodilation, smooth muscle contraction, and increased vascular permeability. These effects lead to the clinical symptoms characteristic of type I hypersensitivity. Omalizumab prevents IgE from binding to IgE receptors on mast cells and basophils, preventing degranulation.

tissue to form a neoantigen that evokes production of antibodies capable of inducing complement-mediated red cell lysis. In some circumstances, subsequent administration of the drug can lead to systemic anaphylaxis (type I hypersensitivity).

3. Type III—Type III hypersensitivity is due to the presence of elevated levels of antigen-antibody complexes in the circulation that ultimately deposit on basement membranes in tissues and vessels. Immune complex deposition activates complement to produce components with anaphylatoxic and chemotactic activities (C5a, C3a, C4a) that increase vascular permeability and recruit neutrophils to the site of complex deposition. Complex deposition and the action of lytic enzymes released by neutrophils can cause skin rashes, glomerulonephritis, and arthritis in these individuals. If patients have type III hypersensitivity against a particular antigen, clinical symptoms usually occur 3–4 days after exposure to the antigen.

4. Type IV: Delayed-type hypersensitivity—Unlike type I, II, and III hypersensitivities, delayed-type hypersensitivity (DTH) is cell-mediated, and responses occur 2–3 days

after exposure to the sensitizing antigen. DTH is caused by antigen-specific DTH Th1 cells and induces a local inflammatory response that causes tissue damage characterized by the influx of antigen-*non*-specific inflammatory cells, especially macrophages. These cells are recruited under the influence of Th1-produced cytokines (Figure 55–6), which chemoattract circulating monocytes and neutrophils, induce myelopoiesis, and activate macrophages. The activated macrophages are primarily responsible for the tissue damage associated with DTH. Although widely considered to be deleterious, DTH responses are very effective in eliminating infections caused by intracellular pathogens such as *Mycobacterium tuberculosis* and *Leishmania* species. Clinical manifestations of DTH include **tuberculin** and **contact hypersensitivities**. Tuberculosis exposure is determined using a DTH skin test. Positive responses show erythema and induration caused by accumulation of macrophages and DTH T (T_{DTH}) cells at the site of the tuberculin injection. **Poison ivy** is the most common cause of contact hypersensitivity, in which pentadecacatechol, the lipophilic chemical in poison ivy, modifies cellular tissue and results in a DTH T-cell response.

FIGURE 55-6 Mechanism of type IV hypersensitivity (DTH). In the **sensitization phase**, the processed allergen (eg, from poison ivy) is presented to CD4 T_{H1} cells by antigen-presenting cells in association with class II MHC. T cells are induced to express IL-2 receptors and are stimulated to proliferate and differentiate into memory T_{DTH} cells. Secondary contact with antigen triggers the **effector phase**, in which memory T_{DTH} cells release cytokines that attract and activate nonspecific inflammatory macrophages and neutrophils. These cells display increased phagocytic and microbicidal activities and release large quantities of lytic enzymes that cause extensive tissue damage.

Autoimmunity

Autoimmune disease arises when the body mounts an immune response against itself due to failure to distinguish self tissues and cells from foreign (non-self) antigens or loss of tolerance to self. This phenomenon derives from the activation of self-reactive T and B lymphocytes that generate cell-mediated or humoral immune responses directed against self antigens. The pathologic consequences of this reactivity constitute several types of autoimmune diseases. Autoimmune diseases are highly complex due to MHC genetics, environmental conditions, infectious entities, and dysfunctional immune regulation. Examples of such diseases include rheumatoid arthritis, psoriasis, systemic lupus erythematosus, multiple sclerosis, and insulin-dependent diabetes mellitus (type 1 diabetes). In rheumatoid arthritis, IgM antibodies (rheumatoid factors) are produced that react with the Fc portion of IgG and may form immune complexes that activate the complement cascade, causing chronic inflammation of the joints and kidneys. In systemic lupus erythematosus, antibodies are made against DNA, histones, red blood cells, platelets, and other cellular components. In multiple sclerosis and type 1 diabetes, cell-mediated autoimmune attack destroys myelin surrounding nerve cells and insulin-producing islet beta cells of the pancreas, respectively. In type 1 diabetes, activated CD4 T_{DTH} cells that infiltrate the islets of Langerhans and recognize self islet beta cell peptides are thought to produce cytokines that stimulate macrophages to produce lytic enzymes, which destroy islet beta cells. Autoantibodies directed against the islet beta cell antigens are produced but do not contribute significantly to disease.

Immunodeficiency Diseases

Immunodeficiency diseases result from inadequate function in the immune system; the consequences include increased susceptibility to infections and prolonged duration and severity of disease. Immunodeficiency diseases are either congenital or arise from extrinsic factors such as bacterial or viral infections or drug treatment. Affected individuals frequently succumb to infections caused by opportunistic organisms of low pathogenicity for the immunocompetent host. Examples of congenitally acquired immunodeficiency diseases include X-linked agammaglobulinemia, DiGeorge's syndrome, and severe combined immunodeficiency disease (SCID) due to adenosine deaminase (ADA) deficiency.

X-linked agammaglobulinemia is a disease affecting males that is characterized by a failure of immature B lymphocytes to mature into antibody-producing plasma cells. These individuals are susceptible to recurrent bacterial infections, although the cell-mediated responses directed against viruses and fungi are preserved. DiGeorge's syndrome is due to failure of the thymus to develop, resulting in diminished T-cell responses (T_{DTH}, CTL), while the humoral response remains functional but does not benefit from T-cell help.

The ADA enzyme normally prevents the accumulation of toxic deoxy-ATP in cells. Deoxy-ATP is particularly toxic to lymphocytes, and it leads to death of T and B cells. Absence of the enzyme therefore results in SCID. Infusion of the purified enzyme (**pegademase**, from bovine sources) and transfer of ADA gene-modified lymphocytes have both been used successfully to treat this disease.

AIDS represents the classic example of immunodeficiency disease caused by extrinsic viral infection, in this instance the human immunodeficiency virus (HIV). This virus exhibits a strong

tropism for CD4 T helper cells; these become depleted, giving rise to increased frequency of opportunistic infections and malignancies in infected individuals. AIDS is also characterized by an imbalance in TH1 and TH2 cells, and the ratios of cells and their functions are skewed toward TH2. This results in loss of cytotoxic T-lymphocyte activity, loss of delayed hypersensitivity, and hypergammaglobulinemia.

■ IMMUNOSUPPRESSIVE THERAPY

Immunosuppressive agents have proved very useful in minimizing the occurrence or impact of deleterious effects of exaggerated or inappropriate immune responses. Unfortunately, these agents also have the potential to cause disease and to increase the risk of infection and malignancies.

GLUCOCORTICOIDS

Glucocorticoids (corticosteroids) were the first hormonal agents recognized as having lympholytic properties. Administration of

any glucocorticoid reduces the size and lymphoid content of the lymph nodes and spleen, although it has no toxic effect on proliferating myeloid or erythroid stem cells in the bone marrow.

Glucocorticoids are thought to interfere with the cell cycle of activated lymphoid cells. The mechanism of their action is described in Chapter 39. Glucocorticoids are quite cytotoxic to certain subsets of T cells, but their immunologic effects are probably due to their ability to modify cellular functions rather than to direct cytotoxicity. Although cellular immunity is more affected than humoral immunity, the primary antibody response can be diminished, and with continued use, previously established antibody responses also are decreased. Additionally, continuous administration of corticosteroid increases the fractional catabolic rate of IgG, the major class of antibody immunoglobulins, thus lowering the effective concentration of specific antibodies. Contact hypersensitivity mediated by DTH T cells, for example, is usually abrogated by glucocorticoid therapy.

Glucocorticoids are used in a wide variety of conditions (Table 55–1). It is thought that the immunosuppressive and anti-inflammatory properties of corticosteroids account for their beneficial effects in diseases like idiopathic thrombocytopenic purpura and rheumatoid arthritis. Glucocorticoids modulate allergic reactions and are useful in the treatment of diseases like

TABLE 55–1 Clinical uses of immunosuppressive agents.

Source	Immunopharmacologic Agents Used	Response
Autoimmune diseases		
Idiopathic thrombocytopenic purpura (ITP)	Prednisone, ¹ vincristine, occasionally cyclophosphamide, mercaptopurine, or azathioprine; commonly high-dose gamma globulin, plasma immunoadsorption or plasma exchange	Usually good
Autoimmune hemolytic anemia	Prednisone, ¹ cyclophosphamide, chlorambucil, mercaptopurine, azathioprine, high-dose gamma globulin	Usually good
Acute glomerulonephritis	Prednisone, ¹ mercaptopurine, cyclophosphamide	Usually good
Acquired factor XIII antibodies	Cyclophosphamide plus factor XIII	Usually good
Autoreactive tissue disorders (autoimmune diseases) ²	Prednisone, cyclophosphamide, methotrexate, interferon- α and - β , azathioprine, cyclosporine, infliximab, etanercept, adalimumab	Often good, variable
Isoimmune disease		
Hemolytic disease of the newborn	Rh ₀ (D) immune globulin	Excellent
Organ transplantation		
Renal	Cyclosporine, azathioprine, prednisone, ALG, OKT3, tacrolimus, basiliximab, ³ daclizumab, ³ sirolimus	Very good
Heart	Cyclosporine, azathioprine, prednisone, ALG, OKT3, tacrolimus, basiliximab, ³ daclizumab, ³ sirolimus	Good
Liver	Cyclosporine, prednisone, azathioprine, tacrolimus, sirolimus	Fair
Bone marrow	Cyclosporine, cyclophosphamide, prednisone, methotrexate, ALG	Good
Prevention of cell proliferation		
Coronary stents	Sirolimus (impregnated stent)	Good
Neovascular macular degeneration	Ranibizumab (labeled), bevacizumab (off-label)	Fair

¹Drug of choice.

²Including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, dermatomyositis, mixed tissue disorder, multiple sclerosis, Wegener's granulomatosis, chronic active hepatitis, lipid nephrosis, and inflammatory bowel disease.

³Basiliximab and daclizumab are approved for renal transplant only.

asthma or as premedication for other agents (eg, blood products, chemotherapy) that might cause undesirable immune responses. Glucocorticoids are first-line immunosuppressive therapy for both solid organ and hematopoietic stem cell transplant recipients, with variable results. The toxicities of long-term glucocorticoid therapy can be severe and are discussed in Chapter 39.

CALCINEURIN INHIBITORS

Cyclosporine

Cyclosporine (cyclosporin A, CSA) is an immunosuppressive agent with efficacy in human organ transplantation, in the treatment of graft-versus-host (GVH) disease after hematopoietic stem cell transplantation, and in the treatment of selected autoimmune disorders. Cyclosporine is a peptide antibiotic that appears to act at an early stage in the antigen receptor-induced differentiation of T cells and blocks their activation. Cyclosporine binds to cyclophilin, a member of a class of intracellular proteins called immunophilins. Cyclosporine and cyclophilin form a complex that inhibits the cytoplasmic phosphatase, calcineurin, which is necessary for the activation of a T cell-specific transcription factor. This transcription factor, NF-AT, is involved in the synthesis of interleukins (eg, IL-2) by activated T cells. In vitro studies have indicated that cyclosporine inhibits the gene transcription of IL-2, IL-3, IFN- γ , and other factors produced by antigen-stimulated T cells, but it does not block the effect of such factors on primed T cells nor does it block interaction with antigen.

Cyclosporine may be given intravenously or orally, though it is slowly and incompletely absorbed (20–50%). The absorbed drug is primarily metabolized by the P450 3A enzyme system in the liver with resultant multiple drug interactions. This propensity for drug interactions contributes to significant interpatient variability in bioavailability, such that cyclosporine requires individual patient dosage adjustments based on steady-state blood levels and the desired therapeutic ranges for the drug. Cyclosporine ophthalmic solution is now available for severe dry eye syndrome, as well as ocular GVH disease. Inhaled cyclosporine is being investigated for use in lung transplantation.

Toxicities are numerous and include nephrotoxicity, hypertension, hyperglycemia, liver dysfunction, hyperkalemia, altered mental status, seizures, and hirsutism. Cyclosporine causes very little bone marrow toxicity. While an increased incidence of lymphoma and other cancers (Kaposi's sarcoma, skin cancer) have been observed in transplant recipients receiving cyclosporine, other immunosuppressive agents may also predispose recipients to cancer. Some evidence suggests that tumors may arise after cyclosporine treatment because the drug induces TGF- β , which promotes tumor invasion and metastasis.

Cyclosporine may be used alone or in combination with other immunosuppressants, particularly glucocorticoids. It has been used successfully as the sole immunosuppressant for cadaveric transplantation of the kidney, pancreas, and liver, and it has proved extremely useful in cardiac transplantation as well. In combination with methotrexate, cyclosporine is a standard

prophylactic regimen to prevent GVH disease after allogeneic stem cell transplantation. Cyclosporine has also proved useful in a variety of autoimmune disorders, including uveitis, rheumatoid arthritis, psoriasis, and asthma. Its combination with newer agents is showing considerable efficacy in clinical and experimental settings where effective and less toxic immunosuppression is needed. Newer formulations of cyclosporine are improving patient compliance (smaller, better-tasting pills) and increasing bioavailability.

Tacrolimus

Tacrolimus (FK 506) is an immunosuppressant macrolide antibiotic produced by *Streptomyces tsukubaensis*. It is not chemically related to cyclosporine, but their mechanisms of action are similar. Both drugs bind to cytoplasmic peptidylprolyl isomerases that are abundant in all tissues. While cyclosporine binds to cyclophilin, tacrolimus binds to the immunophilin FK-binding protein (FKBP). Both complexes inhibit calcineurin, which is necessary for the activation of the T cell-specific transcription factor NF-AT.

On a weight basis, tacrolimus is 10–100 times more potent than cyclosporine in inhibiting immune responses. Tacrolimus is utilized for the same indications as cyclosporine, particularly in organ and stem cell transplantation. Multicenter studies in the USA and in Europe indicate that both graft and patient survival are similar for the two drugs. Tacrolimus has proven to be effective therapy for preventing rejection in solid organ transplant patients even after failure of standard rejection therapy, including anti-T-cell antibodies. It is now considered a standard prophylactic agent (usually in combination with methotrexate or mycophenolate mofetil) for GVH disease.

Tacrolimus can be administered orally or intravenously. The half-life of the intravenous form is approximately 9–12 hours. Like cyclosporine, tacrolimus is metabolized primarily by P450 enzymes in the liver, and there is potential for drug interactions. The dosage is determined by trough blood level at steady state. Its toxic effects are similar to those of cyclosporine and include nephrotoxicity, neurotoxicity, hyperglycemia, hypertension, hyperkalemia, and gastrointestinal complaints.

Because of the effectiveness of systemic tacrolimus in some dermatologic diseases, a topical preparation is now available. Tacrolimus ointment is currently used in the therapy of atopic dermatitis and psoriasis.

PROLIFERATION SIGNAL INHIBITORS

A newer class of immunosuppressive agents called proliferation-signal inhibitors (PSIs) includes **sirolimus** (rapamycin) and its derivative **everolimus**. The mechanism of action of PSIs differs from that of the calcineurin inhibitors. PSIs bind the circulating immunophilin FK506-binding protein 12, resulting in an active complex that blocks the molecular target of rapamycin (mTOR). The mTOR is a key component of a complex intracellular signaling pathway involved in cellular processes such as cell growth and proliferation, angiogenesis, and metabolism. Thus, blockade of mTOR ultimately can lead to inhibition of interleukin-driven

T-cell proliferation. Both everolimus and sirolimus also may inhibit B-cell proliferation and immunoglobulin production.

Sirolimus is available only as an oral drug. Its half-life is about 60 hours, while that of everolimus is about 43 hours. Both drugs are rapidly absorbed and elimination is similar to that of cyclosporine and tacrolimus, being substrates for both cytochrome P450 3A and P-glycoprotein. Hence, significant drug interactions can occur. For example, use with cyclosporine can increase the plasma levels of both sirolimus and everolimus such that drug levels need to be monitored. Target dose-ranges of these drugs vary depending on clinical use.

Sirolimus has been used effectively alone and in combination with other immunosuppressants (corticosteroids, cyclosporine, tacrolimus, and mycophenolate mofetil) to prevent rejection of solid organ allografts. It is used as prophylaxis and as therapy for steroid-refractory acute and chronic GVH disease in hematopoietic stem cell transplant recipients. Topical sirolimus is also used in some dermatologic disorders and, in combination with cyclosporine, in the management of uveoretinitis. Recently, sirolimus-eluting coronary stents have been shown to reduce restenosis and additional adverse cardiac events in patients with severe coronary artery disease, due to the drug's antiproliferative effects. Everolimus is a newer drug that has shown clinical efficacy similar to sirolimus in solid organ transplant recipients; it is under investigation as an additional therapeutic agent for the treatment of chronic cardiac allograft vasculopathy.

Toxicities of the PSIs can include profound myelosuppression (especially thrombocytopenia), hepatotoxicity, diarrhea, hypertriglyceridemia, pneumonitis, and headache. Because nephrotoxicity is of major concern when administering calcineurin inhibitors, and since renal toxicity is less common with PSIs, there is interest in increased early use of the latter agents. However, increased use in stem cell transplantation regimens as GVH disease prophylaxis, particularly when combined with tacrolimus, has revealed an increased incidence of hemolytic-uremic syndrome.

Tofacitinib (Xeljanz) inhibits JAK enzymes that stimulate hematopoiesis and immune cell function in response to cytokine or growth factor signaling. Tofacitinib reduces circulating NK cells, serum immunoglobulins, and C-reactive protein. It is approved for adults with moderate to severe RA. It has a black box warning for serious infections and malignancies, similar to anti-TNF- α Mabs (see below).

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil (MMF) is a semisynthetic derivative of mycophenolic acid, isolated from the mold *Penicillium glaucus*. In vitro, it inhibits T- and B-lymphocyte responses, including mitogen and mixed lymphocyte responses, probably by inhibition of de novo synthesis of purines. Mycophenolate mofetil is hydrolyzed to mycophenolic acid, the active immunosuppressive moiety; it is synthesized and administered as MMF to enhance bioavailability.

Mycophenolate mofetil is available in both oral and intravenous forms. The oral form is rapidly metabolized to mycophenolic acid. Although the cytochrome P450 3A system is not involved,

some drug interactions still occur. Plasma drug levels should be monitored frequently.

Mycophenolate mofetil is used in solid organ transplant patients for refractory rejection and, in combination with prednisone, as an alternative to cyclosporine or tacrolimus in patients who do not tolerate those drugs. Its antiproliferative properties make it the first-line drug for preventing or reducing chronic allograft vasculopathy in cardiac transplant recipients. Mycophenolate mofetil is used as prophylaxis for and treatment of both acute and chronic GVH disease in hematopoietic stem cell transplant patients. Newer immunosuppressant applications for MMF include lupus nephritis, rheumatoid arthritis, inflammatory bowel disease, and some dermatologic disorders.

Toxicities include gastrointestinal disturbances (nausea and vomiting, diarrhea, abdominal pain) headache, hypertension, and reversible myelosuppression (primarily neutropenia).

THALIDOMIDE

Thalidomide is an oral sedative drug that was withdrawn from the market in the 1960s because of disastrous teratogenic effects when used during pregnancy. Nevertheless, it has significant immunomodulatory actions and is currently in active use or in clinical trials for more than 40 different illnesses. Thalidomide inhibits angiogenesis and has anti-inflammatory and immunomodulatory effects. It inhibits tumor necrosis factor- α (TNF- α), reduces phagocytosis by neutrophils, increases production of IL-10, alters adhesion molecule expression, and enhances cell-mediated immunity via interactions with T cells. The complex actions of thalidomide continue to be studied as its clinical use evolves.

Thalidomide is currently used in the treatment of multiple myeloma at initial diagnosis and for relapsed-refractory disease. Patients generally show signs of response within 2–3 months of starting the drug, with response rates of 20–70%. When combined with dexamethasone, the response rates in myeloma are 90% or more in some studies. Many patients have durable responses—up to 12–18 months in refractory disease and even longer in some patients treated at diagnosis. The success of thalidomide in myeloma has led to numerous clinical trials in other diseases such as myelodysplastic syndrome, acute myelogenous leukemia, and GVH disease, as well as in solid tumors like colon cancer, renal cell carcinoma, melanoma, and prostate cancer, with variable results to date. Thalidomide has been used for many years in the treatment of some manifestations of leprosy and has been reintroduced in the USA for erythema nodosum leprosum; it is also useful in management of the skin manifestations of lupus erythematosus.

The adverse effect profile of thalidomide is extensive. The most important toxicity is teratogenesis. Because of this effect, thalidomide prescription and use is closely regulated by the manufacturer. Other adverse effects of thalidomide include peripheral neuropathy, constipation, rash, fatigue, hypothyroidism, and increased risk of deep-vein thrombosis. Thrombosis is sufficiently frequent, particularly in the hematologic malignancy population, that most

patients are placed on some type of anticoagulant when thalidomide treatment is initiated.

Owing to thalidomide's serious toxicity profile, considerable effort has been expended in the development of analogs. Immunomodulatory derivatives of thalidomide are termed **IMiDs**. Some IMiDs are much more potent than thalidomide in regulating cytokines and affecting T-cell proliferation. **Lenalidomide** is an oral IMiD that in animal and in vitro studies has been shown to be similar to thalidomide in action, but with less toxicity, especially teratogenicity. Lenalidomide was approved by the FDA when trials showed its effectiveness in the treatment of the myelodysplastic syndrome with the chromosome 5q31 deletion. Clinical trials using lenalidomide to treat multiple myeloma showed similar efficacy, leading to approval for both primary and relapsed/refractory myeloma. **Pomalidomide** (originally called CC-4047) is a newer oral IMiD that is FDA approved. Like the other IMiDs, it has myriad mechanisms of actions including antiangiogenic activity, inhibition of TNF- α , and stimulation of apoptosis and cytotoxic T-cell activity. Most clinical trials of pomalidomide have targeted patients with relapsed/refractory multiple myeloma, for which the FDA approved the drug in 2013. Both lenalidomide and pomalidomide have side effect profiles similar to that of thalidomide.

CYTOTOXIC AGENTS

Azathioprine

Azathioprine is a prodrug of mercaptopurine and, like mercaptopurine, functions as an antimetabolite (see Chapter 54). Although its action is presumably mediated by conversion to mercaptopurine and further metabolites, it has been more widely used than mercaptopurine for immunosuppression in humans. These agents represent prototypes of the antimetabolite group of cytotoxic immunosuppressive drugs, and many other agents that kill proliferative cells appear to work at a similar level in the immune response.

Azathioprine is well absorbed from the gastrointestinal tract and is metabolized primarily to mercaptopurine. Xanthine oxidase converts much of the active material to 6-thiouric acid prior to excretion in the urine. After administration of azathioprine, small amounts of unchanged drug and mercaptopurine are also excreted by the kidney, and as much as a twofold increase in toxicity may occur in anephric or anuric patients. Since much of the drug's inactivation depends on xanthine oxidase, patients who are also receiving allopurinol (see Chapters 36 and 54) for control of hyperuricemia should have the dose of azathioprine reduced to one-fourth to one-third the usual amount to prevent excessive toxicity.

Azathioprine and mercaptopurine appear to produce immunosuppression by interfering with purine nucleic acid metabolism at steps that are required for the wave of lymphoid cell proliferation that follows antigenic stimulation. The purine analogs are thus cytotoxic agents that destroy stimulated lymphoid cells. Although continued messenger RNA synthesis is necessary for sustained antibody synthesis by plasma cells, these analogs appear to have

less effect on this process than on nucleic acid synthesis in proliferating cells. Cellular immunity as well as primary and secondary serum antibody responses can be blocked by these agents.

Azathioprine and mercaptopurine appear to be of definite benefit in maintaining renal allografts and may be of value in transplantation of other tissues. These antimetabolites have also been used with some success in the management of acute glomerulonephritis, in the renal component of systemic lupus erythematosus, and in some cases of rheumatoid arthritis, Crohn's disease, and multiple sclerosis. The drugs have been of occasional use in prednisone-resistant antibody-mediated idiopathic thrombocytopenic purpura and autoimmune hemolytic anemias.

The chief toxic effect of azathioprine and mercaptopurine is bone marrow suppression, usually manifested as leukopenia, although anemia and thrombocytopenia may occur. Skin rashes, fever, nausea and vomiting, and sometimes diarrhea occur, with the gastrointestinal symptoms seen mainly at higher dosages. Hepatic dysfunction, manifested by very high serum alkaline phosphatase levels and mild jaundice, occurs occasionally, particularly in patients with preexisting hepatic dysfunction.

Cyclophosphamide

The alkylating agent cyclophosphamide is one of the most efficacious immunosuppressive drugs available. Cyclophosphamide destroys proliferating lymphoid cells (see Chapter 54) but also appears to alkylate some resting cells. It has been observed that very large doses (eg, >120 mg/kg intravenously over several days) may induce an apparent specific tolerance to a new antigen if the drug is administered simultaneously with, or shortly after, the antigen. In smaller doses, it has been effective against autoimmune disorders (including systemic lupus erythematosus) and in patients with acquired factor XIII antibodies and bleeding syndromes, autoimmune hemolytic anemia, antibody-induced pure red cell aplasia, and Wegener's granulomatosis.

Treatment with large doses of cyclophosphamide carries considerable risk of pancytopenia and therefore is generally combined with stem cell rescue (transplant) procedures. Although cyclophosphamide appears to induce tolerance for marrow or immune cell grafting, its use does not prevent the subsequent GVH syndrome, which may be serious or lethal if the donor is a poor histocompatibility match (despite the severe immunosuppression induced by high doses of cyclophosphamide). The drug may also cause hemorrhagic cystitis, which can be prevented or treated with **mesna**. Other adverse effects of cyclophosphamide include nausea, vomiting, cardiac toxicity, and electrolyte disturbances.

Pyrimidine Synthesis Inhibitors

Leflunomide is a prodrug of an inhibitor of pyrimidine synthesis. **Teriflunomide** is the principal active metabolite of leflunomide. They both reversibly inhibit the mitochondrial enzyme dihydroorotate dehydrogenase, which is involved in pyrimidine synthesis and ultimately results in decreased lymphocyte activation. They have anti-inflammatory activity in addition to immunomodulatory properties.

Leflunomide is orally active, and the active metabolite has a long half-life of several weeks. Thus, the drug should be started with a loading dose, but it can be taken once daily after reaching steady state. It is approved only for rheumatoid arthritis at present, though studies are underway combining leflunomide with mycophenolate mofetil for a variety of autoimmune and inflammatory skin disorders, as well as preservation of allografts in solid organ transplantation. Leflunomide also appears (from murine data) to have antiviral activity. Toxicities include elevation of liver enzymes with some risk of liver damage and renal impairment. Patients with severe liver disease should not receive leflunomide. This drug is teratogenic and contraindicated in pregnancy. A low frequency of cardiovascular effects (angina, tachycardia) has been reported.

Teriflunomide is FDA-approved for the treatment of relapsing-remitting multiple sclerosis. Although immunomodulatory, its exact mechanism of action in the treatment of multiple sclerosis is unclear. It is hypothesized to decrease the number of activated lymphocytes in the central nervous system. It is a once-daily oral drug that, unlike leflunomide, does not require a loading dose. Teriflunomide's side effect profile is similar to that of leflunomide, and it is contraindicated in pregnancy and severe liver disease. The incidence of neutropenia in patients taking the drug is 15%, and 10% of patients have a decrease in platelet counts.

Hydroxychloroquine

Hydroxychloroquine is an antimalarial agent with immunosuppressant properties. It is thought to suppress intracellular antigen processing and loading of peptides onto MHC class II molecules by increasing the pH of lysosomal and endosomal compartments, thereby decreasing T-cell activation.

Because of these immunosuppressant activities, hydroxychloroquine is used to treat some autoimmune disorders (see Chapter 36), eg, rheumatoid arthritis and systemic lupus erythematosus. It has also been used to both treat and prevent GVH disease after allogeneic stem cell transplantation.

Other Cytotoxic Agents

Other cytotoxic agents, including **methotrexate**, **vincristine**, and **cytarabine** (see Chapter 54), also have immunosuppressive properties. Methotrexate has been used extensively in rheumatoid arthritis (see Chapter 36) and in the treatment of GVH disease. Although the other agents can be used for immunosuppression, their use has not been as widespread as the purine antagonists, and their indications for immunosuppression are less certain. The use of methotrexate (which can be given orally) appears reasonable in patients with idiosyncratic reactions to purine antagonists. The antibiotic dactinomycin has also been used with some success at the time of impending renal transplant rejection. Vincristine appears to be quite useful in idiopathic thrombocytopenic purpura refractory to prednisone. The related vinca alkaloid **vinblastine** has been shown to prevent mast cell degranulation in vitro by binding to microtubule units within the cell and to prevent release of histamine and other vasoactive compounds.

Pentostatin is an adenosine deaminase inhibitor that has been used mainly as an antineoplastic agent for lymphoid malignancies; it produces a profound lymphopenia. It is now frequently used for steroid-resistant GVH disease after allogeneic stem cell transplantation, as well as in preparative regimens prior to those transplants to provide severe immunosuppression to prevent allograft rejection.

Miscellaneous Agents

Three other FDA-approved immunomodulators are used exclusively in the treatment of relapsing-remitting multiple sclerosis.

Dimethyl fumarate (DMF) is the methyl ester of fumaric acid. Its exact mechanism of action is unknown, but it appears to activate the nuclear factor (erythroid-derived 2)-like 2 (NRF-2) transcriptional pathway. Activation of the NRF-2 pathway results in reduction of the oxidative stress that contributes to demyelination; it also appears to help protect the nerve cells from inflammation. DMF is given orally. Lymphopenia may be significant, so blood counts must be monitored regularly and the drug may be withheld if active infection is present. Flushing is common with treatment initiation and usually improves with time. Other less common adverse effects include nausea, diarrhea, abdominal pain, increased hepatic enzymes, and eosinophilia.

Glatiramer acetate (GA) is a mixture of synthetic polypeptides and four amino acids (L-glutamic acid, L-alanine, L-lysine, and L-tyrosine) in a fixed molar ratio. Its mechanism of immunomodulation in multiple sclerosis is unknown. Studies suggest that GA downregulates the immune response to myelin antigens by induction and activation of suppressor T cells that migrate to the central nervous system. It is given as a subcutaneous injection (not intravenously) in variable dosages and schedules. Toxicities include skin hypersensitivity, and rarely lipoatrophy and skin necrosis at the injection site. Other adverse effects include flushing, chest pain, dyspnea, throat constriction, and palpitations, all of which are usually mild and self-limited.

Fingolimod hydrochloride (FH) is an orally active sphingosine 1-phosphate (S1P) receptor modulator that is derived from the fungal metabolite myriocin. The S1P receptor (subtype 1) controls the release of lymphocytes from lymph nodes and the thymus. FH is metabolized to fingolimod phosphate, which subsequently binds the S1P receptor and ultimately decreases circulating lymphocyte numbers in the periphery and central nervous system. S1P receptors are also expressed on neurons, such that FH may also be affecting neurodegeneration, gliosis, and endogenous repair mechanisms as well as resulting in lymphopenia to modify disease activity in multiple sclerosis. FH can cause serious cardiac toxicity including bradycardia, prolongation of the QT interval, and other abnormalities. Because of these potential complications, the drug requires cardiac monitoring for 6 hours after the first dose is given. FH is contraindicated in patients with preexisting conditions such as type II or III heart block, prolonged QTc, recent myocardial infarction, or heart failure. Less common adverse effects include macular edema, elevated hepatic enzymes, headache, diarrhea, and cough. The drug is metabolized primarily

by the cytochrome P450 system; thus caution is needed when it is used in combination with other drugs metabolized in the same manner.

IMMUNOSUPPRESSIVE ANTIBODIES

The development of hybridoma technology by Milstein and Köhler in 1975 revolutionized the antibody field and radically increased the purity and specificity of antibodies used in the clinic and for diagnostic tests in the laboratory. Hybridomas are B cells fused to immortal plasmacytoma cells that secrete monoclonal antibodies specific for a target antigen. Large-scale hybridoma culture facilities are employed by the pharmaceutical industry to produce diagnostic and clinical-grade monoclonal antibodies.

More recently, molecular biology has been used to develop monoclonal antibodies. Combinatorial libraries of cDNAs encoding immunoglobulin heavy and light chains expressed on bacteriophage surfaces are screened against purified antigens. The result is an antibody fragment with specificity and high affinity for the antigen of interest. This technique has been used to develop antibodies specific for viruses (eg, HIV), bacterial proteins, tumor antigens, and even cytokines. Many antibodies developed in this manner are FDA-approved for use in humans.

Other genetic engineering techniques involve production of chimeric and humanized versions of murine monoclonal antibodies in order to reduce their antigenicity and increase the half-life of the antibody in the patient. Murine antibodies administered as such to human patients elicit production of human antimouse antibodies (HAMAs), which clear the original murine proteins very rapidly. Humanization involves replacing most of the murine antibody with equivalent human regions while keeping only the variable, antigen-specific regions intact. Chimeric mouse-human antibodies have similar properties with less complete replacement of the murine components. The current naming convention for these engineered substances uses the suffix “-umab” or “-zumab” for humanized antibodies, and “-imab” or “-ximab” for chimeric products. These molecular engineering procedures have been successful in reducing or preventing HAMA production for many of the antibodies discussed below.

Antilymphocyte & Antithymocyte Antibodies, & Chimeric Molecules

Antisera directed against lymphocytes have been prepared sporadically for over 100 years. With the advent of human organ transplantation as a realistic therapeutic option, heterologous antilymphocyte globulin (ALG) took on new importance. ALG and antithymocyte globulin (ATG) are now in clinical use in many medical centers, especially in transplantation programs. The antiserum is usually obtained by immunization of horses, sheep, or rabbits with human lymphoid cells.

ALG acts primarily on the small, long-lived peripheral lymphocytes that circulate between the blood and lymph. With continued administration, “thymus-dependent” (T) lymphocytes from lymphoid follicles also are depleted, as they normally participate in

the recirculating pool. As a result of the destruction or inactivation of T cells, an impairment of delayed hypersensitivity and cellular immunity occurs while humoral antibody formation remains relatively intact. ALG and ATG are useful for suppressing certain major compartments (ie, T cells) of the immune system and play a definite role in the management of solid organ and bone marrow transplantation.

Monoclonal antibodies directed against specific cell surface proteins such as CD2, CD3, CD25, or cytokine receptors and various integrins much more selectively influence T-cell subset function. The high specificity of these antibodies improves selectivity and reduces toxicity of the therapy, altering the disease course in several different autoimmune disorders.

In the management of transplants, ALG and monoclonal antibodies can be used in the induction of immunosuppression, in the treatment of initial rejection, and in the treatment of steroid-resistant rejection. There has been some success in the use of ALG and ATG plus cyclosporine to prepare recipients for bone marrow transplantation. In this procedure, the recipient is treated with ALG or ATG in large doses for 7–10 days prior to transplantation of bone marrow cells from the donor. ALG appears to destroy the T cells in the donor marrow graft, and the probability of severe GVH disease is reduced.

The adverse effects of ALG are mostly those associated with injection of a foreign protein. Local pain and erythema often occur at the injection site (type III hypersensitivity). Since the humoral antibody response remains active in the recipient, skin-reactive and precipitating antibodies may be formed against the foreign ALG. Similar reactions occur with monoclonal antibodies of murine origin caused by the release of cytokines by T cells and monocytes.

Anaphylactic and serum sickness reactions to ALG and murine monoclonal antibodies have been observed and usually require cessation of therapy. Complexes of host antibodies with horse ALG may precipitate and localize in the glomeruli of the kidneys causing kidney damage.

Immune Globulin Intravenous (IGIV)

A different approach to immunomodulation is the intravenous use of polyclonal human immunoglobulin. This immunoglobulin preparation (usually IgG) is prepared from pools of thousands of healthy donors, and no single, specific antigen is the target of the “therapeutic antibody.” Rather, one expects that the pool of different antibodies will have a normalizing effect upon the patient’s immune networks.

IGIV in high doses (2 g/kg) has proved effective in a variety of different applications ranging from immunoglobulin deficiencies to autoimmune disorders to HIV disease to bone marrow transplantation. In patients with Kawasaki’s disease, it has been shown to be safe and effective, reducing systemic inflammation and preventing coronary artery aneurysms. It has also brought about good clinical responses in systemic lupus erythematosus and refractory idiopathic thrombocytopenic purpura. Possible mechanisms of action of IGIV include a reduction of T helper cells, increase of regulatory T cells, decreased spontaneous

immunoglobulin production, Fc receptor blockade, increased antibody catabolism, and idiotypic–anti-idiotypic interactions with “pathologic antibodies.” Although its precise mechanism of action is still unknown, IGIV brings undeniable clinical benefit to many patients with a variety of immune syndromes.

Rh_o(D) Immune Globulin

One of the earliest major advances in immunopharmacology was the development of a technique for preventing Rh hemolytic disease of the newborn. The technique is based on the observation that a *primary* antibody response to a foreign antigen can be blocked if specific antibody to that antigen is administered passively at the time of exposure to antigen. Rh_o(D) immune globulin is a concentrated (15%) solution of human IgG containing high-titer antibodies against the Rh_o(D) antigen of the red cell.

Sensitization of Rh-negative mothers to the D antigen occurs usually at the time of birth of an Rh_o(D)-positive or D^u-positive infant, when fetal red cells leak into the mother's bloodstream. Sensitization might also occur occasionally with miscarriages or ectopic pregnancies. In subsequent pregnancies, maternal antibody against Rh-positive cells is transferred to the fetus during the third trimester, leading to the development of erythroblastosis fetalis (hemolytic disease of the newborn).

If an injection of Rh_o(D) antibody is administered to the Rh-negative mother within 24–72 hours after the birth of an Rh-positive infant, the mother's own antibody response to the foreign Rh_o(D)-positive cells is suppressed because the infant's red cells are cleared from circulation before the mother can generate a B-cell response against Rh_o(D). Therefore she has no memory B cells that can activate upon subsequent pregnancies with an Rh_o(D)-positive fetus.

When the mother has been treated in this fashion, Rh hemolytic disease of the newborn has not been observed in subsequent pregnancies. For this prophylactic treatment to be successful, the mother must be Rh_o(D)-negative and D^u-negative and must not already be immunized to the Rh_o(D) factor. Treatment is also often advised for Rh-negative mothers antepartum at 26–28 weeks' gestation who have had miscarriages, ectopic pregnancies, or abortions, when the blood type of the fetus is unknown. *Note: Rh_o(D) immune globulin is administered to the mother and must not be given to the infant.*

The usual dose of Rh_o(D) immune globulin is 2 mL intramuscularly, containing approximately 300 mcg anti-Rh_o(D) IgG. Adverse reactions are infrequent and consist of local discomfort at the injection site or, rarely, a slight temperature elevation.

Hyperimmune Immunoglobulins

Hyperimmune immunoglobulins are IGIV preparations made from pools of selected human or animal donors with high titers of antibodies against particular agents of interest such as viruses or toxins (see also Appendix). Various hyperimmune IGIVs are available for treatment of **respiratory syncytial virus, cytomegalovirus, varicella zoster, human herpesvirus 3, hepatitis B virus, rabies, tetanus, and digoxin overdose**. Intravenous

administration of the hyperimmune globulins is a passive transfer of high-titer antibodies that either reduces risk or reduces the severity of infection. Rabies hyperimmune globulin is injected around the wound and given intravenously. Tetanus hyperimmune globulin is administered intravenously when indicated for prophylaxis. **Rattlesnake** and **coral snake** hyperimmune globulins (antivenoms) are of equine or ovine origin and are effective for North and South American rattlesnakes and some coral snakes (but not Arizona coral snake). Equine and ovine antivenoms are available for rattlesnake envenomations, but only equine antivenom is available for coral snake bite. An **Arizona bark scorpion** antivenom is also available as equine (Fab)². This preparation prevents neurologic manifestations of scorpion envenomation and is generally used in young children and infants.

MONOCLONAL ANTIBODIES (Mabs)

Advances in the ability to manipulate the genes for immunoglobulins have resulted in development of a wide array of humanized and chimeric monoclonal antibodies directed against therapeutic targets. As described above, the only murine elements of humanized monoclonal antibodies are the complementarity-determining regions in the variable domains of immunoglobulin heavy and light chains. Complementarity-determining regions are primarily responsible for the antigen-binding capacity of antibodies. Chimeric antibodies typically contain antigen-binding murine variable regions and human constant regions. The following are brief descriptions of the engineered antibodies that have been approved for clinical use; they are presented alphabetically by indication.

Antitumor Mabs

Alemtuzumab is a humanized IgG₁ with a kappa chain that binds to CD52 found on normal and malignant B and T lymphocytes, NK cells, monocytes, macrophages, and a small population of granulocytes. Alemtuzumab was previously approved for the treatment of B-cell chronic lymphocytic leukemia (CLL) in patients who have been treated with alkylating agents and have failed fludarabine therapy. Alemtuzumab appears to deplete leukemic (and normal) cells by direct antibody-dependent lysis. More recently, alemtuzumab was approved by the EU for the treatment of patients diagnosed with relapsing remitting multiple sclerosis. In the latter, alemtuzumab depletes autoimmune inflammatory T and B cells while the drug is in the circulation. Repopulating lymphocytes appear to temporarily rebalance the immune system. Patients receiving this antibody become lymphopenic and may also become neutropenic, anemic, and thrombocytopenic. As a result, patients should be closely monitored for opportunistic infections and hematologic toxicity.

Bevacizumab is a humanized IgG₁ monoclonal antibody that binds to vascular endothelial growth factor (VEGF) and inhibits VEGF from binding to its receptor, especially on endothelial cells. It is an antiangiogenic drug that has been shown to inhibit growth of blood vessels (angiogenesis) in tumors. It is approved for first- and second-line treatment of patients with metastatic colorectal cancer

alone or in combination with appropriate chemotherapy. It is also approved for treatment of non-small cell lung cancer, glioblastoma multiforme that has progressed after prior treatment, and metastatic kidney cancer when used with IFN- α . Since bevacizumab is anti-angiogenic, it should not be administered until patients heal from surgery. Patients taking the drug should be watched for hemorrhage, gastrointestinal perforations, and wound healing problems. Bevacizumab has also been used off label by intravitreal injection to slow progression of neovascular macular degeneration (see ranibizumab under Other Mabs, below).

Catumaxomab is a recombinant bi-specific trifunctional rat-mouse IgG hybrid monoclonal antibody that targets the epithelial cell adhesion molecule (EpCAM) on tumor cells and the CD3 protein on T cells. This bi-specific monoclonal antibody is approved in the USA and EU as an orphan drug for treating abdominal ascites in ovarian and gastric cancers. The rationale behind the bi-specific characteristics of catumaxomab is that it brings CD3-expressing anti-tumor T cells into close proximity of tumor cells expressing EpCAM. The Fc portion of the antibody also recruits phagocytic cells that mediate antibody-dependent cellular cytotoxicity and complement, resulting in complement-dependent cytotoxicity of tumor cells.

Cetuximab is a human-mouse chimeric monoclonal antibody that targets epidermal growth factor receptor (EGFR). Binding of cetuximab to EGFR inhibits tumor cell growth by a variety of mechanisms, including decreases in kinase activity, matrix metalloproteinase activity, and growth factor production, as well as increased apoptosis. It is approved for use in patients with EGFR-positive head and neck squamous cell carcinoma in combination with radiotherapy or appropriate chemotherapy. It is also approved for treatment of KRAS-negative, EGFR-positive metastatic colorectal cancer in combination with radiotherapy or appropriate chemotherapy, or as a single agent in patients who cannot tolerate certain chemotherapies. Cetuximab may be administered in combination with irinotecan or alone in patients who cannot tolerate irinotecan. HAMAs are generated by about 4% of patients being treated with cetuximab.

Daratumumab binds to CD38, which is over-expressed on myeloma cells. Binding of daratumumab to CD38 on myeloma cells likely induces cell death by apoptosis, complement-dependent cytotoxicity, or antibody-dependent cytotoxicity. It is approved by the FDA for use in multiple myeloma patients who are refractory to standard treatments, although phase III trials are ongoing regarding its use as a frontline therapy. **Elotuzumab** is FDA approved for the treatment of relapsed multiple myeloma. This Mab binds signaling lymphocytic activation molecule F7 (SLAMF7) on myeloma cells. It enables killing of multiple myeloma tumor cells by antibody-dependent cell-mediated cytotoxicity (ADCC).

Dinutuximab is a ganglioside D2 (GD2)-binding Mab approved for pediatric patients with high-risk neuroblastoma in combination with granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-2 (IL-2), and 13-cis-retinoic acid (RA) who achieve at least a partial response to prior first-line multiagent, multimodality therapy. It has a black box warning for serious infusion reactions and neurotoxicity in the majority of patients.

Necitumumab is a Mab directed against epidermal growth factor receptor (EGFR) and approved for use in patients with squamous non-small cell lung cancer in combination with gemcitabine and cisplatin. There is a black box warning for cardiopulmonary arrest and hypomagnesemia.

Immune Checkpoint Inhibitor Mabs

Ipilimumab (Yervoy) binds to CTLA-4 on T cells, preventing CD80/86 from delivering a suppressive signal to T cells. This has the effect of maintaining T-cell activation. It is approved for the treatment of unresectable or metastatic melanoma and treatment of cutaneous melanoma with regional nodes in the adjuvant surgical setting.

Nivolumab, Pembrolizumab, and Atezolizumab allow potential anti-tumor T cells to remain activated. By binding to the PD-1 marker on T cells, nivolumab and pembrolizumab block the binding of PD ligand-1 (PD-L1) on tumor cells, which suppresses T cell activity. Atezolizumab and avelumab bind to PD-L1 on tumor cells, also interfering with PD-1 signaling in T cells.

Nivolumab is approved for Hodgkin's lymphoma, renal cell carcinoma, non-small cell lung cancer, and melanoma. Pembrolizumab is approved for the treatment of head and neck cancer, melanoma (and ipilimumab-resistant melanoma), Merkel cell carcinoma, non-small cell lung cancer, and cancers in HIV-positive patients. Atezolizumab is approved for bladder cancer and is in late-stage clinical trials for several other cancer types.

Panitumumab is a fully human IgG₂ kappa light chain monoclonal antibody. It is approved for the treatment of EGFR-expressing metastatic colorectal carcinoma with disease progression on or following fluoropyrimidine-, oxaliplatin-, and irinotecan-containing chemotherapy regimens. Panitumumab binds to EGFR (similar to cetuximab), inhibiting epidermal growth factor from binding to its receptor, and prevents ligand-induced receptor autophosphorylation and activation of receptor-associated kinases. It inhibits cell growth, induces apoptosis, decreases vascular growth factor production, and suppresses internalization of the EGFR. Although dermatologic and infusion-related toxicities are common following infusion of panitumumab, the distinct advantage over cetuximab is that it is fully human (ie, does not elicit HAMAs) and thus has an extended half-life in circulation. This is the first FDA-approved monoclonal antibody produced from transgenic mice expressing the human immunoglobulin gene loci.

Pertuzumab is a recombinant humanized IgG₁ monoclonal antibody. It is approved for the treatment of metastatic or locally advanced HER-2/*neu*-positive breast cancer in combination with trastuzumab (see below) and docetaxel as neoadjuvant therapy. This antibody suppresses tumor growth by preventing heterodimerization of the human epidermal growth factor receptor HER-2/*neu* with other HER family members, thus inhibiting ligand-mediated intracellular signaling through MAP kinase and PI3 kinase pathways. Pertuzumab also mediates antibody-dependent cell-mediated cytotoxicity on HER-2/*neu*-positive tumor cells.

Ofatumumab is a human IgG₁ monoclonal antibody directed against an epitope on CD20 on lymphocytes. Rituximab, the first approved CD20 monoclonal antibody (see below), also binds

CD20, but to a different epitope. Ofatumumab is approved for patients with CLL who are refractory to fludarabine and alemtuzumab. Ofatumumab binds to all B cells including B-CLL. It is thought to lyse B-CLL cells in the presence of complement and to mediate antibody-dependent cellular cytotoxicity. There is a slight risk of hepatitis B virus reactivation in patients taking ofatumumab.

Ramucirumab is a human Mab that binds to VEGF receptor 2 on tumor cells as a receptor antagonist, blocking the binding of VEGF to VEGFR2. It is FDA approved for the following indications: metastatic colon cancer in combination with a FOLFIRI chemotherapy regimen (folinic acid, fluorouracil, and irinotecan), platinum-resistant metastatic small cell lung cancer in combination with docetaxel, and advanced gastric or gastroesophageal junction adenocarcinoma with or without paclitaxel.

Rituximab is a chimeric murine-human monoclonal IgG₁ (human Fc) that binds to the CD20 molecule on normal and malignant B lymphocytes and is approved for the therapy of patients with CD20-positive large-B-cell diffuse non-Hodgkin's lymphoma, and relapsed or refractory low-grade or follicular B-cell non-Hodgkin's lymphoma as a single agent or in combination with appropriate chemotherapy. It is approved for treatment of CLL in combination with chemotherapy. It is also approved for the treatment of rheumatoid arthritis in combination with methotrexate in patients for whom anti-TNF- α therapy has failed. The most recent indication for rituximab is for the treatment of Wegener's granulomatosis and microscopic polyangiitis. The mechanism of action includes complement-mediated lysis, antibody-dependent cellular cytotoxicity, and induction of apoptosis in malignant lymphoma cells and in B cells involved in the pathogenesis of rheumatoid arthritis and granulomatosis and polyangiitis. In lymphoma this drug appears to be synergistic with chemotherapy (eg, fludarabine, CHOP; see Chapter 54). Anemia or neutropenia is an important adverse effect, which can be countered with granulocyte colony-stimulating factor (G-CSF). Other adverse effects include hypotension, rash, gastrointestinal disturbance, fever, and fatigue.

Trastuzumab is a recombinant DNA-derived, humanized monoclonal antibody that binds to the extracellular domain of HER-2/*neu*. This antibody blocks the natural ligand from binding and downregulates the receptor. Trastuzumab is approved for the treatment of HER-2/*neu*-positive tumors in patients with breast cancer and patients with metastatic gastric or gastroesophageal junction adenocarcinoma. As a single agent it induces remission in 15–20% of breast cancer patients; in combination with chemotherapy, it increases response rates and duration as well as 1-year survival. Trastuzumab is under investigation for other tumors that express HER-2/*neu* (see Chapter 54). Patients should be monitored for potential cardiomyopathy while taking this drug.

Mabs Used to Deliver Isotopes & Toxins to Tumors

Ado-trastuzumab emtansine is an antibody-drug conjugate in which the anti-HER-2/*neu* antibody, trastuzumab (see above),

is chemically linked to the cytotoxic agent, mertansine, a microtubule disruptor. Ado-trastuzumab emtansine is approved for patients with HER-2/*neu*-positive breast cancer who have previously received trastuzumab and a taxane separately or in combination, and whose disease recurred or progressed during prior treatment. Toxicities are identical to trastuzumab alone and also include hepatotoxicity due to emtansine.

Arcitumomab is a murine Fab fragment from an anti-carcinoembryonic antigen (CEA) antibody labeled with technetium 99m (^{99m}Tc) that is used for imaging patients with metastatic colorectal carcinoma (immunoscintigraphy) to determine extent of disease. CEA is often upregulated in patients with gastrointestinal carcinomas. The use of the Fab fragment decreases the immunogenicity of the agent so that it can be given more than once; intact murine monoclonal antibodies would elicit stronger HAMA.

Brentuximab vedotin is an antibody-drug conjugate that binds CD30, a cell surface marker in the TNF receptor superfamily that is expressed on anaplastic large T-cell lymphomas and on Reed-Sternberg cells in Hodgkin's lymphoma; it may also be expressed on activated leukocytes. Brentuximab vedotin consists of a chimeric (mouse-human) IgG₁ linked to monomethylauristatin E (MMAE), a microtubule-disrupting agent that induces cell cycle arrest and apoptosis. When this ADC binds CD30 on the cell surface, the complex is internalized followed by proteolytic cleavage of MMAE from the IgG. Brentuximab is approved for treatment of patients with Hodgkin's lymphoma after failure of autologous stem cell transplantation or after failure of at least two previous chemotherapy regimens. It is also approved for patients with systemic anaplastic large cell lymphoma after failure of at least one previous multiagent chemotherapy regimen. Patients taking brentuximab vedotin should be monitored primarily for neutropenia and peripheral sensory neuropathy.

Capromab pendetide is a murine monoclonal antibody specific for prostate specific membrane antigen. It is coupled to isotopic indium (¹¹¹In) and is used in immunoscintigraphy for patients with biopsy-confirmed prostate cancer and post-prostatectomy in patients with rising prostate-specific antibody level to determine extent of disease.

Ibritumomab tiuxetan is an anti-CD20 murine monoclonal antibody labeled with isotopic yttrium (⁹⁰Y) or ¹¹¹In. The radiation of the isotope coupled to the antibody provides the major antitumor activity of this drug. Ibritumomab is approved for use in patients with relapsed or refractory low-grade, follicular, or B-cell non-Hodgkin's lymphoma, including patients with rituximab-refractory follicular disease. It is used in conjunction with rituximab in a two-step therapeutic regimen.

Mabs and Fusion Proteins Used as Immunomodulatory & Anti-Inflammatory Agents

Adalimumab, **certolizumab pegol**, **etanercept**, **golimumab**, and **infliximab** are antibodies that bind and neutralize the biological activity of TNF- α , a proinflammatory cytokine that is important

in adult and juvenile rheumatoid arthritis and similar inflammatory diseases such as psoriatic arthritis, ankylosing spondylitis, Crohn's disease, and ulcerative colitis.

Abatacept and belatacept are recombinant fusion proteins composed of the extracellular domain of cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) fused to the Fc domains of human IgG₁ (Figure 55–7). Abatacept is approved for use in rheumatoid and other forms of arthritis and is discussed in Chapter 36. Belatacept is approved to help prevent rejection in kidney transplants. Both fusion proteins block the activation of T cells by binding CD80, blocking the CD28 activation signal in T cells.

Anakinra is a recombinant form of the naturally occurring IL-1 receptor antagonist that prevents IL-1 from binding to its receptor, stemming the cascade of cytokines that would otherwise be released. Anakinra is approved for use in adult rheumatoid arthritis patients who have failed treatment with one or more disease-modifying antirheumatic drugs. **Rilonacept** is a dimeric fusion protein consisting of the ligand-binding domains of the extracellular portions of the human interleukin-1 receptor component (IL-1RI) and IL-1 receptor accessory protein (IL-1RAcP) fused to the Fc portion of human IgG₁. These molecules are indicated for treatment of cryopyrin-associated periodic syndromes.

Ixekizumab, secukinumab, and brodalumab are FDA-approved for the treatment of patients with moderate to severe plaque psoriasis. Ixekizumab and secukinumab bind the IL-17 cytokine and block it from binding to its receptor, while brodalumab blocks IL-17 by binding to the IL-17 receptor itself.

Reslizumab binds and neutralizes the biological activity of IL-5, thereby suppressing the production and survival of eosinophils. It is approved for adult patients with severe eosinophilic asthma. **Mepolizumab** also binds to IL-5 and selectively inhibits eosinophilic inflammation in patients with severe eosinophilic asthma.

Siltuximab is a Mab that binds to and blocks IL-6 from binding to its cellular receptor. It is approved for the treatment of patients with multicentric Castleman's disease who are HIV-negative and HHV-8-negative.

Tocilizumab is recombinant humanized IgG₁ that binds to soluble and membrane-associated IL-6 receptors. It inhibits IL-6-mediated signaling on lymphocytes, suppressing inflammatory processes. Similar to anti-TNF- α Mabs, patients receiving tocilizumab should be closely monitored for infectious diseases such as tuberculosis and other invasive bacterial, fungal, and viral infections.

Basiliximab is a chimeric mouse-human IgG₁ that binds to CD25, the IL-2 receptor α chain on activated lymphocytes. **Daclizumab** is a humanized IgG₁ that also binds to the α subunit of the IL-2 receptor. Both agents function as IL-2 antagonists, blocking IL-2 from binding to activated lymphocytes, and are therefore immunosuppressive. They are indicated for prophylaxis of acute organ rejection in renal transplant patients, and either drug may be used as part of an immunosuppressive regimen that also includes glucocorticoids and cyclosporine.

Belimumab is a Mab that inhibits B cell activating factor, also known as B lymphocyte stimulator, preventing B cells from being stimulated. It is approved for treatment of adults with active, autoantibody-positive systemic lupus erythematosus (SLE) who are also receiving standard therapy.

Canakinumab is a human IgG kappa chain monoclonal antibody that prevents IL-1 β from binding to its receptor. It is approved for cryopyrin-associated periodic syndromes (CAPS) in adults and children 4 years old and older. CAPS includes familial cold autoinflammatory syndrome, Muckle-Wells syndrome, and systemic juvenile idiopathic arthritis in children 2 years old or older. These diseases are caused by mutations in a gene (*NLRP-3*) that encodes cryopyrin, an important component of the inflammasome. *NLRP-3* mutations cause excessive

FIGURE 55–7 Actions of some monoclonal antibodies (shown in red). CTLA-4-Ig fusion protein (CTLA-4-Ig, abatacept) binds to CD80/86 on DC and inhibits T-cell costimulation. Alefacept inhibits activation of T cells by blocking the interaction of LFA-3 and CD2. Basiliximab and daclizumab block IL-2 from binding to the IL-2 receptor (CD25) on T cells, preventing activation; CD25 is also important for the survival of T regulatory cells. T-cell activation can be maintained or restored if CTLA-4 interaction with CD80/86 is blocked using an anti-CTLA-4 antibody (ipilimumab); ipilimumab inhibits CTLA-4 signaling and prolongs activation. Pembrolizumab and nivolumab bind to PD-1, while atezolizumab binds to PD-L1. Each of these three Mabs inhibits the negative signal delivery by PD-1, also prolonging T cell activation.

release of IL-1 β , causing autoimmune inflammation resulting in fever, urticarial-like rash, arthralgia, myalgia, fatigue, and conjunctivitis.

Natalizumab is a humanized IgG₄ monoclonal antibody that binds to the α 4-subunit of α 4 β 1 and α 4 β 7 integrins expressed on the surfaces of all leukocytes except neutrophils. It inhibits the α 4-mediated adhesion of leukocytes to their cognate receptor. It is indicated for patients with multiple sclerosis and Crohn's disease who have not tolerated or had inadequate responses to conventional treatments. Natalizumab should not be used with any of the anti-TNF- α drugs listed above. Natalizumab increases risk of progressive multifocal leukoencephalopathy.

Omalizumab is an anti-IgE recombinant humanized monoclonal antibody that is approved for the treatment of allergic asthma in adult and adolescent patients whose symptoms are refractory to inhaled corticosteroids (see Chapter 20). The drug is also approved for chronic urticaria. The antibody blocks the binding of IgE to the high-affinity Fc ϵ receptor on basophils and mast cells, which suppresses IgE-mediated release of type I allergy mediators such as histamine and leukotrienes. Total serum IgE levels may remain elevated in patients for up to 1 year after administration of omalizumab.

Ustekinumab is a human IgG₁ monoclonal antibody that binds to the p40 subunit of IL-12 and IL-23 cytokines. It blocks IL-12 and IL-23 from binding to their receptors, therefore inhibiting receptor-mediated signaling in lymphocytes. Ustekinumab is indicated for adult patients with moderate to severe plaque psoriasis either alone or with methotrexate. The advantage of ustekinumab over anti-TNF- α drugs for psoriasis is faster and longer-term improvement in symptoms along with very infrequent dosing.

Vedolizumab is a humanized monoclonal antibody that targets the α 4 β 7 integrin in the gastrointestinal tract. It does not appear to induce systemic immunosuppression of other α 4 β 7 integrin-binding antibodies such as natalizumab because it does not bind to the majority of α 4 β 7 integrin on lymphocytes. It has been recommended for approval for the treatment of adults with Crohn's disease and ulcerative colitis.

Other Mabs

Abciximab is a Fab fragment of a murine-human monoclonal antibody that binds to the integrin GPIIb/IIIa receptor on activated platelets and inhibits fibrinogen, von Willebrand factor, and other adhesion molecules from binding to activated platelets, thus preventing their aggregation. It is indicated as an adjunct to percutaneous coronary intervention in combination with aspirin and heparin for the prevention of cardiac ischemic complications. See Chapter 34 for additional details.

Alirocumab and **Evolocumab** are anti-cholesterol Mabs (see Chapter 35). They lower LDL levels by blocking proprotein convertase subtilisin/kexin type 9 (PCSK9) from binding to LDL receptors (LDLR) and causing LDL receptor degradation. Therefore, these Mabs have the effect of increasing LDLR on hepatocytes, which lowers LDL levels in circulation. They are approved as an adjunct to diet and maximally tolerated statin therapy in adults with homo- or heterozygous familial hypercholesterolemia

or atherosclerotic cardiovascular disease who require additional lowering of LDL-C.

Denosumab is a human IgG₂ monoclonal antibody specific for human RANKL (receptor activator of nuclear factor kappa-B ligand; see Chapter 42). By binding RANKL it inhibits the maturation of osteoclasts, the cells responsible for bone resorption. Denosumab is indicated for treatment of postmenopausal women with osteoporosis at high risk for fracture. Before starting denosumab, patients must be evaluated to be sure they are not hypocalcemic. During treatment, patients should receive supplements of calcium and vitamin D.

Eculizumab is a humanized IgG monoclonal antibody that binds the C5 complement component, inhibiting its cleavage into C5a and C5b thereby inhibiting the terminal pore-forming lytic activity of complement. Eculizumab is approved for patients with paroxysmal nocturnal hemoglobinuria (PNH) and atypical hemolytic uremic syndrome (aHUS). It dramatically reduces the need for red blood cell transfusions. It prevents PNH symptoms of anemia, fatigue, thrombosis, and hemoglobinemia by inhibiting intravascular hemolysis. Similarly in aHUS eculizumab prevents complement-mediated thrombotic microangiopathy. Clinicians must be aware of increased risk of meningococcal infection in patients receiving this anti-C5 monoclonal antibody.

Palivizumab is a humanized IgG₁ monoclonal antibody that binds to the fusion protein of respiratory syncytial virus (RSV), preventing serious lower respiratory tract disease. It is used in neonates at risk for this viral infection and reduces the frequency of infection and hospitalization by about 50% (see Chapter 49).

Ranibizumab is a recombinant human IgG₁ Fab that binds to VEGF-A. It prevents new blood vessel formation by blocking VEGF from binding to its receptor. Ranibizumab is approved for intravitreal injection in patients with neovascular age-related macular degeneration, diabetic macular edema, and sudden blurring or vision loss secondary to macular edema following retinal vein occlusion. **Pegaptanib** is a pegylated oligonucleotide that binds extracellular VEGF and is also given by intravitreal injection to slow macular degeneration.

Obiltoximab and **raxibacumab** are FDA-approved Mabs for treatment of patients after inhalation exposure to *Bacillus anthracis* spores. Both Mabs block the binding of *B anthracis* "protective antigen" to its cellular receptor, preventing entry of anthrax lethal and edema factors into cells. They are approved for the treatment or prophylaxis of adults and children with inhalational anthrax in combination with appropriate antibacterial drugs. Interestingly, these Mabs were not tested in humans because exposing a control cohort to inhalational anthrax is unethical and there are too few naturally infected persons to conduct a proper clinical trial.

■ CLINICAL USES OF IMMUNOSUPPRESSIVE DRUGS

Immunosuppressive agents are commonly used in two clinical circumstances: transplantation and autoimmune disorders. The agents used differ somewhat for the specific disorders treated (see specific agents and Table 55–1), as do administration schedules.

Because autoimmune disorders are very complex, optimal treatment schedules have yet to be established in many of them.

SOLID ORGAN & BONE MARROW TRANSPLANTATION

In organ transplantation, tissue typing—based on donor and recipient histocompatibility matching with the human leukocyte antigen (HLA) haplotype system—is required. Close histocompatibility matching reduces the likelihood of graft rejection and may also reduce the requirements for intensive immunosuppressive therapy. Prior to transplant, patients may receive an immunosuppressive regimen, including antithymocyte globulin, daclizumab, or basiliximab. Four types of rejection can occur in a solid organ transplant recipient: **hyperacute**, **accelerated**, **acute**, and **chronic**. Hyperacute rejection is due to preformed antibodies against the donor organ, such as anti-blood group antibodies. Hyperacute rejection occurs within hours of the transplant and cannot be stopped with immunosuppressive drugs. It results in rapid necrosis and failure of the transplanted organ. Accelerated rejection is mediated by both antibodies and T cells, and it also cannot be stopped by immunosuppressive drugs. Acute rejection of an organ occurs within days to months and involves mainly cellular immunity. Reversal of acute rejection is usually possible with general immunosuppressive drugs such as azathioprine, mycophenolate mofetil, cyclosporine, tacrolimus, glucocorticoids, cyclophosphamide, methotrexate, and sirolimus. Recently, biologic agents such as anti-CD3 monoclonal antibodies have been used to stem acute rejection. Chronic rejection usually occurs months or even years after transplantation. It is characterized by thickening and fibrosis of the vasculature of the transplanted organ, involving both cellular and humoral immunity. Chronic rejection is treated with the same drugs as those used for acute rejection.

Allogeneic hematopoietic stem cell transplantation is a well-established treatment for many malignant and nonmalignant diseases. An HLA-matched donor, usually a family member, is located, patients are conditioned with high-dose chemotherapy and/or radiation therapy, and then donor stem cells are infused. The conditioning regimen is used not only to kill cancer cells in the case of malignant disease, but also to totally suppress the immune system so that the patient does not reject the donor stem cells. As patients' blood counts recover (after reduction by the conditioning regimen) they develop a new immune system that is created from the donor stem cells. Rejection of donor stem cells is uncommon and can only be treated by infusion of more stem cells from the donor.

GVH disease, however, is very common, occurring in the majority of patients who receive an allogeneic transplant. GVH disease occurs because donor T cells fail to recognize the patient's skin, liver, and gut (usually) as self and attack those tissues. Although patients are given immunosuppressive therapy (cyclosporine, methotrexate, and others) early in the transplant course to help prevent this development, it often occurs despite these medications. Acute GVH disease occurs within the first 100 days and is usually manifested as a skin rash, severe diarrhea, or hepatotoxicity. Additional medications are added, invariably starting with high-dose corticosteroids and

adding drugs such as mycophenolate mofetil, sirolimus, tacrolimus, daclizumab, and others, with variable success rates. Patients generally progress to chronic GVH disease (after 100 days) and require therapy for variable periods thereafter. Unlike solid-organ transplant patients, however, most stem cell transplant patients are able to eventually discontinue immunosuppressive drugs as GVH disease resolves (usually 1–2 years after their transplant).

AUTOIMMUNE DISORDERS

The effectiveness of immunosuppressive drugs in autoimmune disorders varies widely. Nonetheless, with immunosuppressive therapy, remissions can be obtained in many instances of autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, type 1 diabetes, Hashimoto's thyroiditis, and temporal arteritis. Improvement is also often seen in patients with systemic lupus erythematosus, acute glomerulonephritis, acquired factor VIII inhibitors (antibodies), rheumatoid arthritis, inflammatory myopathy, scleroderma, and certain other autoimmune states.

Immunosuppressive therapy is utilized in chronic severe asthma, where cyclosporine is often effective and sirolimus is another alternative (see Chapter 20). Omalizumab (anti-IgE antibody) has been approved for the treatment of severe asthma (see previous section). Tacrolimus is currently under clinical investigation for the management of autoimmune chronic active hepatitis and of multiple sclerosis, where IFN- β has a definitive role.

IMMUNOMODULATION THERAPY

The development of agents that modulate the immune response rather than suppress it has become an important area of pharmacology. The rationale underlying this approach is that such drugs may *increase* the immune responsiveness of patients who have either selective or generalized immunodeficiency. The major potential uses are in immunodeficiency disorders, chronic infectious diseases, and cancer. The AIDS epidemic has greatly increased interest in developing more effective immunomodulating drugs.

CYTOKINES

The cytokines are a large and heterogeneous group of proteins with diverse functions. Some are immunoregulatory proteins synthesized by leukocytes and play numerous interacting roles in the function of the immune system and in the control of hematopoiesis. The cytokines that have been clearly identified are summarized in Table 55–2. In most instances, cytokines mediate their effects through receptors on relevant target cells and appear to act in a manner similar to the mechanism of action of hormones. In other instances, cytokines may have antiproliferative, antimicrobial, and antitumor effects.

The first group of cytokines discovered, the interferons (IFNs), were followed by the colony-stimulating factors (CSFs, discussed

TABLE 55-2 The cytokines.

Cytokine	Properties
Interferon- α (IFN- α)	Antiviral, oncostatic, activates NK cells
Interferon- β (IFN- β)	Antiviral, oncostatic, activates NK cells
Interferon- γ (IFN- γ)	Antiviral, oncostatic, secreted by and activates or up-regulates Th1 cells, NK cells, CTLs, and macrophages
Interleukin-1 (IL-1)	T-cell activation, B-cell proliferation and differentiation
Interleukin-2 (IL-2)	T-cell proliferation, Th1, NK, and LAK cell activation
Interleukin-3 (IL-3)	Hematopoietic precursor proliferation and differentiation
Interleukin-4 (IL-4)	Th2 and CTL activation, B-cell proliferation
Interleukin-5 (IL-5)	Eosinophil proliferation, B-cell proliferation and differentiation
Interleukin-6 (IL-6)	HCF, Th2, CTL, and B-cell proliferation
Interleukin-7 (IL-7)	CTL, NK, LAK, and B-cell proliferation, thymic precursor stimulation
Interleukin-8 (IL-8)	Neutrophil chemotaxis, proinflammatory
Interleukin-9 (IL-9)	T-cell proliferation
Interleukin-10 (IL-10)	Th1 suppression, CTL activation, B-cell proliferation
Interleukin-11 (IL-11)	Megakaryocyte proliferation, B-cell differentiation
Interleukin-12 (IL-12)	Th1 and CTL proliferation and activation
Interleukin-13 (IL-13)	Macrophage function modulation, B cell proliferation
Interleukin-14 (IL-14)	B-cell proliferation and differentiation
Interleukin-15 (IL-15)	Th1, CTL, and NK/LAK activation, expansion of T-cell memory pools
Interleukin-16 (IL-16)	T-lymphocyte chemotaxis, suppresses HIV replication
Interleukin-17 (IL-17)	Stromal cell cytokine production
Interleukin-18 (IL-18)	Induces Th1 responses
Interleukin-19 (IL-19)	Proinflammatory
Interleukin-20 (IL-20)	Promotes skin differentiation
Interleukin-21 (IL-21)	Promotes proliferation of activated T cells, maturation of NK cells
Interleukin-22 (IL-22)	Regulator of Th2 cells
Interleukin-23 (IL-23)	Promotes proliferation of Th1 memory cells
Interleukin-24 (IL-24)	Induces tumor apoptosis, induces Th1 responses
Interleukin-27 (IL-27)	Stimulates naive CD4 cells to produce IFN- γ
Interleukin-28 and -29 (IL-28, IL-29)	Antiviral, interferon-like properties
Interleukin-30 (IL-30)	p28 subunit of IL-27
Interleukin-31 (IL-31)	Contributes to type I hypersensitivities and Th2 responses
Interleukin-32 (IL-32)	Involved in inflammation
Interleukin-34 (IL-34)	Stimulates monocyte proliferation via the CSF-1 receptor (CSF-1R)
Interleukin-35 (IL-35)	Induces regulatory T cells (iT _R 35)
Tumor necrosis factor- α (TNF- α)	Oncostatic, macrophage activation, proinflammatory
Tumor necrosis factor- β (TNF- β)	Oncostatic, proinflammatory, chemotactic
Granulocyte colony-stimulating factor	Granulocyte production
Granulocyte-macrophage colony-stimulating factor	Granulocyte, monocyte, eosinophil production
Macrophage colony-stimulating factor	Monocyte production, activation
Erythropoietin (epoetin, EPO)	Red blood cell production
Thrombopoietin (TPO)	Platelet production

Note: Many interleukin activities overlap and are influenced by each other.

HCF, hematopoietic cofactor; LAK, lymphokine-activated killer cell.

in Chapter 33). The latter regulate the proliferation and differentiation of bone marrow progenitor cells. Most of the more recently discovered cytokines have been classified as interleukins (ILs) and numbered in the order of their discovery. Pharmaceutical cytokines are produced using gene cloning techniques.

Most cytokines (including TNF- α , IFN- γ , IL-2, G-CSF, and granulocyte-macrophage colony-stimulating factor [GM-CSF]) have very short serum half-lives (minutes). The usual subcutaneous route of administration provides slower release into the circulation and a longer duration of action. Each cytokine has its own unique toxicity, but some toxicities are shared. For example, IFN- α , IFN- β , IFN- γ , IL-2, and TNF- α all induce fever, flu-like symptoms, anorexia, fatigue, and malaise.

Interferons are proteins that are currently grouped into three families: IFN- α , IFN- β , and IFN- γ . The IFN- α and IFN- β families constitute type I IFNs, ie, acid-stable proteins that bind to the same receptor on target cells. IFN- γ , a type II IFN, is acid-labile and binds to a separate receptor on target cells. Type I IFNs are usually induced by virus infections, with leukocytes producing IFN- α . Fibroblasts and epithelial cells produce IFN- β . IFN- γ is usually the product of activated T lymphocytes.

IFNs interact with cell receptors to produce a wide variety of effects that depend on the cell and IFN types. IFNs, particularly IFN- γ , display immune-enhancing properties, which include increased antigen presentation and macrophage, NK cell, and cytotoxic T-lymphocyte activation. IFNs also inhibit cell proliferation. In this respect, IFN- α and IFN- β are more potent than IFN- γ . Another striking IFN action is increased expression of MHC molecules on cell surfaces. While all three types of IFN induce MHC class I molecules, only IFN- γ induces class II expression. In glial cells, IFN- β antagonizes this effect and may, in fact, decrease antigen presentation within the nervous system.

IFN- α is approved for the treatment of several neoplasms, including hairy cell leukemia, chronic myelogenous leukemia, malignant melanoma, and Kaposi's sarcoma, and for treatment of hepatitis B and C infections. It has also shown activity as an anti-cancer agent in renal cell carcinoma, carcinoid syndrome, and T-cell leukemia. IFN- β is approved for use in relapsing-type multiple sclerosis. IFN- γ is approved for the treatment of chronic granulomatous disease and IL-2, for metastatic renal cell carcinoma and malignant melanoma. Clinical investigations of other cytokines, including IL-1, -3, -4, -6, -10, -11, and -12, are ongoing. Toxicities of IFNs, which include fever, chills, malaise, myalgias, myelosuppression, headache, and depression, can severely restrict their clinical use.

TNF- α has been extensively tested in the therapy of various malignancies, but results have been disappointing due to dose-limiting toxicities. One exception is the use of intra-arterial high-dose TNF- α for malignant melanoma and soft tissue sarcoma of the extremities. In these settings, response rates greater than 80% were noted.

Denileukin diftitox is IL-2 fused to diphtheria toxin, used for the treatment of patients with CD25+ cutaneous T-cell lymphomas. IL-12 and GM-CSF have also shown adjuvant effects with vaccines. GM-CSF is of particular interest because it promotes

recruitment of professional antigen-presenting cells such as the dendritic cells required for priming naive antigen-specific T-lymphocyte responses. There are some reports that GM-CSF can itself stimulate an antitumor immune response, resulting in tumor regression in melanoma and prostate cancer.

It is important to emphasize that cytokine interactions with target cells often result in the release of a cascade of different endogenous cytokines, which exert their effects sequentially or simultaneously. For example, IFN- γ exposure increases the number of cell-surface receptors on target cells for TNF- α . Therapy with IL-2 induces the production of TNF- α , while experimental therapy with IL-12 induces the production of IFN- γ .

■ IMMUNOLOGIC REACTIONS TO DRUGS & DRUG ALLERGY

The basic immune mechanism and the ways in which it can be suppressed or stimulated by drugs have been discussed in previous sections of this chapter. Drugs also activate the immune system in undesirable ways that are manifested as adverse drug reactions. These reactions are generally grouped in a broad classification as “drug allergy.” Indeed, many drug reactions such as those to penicillin, iodides, phenytoin, and sulfonamides are allergic in nature. These drug reactions are manifested as skin eruptions, edema, anaphylactoid reactions, glomerulonephritis, fever, and eosinophilia.

Drug reactions mediated by immune responses can have several different mechanisms. Thus, any of the four major types of hypersensitivity discussed earlier in this chapter (pages 981–983) can be associated with allergic drug reactions:

- **Type I:** IgE-mediated acute allergic reactions to stings, pollens, and drugs, including anaphylaxis, urticaria, and angioedema. IgE is fixed to tissue mast cells and blood basophils, and after interaction with antigen the cells release potent mediators.
- **Type II:** Drugs often modify host proteins, thereby eliciting antibody responses to the modified protein. These allergic responses involve IgG or IgM in which the antibody becomes fixed to a host cell, which is then subject to complement-dependent lysis or to antibody-dependent cellular cytotoxicity.
- **Type III:** Drugs may cause serum sickness, which involves immune complexes containing IgG complexed with a foreign antigen and is a multisystem complement-dependent vasculitis that may also result in urticaria.
- **Type IV:** Cell-mediated allergy is the mechanism involved in allergic contact dermatitis from topically applied drugs or induction of the skin at the site of an antigen injected intradermally.

In some drug reactions, several of these hypersensitivity responses may occur simultaneously. Some adverse reactions to drugs may be mistakenly classified as allergic or immune when they are actually genetic deficiency states or are idiosyncratic and not mediated by immune mechanisms (eg, hemolysis due to primaquine in glucose-6-phosphate dehydrogenase deficiency, or aplastic anemia caused by chloramphenicol). See Figure 55–6.

IMMEDIATE (TYPE I) DRUG ALLERGY

Type I (immediate) sensitivity allergy to certain drugs occurs when the drug, not capable of inducing an immune response by itself, covalently links to a host carrier protein (hapten). When this happens, the immune system detects the drug-hapten conjugate as “modified self” and responds by generating IgE antibodies specific for the drug-hapten. It is not known why some patients mount an IgE response to a drug while others mount IgG responses. Under the influence of IL-4, -5, and -13 secreted by Th2 cells, B cells specific for the drug secrete IgE antibody. The mechanism for IgE-mediated immediate hypersensitivity is diagrammed in Figure 55-5.

Fixation of the IgE antibody to high-affinity Fc receptors (FcεRs) on blood basophils or their tissue equivalent (mast cells) sets the stage for an acute allergic reaction. The most important sites for mast cell distribution are skin, nasal epithelium, lung, and gastrointestinal tract. When the offending drug is reintroduced into the body, it binds and cross-links basophil and mast cell-surface IgE to signal release of the mediators (eg, histamine, leukotrienes; see Chapters 16 and 18) from granules. Mediator release is associated with calcium influx and a fall in intracellular cAMP within the mast cell. Many of the drugs that block mediator release appear to act through the cAMP mechanism (eg, catecholamines, glucocorticoids, theophylline), others block histamine release, and still others block histamine receptors. Other vasoactive substances such as kinins may also be generated during histamine release. These mediators initiate immediate vascular smooth muscle relaxation, increased vascular permeability, hypotension, edema, and bronchoconstriction.

Drug Treatment of Immediate Allergy

One can test an individual for possible sensitivity to a drug by a simple scratch test, ie, by applying an extremely dilute solution of the drug to the skin and making a scratch with the tip of a needle. If allergy is present, an immediate (within 10–15 minutes) wheal (edema) and flare (increased blood flow) will occur. However, skin tests may be negative in spite of IgE hypersensitivity to a hapten or to a metabolic product of the drug, especially if the patient is taking steroids or antihistamines.

Drugs that modify allergic responses act at several links in this chain of events. Prednisone, often used in severe allergic reactions, is immunosuppressive; it blocks proliferation of the IgE-producing clones and inhibits IL-4 production by T helper cells in the IgE response, since glucocorticoids are generally toxic to lymphocytes. In the efferent limb of the allergic response, isoproterenol, epinephrine, and theophylline reduce the release of mediators from mast cells and basophils and produce bronchodilation. Epinephrine opposes histamine; it relaxes bronchiolar smooth muscle and contracts vascular muscle, relieving both bronchospasm and hypotension. *As noted in Chapter 8, epinephrine is the drug of choice in anaphylactic reactions.* The antihistamines competitively inhibit histamine, which would otherwise produce bronchoconstriction and increased capillary permeability in end organs. Glucocorticoids may also act to reduce tissue injury and

edema in the inflamed tissue, as well as facilitating the actions of catecholamines in cells that may have become refractory to epinephrine or isoproterenol. Several agents directed toward the inhibition of leukotrienes may be useful in acute allergic and inflammatory disorders (see Chapter 20).

Desensitization to Drugs

When reasonable alternatives are not available, certain drugs (eg, penicillin, insulin) must be used for life-threatening illnesses even in the presence of known allergic sensitivity. In such cases, desensitization (also called hyposensitization) can sometimes be accomplished by starting with very small doses of the drug and gradually increasing the dose over a period of hours or days to the full therapeutic range (see Chapter 43). This practice is hazardous and must be performed under direct medical supervision with epinephrine available for immediate injection, as anaphylaxis may occur before desensitization has been achieved. It is thought that slow and progressive administration of the drug gradually binds all available IgE on mast cells, triggering a gradual release of granules. Once all of the IgE on the mast cell surfaces has been bound and the cells have been degranulated, therapeutic doses of the offending drug may be given with minimal further immune reaction. Therefore, a patient is desensitized only during administration of the drug.

AUTOIMMUNE (TYPE II) REACTIONS TO DRUGS

Certain autoimmune syndromes can be induced by drugs. Examples include systemic lupus erythematosus following hydralazine or procainamide therapy, “lupoid hepatitis” due to cathartic sensitivity, autoimmune hemolytic anemia resulting from methyldopa administration, thrombocytopenic purpura due to quinidine, and agranulocytosis due to a variety of drugs. As indicated in other chapters of this book, a number of drugs are associated with type I and type II reactions. In these drug-induced autoimmune states, IgG antibodies bind to drug-modified tissue and are destroyed by the complement system or by phagocytic cells with Fc receptors. Fortunately, autoimmune reactions to drugs usually subside within several months after the offending drug is withdrawn. Immunosuppressive therapy is warranted only when the autoimmune response is unusually severe.

SERUM SICKNESS & VASCULITIC (TYPE III) REACTIONS

Immunologic reactions to drugs resulting in serum sickness are more common than immediate anaphylactic responses, but type II and type III hypersensitivities often overlap. The clinical features of serum sickness include urticarial and erythematous skin eruptions, arthralgia or arthritis, lymphadenopathy, glomerulonephritis, peripheral edema, and fever. The reactions generally last 6–12 days and usually subside once the offending drug is eliminated. Antibodies of the IgM or IgG class are usually

involved. The mechanism of tissue injury is immune complex formation and deposition on basement membranes (eg, lung, kidney), followed by complement activation and infiltration of leukocytes, causing tissue destruction. Glucocorticoids are useful in attenuating severe serum sickness reactions to drugs. In severe cases plasmapheresis can be used to remove the offending drug and immune complexes from circulation.

Immune vasculitis can also be induced by drugs. The sulfonamides, penicillin, thiouracil, anticonvulsants, and iodides all have been implicated in the initiation of hypersensitivity angitis. Erythema multiforme is a relatively mild vasculitic skin disorder that may be secondary to drug hypersensitivity. Stevens-Johnson syndrome is probably a more severe form of this hypersensitivity reaction and consists of erythema multiforme, arthritis, nephritis, central nervous system abnormalities, and myocarditis. It frequently has been associated with sulfonamide therapy. Administration of nonhuman monoclonal or polyclonal antibodies such as rattlesnake antivenom may cause serum sickness.

CELL-MEDIATED (TYPE IV) REACTIONS

Type IV hypersensitivity occurs 24–48 hours after exposure to the allergen and therefore is called delayed type hypersensitivity (DTH). Like other drug hypersensitivities, the drug may chemically react with host tissue to create a new antigen. Upon first exposure to the allergen (drug), antigen-presenting cells stimulate a T-cell response specific for that allergen. This takes 1–2 weeks. Upon second and all subsequent exposures, tissue-derived antigen-presenting cells that come in contact with the new antigen (allergen-modified host protein) secrete chemokines and cytokines that attract memory T cells to the site of allergen re-exposure. This takes only 24–48 hours. Lymphocytes and antigen-presenting cells such as macrophages accumulate at the site, causing induration, erythema, and swelling. Contact hypersensitivity is a form of DTH and occurs when an allergen elicits DTH on the skin, resulting in spongiosis such as when an ointment containing an allergen is applied to skin.

PREPARATIONS AVAILABLE*

GENERIC NAME	AVAILABLE AS
Abatacept	Orencia
Abciximab	ReoPro
Adalimumab	Humira
Ado-trastuzumab emtansine	Kadcyla
Alefacept	Amevive
Alemtuzumab	Campath
Alirocumab	Praluent
Anakinra	Kineret
Antithymocyte globulin	Thymoglobulin
Arcitumomab	CEA-Scan
Atezolizumab	Tecentriq
Azathioprine	Generic, Imuran
Basiliximab	Simulect
Belimumab	Benlysta
Bevacizumab	Avastin
Brentuximab vedotin	Adcetris
Canakinumab	Ilaris
Capromab pendetide	ProstaScint
Catumaxomab	Removab
Certolizumab	Cimzia
Cetuximab	Erbix
Cyclophosphamide	generic
Cyclosporine	Generic, Sandimmune, Restasis
Daclizumab	Zenapax
Daratumumab	Darzalex
Denileukin diftitox	Ontak
Denosumab	Prolia
Dimethyl fumarate	Tecfidera
Eculizumab	Soliris

GENERIC NAME	AVAILABLE AS
Etanercept	Enbrel
Everolimus	Afinitor, Zortress
Evolocumab	Repatha
Fingolimod hydrochloride	Gilenya
Glatiramer acetate	Copaxone
Golimumab	Simponi
Ibritumomab tiuxetan	Zevalin
Immune globulin intravenous [IGIV]	Various
Infliximab	Remicade
Interferon alfa-2a	Roferon
Interferon alfa-2b	Intron-A
Interferon beta-1a	Avonex, Rebif
Interferon beta-1b	Betaseron, Extavia
Interferon gamma-1b	Actimmune
Interleukin-2 (IL-2, aldesleukin)	Proleukin
Ipilimumab	Yervoy
Leflunomide	Arava
Lenalidomide	Revlimid
Lymphocyte immune globulin	Atgam
Mepolizumab	Nucala
Mycophenolate mofetil	Generic, CellCept
Natalizumab	Tysabri
Necitumumab	Portrazza
Nivolumab	Opdivo
Obiltoxaximab	Anthem
Ofatumumab	Arzerra
Omalizumab	Xolair
Palivizumab	Synagis
Panitumumab	Vectibix

GENERIC NAME	AVAILABLE AS
Pegademase bovine (bovine adenosine deaminase)	Adagen
Pegaptanib	Macugen
Peginterferon alfa-2a	Pegasys
Peginterferon alfa-2b	PEG-Intron
Pembrolizumab	Keytruda
Pertuzumab	Perjeta
Pomalidomide	Pomalyst
Ramucirumab	Cyramza
Ranibizumab	Lucentis
Raxibacumab	ABthrax
Reslizumab	Cinqair
Rh ₀ (D) immune globulin micro-dose	RhoGam, others

GENERIC NAME	AVAILABLE AS
Rilonacept	Arcalyst
Rituximab	Rituxan
Scorpion antivenom (equine (Fab)¢2)	Anascorp
Siltuximab	Sylvant
Sirolimus	Generic, Rapamune
Tacrolimus (FK 506)	Generic, Prograf, others
Teriflunomide	Aubagio
Thalidomide	Thalomid
Tocilizumab	Actemra
Trastuzumab	Herceptin
Ustekinumab	Stelara
Vedolizumab	Entyvio

*Several drugs discussed in this chapter are available as orphan drugs but are not listed here. Other drugs not listed here will be found in other chapters (see Index).

CASE STUDY ANSWER

Glucocorticoids (steroids) are first-line treatment for acute graft-vs-host disease. Acute graft-vs-host disease is the process of donor T cells attacking host recipient tissues (including skin), despite ongoing immunosuppressive therapy such

as tacrolimus. Adding a steroid (eg, prednisone) can ameliorate the T-cell response of graft-vs-host disease in most cases of grade II disease. See section in this chapter on Clinical Uses of Immunosuppressive Drugs.

SECTION IX TOXICOLOGY

C H A P T E R

56

Introduction to Toxicology: Occupational & Environmental

Daniel T. Teitelbaum, MD*

CASE STUDY

A 6-year-old girl is brought to the emergency department by her parents. She is comatose, tachypneic (25 breaths per minute), and tachycardic (150 bpm), but she appears flushed, and fingertip pulse oximetry is normal (97%) breathing room air. Questioning of her parents reveals that they are homeless and have been living in their car (a small van).

The nights have been cold, and they have used a small charcoal burner to keep warm inside the vehicle. What is the most likely diagnosis? What treatment should be instituted immediately? If her mother is pregnant, what additional measures should be taken?

Humans live in a chemical world. They inhale, ingest, and absorb through the skin many of these chemicals. The occupational-environmental toxicologist is primarily concerned with adverse effects in humans resulting from exposure to chemicals encountered at work or in the general environment. In clinical practice, the occupational-environmental toxicologist must identify and treat the adverse health effects of these

exposures. In addition, the trained occupational-environmental toxicologist will be called upon to assess and identify hazards associated with chemicals used in the workplace or introduced into the human environment.

Occupational and environmental toxicology cases present unusually complex problems. Occupational and environmental exposure is rarely limited to a single type of molecule. Most workplace or environmental materials are compounds or mixtures, and the ingredients are often poorly described in the documentation that is available for physician review. Moreover, although

*The author thanks the late Gabriel L. Plaa, PhD, previous author of this chapter, for his enduring contributions.

regulatory agencies in many countries have requirements for disclosure of hazardous materials and their health impacts, proprietary information exclusions often make it difficult for those who treat occupationally and environmentally poisoned patients to understand the nature and scope of the presenting illness. Because many of these illnesses have long latency periods before they become manifest, it is often a matter of detective work, when patients finally present with disease, to ascertain past exposure and relate it to present clinical effect. Monitoring of exposure concentrations both in the workplace and in the general environment has become more common, but it is far from widespread, and so it is often very difficult to establish the extent of exposure, its duration, and its dose rate when this information is critical to the identification of the toxic disorder and its management.

Occupational Toxicology

Occupational toxicology deals with the chemicals found in the workplace. The major emphasis of occupational toxicology is to identify the agents of concern, identify the acute and chronic diseases that they cause, define the conditions under which they may be used safely, and prevent absorption of harmful amounts of these chemicals. The occupational toxicologist will also be called upon to treat the diseases caused by these chemicals if he or she is a physician. Occupational toxicologists may also define and carry out programs for the surveillance of exposed workers and the environment in which they work. They frequently work hand in hand with occupational hygienists, certified safety professionals, and occupational health nurses in their activities.

Regulatory limits and voluntary guidelines have been elaborated to establish safe ambient air concentrations for many chemicals found in the workplace. Governmental and supragovernmental bodies throughout the world have generated workplace health and safety rules, including short- and long-term exposure limits for workers. These permissible exposure limits (PELs) have the power of law in the United States. Copies of the US Occupational Safety and Health Administration (OSHA) standards may be found on OSHA's website at <http://www.osha.gov>. Copies of the US Mine Safety and Health Administration (MSHA) standards may be found at <http://www.msha.gov>. In addition to the PELs that appear in the OSHA publications and on the website, OSHA promulgates standards for specific materials of particularly serious toxicity. These standards are developed following extensive scientific study, stakeholder input at hearings, public comment, and other steps such as publication in the *Federal Register*. Such standards have the force of law and employers who use these materials are obligated to comply with the standards. OSHA standards may be found in full on the OSHA website at <http://www.osha.gov>.

Voluntary organizations, such as the American Conference of Governmental Industrial Hygienists (ACGIH), periodically prepare lists of recommended **threshold limit values (TLVs)** for many chemicals. These guidelines are periodically updated. Regulatory imperatives in the United States may also be updated from time to time when new information about toxicity becomes available. However, this process is slow and requires input from

many sources except under certain extraordinary circumstances. In those cases, emergency alterations to standards may be made and an emergency temporary standard may be promulgated after appropriate regulatory procedures. The ACGIH TLV guidelines are useful as reference points in the evaluation of potential workplace exposures. Compliance with these voluntary guidelines is not a substitute for compliance with the OSHA requirements in the United States. TLVs do not have the force of law. Current TLV lists may be obtained from the ACGIH at <http://www.acgih.org>.

Environmental Toxicology

Environmental toxicology deals with the potentially deleterious impact of chemicals, present as pollutants of the environment, on living organisms. The term *environment* includes all the surroundings of an individual organism, but particularly the air, soil, and water. Although humans are considered a target species of particular interest, other species are of considerable importance as potential biologic targets. Scientific study of signal occurrences in animals often provides early warning of impending human events as a result of ecotoxic impacts.

Air pollution is usually a product of industrialization, technological development, and increased urbanization. On rare occasions, natural phenomena such as volcanic eruptions may result in air pollution with gases, vapors, or particulates that are harmful to humans. Humans may also be exposed to chemicals used in the agricultural environment as pesticides or in food processing that may persist as residues or ingredients in food products. Air contaminants are regulated in the United States by the Environmental Protection Agency (EPA) based on both health and esthetic considerations. Tables of primary and secondary regulated air contaminants and other regulatory issues that relate to air contaminants in the United States may be found at <http://www.epa.gov>. Many states within the USA also have individual air contaminant regulations that may be more rigorous than those of the EPA. Many other nations and some supragovernmental organizations regulate air contaminants. In the case of adjoining countries, transborder air and water pollution problems have been of concern in recent years. Particulates, radionuclides, acid rain, and similar problems have resulted in cross-contamination of air and water in different countries. Maritime contamination, too, has raised concern about oceanic pollution and has had an impact on the fisheries of some countries. This type of pollution is now the subject of much research and of new international treaties.

The United Nations Food and Agriculture Organization and the World Health Organization (FAO/WHO) Joint Expert Commission on Food Additives adopted the term **acceptable daily intake (ADI)** to denote the daily intake of a chemical from food that, during an entire lifetime, appears to be without appreciable risk. These guidelines are reevaluated as new information becomes available. In the United States, the Food and Drug Administration (FDA) and the Department of Agriculture are responsible for the regulation of contaminants such as pesticides, drugs, and chemicals in foods. Major international problems have occurred because of traffic among nations in contaminated or adulterated foods from countries whose regulations and enforcement of pure

food and drug laws are lax or nonexistent. Recently, for example, both human and animal illnesses have resulted from ingestion of products imported from China that contained melamine.

Ecotoxicology

Ecotoxicology is concerned with the toxic effects of chemical and physical agents on populations and communities of living organisms within defined ecosystems; it includes the transfer pathways of those agents and their interactions with the environment. Traditional toxicology is concerned with toxic effects on individual organisms; ecotoxicology is concerned with the impact on populations of living organisms or on ecosystems. Ecotoxicology research has become one of the foremost areas of study for toxicologists.

TOXICOLOGIC TERMS & DEFINITIONS

Hazard & Risk

Hazard is the ability of a chemical agent to cause injury in a given situation or setting; the conditions of use and exposure are primary considerations. To assess hazard, one needs to have knowledge about both the inherent toxicity of the substance and the amounts to which individuals are liable to be exposed. Hazard is often a description based on subjective estimates rather than objective evaluation.

Risk is defined as the expected frequency of the occurrence of an undesirable effect arising from exposure to a chemical or physical agent. Estimation of risk makes use of dose-response data and extrapolation from the observed relationships to the expected responses at doses occurring in actual exposure situations. The quality and suitability of the biologic data used in such estimates are major limiting factors. Risk assessment has become an integral part of the regulatory process in most countries. However, many of the assumptions of risk assessment scientists remain unproven, and only long-term observation of population causes and outcomes will provide the basis for validation of newer risk assessment technologies.

Routes of Exposure

The route of entry for chemicals into the body differs in different exposure situations. In the industrial setting, inhalation is the major route of entry. The transdermal route is also quite important, but oral ingestion is a relatively minor route. Consequently, primary prevention should be designed to reduce or eliminate absorption by inhalation or by topical contact. Atmospheric pollutants gain entry by inhalation and by dermal contact. Water and soil pollutants are absorbed through inhalation, ingestion, and dermal contact.

Quantity, Duration, & Intensity of Exposure

Toxic reactions may differ depending on the quantity of exposure, its duration, and the rate at which the exposure takes place. An exposure to a toxic substance that is absorbed by the target human

or animal results in a dose. Acute exposure indicates a single exposure or multiple exposures that occur over a brief period from seconds to 1–2 days. Intense, rapidly absorbed acute doses of substances that may ordinarily be detoxified by enzymatic mechanisms in small doses may overwhelm the body's ability to detoxify the substance and may result in serious or even fatal toxicity. The same amount of the substance, absorbed slowly, may result in little or no toxicity. This is the case with cyanide exposure. Rhodanese, a mitochondrial enzyme present in humans, effectively detoxifies cyanide to relatively nontoxic thiocyanate when cyanide is presented in small amounts, but the enzyme is overwhelmed by large, rapidly encountered cyanide doses, with lethal effect.

Single or multiple exposures over a longer period of time represent chronic exposure. In the occupational setting, both acute (eg, accidental discharge) and chronic (eg, repetitive handling of a chemical) exposures occur. Exposures to chemicals found in the environment such as air and water pollutants are often chronic, resulting in chronic disease, as in the Minamata Bay, Japan, methyl mercury disaster. Sudden large chemical releases may result in acute massive population exposure with serious or lethal consequences. The tragedy in Bhopal, India, was such an event, in which methyl isocyanate was released into a crowded population area, resulting in almost 4000 deaths and more than half a million injuries. The release of dioxin in Seveso, Italy, contaminated a populated area with a persistent organic chemical having both acute and long-term chronic effects. More recently, the massive oil spill caused by the explosion of BP's Deepwater Horizon drilling rig in the Gulf of Mexico highlighted the potential for long-term ecotoxic impacts involving widespread geographic areas.

ENVIRONMENTAL CONSIDERATIONS

Certain chemical and physical characteristics are important for the estimation of the potential hazard of environmental toxicants. Data on toxic effects of different organisms, along with knowledge about degradability, bioaccumulation, and transport and biomagnification through food chains, help in this estimation. (See Box: Bioaccumulation & Biomagnification for a classic example involving the Great Lakes.) Poorly degraded chemicals (by abiotic or biotic pathways) exhibit environmental persistence and can accumulate. Such chemicals include the persistent organic pollutants (POPs), polychlorinated biphenyls, dioxins and furans, and similar substances. Lipophilic substances such as the largely banned or abandoned organochlorine pesticides tend to bioaccumulate in body fat. This results in tissue residues that are slowly released over time. These residues and their metabolites may have chronic adverse effects such as endocrine disruption. When the toxicant is incorporated into the food chain, biomagnification occurs as one species feeds on others. This concentrates the chemical in organisms higher on the food chain. Humans stand at the apex of the food chain. They may be exposed to highly concentrated pollutant loads as bioaccumulation and biomagnification occur. The pollutants that have the widest environmental impact are poorly degradable; are relatively mobile in air, water, and soil; exhibit bioaccumulation; and also exhibit biomagnification.

Bioaccumulation & Biomagnification

If the intake of a long-lasting contaminant by an organism exceeds the latter's ability to metabolize or excrete the substance, the chemical accumulates within the tissues of the organism. This is called **bioaccumulation**.

Although the concentration of a contaminant may be virtually undetectable in water, it may be magnified hundreds or thousands of times as the contaminant passes up the food chain. This is called **biomagnification**.

The biomagnification of polychlorinated biphenyls (PCBs) in the Great Lakes of North America is illustrated by the following residue values available from a classic *Environment Canada* report published by the Canadian government, and elsewhere.

The biomagnification for this substance in the food chain, beginning with phytoplankton and ending with the herring gull, is nearly

50,000-fold. Domestic animals and humans may eat fish from the Great Lakes, resulting in PCB residues in these species as well.

Source	PCB Concentration (ppm) ¹	Concentration Relative to Phytoplankton
Phytoplankton	0.0025	1
Zooplankton	0.123	49.2
Rainbow smelt	1.04	416
Lake trout	4.83	1,932
Herring gull	124	49,600

SPECIFIC CHEMICALS

AIR POLLUTANTS

Air pollution may result from vapors, aerosols, smokes, particulates, and individual chemicals. Five major substances have been said to account for about 98% of air pollution: carbon monoxide (about 52%); sulfur oxides (about 14%); hydrocarbons (about 14%); nitrogen oxides (about 14%) and ozone, their breakdown product; and particulate matter (about 4%). Agriculture, especially industrial-scale farming, contributes a variety of air pollutants: dusts as particulates, pesticidal chemicals, hydrogen sulfide, and others. Sources of pollutants include fossil fuel burning, transportation, manufacturing, other industrial activities, generation of electric power, space heating, refuse disposal, and others. Studies in Helsinki and other cities have shown that uncatalyzed automobile traffic emissions are larger contributors to ground-level air pollution than any other source. The introduction of catalytic converters on automobiles and their mandatory use in many countries has greatly reduced automobile-released air pollution. In addition, the ban on tetraethyl lead in gasoline has eliminated a major source of lead contamination and childhood lead poisoning in urban environments. In emerging economies, the use of transport based on two-cycle engines creates heavy ground-level air pollution in very crowded cities. The introduction of "clean, low-sulfur" diesel fuels is helping to reduce urban and highway pollutants such as sulfur oxides.

Sulfur dioxide and smoke from incomplete combustion of coal have been associated with acute adverse effects among children, the elderly, and individuals with preexisting cardiac or respiratory disease. Ambient air pollution has been implicated as a cause of cardiac disease, bronchitis, obstructive ventilatory disease, pulmonary emphysema, bronchial asthma, and airway or lung cancer. Extensive basic science and clinical epidemiologic literature on air pollutant toxicology has been published and has led to modifications of regulatory standards for air pollutants. EPA standards for

these substances apply to the general environment, and OSHA standards apply to workplace exposure. Ambient air standards for carbon monoxide and five other harmful pollutants—particulate matter, nitrogen dioxide, ozone, sulfur dioxide, and lead—may be found at <https://www.epa.gov/criteria-air-pollutants>.

Carbon Monoxide

Carbon monoxide (CO) is a colorless, tasteless, odorless, and nonirritating gas, a byproduct of incomplete combustion. The average concentration of CO in the atmosphere is about 0.1 ppm; in heavy traffic, the concentration may exceed 100 ppm. Current recommended permissible exposure limit (PEL) values are shown in Table 56-1 (see also <http://www.osha.gov>, Standard Number 1910.1000, Table Z-1).

1. Mechanism of action—CO combines tightly but reversibly with the oxygen-binding sites of hemoglobin and has an affinity for hemoglobin that is about 220 times that of oxygen. The product formed—carboxyhemoglobin—cannot transport oxygen. Furthermore, the presence of carboxyhemoglobin interferes with the dissociation of oxygen from the remaining oxyhemoglobin as a result of the Bohr effect. This reduces the transfer of oxygen to tissues. Organs with the highest oxygen demand (the brain, heart, and kidneys) are most seriously affected. Normal nonsmoking adults have carboxyhemoglobin levels of less than 1% saturation (1% of total hemoglobin is in the form of carboxyhemoglobin); this has been attributed to the endogenous formation of CO from heme catabolism. Smokers may exhibit 5–10% CO saturation. The level depends on their smoking habits. A person who breathes air that contains 0.1% CO (1000 ppm) would have a carboxyhemoglobin level of about 50% in a short period of time.

2. Clinical effects—The principal signs of CO intoxication are those of hypoxia. They progress in the following sequence: (1) psychomotor impairment; (2) headache and tightness in the temporal area; (3) confusion and loss of visual acuity;

TABLE 56-1 Examples of permissible exposure limit values (PELs) of some common air pollutants and solvents in parts per million (ppm).¹

Compound	PEL ² (ppm)
Benzene	1.0
Carbon monoxide	50
Carbon tetrachloride	10
Chloroform	50
Nitrogen dioxide	5
Ozone	0.1
Sulfur dioxide	5
Tetrachloroethylene	100
Toluene	200
1,1,1-Trichloroethane	350
Trichloroethylene	100

¹These exposure limits can be found at <http://www.osha.gov>, 1910.1000, Tables Z-1 and Z-2. The OSHA standards are updated frequently and readers are referred to the website for the most current information.

²PELs are 8-hour TWA (time-weighted average) values for a normal 8-hour workday to which workers may be repeatedly exposed without adverse effects.

(4) tachycardia, tachypnea, syncope, and coma; and (5) deep coma, convulsions, shock, and respiratory failure. There is great variability in individual responses to carboxyhemoglobin concentration. Carboxyhemoglobin levels below 15% may produce headache and malaise; at 25% many workers complain of headache, fatigue, decreased attention span, and loss of fine motor coordination. Collapse and syncope may appear at around 40%; and with levels above 60%, death may ensue as a result of irreversible damage to the brain and myocardium. The clinical effects may be aggravated by heavy labor, high altitudes, and high ambient temperatures. CO intoxication is usually thought of as a form of acute toxicity. There is evidence that chronic exposure to low CO levels may lead to adverse cardiac effects, neurologic disturbance, and emotional disorders. The developing fetus is quite susceptible to the effects of CO exposure. Exposure of a pregnant woman to elevated CO levels at critical periods of fetal development may cause fetal death or serious and irreversible but survivable birth defects.

3. Treatment—Patients who have been exposed to CO must be removed from the exposure source immediately. Respiration must be maintained and high flow and concentration of oxygen—the specific antagonist to CO—should be administered promptly. If respiratory failure is present, mechanical ventilation is required. High concentrations of oxygen may be toxic and may contribute to the development of acute respiratory distress syndrome. Therefore, patients should be treated with high concentrations only for a short period. With room air at 1 atm, the elimination half-time of CO is about 320 minutes; with 100% oxygen, the half-time is about 80 minutes; and with hyperbaric oxygen (2–3 atm), the half-time can be reduced to about 20 minutes. Although some controversy exists about hyperbaric oxygen for CO poisoning,

it may be used if it is readily available. It is particularly recommended for the management of pregnant women exposed to CO. Hypothermic therapy to reduce metabolic demand of the brain has also been useful. Cerebral edema that results from CO poisoning does not seem to respond to either mannitol or steroid therapy and may be persistent. Progressive recovery from treated CO poisoning, even of a severe degree can be complete but some patients manifest neuropsychological and motor dysfunction for a long time after recovery from acute CO poisoning.

Sulfur Dioxide

Sulfur dioxide (SO₂) is a colorless irritant gas generated primarily by the combustion of sulfur-containing fossil fuels. The current OSHA PEL (Table 56-1) is given on the OSHA website (see <http://www.osha.gov>, Standard Number 1910.1000, Table Z-1).

1. Mechanism of action—At room temperature, the solubility of SO₂ is approximately 200 g SO₂/L of water. Because of its high solubility, when SO₂ contacts moist membranes, it transiently forms sulfurous acid. This acid has severe irritant effects on the eyes, mucous membranes, and skin. Approximately 90% of inhaled SO₂ is absorbed in the upper respiratory tract, the site of its principal effect. The inhalation of SO₂ causes bronchial constriction and produces profuse bronchorrhea; parasympathetic reflexes and altered smooth muscle tone appear to be involved. The clinical outcome is an acute irritant asthma. Exposure to 5 ppm SO₂ for 10 minutes leads to increased resistance to airflow in most humans. Exposures of 5–10 ppm are reported to cause severe bronchospasm; 10–20% of the healthy young adult population is estimated to be reactive to even lower concentrations. The phenomenon of adaptation to irritating concentrations has been reported in workers. However, current studies have not confirmed this phenomenon. Asthmatic individuals are especially sensitive to SO₂.

2. Clinical effects and treatment—The signs and symptoms of intoxication include irritation of the eyes, nose, and throat, reflex bronchoconstriction, and increased bronchial secretions. In asthmatic subjects, exposure to SO₂ may result in an acute asthmatic episode. If severe exposure has occurred, delayed-onset pulmonary edema may be observed. Cumulative effects from chronic low-level exposure to SO₂ are not striking, particularly in humans, but these effects have been associated with aggravation of chronic cardiopulmonary disease. When combined exposure to high respirable particulate loads and SO₂ occurs, the mixed irritant load may increase the toxic respiratory response. Treatment is not specific for SO₂ but depends on therapeutic maneuvers used to treat irritation of the respiratory tract and asthma. In some severely polluted urban air basins, elevated SO₂ concentrations combined with elevated particulate loads has led to air pollution emergencies and a marked increase in cases of acute asthmatic bronchitis. Children and the elderly seem to be at greatest risk. The principal source of urban SO₂ is the burning of coal, both for domestic heating and in coal-fired power plants. High-sulfur transportation fuels also contribute. Both also contribute to the respirable fine particulate load and to increased urban cardiorespiratory morbidity and mortality.

Nitrogen Oxides

Nitrogen dioxide (NO_2) is a brownish irritant gas sometimes associated with fires. It is formed also from fresh silage; exposure of farmers to NO_2 in the confines of a silo can lead to silo-filler's disease, a severe and potentially lethal form of acute respiratory distress syndrome. The disorder is uncommon today. Miners who are regularly exposed to diesel equipment exhaust have been particularly affected by nitrogen oxide emissions with serious respiratory effects. Today, the most common source of human exposure to oxides of nitrogen, including NO_2 , is automobile and truck traffic emissions. Recent air pollution inventories in cities with high traffic congestion have demonstrated the important role that internal combustion engines have in the increasing NO_2 urban air pollution. A variety of disorders of the respiratory system, cardiovascular system, and other problems have been linked to NO_2 exposure.

1. Mechanism of action— NO_2 is a relatively insoluble deep lung irritant. It is capable of producing pulmonary edema and acute adult respiratory distress syndrome (ARDS). Inhalation damages the lung infrastructure that produces the surfactant necessary to allow smooth and low-effort lung alveolar expansion. The type I cells of the alveoli appear to be the cells chiefly affected by acute low to moderate inhalation exposure. At higher exposure, both type I and type II alveolar cells are damaged. If only type I cells are damaged, after an acute period of severe distress, it is likely that treatment with modern ventilation equipment and medications will result in recovery. Some patients develop nonallergic asthma, or "twitchy airway" disease, after such a respiratory insult. If severe damage to the type I and type II alveolar cells occurs, replacement of the type I cells may be impaired; progressive fibrosis may ensue that eventually leads to bronchial ablation and alveolar collapse. This can result in permanent restrictive respiratory disease. In addition to the direct deep lung effect, long-term exposure to lower concentrations of nitrogen dioxide has been linked to cardiovascular disease, increased incidence of stroke, and other chronic disease.

The current PEL for NO_2 is given in Table 56–1. Exposure to 25 ppm of NO_2 is irritating to some individuals; 50 ppm is moderately irritating to the eyes and nose. Exposure for 1 hour to 50 ppm can cause pulmonary edema and perhaps subacute or chronic pulmonary lesions; 100 ppm can cause pulmonary edema and death.

2. Clinical effects—The signs and symptoms of acute exposure to NO_2 include irritation of the eyes and nose, cough, mucoid or frothy sputum production, dyspnea, and chest pain. Pulmonary edema may appear within 1–2 hours. In some individuals, the clinical signs may subside in about 2 weeks; the patient may then pass into a second stage of abruptly increasing severity, including recurring pulmonary edema and fibrotic destruction of terminal bronchioles (bronchiolitis obliterans). Chronic exposure of laboratory animals to 10–25 ppm NO_2 has resulted in emphysematous changes; thus, chronic effects in humans are of concern.

3. Treatment—There is no specific treatment for acute intoxication by NO_2 ; therapeutic measures for the management of deep lung irritation and noncardiogenic pulmonary edema are

used. These measures include maintenance of gas exchange with adequate oxygenation and alveolar ventilation. Drug therapy may include bronchodilators, sedatives, and antibiotics. New approaches to the management of NO_2 -induced ARDS have been developed and considerable controversy now exists about the precise respiratory protocol to use in any given patient.

Ozone & Other Oxides

Ozone (O_3) is a bluish irritant gas found in the earth's atmosphere, where it is an important absorbent of ultraviolet light at high altitude. At ground level, ozone is an important pollutant. Atmospheric ozone pollution is derived from photolysis of oxides of nitrogen, volatile organic compounds, and CO. These compounds are produced primarily when fossil fuels such as gasoline, oil, or coal are burned or when some chemicals (eg, solvents) evaporate. Nitrogen oxides are emitted from power plants, motor vehicles, and other sources of high-heat combustion. Volatile organic compounds are emitted from motor vehicles, chemical plants, refineries, factories, gas stations, paint, and other sources. More information on ground-level ozone and its sources and consequences may be found at <https://www.epa.gov/arc-x/climate-adaptation-ground-level-ozone-and-health>.

Ozone can be generated in the workplace by high-voltage electrical equipment, and around ozone-producing devices used for air and water purification. Agricultural sources of ozone are also important. There is a near-linear gradient between exposure to ozone (1-hour level, 20–100 ppb) and bronchial smooth muscle response. See Table 56–1 for the current PEL for ozone.

1. Mechanism of action and clinical effects—Ozone is an irritant of mucous membranes. Mild exposure produces upper respiratory tract irritation. Severe exposure can cause deep lung irritation, with pulmonary edema when inhaled at sufficient concentrations. Ozone penetration in the lung depends on tidal volume; consequently, exercise can increase the amount of ozone reaching the distal lung. Some of the effects of O_3 resemble those seen with radiation, suggesting that O_3 toxicity may result from the formation of reactive free radicals. The gas causes shallow, rapid breathing and a decrease in pulmonary compliance. Enhanced sensitivity of the lung to bronchoconstrictors is also observed. Exposure around 0.1 ppm O_3 for 10–30 minutes causes irritation and dryness of the throat; above 0.1 ppm, one finds changes in visual acuity, substernal pain, and dyspnea. Pulmonary function is impaired at concentrations exceeding 0.8 ppm.

Airway hyperresponsiveness and airway inflammation have been observed in humans. The response of the lung to O_3 is a dynamic one. The morphologic and biochemical changes are the result of both direct injury and secondary responses to the initial damage. Long-term exposure in animals results in morphologic and functional pulmonary changes. Chronic bronchitis, bronchiolitis, fibrosis, and emphysematous changes have been reported in a variety of species, including humans, exposed to concentrations above 1 ppm. Increased visits to hospital emergency departments for cardiopulmonary disease during ozone alerts have been reported. A study of the basic physiologic responses of humans to

ozone exposure and the biomarkers evoked provides useful insight into the fundamental toxicologic impacts of ozone.

2. Treatment—There is no specific treatment for acute O₃ intoxication. Management depends on therapeutic measures used for deep lung irritation and noncardiogenic pulmonary edema that have resulted in ARDS. Current national ambient air quality standards for ozone are listed at <https://www.epa.gov/criteria-air-pollutants>.

SOLVENTS

Halogenated Aliphatic Hydrocarbons

These “halohydrocarbon” agents once found wide use as industrial solvents, degreasing agents, and cleaning agents. The substances include carbon tetrachloride, chloroform, trichloroethylene, tetrachloroethylene (perchloroethylene), and 1,1,1-trichloroethane (methyl chloroform). Many halogenated aliphatic hydrocarbons are classified as known or probable human carcinogens. Carbon tetrachloride and trichloroethylene have largely been removed from the workplace. Perchloroethylene and trichloroethane are still in use for dry cleaning and solvent degreasing, but it is likely that their use will be very limited in the future. In 2016, the National Institute of Environmental Sciences (NIEHS) listed trichloroethylene as a known carcinogen. The EPA now considers perchloroethylene a likely human carcinogen. The EPA data sheet may be found at <https://www.epa.gov/haps/health-effects-notebook-hazardous-air-pollutants>. Dry cleaning as an occupation is listed as a class 2B carcinogenic activity by the International Agency for Research on Cancer (IARC). The Canadian Center for Occupational Health and Safety lists occupations and exposures to occupational carcinogens at http://www.ccohs.ca/oshanswers/diseases/carcinogen_occupation.html.

Fluorinated aliphatics such as the freons and closely related compounds have also been used in the workplace, in consumer goods, and in stationary and mobile air conditioning systems. Because of the severe damage they cause to the ozone layer in the troposphere, their use has been limited or eliminated by international treaty agreements. The common halogenated aliphatic solvents also create serious problems as persistent water pollutants. They are widely found in both groundwater and drinking water as a result of poor disposal practices.

Table 56–1 includes recommended OSHA PELs for several of these compounds (see also <http://www.osha.gov>, Table Z-1).

1. Mechanism of action and clinical effects—In laboratory animals, the halogenated hydrocarbons cause central nervous system (CNS) depression, liver injury, kidney injury, and some degree of cardiotoxicity. Several are also carcinogenic in animals and are considered probable human carcinogens. Trichloroethylene and tetrachloroethylene are listed as “reasonably anticipated to be a human carcinogen” by the US National Toxicology Program, and as class 2A probable human carcinogens by IARC. These substances are depressants of the CNS in humans. Chronic workplace exposure to halogenated hydrocarbon solvents can cause

significant neurotoxicity with impaired memory and peripheral neuropathy. All halohydrocarbon solvents can cause cardiac arrhythmias in humans, particularly in situations involving sympathetic excitation and norepinephrine release.

Hepatotoxicity is also a common toxic effect that can occur in humans after acute or chronic halohydrocarbon exposures. Nephrotoxicity can occur in humans exposed to carbon tetrachloride, chloroform, and trichloroethylene. Chloroform, carbon tetrachloride, trichloroethylene, and tetrachloroethylene carcinogenicity have been observed in lifetime exposure studies performed in rats and mice and in some human epidemiologic studies. Dichloromethane (methylene chloride) is a potent neurotoxin, a generator of CO in humans, and a probable human carcinogen. It has been widely used as a paint stripper, plastic glue, and for other purposes. Epidemiologic studies of workers who have been exposed to aliphatic hydrocarbon solvents that include dichloromethane, trichloroethylene, and tetrachloroethylene have found significant associations between the agents and renal, prostate, and testicular cancer. Trichloroethylene is now considered a class 1, known human carcinogen by IARC; renal cancers and non-Hodgkin's lymphoma have been reported. Other cancers are increased but their incidence has not reached statistical significance.

2. Treatment—There is no specific treatment for acute intoxication resulting from exposure to halogenated hydrocarbons. Management depends on the organ system involved.

Aromatic Hydrocarbons

Benzene is used for its solvent properties and as an intermediate in the synthesis of other chemicals. It remains an important component of gasoline. Benzene may be found in premium gasolines at concentrations of about 1.5%. In cold climates such as Alaska, benzene concentrations in gasoline may reach 5% in order to provide an octane boost. It is one of the most widely used industrial chemicals in the world. The current PEL is 1.0 ppm in the air (see Table 56–1 and <http://www.osha.gov>, Table Z-1), and a 5 ppm limit is recommended for skin exposure. The National Institute for Occupational Safety and Health (NIOSH) and others have recommended that the exposure limits for benzene be further reduced to 0.1 ppm because excess blood cancers occur at the current PEL.

The acute toxic effect of benzene is depression of the CNS. Exposure to 7500 ppm for 30 minutes can be fatal. Exposure to concentrations greater than 3000 ppm may cause euphoria, nausea, locomotor problems, and coma. Vertigo, drowsiness, headache, and nausea may occur at concentrations ranging from 250 to 500 ppm. No specific treatment exists for the acute toxic effect of benzene.

Chronic exposure to benzene can result in very serious toxic effects, the most significant of which is bone marrow injury. Aplastic anemia, leukopenia, pancytopenia, and thrombocytopenia occur, as does leukemia. Chronic exposure to low levels of benzene has been associated with leukemia of several types as well as lymphomas, myeloma, and myelodysplastic syndrome. Recent studies have shown the occurrence of leukemia following

exposures as low as 2 ppm-years. The pluripotent bone marrow stem cells appear to be targets of benzene or its metabolites and other stem cells may also be targets.

Benzene has long been known to be a potent clastogen, ie, a mutagen that acts by causing chromosomal breakage. Recent studies have suggested specific chromosome reorganization and genomic patterns that are associated with benzene-induced leukemia. Epidemiologic data confirm a causal association between benzene exposure and leukemia and other bone marrow cancers in workers. IARC classifies benzene as a class 1, known human carcinogen. Most national and international organizations classify benzene as a known human carcinogen.

Toluene (methylbenzene) does not possess the myelotoxic properties of benzene, nor has it been associated with leukemia. It is not carcinogenic and is listed as class 3 by IARC. It is, however, a CNS depressant and a skin and eye irritant. It is also fetotoxic. See Table 56–1 and OSHA Tables Z-1 and Z-2 (<http://www.osha.gov>) for the PELs. Exposure to 800 ppm can lead to severe fatigue and ataxia; 10,000 ppm can produce rapid loss of consciousness. Chronic effects of long-term toluene exposure are unclear because human studies indicating behavioral effects usually concern exposures to several solvents. In limited occupational studies, however, metabolic interactions and modification of toluene's effects have not been observed in workers also exposed to other solvents. Less refined grades of toluene contain benzene. If technical grade toluene is to be used where there is human contact or exposure, analysis of the material for benzene content is advisable.

Xylene (dimethylbenzene) has been substituted for benzene in many solvent degreasing operations. Like toluene, the three xylenes do not possess the myelotoxic properties of benzene, nor have they been associated with leukemia. Xylene is a CNS depressant and a skin irritant. Less refined grades of xylene contain benzene. Estimated TLV–time-weighted average and TLV–short-term exposure limit are 100 and 150 ppm, respectively. The current OSHA PELs may be found at <http://www.osha.gov>, Table Z-1.

PESTICIDES

Organochlorine Pesticides

These agents are usually classified into four groups: DDT (chlorophenothane) and its analogs, benzene hexachlorides, cyclodienes, and toxaphenes (Table 56–2). They are aryl, carbocyclic, or heterocyclic compounds containing chlorine substituents. The individual compounds differ widely in their biotransformation and capacity for storage in tissues; toxicity and storage are not always correlated. They can be absorbed through the skin as well as by inhalation or oral ingestion. There are, however, important quantitative differences between the various derivatives; DDT in solution is poorly absorbed through the skin, whereas dieldrin absorption from the skin is very efficient. Organochlorine pesticides have largely been abandoned because they cause severe environmental damage. They are now known to be endocrine disruptors in animals and humans. DDT continues to have very restricted use for domestic mosquito elimination in malaria-infested areas of Africa. This use is controversial, but it is very effective and is likely to remain in place for the foreseeable future. Organochlorine pesticide residues in humans, animals, and the environment present long-term problems that are not yet fully understood.

1. Human toxicology—The acute toxic properties of all the organochlorine pesticides in humans are qualitatively similar. These agents interfere with inactivation of the sodium channel in excitable membranes and cause rapid repetitive firing in most neurons. Calcium ion transport is inhibited. These events affect repolarization and enhance the excitability of neurons. The major effect is CNS stimulation. With DDT, tremor may be the first manifestation, possibly continuing to convulsions, whereas with the other compounds convulsions often appear as the first sign of intoxication. There is no specific treatment for the acute intoxicated state, and management is symptomatic.

The potential carcinogenic properties of organochlorine pesticides have been extensively studied, and results indicate that

TABLE 56–2 Organochlorine pesticides.

Chemical Class	Compounds	Toxicity Rating ¹	ADI ²
DDT and analogs	Dichlorodiphenyltrichloroethane (DDT)	4	0.005

¹Toxicity rating: Probable human oral lethal dosage for class 3 = 500–5000 mg/kg, class 4 = 50–500 mg/kg, and class 5 = 5–50 mg/kg. (See Gosselin et al, 1984.)

²ADI, acceptable daily intake (mg/kg/d).

chronic administration to laboratory animals over long periods results in enhanced carcinogenesis. Endocrine pathway disruption is the postulated mechanism. Numerous mechanisms for xenoestrogen (estrogen-like) carcinogenesis have been postulated. To date, however, several large epidemiologic studies in humans have not found a significant association between the risk of cancer and specific compounds or serum levels of organochlorine pesticide metabolites. The results of a case-control study conducted to investigate the relation between dichlorodiphenyldichloroethylene (DDE, the primary metabolite of DDT) and DDT breast adipose tissue levels and breast cancer risk did not confirm a positive association. In contrast, recent work supports an association between prepubertal exposure to DDT and brain cancer. Recent studies also suggest that the risk of testicular cancer and non-Hodgkin's lymphoma is increased in persons with elevated organochlorine levels. Noncancer end points are also of concern. Recent work associates cryptorchidism and hypospadias in newborns with maternal adipose levels of chlordane metabolites. These residues are also linked to testicular cancer.

2. Environmental toxicology—The organochlorine pesticides are considered persistent chemicals. Degradation is quite slow when compared with other pesticides, and bioaccumulation, particularly in aquatic ecosystems, is well documented. Their mobility in soil depends on the composition of the soil; the presence of organic matter favors the adsorption of these chemicals onto the soil particles, whereas adsorption is poor in sandy soils. Once adsorbed, they do not readily desorb. These compounds induce significant abnormalities in the endocrine balance of sensitive animal and bird species, in addition to their adverse impact on humans. Since the early 1960s, when Rachel Carson's work and subsequent book, *Silent Spring*, brought attention to the issue, the organochlorine pesticides have been recognized as pernicious environmental toxins. Their use is banned in most jurisdictions.

Organophosphorus Pesticides

These agents, some of which are listed in Table 56–3, are used to combat a large variety of pests. They are useful pesticides when in direct contact with insects or when used as **plant systemics**, where the agent is translocated within the plant and exerts its effects on insects that feed on the plant. The many varieties currently in use are applied by spray techniques including hand, tractor, and aerial methods. They are often spread widely by wind and weather and are subject to widespread drift. The organophosphate pesticides are based on compounds such as soman, sarin, and tabun, which were developed for use as war gases. Some of the less toxic organophosphorus compounds are used in human and veterinary medicine as local or systemic antiparasitics (see Chapters 7 and 53). The compounds are absorbed by the skin as well as by the respiratory and gastrointestinal tracts. Biotransformation is rapid, particularly when compared with the rates observed with the chlorinated hydrocarbon pesticides. Storm and collaborators reviewed current and suggested human inhalation occupational exposure limits for 30 organophosphate pesticides (see References).

TABLE 56–3 Organophosphorus pesticides.

²ADI, acceptable daily intake (mg/kg/d).

1. Human toxicology—In mammals as well as insects, the major effect of these agents is inhibition of acetylcholinesterase through phosphorylation of the esteratic site. The signs and symptoms that characterize acute intoxication are due to inhibition of this enzyme and accumulation of acetylcholine; some of the agents also possess direct cholinergic activity. Specific treatment with antidotes and useful antagonists is available. In addition, pretreatment with physostigmine and other short-acting compounds may provide protection against these pesticides or their war gas analogs if used in timely fashion. These effects and their treatment are described in Chapters 7 and 8 of this book. Altered neurologic and cognitive functions, as well as psychological symptoms of variable duration, have been associated with exposure to these pesticides. Furthermore, there is some indication of an association of low arylesterase activity with neurologic symptom complexes in Gulf War veterans.

In addition to—and independently of—inhibition of acetylcholinesterase, some of these agents are capable of phosphorylating another enzyme present in neural tissue, the so-called **neuropathy target esterase (NTE)**. This results in progressive demyelination of the longest nerves. Associated with paralysis and axonal degeneration, this lesion is sometimes called organophosphorus ester-induced delayed polyneuropathy (OPIDP). Delayed central and autonomic neuropathy may occur in some poisoned patients. Hens are particularly sensitive to these properties and have proved very useful for studying the pathogenesis of the lesion and for identifying potentially neurotoxic organophosphorus derivatives. There is no specific treatment for NTE toxicity.

In humans, progressive chronic axonal neurotoxicity has been observed with **triorthocresyl phosphate (TOCP)**, a noninsecticidal organophosphorus compound. It is also thought to occur with the pesticides dichlorvos, trichlorfon, leptophos, methamidophos, mipafox, trichloronat, and others. The polyneuropathy usually begins as burning and tingling sensations, particularly in the feet, with motor weakness occurring a few days later. Sensory and motor difficulties may extend to the legs and hands. Gait is

affected, and ataxia may be present. Central nervous system and autonomic changes may develop still later. There is no specific treatment for this form of delayed neurotoxicity. The long-term prognosis of NTE inhibition is highly variable. Reports of this type of neuropathy (and other toxicities) in pesticide manufacturing workers and in agricultural pesticide applicators have been published (see References).

Recent clinical observation has also defined an intermediate syndrome in severely organophosphate-poisoned patients. This syndrome is characterized by neuromuscular transmission failure, and cardiac failure more typical of nicotinic than muscarinic poisoning. Progressive neuromuscular failure leads to weakness of the respiratory muscles and eventually to death. The physiologic abnormalities are complex but involve a progressive decrement in neuromuscular junction transmission efficiency. Patients who develop this intermediate syndrome are at great risk of cardiorespiratory failure and may require mechanical ventilation. Because organophosphorus poisoning frequently occurs in less developed parts of the world where medical resources are very limited, the development of the intermediate syndrome is frequently a lethal complication. It is not effectively treated with the usual management protocol for organophosphate pesticide poisoning.

2. Environmental toxicology—Organophosphorus pesticides are not considered to be persistent pesticides. They are relatively unstable and break down in the environment as a result of hydrolysis and photolysis. As a class they are considered to have a small permanent impact on the environment, in spite of their acute effects on organisms.

Carbamate Pesticides

These compounds (Table 56–4) inhibit acetylcholinesterase by carbamoylation of the esteratic site. Thus, they possess the toxic properties associated with inhibition of this enzyme as described

for the organophosphorus pesticides. However, as described in Chapters 7 and 8, the binding is relatively weak, dissociation occurs after minutes to hours, and clinical effects are of shorter duration than those observed with organophosphorus compounds. Spontaneous reactivation of cholinesterase is more rapid after inhibition by the carbamates. The therapeutic index, the ratio of the doses that cause severe toxicity or death to those that result in minor intoxication, is larger with carbamates than with the organophosphorus agents. Although the clinical approach to carbamate poisoning is similar to that for organophosphates, the use of pralidoxime is not recommended.

The carbamates are considered to be nonpersistent pesticides. They exert only a small impact on the environment.

Botanical Pesticides

Pesticides derived from natural sources include **nicotine**, **rotenone**, and **pyrethrum**. Nicotine is obtained from the dried leaves of *Nicotiana tabacum* and *N. rustica*. It is rapidly absorbed from mucosal surfaces; the free alkaloid, but not the salt, is readily absorbed from the skin. Nicotine reacts with the acetylcholine receptor of the postsynaptic membrane (sympathetic and parasympathetic ganglia, neuromuscular junction), resulting in depolarization of the membrane. Toxic doses cause stimulation rapidly followed by blockade of transmission. These actions are described in Chapter 7. Treatment is directed toward maintenance of vital signs and suppression of convulsions. Nicotine analogs (**neonicotinoids**) have been developed for use as agricultural pesticides and have been accused of a role in bee colony collapse.

Rotenone (Figure 56–1) is obtained from *Derris elliptica*, *D. mallaccensis*, *Lonchocarpus utilis*, and *L. urucu*. The oral ingestion of rotenone produces gastrointestinal irritation. Conjunctivitis, dermatitis, pharyngitis, and rhinitis can also occur. Treatment is symptomatic.

Pyrethrum consists of six known insecticidal esters: pyrethrin I (Figure 56–1), pyrethrin II, cinerin I, cinerin II, jasmolin I, and jasmolin II. Synthetic pyrethroids account for an increasing percentage of worldwide pesticide usage. Pyrethrum may be absorbed after inhalation or ingestion. When absorbed in sufficient quantities, the major site of toxic action is the CNS; excitation, convulsions, and tetanic paralysis can occur. Voltage-gated sodium, calcium, and chloride channels are considered targets, as well as peripheral-type benzodiazepine receptors. Treatment of exposure is usually directed at management of symptoms. Anticonvulsants are not consistently effective. The chloride channel agonist, ivermectin is of use, as are pentobarbital and mephensin. The pyrethroids are highly irritating to the eyes, skin, and respiratory tree. They may cause irritant asthma and, potentially, reactive airways dysfunction syndrome (RADS) and even anaphylaxis. The most common injuries reported in humans result from their allergenic and irritant effects on the airways and skin. Cutaneous paresthesias have been observed in workers spraying synthetic pyrethroids. The use of persistent synthetic pyrethroids to exterminate insects on aircraft has caused respiratory and skin problems as well as some neurologic complaints in flight attendants and other aircraft workers. Severe occupational exposures to synthetic pyrethroids in

FIGURE 56-1 Chemical structures of selected herbicides and pesticides.

China resulted in marked effects on the CNS, including convulsions. Other previously unreported toxic manifestations have been observed in pyrethrin-exposed individuals.

HERBICIDES

Chlorophenoxy Herbicides

2,4-Dichlorophenoxyacetic acid (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), and their salts and esters have been used as herbicides for the destruction of weeds (Figure 56-1). These compounds are of relatively low acute human toxicity. However, despite their low acute hazard, they cause serious long-term human and environmental toxicity. 2,4-D remains in wide commercial and domestic use for lawn weed control. 2,4,5-T had similar uses but was infamously incorporated into Agent Orange, used as a defoliant during the Vietnam conflict. Agent Orange was

contaminated with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (a potent animal carcinogen and likely human carcinogen) and other toxic, persistent, and undesirable polychlorinated compounds. When this toxicity was discovered, the US Department of Agriculture canceled the domestic pesticide registrations for trichlorophenoxy herbicides, and these compounds are no longer used. However, other, less thoroughly studied compounds, eg, chlorinated xanthenes, are present in both the dichlorophenoxy and trichlorophenoxy herbicides (see below).

In humans, 2,4-D in large doses can cause coma and generalized muscle hypotonia. Rarely, muscle weakness and marked hypotonia may persist for several weeks. In laboratory animals, signs of liver and kidney dysfunction have also been reported with chlorophenoxy herbicides. Several epidemiologic studies performed by the U.S. National Cancer Institute confirmed the causal link between 2,4-D and non-Hodgkin's lymphoma. Evidence for a causal link to soft tissue sarcoma, however, is considered equivocal.

The dichlorophenoxy and related herbicides have been found to contain and to generate dimethylnitrosamine (*N*-nitrosodimethylamine; NDMA), a potent human carcinogen, during environmental transformation as well as non-chlorine water disinfection. Studies by Environment Canada and others have questioned the use of this compound because of water contamination. Studies of related nitrosamine-forming herbicidal compounds have raised questions about the suitability of these compounds for general weed control. Because of the extremely high economic value of herbicides to the agricultural community, however, long-term decisions on their use have been delayed.

Glyphosate

Glyphosate (*N*-[phosphonomethyl] glycine, Figure 56–1), the principle ingredient in Roundup, is now the most widely used herbicide in the world. It functions as a contact herbicide and is absorbed through the leaves and roots of plants. It is generally formulated with surfactant to enhance its intended effect on noxious plants. Because it is nonselective, it may damage important crops and desirable ornamental plants even when used as directed. Therefore, genetically modified plants such as soybean, corn, and cotton that are glyphosate-resistant have been developed and patented. They are widely grown throughout the world. Almost all soybean crops and many corn crops grown today are of the glyphosate-resistant type. These genetically modified (GMO) crops are grown from patented seeds and have great economic value to growers, contributing to the food supply in a meaningful way. However, in some jurisdictions their use is highly controversial. While there is no evidence that the modified crops are toxic or dangerous to humans or animals, the long-term agricultural impact of widespread use of glyphosate herbicides on resistant crops remains to be determined. Additionally, the impact of effective weed elimination on the food supply and habitat of critical insect species, eg, bees, and some migrating birds has been a source of increasing concern.

Because of the widespread availability and use of this herbicide, glyphosate-surfactant poisonings are common. Many of the observed ingestions and reports of poisoning are from developing countries, where suicide by pesticide is common. Many injuries are minor, but some serious and lethal poisonings have been reported. Glyphosate is a significant eye and skin irritant. When ingested it can cause mild to moderate esophageal erosion. It also causes aspiration pneumonia and renal failure. There have been some reports of teratogenic outcomes in workers who handle and apply glyphosate, but the epidemiologic evidence is not clear. There is a growing literature on management of acute glyphosate poisoning. Treatment is symptomatic and no specific protocol is indicated. Hemodialysis has been used with success in cases of renal failure.

Although glyphosate seems to have little persistence and lower toxicity than other herbicides, the commercial formulations often contain surfactants and other active compounds that complicate the toxicity of the product. Some of the toxic effects are related to the surfactant material.

Bipyridyl Herbicides

Paraquat is the most important agent of this class (Figure 56–1). Its mechanism of action is said to be similar in plants and animals and involves single-electron reduction of the herbicide to free radical species. Ingestion (accidental or suicidal) is among the most serious and potentially lethal pesticide poisonings. Many serious exposures take place in developing countries where limited treatment resources are available. Paraquat accumulates slowly in the lung by an active process and causes lung edema, alveolitis, and progressive fibrosis. It probably inhibits superoxide dismutase, resulting in intracellular free-radical oxygen toxicity.

In humans, the first signs and symptoms after oral exposure are hematemesis and bloody stools. Within a few days, however, delayed toxicity occurs, with respiratory distress and the development of congestive hemorrhagic pulmonary edema accompanied by widespread cellular proliferation. During the acute period, oxygen should be used cautiously to combat dyspnea or cyanosis, because it may aggravate the pulmonary lesions. Hepatic, renal, or myocardial involvement may develop. The interval between ingestion and death may be several weeks.

Because of the delayed pulmonary toxicity, prompt immobilization of the paraquat to prevent absorption is important. Adsorbents (eg, activated charcoal, Fuller's earth) are routinely given to bind the paraquat and minimize its absorption. Gastric lavage is not recommended as it may promote aspiration from the stomach into the lungs. Once the paraquat is absorbed, treatment is successful in less than 50% of cases. Monitoring of plasma and urine paraquat concentrations is useful for prognostic assessment. Computed tomography scanning has also been used to follow the pulmonary lesions as they develop and to help with prognosis. The pulmonary proliferative phase begins 1–2 weeks after paraquat ingestion. Although a few reports indicate some success with dialysis, hemodialysis and hemoperfusion rarely change the clinical course. Many approaches have been used to slow or stop the progressive pulmonary fibrosis. Immunosuppression using corticosteroids and cyclophosphamide is widely practiced, but evidence for efficacy is weak. Antioxidants such as acetylcysteine and salicylate might be beneficial through free radical-scavenging, anti-inflammatory, and nuclear factor kappa-B inhibitory actions. However, there are no published human trials. The case fatality rate is high in all centers despite large variations in treatment. Patients require prolonged observation and treatment for respiratory and renal insufficiency if they survive the acute stage of poisoning.

ENVIRONMENTAL POLLUTANTS

Polychlorinated & Polybrominated Biphenyls

Highly halogenated biphenyl compounds, which have desirable properties for insulation, fire retardancy, and many other uses, were manufactured in large quantities during the mid-20th century. The quantities produced and the almost universal dispersion of the materials in which they were incorporated have produced

an enormous environmental problem. Both chlorinated and brominated biphenyls are environmentally dangerous and significantly toxic, and are now banned from use.

The **polychlorinated biphenyls (PCBs, coplanar biphenyls)** were used as dielectric and heat transfer fluids, lubricating oils, plasticizers, wax extenders, and flame retardants. Their industrial use and manufacture in the USA were terminated by 1977. The chlorinated products used commercially were actually mixtures of PCB isomers and homologs containing 12–68% chlorine. These chemicals are very stable, highly lipophilic, poorly metabolized, and very resistant to environmental degradation; thus they bioaccumulate in food chains.

Food is the major source of PCB residues in humans. Accumulation of PCB in fish species led Canada and the USA to restrict commercial fishing and to limit consumption of fish from the Great Lakes of North America (see Box: Bioaccumulation & Biomagnification, earlier). In addition, large industrial site contamination, illegal dumping, migration from hazardous waste sites and other large-scale sources, and widespread use of PCBs in electrical transformers has led to multiple localized areas of contamination and human exposure. Leakage of transformer dielectric fluids in neighborhoods and backyards has caused significant numbers of serious but highly localized PCB exposure events.

There are numerous reports of large population exposures to PCBs. A serious exposure to PCBs—lasting several months—occurred in Japan in 1968 as a result of cooking oil contamination with PCB-containing transfer medium (Yusho disease). A similar outbreak called Yucheng disease occurred at about the same time in Taiwan. Effects on the fetus and on the development of the offspring of poisoned women were reported. It is now known that the contaminated cooking oil contained not only PCBs but also polychlorinated dibenzofurans (PCDFs) and polychlorinated quaterphenyls (PCQs). It is likely that the effects initially attributed to the PCBs were actually caused by a mixture of contaminants. Workers occupationally exposed to PCBs develop dermatologic problems that include chloracne, folliculitis, erythema, dryness, rash, hyperkeratosis, and hyperpigmentation. Some hepatic abnormalities have been found in PCB poisoning, and plasma triglycerides are elevated.

Information about the effects of PCBs on reproduction and development is accumulating. The halogenated pesticides are potent endocrine disrupters and there is widespread concern about the persistent estrogenic effect of these chemicals. Adverse reproductive impacts of PCBs have been found in many animal studies. Direct teratogenic effects in humans have yet to be established: studies in workers and in the general population exposed to moderate or to very high levels of PCBs have not been conclusive. Some adverse behavioral effects in infants have been reported. An association between prenatal exposure to PCBs and deficits in childhood intellectual function was described for children born to mothers who had eaten large quantities of contaminated fish. Epidemiologic studies have established increases in various cancers including melanoma, breast, pancreatic, and thyroid cancers. These findings and animal studies provided a sufficient basis for the IARC to classify some co-planar PCBs as class 1, carcinogenic to humans, in volume 100 of the IARC monographs.

A comprehensive EPA fact sheet on PCBs may be found at <https://www.epa.gov/pcbs>.

The polybrominated biphenyls (PBBs) and their ethers (PBDEs) share many of the toxic and environmentally damaging persistent qualities of PCBs. They were introduced as fire retardants in the 1950s and have been used in massive quantities since that time. The biphenyls are no longer produced and may no longer be used, but the biphenyl ethers remain in use as fire retardants in plastics for bedding and in automobile upholstery. PBB fire retardant contamination has been extensive in the Great Lakes region, resulting in large exposure to the population. PBBs are considered IARC class 2a: probable human carcinogens. PBDEs are not classified. An EPA technical fact sheet on PBB and PBDEs may be found at <http://www2.epa.gov/fedfac/technical-fact-sheet-polybrominated-diphenyl-ethers-pbdes-and-polybrominated-biphenyls-pbbs>.

The **polychlorinated dibenzo-*p*-dioxins (PCDDs)**, or **dioxins**, are a group of halogenated congeners of which tetrachlorodibenzodioxin (TCDD) has been the most carefully studied. There is a large group of dioxin-like compounds, including **polychlorinated dibenzofurans (PCDFs)** and **coplanar biphenyls**. While PCBs were used commercially, PCDDs and PCDFs are unwanted byproducts that appear in the environment and in manufactured products as contaminants because of improperly controlled combustion processes. They are also produced when unexpected heating to temperatures over 600°C occurs as in lightning strikes or electrical fires in PCB-containing transformers. Like PCBs, these chemicals are very stable and highly lipophilic. They are poorly metabolized and very resistant to environmental degradation. Several significant environmental contamination episodes involving dioxins and furans from industrial sites have occurred. Recent publications have demonstrated an elevated incidence of subsequent chronic diseases (eg, diabetes, metabolic syndrome, and obesity) in exposed persons. Laboratory studies of the blood concentrations of TCDD and its metabolites have provided insight into the persistence and metabolism of the contaminants.

In laboratory animals, TCDD has produced a variety of toxic effects. Wasting syndrome (severe weight loss accompanied by reduction of muscle mass and adipose tissue), thymic atrophy, epidermal changes, hepatotoxicity, immunotoxicity, effects on reproduction and development, teratogenicity, and carcinogenicity have been produced. The effects observed in workers involved in the manufacture of 2,4,5-T (and therefore presumably exposed to TCDD) consisted of contact dermatitis and chloracne. In severely TCDD-intoxicated patients, discrete chloracne may be the only manifestation.

The presence of TCDD in 2,4,5-T, commercially known as Silvex, was believed to be responsible for other human toxicities associated with the herbicide. There is epidemiologic evidence for an association between occupational exposure to the phenoxy herbicides and an excess incidence of non-Hodgkin's lymphoma. The TCDD contaminant in these herbicides seems to play a role in a number of cancers such as soft tissue sarcomas, lung cancer, Hodgkin's lymphomas, and others. TCDD is considered an IARC class 1, known human carcinogen. Other halogenated compounds

of this type are not currently classifiable as to carcinogenicity; they are listed as IARC class 3.

Perfluorinated Compounds (PFCs)

Fluorinated hydrocarbon chemicals have been of commercial interest since the mid-20th century. Their uses have included coolant materials in air conditioning systems; artificial oxygen-carrying substances in experimental clinical studies; and heat-, stain-, and stick-resistant coatings for cookware, fabrics, and other materials. The fluorocarbons were produced in very large quantities and have become widespread in the environment. When it later became apparent that migration of lower molecular weight fluorocarbons to the troposphere had a deleterious effect on the protective ozone layer, they were banned from use. The higher molecular weight, more highly fluorinated compounds, now called *perfluorinated substances* (eg, Teflon), have remained in broad use. Like the heavily chlorinated and brominated hydrocarbons, their commercial usefulness has been complicated by a recognition of adverse environmental and suspected human toxic impacts that resemble some of the adverse qualities of the other halogenated hydrocarbons. A useful reference is the Centers for Disease Control and Prevention (CDC) fact sheet on PFCs. It is found at https://www.cdc.gov/biomonitoring/pdf/PFCs_FactSheet.pdf.

1. Human toxicology—Concerns about the toxicology of PFCs have centered on their estrogenic properties and accumulation and persistence in humans. Human exposure to perfluoro compounds takes place through ingestion and inhalation. Since these compounds enter the food chain and water sources and are persistent, ingestion of contaminated food and water products is a major source of human accumulation. The human half-life of PFOA is estimated to be about 3 years. As a persistent chemical and an endocrine disrupter, it is likely that it has some long-term adverse impact on reproductive function, cellular proliferation, and other cellular homeostatic mechanisms. Several PFCs (but not perfluoro compounds derived from PFOA) have been found to act as proliferators of breast cancer cells. However, a large epidemiologic study recently demonstrated a statistically significant association between high and very high serum PFOA levels in workers and kidney cancer, and possibly prostate cancer, ovarian cancer, and non-Hodgkin's lymphoma. There also may be modest associations with cholesterol elevation and uric acid abnormalities. Finally, an acute pulmonary disorder, **polymer fume fever**, is caused by the pyrolysis of PFOA. Like metal fume fever, seen in welders as a result of cadmium vaporization, polymer fume fever has an acute onset several hours after exposure to the vaporized PFOA and may cause severe respiratory distress. The onset of constitutional symptoms, malaise, chills and fever, and respiratory distress is characteristic of fume fevers. While polymer fume fever is usually mild and self-limited, noncardiogenic pulmonary edema has occurred. Whenever PFOA is heated above 350–400°C, toxic fumes capable of causing polymer fume fever are emitted. Overheated household cookware or burning of coated fabrics present this risk.

Other human effects are not clearly defined, although animal studies have shown toxic effects on immune, liver, and endocrine function, and some increase in tumors and neonatal deaths. A useful American Cancer Society fact sheet on the subject may be found at <https://www.cancer.org/cancer/cancer-causes/teflon-and-perfluorooctanoic-acid-pfoa.html>.

2. Environmental toxicology—Perfluoro compounds are persistent environmental chemicals having a broad environmental impact. PFOA and related compounds are now found widely in water, soil, and many terrestrial and avian species. Aquatic organisms have accumulated significant loads of PFCs. An extensive risk assessment of the perfluoro chemicals has been carried out by Environment Canada, and guidelines have been developed for the management of PFOA and related compounds. These may be found at <http://www.ec.gc.ca/ese-ees/default.asp?lang=En&n=451C95ED-1>.

Endocrine Disruptors

As described above, the potential hazardous effects of some chemicals in the environment are receiving considerable attention because of their estrogen-like or antiandrogenic properties. Compounds that affect thyroid function are also of concern. Since 1998, the process of prioritization, screening, and testing of chemicals for such actions has been undergoing worldwide development. These chemicals mimic, enhance, or inhibit a hormonal action. They include a number of plant constituents (phytoestrogens) and some mycoestrogens as well as industrial chemicals, persistent organochlorine agents (eg, DDT), PCBs, and brominated flame retardants. Concerns exist because of their increasing contamination of the environment, the appearance of bioaccumulation, and their potential for toxicity. In vitro assays alone are unreliable for regulatory purposes, and animal studies are considered indispensable. Modified endocrine responses in reptiles and marine invertebrates have been observed. In humans, however, a causal relation between exposure to a specific environmental agent and an adverse health effect due to endocrine modulation has not been fully established. Epidemiologic studies of populations exposed to higher concentrations of endocrine-disrupting environmental chemicals are underway. There are indications that breast and other reproductive cancers are increased in these patients. Prudence dictates that exposure to environmental chemicals that disrupt endocrine function should be reduced.

Asbestos

Asbestos in many of its forms has been widely used in industry for over 100 years. All forms of asbestos have been shown to cause progressive fibrotic lung disease (asbestosis), lung cancer, and mesothelioma. Every form of asbestos, including chrysotile asbestos, causes an increase in lung cancer and mesothelioma. Lung cancer occurs in people exposed at fiber concentrations well below concentrations that produce asbestosis. Very large-scale studies of insulation workers have shown that cigarette smoking and exposure to radon daughters increase the incidence of asbestos-caused

lung cancer in a synergistic fashion. Asbestos exposure and smoking is a very hazardous combination.

All forms of asbestos cause mesothelioma of the pleura or peritoneum at very low doses. Other cancers (colon, laryngeal, stomach, and perhaps even lymphoma) are increased in asbestos-exposed patients. The mechanism for asbestos-caused cancer is not yet delineated. Arguments that chrysotile asbestos does not cause mesothelioma are contradicted by many epidemiologic studies of worker populations. Recognition that all forms of asbestos are dangerous and carcinogenic has led many countries to ban all uses of asbestos. Countries such as Canada, Zimbabwe, Russia, Brazil, and others that still produce asbestos argue that asbestos can be used safely with careful workplace environmental controls. However, studies of industrial practice make the “safe use” of asbestos highly improbable. Recent attempts to limit international trade in asbestos have been thwarted by heavy pressure from the asbestos industry and the producing countries. Information on countries that currently ban asbestos and the International Ban Asbestos movement may be found at http://ibasecretariat.org/alpha_ban_list.php.

METALS

Occupational and environmental poisoning with metals, metal-oids, and metal compounds is a major health problem. Toxic metal exposure occurs in many industries, in the home, and elsewhere in the nonoccupational environment. The classic metal poisons (arsenic, lead, and mercury) continue to be widely used. (Treatment of their toxicities is discussed in Chapter 57.) Occupational exposure and poisoning due to **beryllium**, **cadmium**, **manganese**, and **uranium** are relatively new occupational problems. In 2016, **cobalt** and cobalt-releasing compounds were listed by the National Institute of Environmental Health Sciences as “reasonably anticipated to be” human carcinogens.

Beryllium

Beryllium (Be) is a light alkaline metal that confers special properties on the alloys and ceramics in which it is incorporated. Beryllium-copper alloys find use as components of computers, in the encasement of the first stage of nuclear weapons, in devices that require hardening such as missile ceramic nose cones, and in heat shield tiles used in space vehicles. Because of the use of beryllium in dental appliances, dentists and dental appliance makers are often exposed to beryllium dust in toxic concentrations and may develop beryllium disease.

Beryllium is highly toxic by inhalation and is classified by the IARC as a class 1, known human carcinogen. Inhalation of beryllium particles produces both acute beryllium disease and chronic disease characterized by progressive pulmonary fibrosis. Skin disease also develops in workers exposed to beryllium. The pulmonary disease is called chronic beryllium disease (CBD) and is a chronic granulomatous pulmonary fibrosis. In the 5–15% of the population that is immunologically sensitive to beryllium, CBD is the result of activation of an autoimmune attack on the skin and lungs. The disease is progressive and may lead to severe disability,

cancer, and death. Although some treatment approaches to CBD show promise, the prognosis is poor in most cases.

The current permissible exposure levels for beryllium of 0.01 mcg/m³ averaged over a 30-day period or 2 mcg/m³ over an 8-hour period are insufficiently protective to prevent CBD. Both NIOSH and the ACGIH have recommended that the 8-hour PEL and TLV be reduced to 0.05 mcg/m³. These recommendations have not yet been implemented. Current OSHA information on beryllium appears at <https://www.osha.gov/SLTC/beryllium/index.html>.

Environmental beryllium exposure is not generally thought to be a hazard to human health except in the vicinity of industrial sites where air, water, and soil pollution have occurred.

Cadmium

Cadmium (Cd) is a transition metal widely used in industry. Workers are exposed to cadmium in the manufacture of nickel cadmium batteries, pigments, low-melting-point eutectic materials; in solder; in television phosphors; and in plating operations. It is also used extensively in semiconductors and in plastics as a stabilizer. Cadmium smelting is often done from residual dust from lead smelting operations, and cadmium smelter workers often face both lead and cadmium toxicity.

Cadmium is toxic by inhalation and by ingestion. When metals that have been plated with cadmium or welded with cadmium-containing materials are vaporized by the heat of torches or cutting implements, the fine dust and fumes released produce an acute respiratory disorder called **cadmium fume fever**. This disorder, common in welders, is usually characterized by shaking chills, cough, fever, and malaise. Although it may produce pneumonia, it is usually transient. However, chronic exposure to cadmium dust produces a far more serious progressive pulmonary fibrosis. Cadmium also causes severe kidney damage, including renal failure if exposure continues. Cadmium is a human carcinogen and is listed as a class 1, known human carcinogen by the IARC.

The current OSHA PEL for cadmium is 5 mcg/m³ but is insufficiently protective of worker health. The OSHA cadmium standard may be found at https://www.osha.gov/pls/oshaweb/owadisp.show_document?p_table=STANDARDS&p_id=10036.

Nanomaterials

Nanomaterials are defined as any material, natural or manufactured, that has at least one dimension that lies between 1 and 100 nanometers (nm) in size. The Stanford University Health and Safety Department gives a more precise definition at <https://ehs.stanford.edu/topic/hazardous-materials/nanomaterials>.

Nanomaterials have been of increasing commercial interest and are now used for an extraordinary range of purposes. In the pharmaceutical manufacturing industry, nanoparticles are being tested and used to deliver cancer chemotherapeutic and other drugs. Currently produced nanomaterials include gold, silver, cadmium, germanium, ceramic, and aluminum oxide nanowires; carbon, silicon, and germanium nanotubes; zinc oxide nanocrystals; gold nanowafers; and copper oxide nanocubes. The increasing use of nanomaterials has led to release of these nanoscale substances into the workplace and the general environment. Because nanomaterials

behave in unique patterns of chemical and physical reactivity, their toxicology is often novel and there is insufficient information on the likely human or environmental impact of dispersal of these manufactured products in the environment. The University of North Carolina laboratory safety and health manual outlines the problems of working with nanomaterials in the laboratory and their safe use at <http://ehs.unc.edu/manuals/laboratory/chapter-18/>.

1. Human toxicology—Inhalation, oral ingestion, dermal absorption, and parenteral administration of nanomaterials have been the sources of human exposure. Because of the unique physicochemical properties of nanomaterials, their toxicity may be similar to or very different from the larger, bulk materials encountered in traditional toxicology studies. The nature of the exposure will impact the likelihood that nanomaterials will reach target organs or cells. Nanomaterials can cross cellular membranes, penetrate nuclear material and genetic information, and may impact cellular response at a nanoscale. Silica nanoparticles have been demonstrated to produce kidney toxicity in humans, and zinc oxide nanoparticles are toxic to human liver cells. Multiwalled carbon nanotubes have been found to be cytotoxic in human lung cells. Titanium dioxide nanoparticles that are widely used in sunscreens, other cosmetics, pharmaceuticals, and many other products have been noted to be toxic in the lungs and elsewhere.

2. Environmental toxicology—Nanomaterials can enter the environment at all stages of their industrial life cycle, including manufacturing, delivery, use, and disposal. When nanomaterials are placed into waste streams they may enter water systems, or be carried by wind or soils, and enter the food chain. An EPA fact sheet on nanomaterials in the environment is available at https://www.epa.gov/sites/production/files/2014-03/documents/ffrrofactsheet_emergingcontaminant_nanomaterials_jan2014_final.pdf.

The increasing production of nanomaterials and their multiple uses has led to environmental contamination. Many species, including bacteria, small mammals, and fish and other aquatic organisms have been studied in laboratory assessments of nanomaterial toxicity. The ecotoxicology of nanomaterials remains an area of deep concern and ongoing research.

CASE STUDY ANSWER

The child presents with classic signs (and history) of carbon monoxide (CO) exposure. Pulse oximetry is unreliable in CO poisoning, although newer instruments may distinguish between carboxyhemoglobin (CO-Hgb) and oxyhemoglobin. Institute the ABCDs of poisoning (see Chapter 58). Immediate high-flow oxygen is mandatory and should be administered via a tight-fitting face mask or endotracheal catheter. A blood sample for blood gases and carboxyhemoglobin content should be obtained. If the CO-Hgb is greater

than 50%, hyperbaric oxygen treatment (if available) may be considered. The electrocardiogram should be continuously monitored for arrhythmias. Anticonvulsant drugs may be required if seizures occur. Neurologic damage due to CO exposure may be subtle and long-lasting; the child should be followed for years if necessary. The fetus is particularly susceptible to hypoxia, and if the mother is pregnant, her blood gases and CO-Hgb should be measured. If the latter is high, hyperbaric oxygen therapy should be considered.

57

Heavy Metal Intoxication
& Chelators

Michael J. Kosnett, MD, MPH

CASE STUDY

Following Sunday morning services, 27 people attended a church social where coffee, baked goods, and sandwiches were served. Within 15–60 minutes, 13 people developed vomiting and abdominal discomfort, accompanied over the next several hours by nonbloody diarrhea. Within 12 hours, seven of these

individuals were hospitalized with ongoing gastrointestinal symptoms, hypotension, and anion gap metabolic acidosis. Fluid resuscitation and pressors were accompanied by adequate urine output. What diagnoses should be considered? What tests should be conducted, and what therapy should be considered?

Some metals such as iron are essential for life, whereas others such as lead are present in all organisms but serve no useful biologic purpose. Some of the oldest diseases of humans can be traced to heavy metal poisoning associated with metal mining, refining, and use. Even with the present recognition of the hazards of heavy metals, the incidence of intoxication remains significant, and the need for preventive strategies and effective therapy remains high. Toxic heavy metals interfere with the function of essential cations, cause enzyme inhibition, generate oxidative stress, alter gene expression, and perturb cell signaling. As a result, multisystem signs and symptoms are a hallmark of heavy metal intoxication.

When intoxication occurs, chelator molecules (from *chela* “claw”), or their in vivo biotransformation products, may be used to bind the metal and facilitate its excretion from the body. Chelator drugs are discussed in the second part of this chapter.

■ TOXICOLOGY OF HEAVY METALS

LEAD

Lead poisoning is one of the oldest occupational and environmental diseases in the world. Despite its recognized hazards, lead continues to have widespread commercial application, including production

of storage batteries (nearly 90% of US consumption), ammunition, metal alloys, solder, glass, plastics, pigments, and ceramics. Corrosion of lead plumbing in older buildings or supply lines may increase the lead concentration of tap water. Environmental lead exposure, ubiquitous by virtue of the anthropogenic distribution of lead to air, water, and food, has declined considerably in the last three decades as a result of the elimination of lead as an additive in gasoline, as well as diminished contact with lead-based paint and other lead-containing consumer products, such as lead solder in cans used as food containers. Legislation in the United States in 2011 further reduced the maximum permissible lead content of children’s products to 100 ppm. Lead continues to be used in some formulations of aviation gasoline for piston-engine aircraft. The presence of lead in certain folk medicines (eg, the Mexican remedies *azarcon* and *greta*, and certain Ayurvedic preparations) and in cosmetics (eg, *kohl* utilized around the eyes in certain African and Asian communities) has contributed to lead exposure to children and adults. Although public health measures, together with improved workplace conditions, have decreased the incidence of serious overt lead poisoning, there remains considerable concern over the effects of low-level lead exposure. Extensive evidence indicates that low levels of lead exposure may have subtle subclinical adverse effects on neurocognitive function in children and may contribute to hypertension and cardiovascular disease in adults. Lead serves no useful purpose in the human body. In key target organs such as the developing central

nervous system, no level of lead exposure has been shown to be without deleterious effects.

Pharmacokinetics

Inorganic lead is slowly but consistently absorbed via the respiratory and gastrointestinal tracts. It is poorly absorbed through the skin. Absorption of lead dust via the respiratory tract is the most common cause of industrial poisoning. The intestinal tract is the primary route of entry in nonindustrial exposure (Table 57–1). Absorption via the gastrointestinal tract varies with the nature of the lead compound, but in general, adults absorb about 10–15% of the ingested amount, whereas young children absorb up to 50%. Low dietary calcium, iron deficiency, and ingestion on an empty stomach all have been associated with increased lead absorption.

Once absorbed from the respiratory or gastrointestinal tract, lead enters the bloodstream, where approximately 99% is bound to erythrocytes and 1% is present in the plasma. Lead is subsequently distributed to soft tissues such as the bone marrow, brain, kidney, liver, muscle, and gonads; then to the subperiosteal surface of bone; and later to bone matrix. Lead also crosses the placenta and poses a potential hazard to the fetus. The kinetics of lead clearance from the body follows a multicompartment model, composed predominantly of the blood and soft tissues,

with a half-life of 1–2 months; and the skeleton, with a half-life of years to decades. Approximately 70% of the lead that is eliminated appears in the urine, with lesser amounts excreted through the bile, skin, hair, nails, sweat, and breast milk. The fraction not undergoing prompt excretion, approximately half of the absorbed lead, may be incorporated into the skeleton, the repository of more than 90% of the body lead burden in most adults. In patients with high bone lead burdens, slow release from the skeleton may elevate blood lead concentrations for years after exposure ceases, and pathologic high bone turnover states such as hyperthyroidism or prolonged immobilization may result in frank lead intoxication. Migration of retained lead bullet fragments into a joint space or adjacent to bone has been associated with the development of lead poisoning signs and symptoms years or decades after an initial gunshot injury.

Pharmacodynamics

Lead exerts multisystemic toxic effects that are mediated by multiple modes of action, including inhibition of enzymatic function; interference with the action of essential cations, particularly calcium, iron, and zinc; generation of oxidative stress; changes in gene expression; alterations in cell signaling; and disruption of the integrity of membranes in cells and intracellular organelles.

TABLE 57–1 Toxicology of selected arsenic, lead, and mercury compounds.

	Form Entering Body	Major Route of Absorption	Distribution	Major Clinical Effects	Key Aspects of Mechanism	Metabolism and Elimination
Arsenic	Inorganic arsenic salts	Gastrointestinal, respiratory (all mucosal surfaces)	Predominantly soft tissues (highest in liver, kidney). Avidly bound in skin, hair, nails	Cardiovascular: shock, arrhythmias. CNS: encephalopathy, peripheral neuropathy. Gastroenteritis; pancytopenia; cancer (many sites)	Inhibits enzymes; interferes with oxidative phosphorylation; alters cell signaling, gene expression	Methylation. Renal (major); sweat and feces (minor)
Lead	Inorganic lead oxides and salts	Gastrointestinal, respiratory	Soft tissues; redistributed to skeleton (>90% of adult body burden)	CNS deficits; peripheral neuropathy; anemia; nephropathy; hypertension; reproductive toxicity	Inhibits enzymes; interferes with essential cations; alters membrane structure	Renal (major); feces and breast milk (minor)
	Organic (tetraethyl lead)	Skin, gastrointestinal, respiratory	Soft tissues, especially liver, CNS	Encephalopathy	Hepatic dealkylation (fast) → trialkyl metabolites (slow) → dissociation to lead	Urine and feces (major); sweat (minor)
Mercury	Elemental mercury	Respiratory tract	Soft tissues, especially kidney, CNS	CNS: tremor, behavioral (erethism); gingivo-stomatitis, peripheral neuropathy; acrodynia; pneumonitis (high-dose)	Inhibits enzymes; alters membranes	Elemental Hg converted to Hg ²⁺ . Urine (major); feces (minor)
	Inorganic: Hg ⁺ (less toxic); Hg ²⁺ (more toxic)	Gastrointestinal, skin (minor)	Soft tissues, especially kidney	Acute renal tubular necrosis; gastroenteritis; CNS effects (rare)	Inhibits enzymes; alters membranes	Urine
	Organic: alkyl, aryl	Gastrointestinal, skin, respiratory (minor)	Soft tissues	CNS effects, birth defects	Inhibits enzymes; alters microtubules, neuronal structure	Deacylation. Fecal (alkyl, major); urine (Hg ²⁺ after deacylation, minor)

A. Nervous System

The developing central nervous system of the fetus and young child is the most sensitive target organ for lead's toxic effect. Epidemiologic studies suggest that blood lead concentrations <5 mcg/dL may result in subclinical deficits in neurocognitive function in lead-exposed young children, with no demonstrable threshold or "no effect" level. The dose response between low blood lead concentrations and cognitive function in young children is nonlinear, such that the decrement in intelligence associated with an increase in blood lead from <1–10 mcg/dL (6.2 IQ points) exceeds that associated with a change from 10 to 30 mcg/dL (3.0 IQ points).

Adults are less sensitive to the central nervous system (CNS) effects of lead, but long-term exposure to blood lead concentrations in the range of 10–30 mcg/dL may be associated with subclinical effects on neurocognitive function. At blood lead concentrations higher than 30 mcg/dL, behavioral and neurocognitive signs or symptoms may gradually emerge, including irritability, fatigue, decreased libido, anorexia, sleep disturbance, impaired visual-motor coordination, and slowed reaction time. Headache, arthralgias, and myalgias are also common complaints. Tremor occurs but is less common. Lead encephalopathy, usually occurring at blood lead concentrations higher than 100 mcg/dL, is typically accompanied by increased intracranial pressure and may cause ataxia, stupor, coma, convulsions, and death. Recent epidemiological studies suggest that lead may accentuate an age-related decline in cognitive function in older adults. In experimental animals, developmental lead exposure, possibly acting through epigenetic mechanisms, has been associated with increased expression of beta-amyloid, increased phosphorylated tau protein, oxidative DNA damage, and Alzheimer's-type pathology in the aging brain. There is wide interindividual variation in the magnitude of lead exposure required to cause overt lead-related signs and symptoms.

Overt peripheral neuropathy may appear after chronic high-dose lead exposure, usually following months to years of blood lead concentrations higher than 100 mcg/dL. Predominantly motor in character, the neuropathy may present clinically with painless weakness of the extensors, particularly in the upper extremity, resulting in classic wrist-drop. Preclinical signs of lead-induced peripheral nerve dysfunction may be detectable by electrodiagnostic testing.

B. Blood

Lead can induce an anemia that may be either normocytic or microcytic and hypochromic. Lead interferes with heme synthesis by blocking the incorporation of iron into protoporphyrin IX and by inhibiting the function of enzymes in the heme synthesis pathway, including aminolevulinic acid dehydratase and ferrochelatase. Within 2–8 weeks after an elevation in blood lead concentration (generally to 30–50 mcg/dL or greater), increases in heme precursors, notably free erythrocyte protoporphyrin or its zinc chelate, zinc protoporphyrin, may be detectable in whole blood. Lead also contributes to anemia by increasing erythrocyte membrane fragility and decreasing red cell survival time. Frank

hemolysis may occur with high exposure. Basophilic stippling on the peripheral blood smear, thought to be a consequence of lead inhibition of the enzyme 3',5'-pyrimidine nucleotidase, is sometimes a suggestive—albeit insensitive and nonspecific—diagnostic clue to the presence of lead intoxication.

C. Kidneys

Chronic high-dose lead exposure, usually associated with months to years of blood lead concentrations >80 mcg/dL, may result in renal interstitial fibrosis and nephrosclerosis. Lead nephropathy may have a latency period of years. Lead may alter uric acid excretion by the kidney, resulting in recurrent bouts of gouty arthritis ("saturnine gout"). Acute high-dose lead exposure sometimes produces transient azotemia, possibly as a consequence of intrarenal vasoconstriction. Studies conducted in general population samples have documented an association between blood lead concentration and measures of renal function, including serum creatinine and creatinine clearance. The presence of other risk factors for renal insufficiency, including hypertension and diabetes, may increase susceptibility to lead-induced renal dysfunction.

D. Reproductive Organs

High-dose lead exposure is a recognized risk factor for stillbirth or spontaneous abortion. Epidemiologic studies of the impact of low-level lead exposure on reproductive outcome such as low birth weight, preterm delivery, or spontaneous abortion have yielded mixed results. However, a well-designed nested case-control study detected an odds ratio for spontaneous abortion of 1.8 (95% CI 1.1–3.1) for every 5 mcg/dL increase in maternal blood lead across an approximate range of 5–20 mcg/dL. Recent studies have linked prenatal exposure to low levels of lead (eg, maternal blood lead concentrations of 5–15 mcg/dL) to decrements in physical and cognitive development assessed during the neonatal period and early childhood. In males, blood lead concentrations higher than 40 mcg/dL have been associated with diminished or aberrant sperm production.

E. Gastrointestinal Tract

Moderate lead poisoning may cause loss of appetite, constipation, and, less commonly, diarrhea. At high dosage, intermittent bouts of severe colicky abdominal pain ("lead colic") may occur. The mechanism of lead colic is unclear but is believed to involve spasmodic contraction of the smooth muscles of the intestinal wall, mediated by alteration in synaptic transmission at the smooth muscle-neuromuscular junction. In heavily exposed individuals with poor dental hygiene, the reaction of circulating lead with sulfur ions released by microbial action may produce dark deposits of lead sulfide at the gingival margin ("gingival lead lines"). Although frequently mentioned as a diagnostic clue in the past, in recent times this has been a relatively rare sign of lead exposure.

F. Cardiovascular System

Epidemiologic, experimental, and in vitro mechanistic data indicate that lead exposure elevates blood pressure in experimental animals and in susceptible humans. The pressor effect of lead may

be mediated by an interaction with calcium-mediated contraction of vascular smooth muscle, as well as generation of oxidative stress and an associated interference in nitric oxide signaling pathways. In populations with environmental or occupational lead exposure, blood lead concentration is linked with increases in systolic and diastolic blood pressure. Studies of middle-aged and elderly men and women have identified relatively low levels of lead exposure sustained by the general population to be an independent risk factor for hypertension. Lead exposure has also been associated with prolongation of the QT_c interval on the electrocardiogram. Epidemiologic studies have linked chronic environmental lead exposure associated with population blood lead concentrations in the range of 10–25 mcg/dL to a significantly increased risk of cardiovascular mortality. This is of considerable public health concern because these concentrations were prevalent in the USA prior to the 1980s. Although general population blood lead concentrations have since fallen considerably (see below), exposure associated with blood lead in this range persists in occupational settings worldwide.

Major Forms of Lead Intoxication

A. Inorganic Lead Poisoning (Table 57–1)

1. Acute—Acute inorganic lead poisoning is uncommon today. It usually results from industrial inhalation of large quantities of lead oxide fumes or, in small children, from ingestion of a large oral dose of lead in the form of lead-based paint chips; small objects, eg, toys coated or fabricated from lead; or contaminated food or drink. The onset of severe symptoms usually requires several days or weeks of recurrent exposure and manifests as signs and symptoms of encephalopathy or colic. Evidence of hemolytic anemia (or anemia with basophilic stippling if exposure has been subacute) and elevated hepatic aminotransferases may be present.

The diagnosis of acute inorganic lead poisoning may be difficult, and depending on the presenting symptoms, the condition has sometimes been mistaken for appendicitis, peptic ulcer, biliary colic, pancreatitis, or infectious meningitis. Subacute presentation, featuring headache, fatigue, intermittent abdominal cramps, myalgias, and arthralgias, has often been mistaken for a flu-like viral illness. When there has been recent ingestion of lead-containing paint chips, glazes, pellets, or weights, radiopacities may be visible on abdominal radiographs.

2. Chronic—The patient with symptomatic chronic lead intoxication typically presents with multisystemic findings, including complaints of anorexia, fatigue, and malaise; neurologic complaints, including headache, difficulty in concentrating, and irritability or depressed mood; weakness, arthralgias, or myalgias; and gastrointestinal symptoms. Lead poisoning should be strongly suspected in any patient presenting with headache, abdominal pain, and anemia; and less commonly with motor neuropathy, gout, and renal insufficiency. Chronic lead intoxication should be considered in any child with neurocognitive deficits, growth retardation, or developmental delay. It is important to recognize that adverse effects of lead that are of considerable public health significance, such as subclinical decrements in neurodevelopment

in children and hypertension in adults, are usually nonspecific and may not come to medical attention.

The diagnosis of lead intoxication is best confirmed by measuring lead in whole blood. Although this test reflects lead currently circulating in blood and soft tissues and is not a reliable marker of either recent or cumulative lead exposure, most patients with lead-related disease have blood lead concentrations higher than the normal range. Average background blood lead concentrations in North America and Europe have declined by 90% in recent decades, and the geometric mean blood lead concentration in the United States in 2011–2012 was estimated to be 0.973 mcg/dL. Though predominantly a research tool, the concentration of lead in bone assessed by noninvasive K X-ray fluorescence measurement of lead has been correlated with long-term cumulative lead exposure, and its relationship to numerous lead-related disorders is the subject of ongoing investigation. Measurement of lead excretion in the urine after a single dose of a chelating agent (sometimes called a “chelation challenge test”) primarily reflects the lead content of soft tissues and may not be a reliable marker of long-term lead exposure, remote past exposure, or skeletal lead burden. Accordingly, this test is rarely indicated in clinical practice. Because of the lag time associated with lead-induced elevations in circulating heme precursors, the finding of a blood lead concentration of 30 mcg/dL or more with no concurrent increase in zinc protoporphyrin suggests that the lead exposure was of recent onset.

B. Organolead Poisoning

Poisoning from organolead compounds is now very rare, in large part because of the worldwide phase-out of tetraethyl and tetramethyl lead as antiknock additives in gasoline. However, organolead compounds such as lead stearate or lead naphthenate are still used in certain commercial processes. Because of their volatility or lipid solubility, organolead compounds tend to be well absorbed through either the respiratory tract or the skin. Organolead compounds predominantly target the CNS, producing dose-dependent effects that may include neurocognitive deficits, insomnia, delirium, hallucinations, tremor, convulsions, and death.

Treatment

A. Inorganic Lead Poisoning

Treatment of inorganic lead poisoning involves immediate termination of exposure, supportive care, and the judicious use of chelation therapy. (Chelation is discussed later in this chapter.) Lead encephalopathy is a medical emergency that requires intensive supportive care. Cerebral edema may improve with corticosteroids and mannitol or hypertonic saline, and anticonvulsants may be required to treat seizures. Radiopacities on abdominal radiographs may suggest the presence of retained lead objects requiring gastrointestinal decontamination. Adequate urine flow should be maintained, but overhydration should be avoided. Intravenous **edetate calcium disodium (CaNa₂EDTA)** is administered at a dosage of 1000–1500 mg/m²/d (approximately 30–50 mg/kg/d) by continuous infusion for up to 5 days. Some clinicians advocate

Prevention of Lead Poisoning: An Ongoing Effort

Exposure: Sources	Examples of Preventive Measures
Home exposure: The US Consumer Product Safety Commission adopted major restrictions on the use of lead in residential house paint in 1977. Prior to then, thousands of tons of lead pigments were applied in millions of homes. The American Healthy Homes Survey (2005–2006) estimated that 35% of homes had some lead-based paint and 22% had one or more lead-based paint hazards.	<p>The US Environmental Protection Agency's (EPA) Lead Renovation, Repair, and Painting Rule requires that companies performing renovation, repair, and painting projects that disturb lead-based paint in homes, child care facilities, and preschools built before 1978 have their firm certified by EPA (or an EPA-authorized state), use certified renovators who are trained by EPA-approved training providers, and follow lead-safe work practices.</p> <p>[https://www.epa.gov/lead/renovation-repair-and-painting-program]</p>
Workplace exposure: The US Occupational Health and Safety Administration (OSHA) estimates that more than 1.6 million workers are potentially exposed to lead. State and federal OSHA programs have established permissible exposure levels for lead in workplace air, as well as medical surveillance requirements for workers that may mandate periodic blood lead monitoring.	<p>Present OSHA rules regarding workplace lead exposure and medical removal protection date from the late 1970s and no longer offer adequate protection. The Occupational Lead Poisoning Prevention Program of the California Department of Public Health offers up-to-date, health protective guidance.</p> <p>[https://archive.cdph.ca.gov/programs/olppp/Pages/default.aspx]</p>
Water: Lead may enter drinking water when service pipes contain lead, especially when the water has high acidity or low mineral content that corrodes pipes and plumbing fixtures.	<p>Under EPA's Lead and Copper Rule [https://www.epa.gov/dwreginfo/lead-and-copper-rule], if more than 10% of tap water samples at sites likely to have lead plumbing exceed the lead action level of 15 parts per billion, water systems are required to institute corrosion control and other measures. The Safe Drinking Water Act, amended by the Reduction of Lead in Drinking Water Act of 2011, sets limits on the lead content of new plumbing materials for potable water.</p> <p>[https://www.epa.gov/dwstandardsregulations/use-lead-free-pipes-fittings-fixtures-solder-and-flux-drinking-water]</p>
Children: Because of normal mouthing behavior, children are at special risk of exposure to lead present in toys, jewelry, printed material, and other consumer products.	<p>The US Consumer Product Safety Commission has promulgated rules that limit the amount of lead that can be present in children's products.</p> <p>[https://www.cpsc.gov/Business--Manufacturing/Business-Education/Lead/Lead-in-Paint]</p> <p>[https://www.cpsc.gov/Business--Manufacturing/Business-Education/Lead/Total-Lead-Content]</p>

Production of lead began 6000 years ago, and lead poisoning is one of the oldest known occupational illnesses. Worldwide, lead production has doubled over the past two decades in part because of the growing demand for lead acid storage batteries. Efforts to prevent lead poisoning from multiple industrial, commercial, and environmental sources remain an active focus of public health in the USA.

that chelation treatment for lead encephalopathy be initiated with an intramuscular injection of **dimercaprol**, followed in 4 hours by concurrent administration of dimercaprol and EDTA. Parenteral chelation is limited to 5 or fewer days, at which time oral treatment with another chelator, **succimer (DMSA)**, may be instituted. In symptomatic lead intoxication without encephalopathy, treatment may sometimes be initiated with succimer. The end point for chelation is usually resolution of symptoms or return of the blood lead concentration to the premorbid range. In patients with chronic exposure, cessation of chelation may be followed by an upward rebound in blood lead concentration as the lead re-equilibrates from bone lead stores.

Although most clinicians support chelation for symptomatic patients with elevated blood lead concentrations, the decision to chelate asymptomatic subjects is more controversial. Since 1991, the Centers for Disease Control and Prevention (CDC) has recommended chelation for all children with blood lead concentrations of 45 mcg/dL or greater. However, a randomized, double-blind, placebo-controlled clinical trial of succimer in children with blood lead concentrations between 25 and 44 mcg/dL found no benefit on neurocognitive function or long-term blood lead reduction. Prophylactic use of chelating agents in the workplace should never be a substitute for reduction or prevention of excessive exposure.

Management of elevated blood lead levels in children and adults should include a conscientious effort to identify and reduce all potential sources of future lead exposure. Many local, state, or national governmental agencies maintain lead poisoning prevention programs that can assist in case management. Blood lead screening of family members or coworkers of a lead poisoning patient is often indicated to assess the scope of the exposure. In 2012, the CDC adopted a new policy that defined as elevated any childhood blood lead concentrations at or exceeding a reference value corresponding to the 97.5th percentile of quadrennial reports of the National Health and Nutrition Examination Survey (NHANES). The blood lead reference value established in 2012 was 5 mcg/dL, and it is projected to decline in the future. Because there is no blood lead concentration known to be devoid of deleterious effects, the finding of a blood lead concentration exceeding the reference value (ie, elevated in relation to the general population) should prompt clinical and environmental investigation (https://www.cdc.gov/nceh/lead/acclpp/final_document_030712.pdf). Although the US Occupational Safety and Health Administration (OSHA) lead regulations introduced in the late 1970s mandate that workers be removed from lead exposure for blood lead levels higher than 50–60 mcg/dL, an expert panel in 2007 recommended that removal be initiated for a single blood lead level >30 mcg/dL or when two successive blood lead levels measured over a 4-week interval are 20 mcg/dL or greater (<https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1849937/pdf/ehp0115-000463.pdf>). The longer-term goal should be for workers to maintain blood lead levels <10 mcg/dL, and for pregnant women to avoid occupational or avocational exposure that would result in blood lead levels higher than 5 mcg/dL. Environmental Protection Agency (EPA) regulations effective since 2010 require that contractors who perform renovation, repair, and painting projects that disturb lead-based paint in pre-1978 residences and child-occupied facilities must be certified and must follow specific work practices to prevent lead contamination (see Box: Prevention of Lead Poisoning: An Ongoing Effort).

B. Organic Lead Poisoning

Initial treatment consists of decontaminating the skin and preventing further exposure. Treatment of seizures requires appropriate use of anticonvulsants. Empiric chelation may be attempted if high blood lead concentrations are present.

ARSENIC

Arsenic is a naturally occurring element in the earth's crust with a long history of use as a constituent of commercial and industrial products, as a component in pharmaceuticals, and as an agent of deliberate poisoning. Recent commercial applications of arsenic include its use in the manufacture of semiconductors, wood preservatives for industrial applications (eg, marine timbers or utility poles), nonferrous alloys, glass, and the turf herbicide monosodium methane arsonate (MSMA). The use of phenyl-arsenic compounds as feed additives for poultry and swine was terminated in the United States in 2015. In some regions of the

world, groundwater may contain high levels of arsenic that has leached from natural mineral deposits. Arsenic in drinking water in the Ganges delta of India and Bangladesh is now recognized as one of the world's most pressing environmental health problems. Environmental risk assessments have suggested that arsenic migrating from coal combustion wastes (eg, coal ash) deposited in unlined landfills may contaminate underlying groundwater. Arsine, an arsenous hydride (AsH_3) gas with potent hemolytic effects, is manufactured predominantly for use in the semiconductor industry but may also be generated accidentally when arsenic-containing ores or scrap gallium arsenide semiconductors come in contact with acidic solutions.

It is of historical interest that Fowler's solution, which contains 1% potassium arsenite, was widely used as a medicine for many conditions from the eighteenth century through the mid-twentieth century. Organic arsenicals were the first pharmaceutical antimicrobials* and were widely used for the first half of the twentieth century until supplanted by sulfonamides and other more effective and less toxic agents.

Other organoarsenicals, most notably lewisite (dichloro-[2-chlorovinyl]arsine), were developed in the early 20th century as chemical warfare agents. Arsenic trioxide was reintroduced into the United States Pharmacopeia in 2000 as an orphan drug for the treatment of relapsed acute promyelocytic leukemia and is finding expanded use in experimental cancer treatment protocols. Melarsoprol, another trivalent arsenical, is used in the treatment of advanced African trypanosomiasis (see Chapter 52).

Pharmacokinetics

Soluble arsenic compounds are well absorbed through the respiratory and gastrointestinal tracts (Table 57–1). Percutaneous absorption is limited but may be clinically significant after heavy exposure to concentrated arsenic reagents. Most of the absorbed inorganic arsenic undergoes methylation, mainly in the liver, to monomethyl-arsenic acid and dimethylarsinic acid, which are excreted, along with residual inorganic arsenic, in the urine. When chronic daily absorption is <1000 mcg of soluble inorganic arsenic, approximately two thirds of the absorbed dose is excreted in the urine within 2–3 days. After massive ingestions, the elimination half-life is prolonged. Inhalation of arsenic compounds of low solubility may result in prolonged retention in the lung and may not be reflected by urinary arsenic excretion. Arsenic binds to sulfhydryl groups present in keratinized tissue, and following cessation of exposure, hair, nails, and skin may contain elevated levels after urine values have returned to normal. However, arsenic in hair and nails as a result of external deposition may be indistinguishable from that incorporated after internal absorption.

Pharmacodynamics

Arsenic compounds are thought to exert their toxic effects by several modes of action. Interference with enzyme function may result from sulfhydryl group binding by trivalent arsenic or by

*Paul Ehrlich's "magic bullet" for syphilis (arsphenamine, Salvarsan) was an arsenical.

substitution for phosphate. Inorganic arsenic or its metabolites may induce oxidative stress, alter gene expression, and interfere with cell signal transduction. Although on a molar basis, inorganic trivalent arsenic (As^{3+} , arsenite) is generally two to ten times more acutely toxic than inorganic pentavalent arsenic (As^{5+} , arsenate), in vivo interconversion is known to occur, and the full spectrum of arsenic toxicity has occurred after sufficient exposure to either form. Recent studies suggest that the trivalent form of the methylated metabolites (eg, monomethylarsonous acid [MMA^{III}]) may be more toxic than the inorganic parent compounds. Reduced efficiency in the methylation of MMA to dimethylarsonous acid (DMA), resulting in an elevated percentage of MMA in the urine, has been associated with an increased risk of chronic adverse effects. Arsenic methylation requires *S*-adenosylmethionine, a universal methyl donor in the body, and arsenic-associated perturbations in one-carbon metabolism may underlie some arsenic-induced epigenetic effects such as altered gene expression.

Arsine gas is oxidized in vivo and exerts a potent hemolytic effect associated with alteration of ion flux across the erythrocyte membrane; it also disrupts cellular respiration in other tissues. Arsenic is a recognized human carcinogen and has been associated with cancer of the lung, skin, and bladder. Marine organisms may contain large amounts of a well-absorbed trimethylated organoarsenic, arsenobetaine, as well as a variety of arsenosugars and arsenolipids. Arsenobetaine exerts no known toxic effects when ingested by mammals and is excreted in the urine unchanged; arsenosugars are partially metabolized to dimethylarsinic acid. Thioarsenite compounds that occur as minor metabolites of inorganic arsenic and methylated arsenic compounds in vivo may contribute to toxicity.

Major Forms of Arsenic Intoxication

A. Acute Inorganic Arsenic Poisoning

Within minutes to hours after exposure to high doses (tens to hundreds of milligrams) of soluble inorganic arsenic compounds, many systems are affected. Initial gastrointestinal signs and symptoms include nausea, vomiting, diarrhea, and abdominal pain. Diffuse capillary leak, combined with gastrointestinal fluid loss, may result in hypotension, shock, and death. Cardiopulmonary toxicity, including congestive cardiomyopathy, cardiogenic or noncardiogenic pulmonary edema, and ventricular arrhythmias (particularly in association with QT_c prolongation on the electrocardiogram) may occur promptly or after a delay of several days. Pancytopenia usually develops within 1 week, and basophilic stippling of erythrocytes may be present soon after. Central nervous system effects, including delirium, encephalopathy, and coma, may occur within the first few days of intoxication. An ascending sensorimotor peripheral neuropathy may begin to develop after a delay of 2–6 weeks. This neuropathy may ultimately involve the proximal musculature and result in neuromuscular respiratory failure. Months after an acute poisoning, transverse white striae (Aldrich-Mees lines) may be visible in the nails.

Acute inorganic arsenic poisoning should be considered in an individual presenting with abrupt onset of gastroenteritis in combination with hypotension and metabolic acidosis. Suspicion should be further heightened when these initial findings are

followed by cardiac dysfunction, pancytopenia, and peripheral neuropathy. The diagnosis may be confirmed by demonstration of elevated amounts of inorganic arsenic and its metabolites in the urine (typically in the range of several thousand micrograms in the first 2–3 days after acute symptomatic poisoning). Arsenic disappears rapidly from the blood, and except in anuric patients, blood arsenic levels should not be used for diagnostic purposes. Treatment is based on appropriate gut decontamination, intensive supportive care, and prompt chelation with **unithiol**, 3–5 mg/kg intravenously every 4–6 hours, or **dimercaprol**, 3–5 mg/kg intramuscularly every 4–6 hours. In animal studies, the efficacy of chelation has been highest when it is administered within minutes to hours after arsenic exposure; therefore, if diagnostic suspicion is high, treatment should not be withheld for the several days to weeks often required to obtain laboratory confirmation.

Succimer has also been effective in animal models and has a higher therapeutic index than dimercaprol. However, because it is available in the United States only for oral administration, its use may not be advisable in the initial treatment of acute arsenic poisoning, when severe gastroenteritis and splanchnic edema may limit absorption by this route.

B. Chronic Inorganic Arsenic Poisoning

Chronic inorganic arsenic poisoning also results in multisystemic signs and symptoms. Overt noncarcinogenic effects may be evident after chronic absorption of more than 0.01 mg/kg/d (~500–1000 mcg/d in adults). The time to appearance of symptoms varies with dose and interindividual tolerance. Constitutional symptoms of fatigue, weight loss, and weakness may be present, along with anemia, nonspecific gastrointestinal complaints, and a sensorimotor peripheral neuropathy, particularly featuring a stocking-glove pattern of dysesthesia. Skin changes—among the most characteristic effects—typically develop after years of exposure and include a “raindrop” pattern of hyperpigmentation, and hyperkeratoses involving the hands and feet (Figure 57–1). Peripheral vascular disease and noncirrhotic portal hypertension may also occur. Epidemiologic studies suggest a possible link to hypertension, cardiovascular disease mortality, diabetes, chronic nonmalignant respiratory disease, and adverse reproductive outcomes. Cancer of the lung, skin, bladder, and possibly other sites, including the kidney and liver, may appear years after exposure to doses of arsenic that are not high enough to elicit other acute or chronic effects. Some studies suggest that tobacco smoking may interact synergistically with arsenic in increasing the risk of certain adverse health outcomes.

Administration of arsenite in cancer chemotherapy regimens, often at a daily dose of 10–20 mg for weeks to a few months, has been associated with prolongation of the QT interval on the electrocardiogram and occasionally has resulted in malignant ventricular arrhythmias such as torsades de pointes.

The diagnosis of chronic arsenic poisoning involves integration of the clinical findings with confirmation of exposure. The urine concentration of the sum of inorganic arsenic and its primary metabolites MMA and DMA is <20 mcg/L in the general population. High urine levels associated with overt adverse effects may return to normal within days to weeks after exposure ceases. Because it may contain large amounts of nontoxic organoarsenic

FIGURE 57-1 Dermatologic lesions associated with chronic ingestion of arsenic in drinking water. (Photo courtesy of Dipankar Chakraborti, PhD.)

such as arsenobetaine, or arsenosugars that are metabolized to DMA, all seafood should be avoided for at least 3 days before submission of a urine sample for diagnostic purposes. The arsenic content of hair and nails (normally <1 ppm) may sometimes reveal past elevated exposure, but results should be interpreted cautiously in view of the potential for external contamination. Segmental analysis of hair or nails using sensitive methods such as neutron activation analysis or synchrotron radiation sources may sometimes have forensic value for investigation of the temporal pattern of arsenic poisoning.

Management of chronic arsenic poisoning consists primarily of termination of exposure and nonspecific supportive care. Although empiric short-term oral chelation with **unithiol** or **succimer** for symptomatic individuals with elevated urine arsenic concentrations may be considered, it has no proven benefit beyond removal from exposure alone. Preliminary studies suggest that dietary supplementation of folate—thought to be a cofactor in arsenic methylation—might be of value in arsenic-exposed individuals, particularly men, who are also deficient in folate.

C. Arsenic Gas Poisoning

Arsenic gas poisoning produces a distinctive pattern of intoxication dominated by profound hemolytic effects. After a latent period that

may range from 2 to 24 hours postinhalation (depending on the magnitude of exposure), massive intravascular hemolysis may occur. Initial symptoms may include malaise, headache, dyspnea, weakness, nausea, vomiting, abdominal pain, jaundice, and hemoglobinuria. Oliguric renal failure, a consequence of hemoglobin deposition in the renal tubules, often appears within 1–3 days. In massive exposures, lethal effects on cellular respiration may occur before renal failure develops. Urinary arsenic levels are elevated but are seldom available to confirm the diagnosis during the critical period of illness. Intensive supportive care—including exchange transfusion, vigorous hydration, and, in the case of acute renal failure, hemodialysis—is the mainstay of therapy. Currently available chelating agents have not been demonstrated to be of clinical value in arsenic poisoning.

MERCURY

Metallic mercury as “quicksilver”—the only metal that is liquid under ordinary conditions—has attracted scholarly and scientific interest from antiquity. The mining of mercury was early recognized as being hazardous to health. As industrial use of mercury became common during the last 200 years, new forms of toxicity were recognized that were found to be associated with various transformations of the metal. In the early 1950s, a mysterious epidemic of birth defects and neurologic disease occurred in the Japanese fishing village of Minamata. The causative agent was determined to be methylmercury in contaminated seafood, traced to industrial discharges into the bay from a nearby factory. In addition to elemental mercury and alkylmercury (including methylmercury), other key mercurials include inorganic mercury salts and aryl mercury compounds, each of which exerts a relatively unique pattern of clinical toxicity.

Mercury is mined predominantly as HgS in cinnabar ore and is then converted commercially to a variety of chemical forms. Key industrial and commercial applications of mercury are found in the electrolytic production of chlorine and caustic soda; the manufacture of electrical equipment, thermometers, and other instruments; fluorescent lamps; and dental amalgam. The widespread use of elemental mercury in artisanal gold production is a growing problem in many developing countries. Mercury use in pharmaceuticals and in biocides has declined substantially in recent years, but occasional use in antiseptics, folk medicines, and cosmetic skin-lightening creams is still encountered. Thimerosal, an organomercurial preservative that is metabolized in part to ethylmercury, has been removed from almost all the vaccines in which it was formerly present. Environmental releases of mercury from the burning of fossil fuels, which contributes to the bioaccumulation of methylmercury in fish, remains a concern in some regions of the world. Low-level exposure to mercury released from dental amalgam fillings occurs, but systemic toxicity from this source has not been established.

The United States banned the export of elemental mercury in 2013. Once fully implemented, the international Minamata Convention on Mercury, signed by 128 countries since 2013, will result in a worldwide phase-out by 2020 of mercury in numerous products including batteries, switches and relays, fluorescent

lamps, pesticides, biocides and antiseptics, measuring instruments (eg, thermometers, sphygmomanometers), and manufacturing processes such as chloralkali production (by 2025)

Pharmacokinetics

The absorption of mercury varies considerably depending on the chemical form of the metal. Elemental mercury is quite volatile and can be absorbed from the lungs (Table 57–1). It is poorly absorbed from the intact gastrointestinal tract. Inhaled mercury is the primary source of occupational exposure. Organic short-chain alkylmercury compounds are volatile and potentially harmful by inhalation as well as by ingestion. Percutaneous absorption of metallic mercury and inorganic mercury can be of clinical concern following massive acute or long-term chronic exposure. Alkylmercury compounds appear to be well absorbed through the skin, and acute contact with a few drops of dimethylmercury has resulted in severe, delayed toxicity. After absorption, mercury is distributed to the tissues within a few hours, with the highest concentration occurring in the kidney. Inorganic mercury is excreted through the urine and feces. Excretion of inorganic mercury follows a multi-compartment model: most is excreted within weeks to months, but a fraction may be retained in the kidneys and brain for years. After inhalation of elemental mercury vapor, urinary mercury levels decline with a half-life of approximately 1–3 months. Urine mercury concentration is <3 mcg/L in most individuals without occupational exposure, and the median general population urine mercury concentration in the 2011–2012 NHANES was 0.324 mcg/L. Methylmercury, which has a blood and whole-body half-life of approximately 50 days, undergoes biliary excretion and enterohepatic circulation, with more than two thirds eventually excreted in the feces. The geometric mean total blood mercury concentration in the US population in the 2011–2012 NHANES was 0.703 mcg/L; the 95th percentile was 4.40 mcg/L (~90% present as methylmercury). Mercury binds to sulfhydryl groups in keratinized tissue, and as with lead and arsenic, traces appear in the hair and nails. Mercury in hair has served as a valid biomarker of methylmercury exposure over an interval of weeks to months in epidemiologic studies.

Major Forms of Mercury Intoxication

Mercury interacts with sulfhydryl groups *in vivo*, inhibiting enzymes and altering cell membranes. The pattern of clinical intoxication from mercury depends to a great extent on the chemical form of the metal and the route and severity of exposure.

A. Acute

Acute inhalation of elemental mercury vapors may cause chemical pneumonitis and noncardiogenic pulmonary edema. Acute gingivostomatitis may occur, and neurologic sequelae (see following text) may also ensue. Acute ingestion of inorganic mercury salts, such as mercuric chloride, can result in a corrosive, potentially life-threatening hemorrhagic gastroenteritis followed within hours to days by acute tubular necrosis and oliguric renal failure.

B. Chronic

Chronic poisoning from inhalation of mercury vapor results in a classic triad of tremor, neuropsychiatric disturbance, and gingivostomatitis. The tremor usually begins as a fine intention tremor of the hands, but the face may also be involved, and progression to choreiform movements of the limbs may occur. Neuropsychiatric manifestations, including memory loss, fatigue, insomnia, and anorexia, are common. There may be an insidious change in mood to shyness, withdrawal, and depression along with explosive anger or blushing (a behavioral pattern referred to as **erethism**). Recent studies suggest that low-dose exposure may produce subclinical neurologic effects. Gingivostomatitis, sometimes accompanied by loosening of the teeth, may be reported after high-dose exposure. Evidence of peripheral nerve damage may be detected on electrodiagnostic testing, but overt peripheral neuropathy is rare. Acrodynia is an uncommon idiosyncratic reaction to subacute or chronic mercury exposure and occurs mainly in children. It is characterized by painful erythema of the extremities and may be associated with hypertension, diaphoresis, anorexia, insomnia, irritability or apathy, and a miliary rash. Chronic exposure to inorganic mercury salts, sometimes via topical application in cosmetic skin-lightening creams, has been associated with neurological symptoms and renal toxicity in case reports and case series.

Methylmercury intoxication affects mainly the CNS and results in paresthesias, ataxia, hearing impairment, dysarthria, and progressive constriction of the visual fields. Signs and symptoms of methylmercury intoxication may first appear several weeks or months after exposure begins. Methylmercury is a reproductive toxin. High-dose prenatal exposure to methylmercury may produce mental retardation and a cerebral palsy-like syndrome in the offspring. Low-level prenatal exposures to methylmercury have been associated with a risk of subclinical neurodevelopmental deficits.

A 2004 report by the Institute of Medicine's Immunization Safety Review Committee concluded that available evidence favored rejection of a causal relation between thimerosal-containing vaccines and autism. In like manner, a recent retrospective cohort study conducted by the CDC did not support a causal association between early prenatal or postnatal exposure to mercury from thimerosal-containing vaccines and neuropsychological functioning later in childhood.

Dimethylmercury is a rarely encountered but extremely neurotoxic form of organomercury that may be lethal in small quantities.

The diagnosis of mercury intoxication involves integration of the history and physical findings with confirmatory laboratory testing or other evidence of exposure. In the absence of occupational exposure, the urine mercury concentration is usually <5 mcg/L, and whole blood mercury is <5 mcg/L. In 1990, the Biological Exposure Index (BEI) Committee of the American Conference of Governmental Industrial Hygienists (ACGIH) recommended that workplace exposures should result in urinary mercury concentrations <35 mcg per gram of creatinine and end-of-work-week whole blood mercury concentrations <15 mcg/L. To minimize the risk of developmental neurotoxicity from methylmercury, the EPA

and the US Food and Drug Administration (FDA) have advised pregnant women, women who might become pregnant, nursing mothers, and young children to avoid consumption of fish with high mercury levels (eg, swordfish) and to limit consumption of albacore tuna to 6 ounces a week, but to otherwise consume 8–12 ounces of fish per week (see <http://www.fda.gov/Food/FoodborneIllnessContaminants/Metals/ucm393070.htm>).

Treatment

A. Acute Exposure

In addition to intensive supportive care, prompt chelation with oral or intravenous **unithiol**, intramuscular **dimercaprol**, or oral **succimer** may be of value in diminishing nephrotoxicity after acute exposure to inorganic mercury salts. Vigorous hydration may help to maintain urine output, but if acute renal failure ensues, days to weeks of hemodialysis or hemodiafiltration in conjunction with chelation may be necessary. Because the efficacy of chelation declines with time since exposure, treatment should not be delayed until the onset of oliguria or other major systemic effects.

B. Chronic Exposure

Unithiol and **succimer** increase urine mercury excretion following acute or chronic elemental mercury inhalation, but the impact of such treatment on clinical outcome is unknown. Dimercaprol has been shown to redistribute mercury to the central nervous system from other tissue sites, and since the brain is a key target organ, dimercaprol should not be used in treatment of exposure to elemental or organic mercury. Limited data suggest that succimer, unithiol, and *N*-acetyl-L-cysteine (NAC) may enhance body clearance of methylmercury.

■ PHARMACOLOGY OF CHELATORS

Chelating agents are drugs used to prevent or reverse the toxic effects of a heavy metal on an enzyme or other cellular target, or to accelerate the elimination of the metal from the body. By forming a complex with the heavy metal, the chelating agent renders the metal unavailable for toxic interactions with functional groups of enzymes or other proteins, coenzymes, cellular nucleophiles, and membranes. Chelating agents contain one or more coordinating atoms, usually oxygen, sulfur, or nitrogen, which donate a pair of electrons to a cationic metal ion to form one or more coordinate-covalent bonds. Depending on the number of metal-ligand bonds, the complex may be referred to as mono-, bi-, or polydentate. Figure 57–2 depicts the hexadentate chelate formed by interaction of edetate (ethylenediaminetetraacetate) with a metal atom, such as lead.

In some cases, the metal-mobilizing effect of a therapeutic chelating agent may not only enhance that metal's excretion—a desired effect—but may also redistribute some of the metal to other vital organs. This has been demonstrated for dimercaprol,

FIGURE 57–2 Salt and chelate formation with edetate (ethylenediaminetetraacetate, EDTA). **A:** In a solution of the disodium salt of EDTA, the sodium and hydrogen ions are chemically and biologically available. **B:** In solutions of calcium disodium edetate, calcium is bound by coordinate-covalent bonds with nitrogens as well as by the usual ionic bonds. **C:** In the lead–edetate chelate, lead is incorporated into five heterocyclic rings. (Adapted, with permission, from Meyers FH, Jawetz E, Goldfine A: *Review of Medical Pharmacology*, 7th ed. Originally published by Lange Medical Publications. McGraw-Hill, 1980. Copyright © The McGraw-Hill Companies, Inc.)

which redistributes mercury and arsenic to the brain while also enhancing urinary mercury and arsenic excretion. Although several chelating agents have the capacity to mobilize cadmium, their tendency to redistribute cadmium to the kidney and increase nephrotoxicity has negated their therapeutic value in cadmium intoxication.

In addition to removing the target metal that is exerting toxic effects on the body, some chelating agents may enhance excretion of essential cations, such as zinc in the case of calcium EDTA and diethylenetriaminepentaacetic acid (DTPA), and zinc and copper in the case of succimer. No clinical significance of this effect has been demonstrated, although some animal data suggest the possibility of adverse developmental impact. If prolonged

chelation during the prenatal period or early childhood period is necessary, judicious supplementation of the diet with zinc might be considered.

The longer the half-life of a metal in a particular organ, the less effectively it will be removed by chelation. For example, in the case of lead chelation with calcium EDTA or succimer, or of plutonium chelation with DTPA, the metal is more effectively removed from soft tissues than from bone, where incorporation into bone matrix results in prolonged retention.

In most cases, the capacity of chelating agents to prevent or reduce the adverse effects of toxic metals appears to be greatest when such agents are administered very soon after an acute metal exposure. Use of chelating agents days to weeks after an acute metal exposure ends—or their use in the treatment of chronic metal intoxication—may still be associated with increased metal excretion. However, at that point, the capacity of such enhanced excretion to mitigate the pathologic effect of the metal exposure may be reduced.

The most important chelating agents currently in use in the USA are described below.

DIMERCAPROL (2,3-DIMERCAPTOPROPANOL, BAL)

Dimercaprol (Figure 57–3), an oily, colorless liquid with a strong mercaptan-like odor, was developed in Great Britain during World War II as a therapeutic antidote against poisoning by the

arsenic-containing warfare agent lewisite. It thus became known as British anti-lewisite, or BAL. Because aqueous solutions of dimercaprol are unstable and oxidize readily, it is dispensed in 10% solution in peanut oil and must be administered by intramuscular injection, which is often painful.

In animal models, dimercaprol prevents and reverses arsenic-induced inhibition of sulfhydryl-containing enzymes and, if given soon after exposure, may protect against the lethal effects of inorganic and organic arsenicals. Human data indicate that it can increase the rate of excretion of arsenic and lead and may offer therapeutic benefit in the treatment of acute intoxication by arsenic, lead, and mercury.

Indications & Toxicity

Dimercaprol is FDA approved as single-agent treatment of acute poisoning by arsenic and inorganic mercury and for the treatment of severe lead poisoning when used in conjunction with edetate calcium disodium (EDTA; see below). Although studies of its metabolism in humans are limited, intramuscularly administered dimercaprol appears to be readily absorbed, metabolized, and excreted by the kidney within 4–8 hours. Animal models indicate that it may also undergo biliary excretion, but the role of this excretory route in humans and other details of its biotransformation are uncertain.

When used in therapeutic doses, dimercaprol is associated with a high incidence of adverse effects, including hypertension, tachycardia, nausea, vomiting, lacrimation, salivation, fever (particularly in children), and pain at the injection site. Its use has also been associated with thrombocytopenia and increased prothrombin time—factors that may limit intramuscular injection because of the risk of hematoma formation at the injection site. Despite its protective effects in acutely intoxicated animals, dimercaprol may redistribute arsenic and mercury to the central nervous system, and it is not advocated for treatment of chronic poisoning. Water-soluble analogs of dimercaprol—unithiol and succimer—have higher therapeutic indices and have replaced dimercaprol in many settings.

SUCCIMER (DIMERCAPTOSUCCINIC ACID, DMSA)

Succimer is a water-soluble analog of dimercaprol, and like that agent it has been shown in animal studies to prevent and reverse metal-induced inhibition of sulfhydryl-containing enzymes and to protect against the acute lethal effects of arsenic. In humans, treatment with succimer is associated with an increase in urinary lead excretion and a decrease in blood lead concentration. It may also decrease the mercury content of the kidney, a key target organ of inorganic mercury salts. In the USA, succimer is formulated exclusively for oral use, but intravenous formulations have been used successfully elsewhere. It is absorbed rapidly but somewhat variably after oral administration. Peak blood levels of succimer occur at approximately 3 hours. The drug binds in vivo to the amino acid cysteine to form 1:1 and 1:2 mixed disulfides, possibly in the kidney, and it may be these complexes that are the active chelating

FIGURE 57–3 Chemical structures of several chelators. Ferroxamine (ferrioxamine) without the chelated iron is deferoxamine. It is represented here to show the functional groups; the iron is actually held in a caged system. The structures of the in vivo metal-chelator complexes for dimercaprol, succimer, penicillamine, and unithiol (see text) are not known and may involve the formation of mixed disulfides with amino acids. (Adapted, with permission from Meyers FH, Jawetz E, Goldfien A: *Review of Medical Pharmacology*, 7th ed. Originally published by Lange Medical Publications. McGraw-Hill, 1980. Copyright © The McGraw-Hill Companies, Inc.)

moieties. Experimental data suggest that multidrug-resistance protein 2 (Mrp2), one of a group of transporter proteins involved in the cellular excretion of xenobiotics, facilitates the renal excretion of mercury compounds that are bound to the transformed succimer and to unithiol. The elimination half-time of transformed succimer is approximately 2–4 hours.

Indications & Toxicity

Succimer is currently FDA approved for the treatment of children with blood lead concentrations >45 mcg/dL, but it is also commonly used in adults. The typical dosage is 10 mg/kg orally three times a day. Oral administration of succimer is comparable to parenteral EDTA in reducing blood lead concentration and has supplanted EDTA in outpatient treatment of patients who are capable of absorbing the oral drug. However, despite the demonstrated capacity of both succimer and EDTA to enhance lead elimination, their value in reversing established lead toxicity or in otherwise improving therapeutic outcome has yet to be established by a placebo-controlled clinical trial. In a recent study in lead-exposed juvenile rats, high-dose succimer did reduce lead-induced neurocognitive impairment when administered to animals with moderate- and high-dose lead exposure. Conversely, when administered to the control group that was not lead exposed, succimer was associated with a decrement in neurocognitive performance. Based on its protective effects against arsenic in animals and its ability to mobilize mercury from the kidney, succimer has also been used in the treatment of arsenic and mercury poisoning.

In limited clinical trials, succimer has been well tolerated. It has a negligible impact on body stores of calcium, iron, and magnesium. It induces a mild increase in urinary excretion of zinc and, less consistently, copper. This effect on trace metal balance has not been associated with overt adverse effects, but its long-term impact on neurodevelopment is uncertain. Gastrointestinal disturbances, including anorexia, nausea, vomiting, and diarrhea, are the most common side effects, occurring in <10% of patients. Rashes, sometimes requiring discontinuation of the medication, have been reported in <5% of patients. Mild, reversible increases in liver aminotransferases have been noted in <5% of patients, and isolated cases of mild to moderate neutropenia have been reported.

EDETATE CALCIUM DISODIUM (ETHYLENEDIAMINETETRAACETIC ACID, EDTA)

Ethylenediaminetetraacetic acid (Figure 57–2) is an efficient chelator of many divalent and trivalent metals in vitro. To prevent potentially life-threatening depletion of calcium, treatment of metal intoxication should only be performed with the calcium disodium salt form of EDTA (edetate calcium disodium).

EDTA penetrates cell membranes relatively poorly and therefore chelates extracellular metal ions much more effectively than intracellular ions.

The highly polar ionic character of EDTA limits its oral absorption. Moreover, oral administration may increase lead absorption from the gut. Consequently, EDTA should be administered by intravenous infusion. In patients with normal renal function, EDTA is rapidly excreted by glomerular filtration, with 50% of an injected dose appearing in the urine within 1 hour. EDTA mobilizes lead from soft tissues, causing a marked increase in urinary lead excretion and a corresponding decline in blood lead concentration. In patients with renal insufficiency, excretion of the drug—and its metal-mobilizing effects—may be delayed.

Indications & Toxicity

Edetate calcium disodium is indicated chiefly for the chelation of lead, but it may also have usefulness in poisoning by zinc, manganese, and certain heavy radionuclides. A recent randomized, double-blind, placebo-controlled prospective trial of *edetate disodium* (not edetate calcium disodium) observed a significant decrease in cardiovascular events in a subgroup consisting of diabetic patients with a prior history of myocardial infarction. Further study is indicated to replicate the findings and explore potential mechanisms of benefit.

Because the drug and the mobilized metals are excreted via the urine, the drug is relatively contraindicated in anuric patients. In such instances, the use of low doses of EDTA in combination with high-flux hemodialysis or hemofiltration has been described. Nephrotoxicity from EDTA has been reported, but in most cases can be prevented by maintenance of adequate urine flow, avoidance of excessive doses, and limitation of a treatment course to 5 or fewer consecutive days. EDTA may result in temporary zinc depletion that is of uncertain clinical significance. Analogs of EDTA, the calcium and zinc disodium salts of DTPA, pentetate, have been used for removal (“decorporation”) of certain transuranic, rare earth, and transition metal radioisotopes, and in 2004 were approved by the FDA for treatment of contamination with plutonium, americium, and curium.

UNITHIOL (DIMERCAPTOPROPANESULFONIC ACID, DMPS)

Unithiol, a dimercapto chelating agent that is a water-soluble analog of dimercaprol, has been available in the official formularies of Russia and other former Soviet countries since 1958 and in Germany since 1976. It has been legally available from compounding pharmacies in the USA since 1999. Unithiol can be administered orally and intravenously. Bioavailability by the oral route is approximately 50%, with peak blood levels occurring in approximately 4 hours. Over 80% of an intravenous dose is excreted in the urine, mainly as cyclic DMPS sulfides. The elimination half-time of total unithiol (parent drug and its transformation products) is approximately 20 hours. Unithiol exhibits protective effects against the toxic action of mercury and arsenic in animal models, and it increases the excretion of mercury, arsenic,

and lead in humans. Animal studies and a few case reports suggest that unithiol may also have usefulness in the treatment of poisoning by bismuth compounds.

Indications & Toxicity

Unithiol has no FDA-approved indications, but experimental studies and its pharmacologic and pharmacodynamic profile suggest that intravenous unithiol offers advantages over intramuscular dimercaprol or oral succimer in the initial treatment of severe acute poisoning by inorganic mercury or arsenic. Aqueous preparations of unithiol (usually 50 mg/mL in sterile water) can be administered at a dosage of 3–5 mg/kg every 4 hours by slow intravenous infusion over 20 minutes. If a few days of treatment are accompanied by stabilization of the patient's cardiovascular and gastrointestinal status, it may be possible to change to oral administration of 4–8 mg/kg every 6–8 hours. Oral unithiol may also be considered as an alternative to oral succimer in the treatment of lead intoxication. Intravenous unithiol in conjunction with high flux hemodialysis or hemodiafiltration may be useful in the treatment of patients with anuric renal failure caused by mercury salts and bismuth.

Unithiol has been reported to have a low overall incidence of adverse effects (<4%). Self-limited dermatologic reactions (drug exanthems or urticaria) are the most commonly reported adverse effects, although isolated cases of major allergic reactions, including erythema multiforme and Stevens-Johnson syndrome, have been reported. Because rapid intravenous infusion may cause vasodilation and hypotension, unithiol should be infused slowly over 15–20 minutes.

PENICILLAMINE (D-DIMETHLCYSTEINE)

Penicillamine (Figure 57–3) is a white, crystalline, water-soluble derivative of penicillin. D-Penicillamine is less toxic than the L-isomer and consequently is the preferred therapeutic form. Penicillamine is readily absorbed from the gut and is resistant to metabolic degradation.

Indications & Toxicity

Penicillamine is used chiefly for treatment of poisoning with copper or to prevent copper accumulation, as in Wilson's disease (hepatolenticular degeneration). It is also used occasionally in the treatment of severe rheumatoid arthritis (see Chapter 36). Its ability to increase urinary excretion of lead and mercury had occasioned its use in outpatient treatment for intoxication with these metals, but succimer, with its stronger metal-mobilizing capacity and lower adverse-effect profile, has generally replaced penicillamine for these purposes.

Adverse effects have been seen in up to one third of patients receiving penicillamine. Hypersensitivity reactions include rash,

pruritus, and drug fever, and the drug should be used with extreme caution, if at all, in patients with a history of penicillin allergy. Nephrotoxicity with proteinuria has also been reported, and protracted use of the drug may result in renal insufficiency. Pancytopenia has been associated with prolonged drug intake. Pyridoxine deficiency is a frequent toxic effect of other forms of the drug but is rarely seen with the D isomer. An acetylated derivative, *N*-acetylpenicillamine, has been used experimentally in mercury poisoning and may have superior metal-mobilizing capacity, but it is not commercially available.

DEFEROXAMINE

Deferoxamine is isolated from *Streptomyces pilosus*. It binds iron avidly (Figure 57–3) but binds essential trace metals poorly. Furthermore, though competing for loosely bound iron in iron-carrying proteins (hemosiderin and ferritin), it fails to compete for biologically chelated iron, as in microsomal and mitochondrial cytochromes and hemoproteins. Consequently, it is the parenteral chelator of choice for iron poisoning (see Chapters 33 and 58). Deferoxamine plus hemodialysis may also be useful in the treatment of aluminum toxicity in renal failure. Deferoxamine is poorly absorbed when administered orally and may increase iron absorption when given by this route. It should therefore be administered intramuscularly or, preferably, intravenously. It is believed to be metabolized, but the pathways are unknown. The iron-chelator complex is excreted in the urine, often turning the urine an orange-red color.

Rapid intravenous administration may result in hypotension. Adverse idiosyncratic responses such as flushing, abdominal discomfort, and rash have also been observed. Pulmonary complications (eg, acute respiratory distress syndrome) have been reported in some patients undergoing deferoxamine infusions lasting longer than 24 hours, and neurotoxicity and increased susceptibility to certain infections (eg, with *Yersinia enterocolitica*) have been described after long-term therapy of iron overload conditions (eg, thalassemia major).

DEFERASIROX & DEFERIPRONE

Deferasirox is a tridentate chelator with a high affinity for iron and low affinity for other metals, eg, zinc and copper. It is orally active and well absorbed. In the circulation, it binds iron, and the complex is excreted in the bile. Deferasirox was approved by the FDA in 2005 for the oral treatment of iron overload caused by blood transfusions, a problem in the treatment of thalassemia and myelodysplastic syndrome. More than 5 years of clinical experience suggest that daily long-term usage is generally well tolerated, with the most common adverse effects consisting of mild to moderate gastrointestinal disturbances and skin rash. Monitoring of liver and renal function has been advised because renal and liver impairment and failure associated with deferasirox have been reported during treatment of older adults with myelodysplastic syndromes.

Deferiprone, a bidentate iron chelator cleared predominantly via the kidney, was approved by the FDA in 2011 as a second-line oral chelator for patients with transfusional iron overload due to

thalassemia. Compared to deferasirox, deferiprone appears to be relatively more efficient in decreasing cardiac iron but less efficient in decreasing hepatic iron. Because neutropenia has occurred in 5–10% of patients, with agranulocytosis in approximately 1%, regular hematologic monitoring is recommended.

Magnetic resonance imaging has been increasingly used to evaluate cardiac and hepatic iron burden and to guide iron chelation therapy. Regimens that combine iron-chelating agents have been used in cases when monotherapy has yielded suboptimal results.

PRUSSIAN BLUE (FERRIC HEXACYANOFERRATE)

Ferric hexacyanoferrate (insoluble Prussian blue) is a hydrated crystalline compound in which Fe^{2+} and Fe^{3+} atoms are coordinated with cyanide groups in a cubic lattice structure. Although used as a dark blue commercial pigment for nearly 300 years, it was only three decades ago that its potential usefulness as a pharmaceutical chelator was recognized. Primarily by ion exchange, and secondarily by mechanical trapping or adsorption, the compound has high affinity for certain univalent cations, particularly cesium and thallium. Used as an oral drug, insoluble Prussian blue undergoes minimal gastrointestinal absorption (<1%). Because the complexes it forms with cesium or thallium are nonabsorbable, oral administration of the chelator diminishes intestinal absorption or interrupts enterohepatic and enteroenteric circulation of these cations, thereby accelerating their elimination in the feces. In clinical case series, the use of Prussian blue has been associated with a decline in the biologic half-life (ie, in vivo retention) of radioactive cesium and thallium.

Indications & Toxicity

In 2003, the FDA approved Prussian blue for the treatment of contamination with radioactive cesium (^{137}Cs) and intoxication with thallium salts. Approval was prompted by concern over potential widespread human contamination with radioactive cesium caused by terrorist use of a radioactive dispersal device (“dirty bomb”). The drug is part of the Strategic National Stockpile of pharmaceuticals and medical material maintained by the CDC (<https://www.cdc.gov/phpr/stockpile/>). (*Note:* Although soluble forms of Prussian blue, such as potassium ferric hexacyanoferrate, may have better utility in thallium poisoning, only the insoluble form is currently available as a pharmaceutical.)

After exposure to ^{137}Cs or thallium salts, the approved adult dosage of Prussian blue is 3 g orally three times a day; the corresponding pediatric dosage (2–12 years of age) is 1 g orally three times a day. Serial monitoring of urine and fecal radioactivity (^{137}Cs) and urinary thallium concentrations can guide the recommended duration of therapy. Adjunctive supportive care for possible acute radiation illness (^{137}Cs) or systemic thallium toxicity should be instituted as needed.

Prussian blue has not been associated with significant adverse effects. Constipation, which may occur in some cases, should be treated with laxatives or increased dietary fiber.

PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS
Deferasirox	Exjade, Jadenu
Deferiprone	Ferriprox
Deferoxamine	Generic, Desferal
Dimercaprol	BAL in Oil
Edetate calcium [calcium EDTA]	Calcium Disodium Versenate
Penicillamine	Cuprimine, Depen
Pentetate Calcium Trisodium [calcium DTPA] and Pentetate Zinc Trisodium [zinc DTPA]	Generic
Prussian Blue	Radiogardase
Succimer	Chemet, Succinapital (in Europe)
Unithiol	Dimaval

CASE STUDY ANSWER

Bacterial food poisoning is the most common cause of gastrointestinal signs and symptom appearing in a group of individuals within several hours of a common meal. Consumption of food contaminated with preformed bacterial toxins such as *Staphylococcus* or *Bacillus cereus* toxins can result in vomiting after an incubation interval as short as 1–2 hours. However, the onset of vomiting in some individuals within 15 minutes and the progression to hypotension and metabolic acidosis in several individuals are *not* typical for bacterial food poisoning and are more suggestive of intoxication by certain toxic chemicals or drugs, including inorganic arsenic and mercury salts (eg, sodium arsenite or mercuric chloride). The absence of hematemesis, bloody diarrhea, or renal insufficiency lowered

the likelihood that inorganic mercury was responsible. An epidemiologic investigation subsequently revealed that all affected individuals had consumed the deliberately adulterated coffee, which contained 6300 ppm of inorganic arsenic. Analysis of urine for arsenic and mercury and stool and emesis for bacterial pathogens would be reasonable initial diagnostic tests. Pending test results, prompt empiric treatment of this constellation of findings with the chelating agents unithiol, succimer, or dimercaprol would be appropriate. [Based on an actual incident, see: Gensheimer KF et al: Arsenic poisoning caused by intentional contamination of coffee at a church gathering: An epidemiological approach to a forensic investigation. *J Forensic Sci* 2010;55:1116].

Management of the Poisoned Patient

Kent R. Olson, MD

CASE STUDY

A 62-year-old woman with a history of depression is found in her apartment in a lethargic state. An empty bottle of bupropion is on the bedside table. In the emergency department, she is unresponsive to verbal and painful stimuli. She has a brief generalized seizure, followed by a respiratory arrest. The emergency physician performs endotracheal intubation and

administers a drug intravenously, followed by another substance via a nasogastric tube. The patient is admitted to the intensive care unit for continued supportive care and recovers the next morning. What drug might be used intravenously to prevent further seizures? What substance is commonly used to adsorb drugs still present in the gastrointestinal tract?

Over 1 million cases of acute poisoning occur in the USA each year, although only a small number are fatal. Most deaths are due to intentional suicidal overdose by an adolescent or adult. Childhood deaths due to accidental ingestion of a drug or toxic household product have been markedly reduced in the last 50 years as a result of safety packaging and effective poisoning prevention education.

Even with a serious exposure, poisoning is rarely fatal if the victim receives prompt medical attention and good supportive care. Careful management of respiratory failure, hypotension, seizures, and thermoregulatory disturbances has resulted in improved survival of patients who reach the hospital alive.

This chapter reviews the basic principles of poisoning, initial management, and specialized treatment of poisoning, including methods of increasing the elimination of drugs and toxins.

■ TOXICOKINETICS & TOXICODYNAMICS

The term **toxicokinetics** denotes the absorption, distribution, excretion, and metabolism of toxins, toxic doses of therapeutic agents, and their metabolites. The term **toxicodynamics** is used to

denote the injurious effects of these substances on body functions. Although many similarities exist between the pharmacokinetics and toxicokinetics of most substances, there are also important differences. The same caution applies to pharmacodynamics and toxicodynamics.

SPECIAL ASPECTS OF TOXICOKINETICS

Volume of Distribution

The volume of distribution (V_d) is defined as the apparent volume into which a substance is distributed in the body (see Chapter 3). A large V_d implies that the drug is not readily accessible to measures aimed at purifying the blood, such as hemodialysis. Examples of drugs with large volumes of distribution (>5 L/kg) include antidepressants, antipsychotics, antimalarials, opioids, propranolol, and verapamil. Drugs with a relatively small V_d (<1 L/kg) include salicylate, ethanol, phenobarbital, lithium, valproic acid, and phenytoin (see Table 3–1).

Clearance

Clearance is a measure of the volume of plasma that is cleared of drug per unit time (see Chapter 3). The total clearance for most

drugs is the sum of clearances via excretion by the kidneys and metabolism by the liver. In planning a detoxification strategy, it is important to know the contribution of each organ to total clearance. For example, if a drug is 95% cleared by liver metabolism and only 5% cleared by renal excretion, even a dramatic increase in urinary concentration of the drug will have little effect on overall elimination.

Overdosage of a drug can alter the usual pharmacokinetic processes, and this must be considered when applying kinetics to poisoned patients. For example, dissolution of tablets or gastric emptying time may be slowed so that absorption and peak toxic effects are delayed. Drugs may injure the epithelial barrier of the gastrointestinal tract and thereby increase absorption. If the capacity of the liver to metabolize a drug is exceeded, the first-pass effect will be reduced and more drug will be delivered to the circulation. With a dramatic increase in the concentration of drug in the blood, protein-binding capacity may be exceeded, resulting in an increased fraction of free drug and greater toxic effect. At normal dosage, most drugs are eliminated at a rate proportional to the plasma concentration (first-order kinetics). If the plasma concentration is very high and normal metabolism is saturated, the rate of elimination may become fixed (zero-order kinetics). This change in kinetics may markedly prolong the apparent serum half-life and increase toxicity.

SPECIAL ASPECTS OF TOXICODYNAMICS

The general dose-response principles described in Chapter 2 are relevant when estimating the potential severity of an intoxication. When considering quantal dose-response data, both the therapeutic index and the overlap of therapeutic and toxic response curves must be considered. For instance, two drugs may have the same therapeutic index but unequal safe dosing ranges if the slopes of their dose-response curves are not the same. For some drugs, eg, sedative-hypnotics, the major toxic effect is a direct extension of the therapeutic action, as shown by their graded dose-response curve (see Figure 22-1). In the case of a drug with a linear dose-response curve (drug A), lethal effects may occur at 10 times the normal therapeutic dose. In contrast, a drug with a curve that reaches a plateau (drug B) may not be lethal at 100 times the normal dose.

For many drugs, at least part of the toxic effect may be different from the therapeutic action. For example, intoxication with drugs that have atropine-like effects (eg, tricyclic antidepressants) reduces sweating, making it more difficult to dissipate heat. In tricyclic antidepressant intoxication, there may also be increased muscular activity or seizures; the body's production of heat is thus enhanced, and lethal hyperpyrexia may result. Overdoses of drugs that depress the cardiovascular system, eg, β blockers or calcium channel blockers, can profoundly alter not only cardiac function but all functions that are dependent on blood flow. These include renal and hepatic elimination of the toxin and that of any other drugs that may be given.

■ APPROACH TO THE POISONED PATIENT

HOW DOES THE POISONED PATIENT DIE?

An understanding of common mechanisms of death due to poisoning can help prepare the caregiver to treat patients effectively. Many toxins depress the central nervous system (CNS), resulting in obtundation or coma. Comatose patients frequently lose their airway protective reflexes and their respiratory drive. Thus, they may die as a result of airway obstruction by the flaccid tongue, aspiration of gastric contents into the tracheobronchial tree, or respiratory arrest. These are the most common causes of death due to overdoses of narcotics and sedative-hypnotic drugs (eg, barbiturates and alcohol).

Cardiovascular toxicity is also frequently encountered in poisoning. Hypotension may be due to depression of cardiac contractility; hypovolemia resulting from vomiting, diarrhea, or fluid sequestration; peripheral vascular collapse due to blockade of α -adrenoceptor-mediated vascular tone; or cardiac arrhythmias. Hypothermia or hyperthermia due to exposure as well as the temperature-dysregulating effects of many drugs can also produce hypotension. Lethal arrhythmias such as ventricular tachycardia and fibrillation can occur with overdoses of many cardioactive drugs such as ephedrine, amphetamines, cocaine, digitalis, and theophylline; and drugs not usually considered cardioactive, such as tricyclic antidepressants, antihistamines, and some opioid analogs.

Cellular hypoxia may occur despite adequate ventilation and oxygen administration when poisoning is due to cyanide, hydrogen sulfide, carbon monoxide, and other poisons that interfere with transport or utilization of oxygen. Such patients may not be cyanotic, but cellular hypoxia is evident by the development of tachycardia, hypotension, severe lactic acidosis, and signs of ischemia on the electrocardiogram.

Seizures, muscular hyperactivity, and rigidity may result in death. Seizures may cause pulmonary aspiration, hypoxia, and brain damage. Hyperthermia may result from sustained muscular hyperactivity and can lead to muscle breakdown and myoglobinuria, renal failure, lactic acidosis, and hyperkalemia. Drugs and poisons that often cause seizures include antidepressants, isoniazid (INH), diphenhydramine, cocaine, and amphetamines.

Other organ system damage may occur after poisoning and is sometimes delayed in onset. Paraquat attacks lung tissue, resulting in pulmonary fibrosis, beginning several days after ingestion. Massive hepatic necrosis due to poisoning by acetaminophen or certain mushrooms results in hepatic encephalopathy and death 48–72 hours or longer after ingestion.

Finally, some patients may die before hospitalization because the behavioral effects of the ingested drug may result in traumatic injury. Intoxication with alcohol and other sedative-hypnotic drugs is a common contributing factor to motor vehicle accidents. Patients under the influence of hallucinogens such as

phencyclidine (PCP) or lysergic acid diethylamide (LSD) may suffer trauma when they become combative or fall from a height.

■ INITIAL MANAGEMENT OF THE POISONED PATIENT

The initial management of a patient with coma, seizures, or otherwise altered mental status should follow the same approach regardless of the poison involved: supportive measures are the basics (“**ABCDs**”) of poisoning treatment.

First, the **airway** should be cleared of vomitus or any other obstruction and an oral airway or endotracheal tube inserted if needed. For many patients, simple positioning in the lateral, left-side-down position is sufficient to move the flaccid tongue out of the airway. **Breathing** should be assessed by observation and pulse oximetry and, if in doubt, by measuring arterial blood gases. Patients with respiratory insufficiency should be intubated and mechanically ventilated. The **circulation** should be assessed by continuous monitoring of pulse rate, blood pressure, urinary output, and evaluation of peripheral perfusion. An intravenous line should be placed and blood drawn for serum glucose and other routine determinations.

At this point, every patient with altered mental status should receive a challenge with concentrated **dextrose**, unless a rapid bedside blood glucose test demonstrates that the patient is not hypoglycemic. Adults are given 25 g (50 mL of 50% dextrose solution) intravenously, children 0.5 g/kg (2 mL/kg of 25% dextrose). Hypoglycemic patients may appear to be intoxicated, and there is no rapid and reliable way to distinguish them from poisoned patients. Alcoholic or malnourished patients should also receive 100 mg of thiamine intramuscularly or in the intravenous infusion solution at this time to prevent Wernicke’s syndrome.

The opioid antagonist **naloxone** may be given in a dose of 0.4–2 mg intravenously. Naloxone reverses respiratory and CNS depression due to all varieties of opioid drugs (see Chapter 31). It is useful to remember that these drugs cause death primarily by respiratory depression; therefore, if airway and breathing assistance have already been instituted, naloxone may not be necessary. Larger doses of naloxone may be needed for patients with overdose involving propoxyphene, codeine, and some other opioids. The benzodiazepine antagonist **flumazenil** (see Chapter 22) may be of value in patients with suspected benzodiazepine overdose, but it should not be used if there is a history of tricyclic antidepressant overdose or a seizure disorder, as it can induce convulsions in such patients.

History & Physical Examination

Once the essential initial ABCD interventions have been instituted, one can begin a more detailed evaluation to make a specific diagnosis. This includes gathering any available history and performing a toxicologically oriented physical examination. Other causes of coma or seizures such as head trauma, meningitis, or metabolic abnormalities should be sought and treated.

Some common intoxications are described under Common Toxic Syndromes.

A. History

Oral statements about the amount and even the type of drug ingested in toxic emergencies may be unreliable. Even so, family members, police, and fire department or paramedical personnel should be asked to describe the environment in which the toxic emergency occurred and should bring to the emergency department any syringes, empty bottles, household products, or over-the-counter medications in the immediate vicinity of the possibly poisoned patient.

B. Physical Examination

A brief examination should be performed, emphasizing those areas most likely to give clues to the toxicologic diagnosis. These include vital signs, eyes and mouth, skin, abdomen, and nervous system.

1. Vital signs—Careful evaluation of vital signs (blood pressure, pulse, respirations, and temperature) is essential in all toxicologic emergencies. Hypertension and tachycardia are typical with amphetamines, cocaine, and antimuscarinic (anticholinergic) drugs. Hypotension and bradycardia are characteristic features of overdose with calcium channel blockers, β blockers, clonidine, and sedative hypnotics. Hypotension with tachycardia is common with tricyclic antidepressants, trazodone, quetiapine, vasodilators, and β agonists. Rapid respirations are typical of salicylates, carbon monoxide, and other toxins that produce metabolic acidosis or cellular asphyxia. Hyperthermia may be associated with sympathomimetics, anticholinergics, salicylates, and drugs producing seizures or muscular rigidity. Hypothermia can be caused by any CNS-depressant drug, especially when accompanied by exposure to a cold environment.

2. Eyes—The eyes are a valuable source of toxicologic information. Constriction of the pupils (miosis) is typical of opioids, clonidine, phenothiazines, and cholinesterase inhibitors (eg, organophosphate insecticides), and deep coma due to sedative drugs. Dilation of the pupils (mydriasis) is common with amphetamines, cocaine, LSD, and atropine and other anticholinergic drugs. Horizontal nystagmus is characteristic of intoxication with phenytoin, alcohol, barbiturates, and other sedative drugs. The presence of both vertical and horizontal nystagmus is strongly suggestive of phencyclidine poisoning. Ptosis and ophthalmoplegia are characteristic features of botulism.

3. Mouth—The mouth may show signs of burns due to corrosive substances, or soot from smoke inhalation. Typical odors of alcohol, hydrocarbon solvents, or ammonia may be noted. Poisoning due to cyanide can be recognized by some examiners as an odor like bitter almonds.

4. Skin—The skin often appears flushed, hot, and dry in poisoning with atropine and other antimuscarinics. Excessive sweating occurs with organophosphates, nicotine, and sympathomimetic drugs.

Cyanosis may be caused by hypoxemia or by methemoglobinemia. Icterus may suggest hepatic necrosis due to acetaminophen or *Amanita phalloides* mushroom poisoning.

5. Abdomen—Abdominal examination may reveal ileus, which is typical of poisoning with antimuscarinic, opioid, and sedative drugs. Hyperactive bowel sounds, abdominal cramping, and diarrhea are common in poisoning with organophosphates, iron, arsenic, theophylline, *A phalloides*, and *A muscaria*.

6. Nervous system—A careful neurologic examination is essential. Focal seizures or motor deficits suggest a structural lesion (eg, intracranial hemorrhage due to trauma) rather than toxic or metabolic encephalopathy. Nystagmus, dysarthria, and ataxia are typical of phenytoin, carbamazepine, alcohol, and other sedative intoxication. Twitching and muscular hyperactivity are common with atropine and other anticholinergic agents, and cocaine and other sympathomimetic drugs. Muscular rigidity can be caused by haloperidol and other antipsychotic agents, and by strychnine or by tetanus. Generalized hypertonicity of muscles and lower extremity clonus are typical of serotonin syndrome. Seizures are often caused by overdose with antidepressants (especially tricyclic antidepressants and bupropion [as in the case study]), cocaine, amphetamines, theophylline, isoniazid, and diphenhydramine. Flaccid coma with absent reflexes and even an isoelectric electroencephalogram may be seen with deep coma due to sedative-hypnotic or other CNS depressant intoxication and may be mistaken for brain death.

Laboratory & Imaging Procedures

A. Arterial Blood Gases

Hypoventilation results in an elevated P_{CO_2} (hypercapnia) and a low P_{O_2} (hypoxia). The P_{O_2} may also be low in a patient with aspiration pneumonia or drug-induced pulmonary edema. Poor tissue oxygenation due to hypoxia, hypotension, or cyanide poisoning will result in metabolic acidosis. The P_{O_2} measures only oxygen dissolved in the plasma and not total blood oxygen content or oxyhemoglobin saturation and may appear normal in patients with severe carbon monoxide poisoning. Pulse oximetry may also give falsely normal results in carbon monoxide intoxication.

B. Electrolytes

Sodium, potassium, chloride, and bicarbonate should be measured. The anion gap is then calculated by subtracting the measured anions from cations:

$$\text{Anion gap} = (Na^+ + K^+) - (HCO_3^- + Cl^-)$$

Normally, the sum of the cations exceeds the sum of the anions by no more than 12–16 mEq/L (or 8–12 mEq/L if the formula used for estimating the anion gap omits the potassium level). A larger than expected anion gap is caused by the presence of unmeasured anions (lactate, etc) accompanying metabolic acidosis. This may occur with numerous conditions, such as diabetic ketoacidosis, renal failure, or shock-induced lactic acidosis. Drugs that may induce an elevated anion gap metabolic acidosis

TABLE 58–1 Examples of drug-induced anion gap acidosis.

Type of Elevation of the Anion Gap	Agents
Organic acid metabolites	Methanol, ethylene glycol, diethylene glycol, oxoprolinuria (rare complication of acetaminophen)
Lactic acidosis	Cyanide, carbon monoxide, ibuprofen, isoniazid, metformin, salicylates, valproic acid; any drug-induced seizures, hypoxia, or hypotension

Note: The normal anion gap calculated from $(Na^+ + K^+) - (HCO_3^- + Cl^-)$ is 12–16 mEq/L; calculated from $(Na^+) - (HCO_3^- + Cl^-)$, it is 8–12 mEq/L.

(Table 58–1) include aspirin, metformin, methanol, ethylene glycol, isoniazid, and iron.

Alterations in the serum potassium level are hazardous because they can result in cardiac arrhythmias. Drugs that may cause hyperkalemia despite normal renal function include potassium itself, β blockers, digitalis glycosides, potassium-sparing diuretics, and fluoride. Drugs associated with hypokalemia include barium, β agonists, caffeine, theophylline, and thiazide and loop diuretics.

C. Renal Function Tests

Some toxins have direct nephrotoxic effects; in other cases, renal failure is due to shock or myoglobinuria. Blood urea nitrogen and creatinine levels should be measured and urinalysis performed. Elevated serum creatine kinase (CK) and myoglobin in the urine suggest muscle necrosis due to seizures or muscular rigidity. Oxalate crystals in large numbers in the urine suggest ethylene glycol poisoning.

D. Serum Osmolality

The calculated serum osmolality is dependent mainly on the serum sodium and glucose and the blood urea nitrogen and can be estimated from the following formula:

$$2 \times Na^+ (\text{mEq/L}) + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{3}$$

This calculated value is normally 280–290 mOsm/L. Ethanol and other alcohols may contribute significantly to the measured serum osmolality but, since they are not included in the calculation, cause an osmol gap:

$$\text{Osmol gap} = \text{Measured osmolality} - \text{Calculated osmolality}$$

Substances that are often associated with an abnormal osmol gap include acetone, ethanol, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol.

E. Electrocardiogram

Widening of the QRS complex duration (to more than 100 milliseconds) is typical of overdose of tricyclic antidepressants and other drugs that block the sodium channel in cardiac conducting tissue (Figure 58–1). The QT_c interval may be prolonged in many poisonings, including antidepressants and antipsychotics,

FIGURE 58-1 Changes in the electrocardiogram in tricyclic antidepressant overdose. **A:** Slowed intraventricular conduction results in prolonged QRS interval (0.18 seconds; normal, 0.08 seconds). **B and C:** Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia. (Reproduced, with permission, from Benowitz NL, Goldschlager N: Cardiac disturbances. In: Haddad LM, Shannon MW, Winchester JF [editors]. *Clinical Management of Poisoning and Drug Overdose*, 3rd ed. WB Saunders, 1998. © Elsevier.)

lithium, and arsenic (see also <https://www.crediblemeds.org/everyone/composite-list-all-qtdrugs/>). Variable atrioventricular (AV) block and a variety of atrial and ventricular arrhythmias are common with poisoning by digoxin and other cardiac glycosides. Hypoxemia due to carbon monoxide poisoning may result in ischemic changes on the electrocardiogram.

F. Imaging Findings

A plain film of the abdomen may be useful because some tablets, particularly iron and potassium, may be radiopaque. Chest radiographs may reveal aspiration pneumonia, hydrocarbon pneumonia, or pulmonary edema. When head trauma is suspected, a computed tomography (CT) scan is recommended.

Toxicology Screening Tests

It is a common misconception that a toxicology “screen” is the best way to diagnose and manage an acute poisoning. Unfortunately, rapid urine “drugs of abuse” screens are limited to a few classes of drugs and are subject to many false-positive and false-negative results, and more reliable comprehensive toxicology screening is time-consuming and expensive and results of tests may not be available for days. Moreover, many highly toxic drugs such as calcium channel blockers, β blockers, and isoniazid are not included in the screening process. The clinical examination of the patient and selected routine laboratory tests are usually sufficient to generate a tentative diagnosis and an appropriate treatment plan. Although screening tests (so-called “drugs of abuse” panels) may be helpful in confirming a suspected intoxication, they should not delay needed treatment. More formal, comprehensive screening may be necessary in cases of suspected brain death (to rule out drugs as a cause of coma), child abuse, or as part of a postmortem examination.

When a specific antidote or other treatment is under consideration, quantitative laboratory testing may be indicated.

For example, determination of the acetaminophen level is useful in assessing the need for antidotal therapy with acetylcysteine. Serum levels of salicylate (aspirin), ethylene glycol, methanol, theophylline, carbamazepine, lithium, valproic acid, and other drugs and poisons may indicate the need for hemodialysis (Table 58–2).

Decontamination

Decontamination procedures should be undertaken simultaneously with initial stabilization, diagnostic assessment, and laboratory evaluation. Decontamination involves removing toxins from the skin or gastrointestinal tract.

A. Skin

Contaminated clothing should be completely removed and double-bagged to prevent illness in health care providers and for possible laboratory analysis. Wash contaminated skin with soap and water.

B. Gastrointestinal Tract

Controversy remains regarding the efficacy of gastrointestinal decontamination, especially when treatment is initiated more than 1 hour after ingestion. For most ingestions, clinical toxicologists recommend simple administration of activated charcoal to bind ingested poisons in the gut before they can be absorbed (as in the case study). In unusual circumstances, gastric lavage or whole bowel irrigation may also be used.

TABLE 58-2 Hemodialysis in drug overdose and poisoning.¹

Hemodialysis may be indicated depending on the severity of poisoning or the blood concentration:
Carbamazepine
Ethylene glycol
Lithium
Methanol
Metformin
Phenobarbital
Salicylate
Theophylline
Valproic acid
Hemodialysis is ineffective or is not useful:
Amphetamines
Antidepressants
Antipsychotic drugs
Benzodiazepines
Calcium channel blockers
Digoxin
Metoprolol and propranolol
Opioids

¹This listing is not comprehensive.

1. Emesis—Emesis induced by ipecac syrup was previously used to treat some childhood ingestions at home under telephone supervision of a physician or poison control center personnel. However, the risks involved with inappropriate use outweighed the unproven benefits, and this treatment is no longer used in the home or hospital. Other methods of inducing emesis such as fingertip stimulation of the pharynx, salt water, and apomorphine are ineffective or dangerous and should not be used.

2. Gastric lavage—If the patient is awake or if the airway is protected by an endotracheal tube, gastric lavage may be performed using an orogastric or nasogastric tube—as large a tube as possible. Lavage solutions (usually 0.9% saline) should be at body temperature to prevent hypothermia.

3. Activated charcoal—Owing to its large surface area, activated charcoal can adsorb many drugs and poisons. It is most effective if given in a ratio of at least 10:1 of charcoal to estimated dose of toxin by weight. Charcoal does not bind iron, lithium, or potassium, and it binds alcohols and cyanide only poorly. It does not appear to be useful in poisoning due to corrosive mineral acids and alkali. Repeated doses of oral activated charcoal may enhance systemic elimination of some drugs (including carbamazepine, dapsone, and phenobarbital) by a mechanism referred to as “gut dialysis,” although the clinical benefit is unproved.

4. Cathartics—Administration of a cathartic (laxative) agent may hasten removal of toxins from the gastrointestinal tract and reduce absorption, although no controlled studies have been done. Whole bowel irrigation with a balanced polyethylene glycol-electrolyte solution (GoLYTELY, CoLyte) can enhance gut decontamination after ingestion of iron tablets, enteric-coated medicines, illicit drug-filled packets, and foreign bodies. The solution is administered orally at 1–2 L/h (500 mL/h in children) for several hours until the rectal effluent is clear.

Specific Antidotes

There is a popular misconception that there is an antidote for every poison. Actually, selective antidotes are available for only a few classes of toxins. The major antidotes and their characteristics are listed in Table 58–3.

Methods of Enhancing Elimination of Toxins

After appropriate diagnostic and decontamination procedures and administration of antidotes, it is important to consider whether measures for enhancing elimination, such as hemodialysis or urinary alkalization, can improve the clinical outcome. Table 58–2 lists intoxications for which dialysis may be beneficial.

A. Dialysis Procedures

1. Peritoneal dialysis—Although it is a relatively simple and available technique, peritoneal dialysis is inefficient in removing most drugs.

2. Hemodialysis—Hemodialysis is more efficient than peritoneal dialysis and has been well studied. It assists in correction of fluid and electrolyte imbalance and may also enhance removal of toxic metabolites (eg, formic acid in methanol poisoning; oxalic and glycolic acids in ethylene glycol poisoning). The efficiency of both peritoneal dialysis and hemodialysis is a function of the molecular weight, water solubility, protein binding, endogenous clearance, and distribution in the body of the specific toxin. Hemodialysis is especially useful in overdose cases in which the precipitating drug can be removed and fluid and electrolyte imbalances are present and can be corrected (eg, salicylate intoxication).

B. Forced Diuresis and Urinary pH Manipulation

Previously popular but of unproved value, forced diuresis may cause volume overload and electrolyte abnormalities and is not recommended. Renal elimination of a few toxins can be enhanced by alteration of urinary pH. For example, urinary alkalization is useful in cases of salicylate overdose. Acidification may increase the urine concentration of drugs such as phencyclidine and amphetamines but is not advised because it may worsen renal complications from rhabdomyolysis, which often accompanies the intoxication.

COMMON TOXIC SYNDROMES

ACETAMINOPHEN

Acetaminophen is one of the drugs commonly involved in suicide attempts and accidental poisonings, both as the sole agent and in combination with other drugs. Acute ingestion of more than 150–200 mg/kg (children) or 7 g total (adults) is considered potentially toxic. A highly toxic metabolite is produced in the liver (see Figure 4–5).

Initially, the patient is asymptomatic or has mild gastrointestinal upset (nausea, vomiting). After 24–36 hours, evidence of liver injury appears, with elevated aminotransferase levels and hypoprothrombinemia. Fulminant liver failure may ensue, leading to metabolic acidosis, hypoglycemia, encephalopathy, and death. Renal failure may also occur. With acute massive ingestion and very high serum levels, metabolic acidosis can occur in the absence of liver failure. Rarely, acetaminophen ingestion can cause 5-oxoprolinuria due to glutathione depletion.

The severity of poisoning is estimated from a serum acetaminophen concentration measurement. If the level is greater than 150 mg/L approximately 4 hours after ingestion, the patient is at risk for liver injury. (Chronic alcoholics or patients taking drugs that enhance P450 production of toxic metabolites may be at risk with lower levels.) The antidote acetylcysteine acts as a glutathione substitute, binding the toxic metabolite as it is produced. It is most effective when given early and should be started within 8–10 hours if possible. Liver transplantation may be required for patients with fulminant hepatic failure.

TABLE 58-3 Examples of specific antidotes.

Antidote	Poison(s)	Comments
Acetylcysteine (Acetadote, Mucomyst)	Acetaminophen	Best results if given within 8–10 hours of overdose. Follow liver function tests and acetaminophen blood levels. Acetadote is given intravenously; Mucomyst is given orally.
Atropine	Anticholinesterase intoxication: organophosphates, carbamates	An initial dose of 1–2 mg (for children, 0.05 mg/kg) is given IV, and if there is no response, the dose is doubled every 10–15 minutes, with decreased wheezing and pulmonary secretions as therapeutic end points.
Atropine	Rapid-onset mushroom poisoning with predominant muscarinic excess symptoms	Useful for control of muscarinic symptoms. <i>Note:</i> Of no value in delayed-onset mushroom poisoning.
Bicarbonate, sodium	Membrane-depressant cardiotoxic drugs (tricyclic antidepressants, quinidine, etc)	1–2 mEq/kg IV bolus usually reverses cardiotoxic effects (wide QRS, hypotension). Give cautiously in heart failure (avoid sodium overload).
Calcium	Fluoride; calcium channel blockers	Large doses may be needed in severe calcium channel blocker overdose. Start with 15 mg/kg IV.
Deferoxamine	Iron salts	If poisoning is severe, give 15 mg/kg/h IV. 100 mg of deferoxamine binds 8.5 mg of iron.
Digoxin antibodies	Digoxin and related cardiac glycosides	One vial binds 0.5 mg digoxin; indications include serious arrhythmias, hyperkalemia.
Esmolol	Theophylline, caffeine, metaproterenol	Short-acting β blocker. Infuse 25–50 mcg/kg/min IV.
Ethanol	Methanol, ethylene glycol	A loading dose is calculated so as to give a blood level of at least 100 mg/dL (42 g/70 kg in adults). Fomepizole (see below) is easier to use.
Flumazenil	Benzodiazepines	Adult dose is 0.2 mg IV, repeated as necessary to a maximum of 3 mg. <i>Do not give to patients with seizures, benzodiazepine dependence, or tricyclic overdose.</i>
Fomepizole	Methanol, ethylene glycol	More convenient than ethanol. Give 15 mg/kg; repeat every 12 hours.
Glucagon	β blockers	5–10 mg IV bolus may reverse hypotension and bradycardia.
Hydroxocobalamin	Cyanide	Adult dose is 5 g IV over 15 minutes. Converts cyanide to cyanocobalamin (vitamin B ₁₂).
Naloxone	Narcotic drugs, other opioid derivatives	A specific antagonist of opioids; give 0.4–2 mg initially by IV, IM, or SC injection. Larger doses may be needed to reverse the effects of overdose with propoxyphene, codeine, or fentanyl derivatives. Duration of action (2–3 hours) may be significantly shorter than that of the opioid being antagonized.
Oxygen	Carbon monoxide	Give 100% by high-flow nonrebreathing mask; use of hyperbaric chamber is controversial but often recommended for severe poisoning.
Physostigmine	Suggested for delirium caused by anticholinergic agents	Adult dose is 0.5–1 mg IV slowly. The effects are transient (30–60 minutes), and the lowest effective dose may be repeated when symptoms return. May cause bradycardia, increased bronchial secretions, seizures. Have atropine ready to reverse excess effects. <i>Do not use for tricyclic antidepressant overdose.</i>
Pralidoxime (2-PAM)	Organophosphate (OP) cholinesterase inhibitors	Adult dose is 1 g IV, which should be repeated every 3–4 hours as needed or preferably as a constant infusion of 250–400 mg/h. Pediatric dose is approximately 250 mg. No proved benefit in carbamate poisoning; uncertain benefit in established OP poisoning.

AMPHETAMINES & OTHER STIMULANTS

Stimulant drugs commonly abused in the USA include methamphetamine (“crank,” “crystal”), methylenedioxymethamphetamine (MDMA, “ecstasy”), and cocaine (“crack”) as well as pharmaceuticals such as pseudoephedrine (Sudafed) and ephedrine (as such and in the herbal agent *Ma-huang*) (see Chapter 32). Caffeine is often added to dietary supplements sold as “metabolic enhancers” or “fat burners.” Newer synthetic analogs of amphetamines (often sold on the street as “bath salts”) and synthetic agonists of the endogenous cannabinoid receptors (sold as “research chemicals” or “spice”) are becoming popular drugs of abuse.

At the doses usually used by stimulant abusers, euphoria and wakefulness are accompanied by a sense of power and well-being. At higher doses, restlessness, agitation, and acute psychosis may occur, accompanied by hypertension and tachycardia. Prolonged muscular hyperactivity or seizures may contribute to hyperthermia and rhabdomyolysis. Body temperatures as high as 42°C (107.6°F) have been recorded. Hyperthermia can cause brain damage, hypotension, coagulopathy, and renal failure.

Treatment for stimulant toxicity includes general supportive measures as outlined earlier. There is no specific antidote. Seizures and hyperthermia are the most dangerous manifestations and must be treated aggressively. Seizures are usually managed with

intravenous benzodiazepines (eg, lorazepam). Temperature is reduced by removing clothing, spraying with tepid water, and encouraging evaporative cooling with fanning. For very high body temperatures (eg, $>40\text{--}41^{\circ}\text{C}$ [$104\text{--}105.8^{\circ}\text{F}$]), neuromuscular paralysis (eg, with vecuronium) is used to abolish muscle activity quickly.

ANTICHOLINERGIC AGENTS

A large number of prescription and nonprescription drugs, as well as a variety of plants and mushrooms, can inhibit the effects of acetylcholine at muscarinic receptors. Some drugs used for other purposes (eg, antihistamines) also have anticholinergic effects, in addition to other potentially toxic actions. For example, antihistamines such as diphenhydramine can cause seizures; tricyclic antidepressants, which have anticholinergic, quinidine-like, and α -blocking effects, can cause severe cardiovascular toxicity.

The classic anticholinergic (technically, “antimuscarinic”) syndrome is remembered as “red as a beet” (skin flushed), “hot as a hare” (hyperthermia), “dry as a bone” (dry mucous membranes, no sweating), “blind as a bat” (blurred vision, cycloplegia), and “mad as a hatter” (confusion, delirium). Patients usually have sinus tachycardia, and the pupils are usually dilated (see Chapter 8). Agitated delirium or coma may be present. Muscle twitching is common, but seizures are unusual unless the patient has ingested an antihistamine or a tricyclic antidepressant. Urinary retention is common, especially in older men.

Treatment for anticholinergic syndrome is largely supportive. Agitated patients may require sedation with a benzodiazepine or an antipsychotic agent (eg, haloperidol or olanzapine). The specific antidote for peripheral and central anticholinergic syndrome is physostigmine, which has a prompt and dramatic effect and is especially useful for patients who are very agitated. Physostigmine is given in small intravenous doses (0.5–1 mg) with careful monitoring, because it can cause bradycardia and seizures if given too rapidly. Physostigmine should not be given to a patient with serious tricyclic antidepressant overdose because it can aggravate cardiotoxicity, resulting in heart block or asystole. Catheterization may be needed to prevent excessive distention of the bladder.

ANTIDEPRESSANTS

Tricyclic antidepressants (eg, amitriptyline, desipramine, doxepin, many others; see Chapter 30) are among the most common prescription drugs involved in life-threatening drug overdose. Ingestion of more than 1 g of a tricyclic (or about 15–20 mg/kg) is considered potentially lethal.

Tricyclic antidepressants are competitive antagonists at muscarinic cholinergic receptors, and anticholinergic findings (tachycardia, dilated pupils, dry mouth) are common even at moderate doses. Some tricyclics are also strong α blockers, which can lead to vasodilation. Centrally mediated agitation and seizures may be followed by depression and hypotension. Most important is the fact that tricyclics inhibit the cardiac sodium channel, causing slowed conduction with a wide QRS interval and depressed

cardiac contractility. This cardiac toxicity may result in serious arrhythmias (Figure 58–1), including ventricular conduction block and ventricular tachycardia.

Treatment of tricyclic antidepressant overdose includes general supportive care as outlined earlier. Endotracheal intubation and assisted ventilation may be needed. Intravenous fluids are given for hypotension, and dopamine or norepinephrine is added if necessary. Many toxicologists recommend norepinephrine as the initial drug of choice for tricyclic-induced hypotension. The antidote for cardiac toxicity (manifested by a wide QRS complex) is sodium bicarbonate: a bolus of 50–100 mEq (or 1–2 mEq/kg) provides a rapid increase in extracellular sodium that helps overcome sodium channel blockade. Although physostigmine does effectively reverse anticholinergic signs, it can aggravate depression of cardiac conduction and cause seizures and is not recommended.

Monoamine oxidase inhibitors (eg, tranylcypromine, phenelzine) are older antidepressants that are occasionally used for resistant depression. They can cause severe hypertensive reactions when interacting foods or drugs are taken (see Chapters 9 and 30), and they can interact with the selective serotonin reuptake inhibitors (SSRIs).

Newer antidepressants (eg, fluoxetine, paroxetine, citalopram, venlafaxine) are mostly SSRIs and are generally safer than the tricyclic antidepressants and monoamine oxidase inhibitors, although they can cause seizures. **Bupropion** (not an SSRI) has caused seizures even in therapeutic doses. Some antidepressants have been associated with QT prolongation and torsades de pointes arrhythmia. SSRIs may interact with each other or especially with monoamine oxidase inhibitors to cause the **serotonin syndrome**, characterized by agitation, muscle hyperactivity, and hyperthermia (see Chapter 16).

ANTIPSYCHOTICS

Antipsychotic drugs include the older phenothiazines and butyrophenones, as well as newer so-called “atypical” drugs. All of these can cause CNS depression, seizures, and hypotension. Some can cause QT prolongation. The potent dopamine D_2 blockers are also associated with parkinsonian movement disorders (dystonic reactions) and in rare cases with the neuroleptic malignant syndrome, characterized by “lead-pipe” rigidity, hyperthermia, and autonomic instability (see Chapters 16 and 29).

ASPIRIN (SALICYLATE)

Salicylate poisoning (see Chapter 36) is a much less common cause of childhood poisoning deaths since the introduction of child-resistant containers and the reduced use of children’s aspirin. It still accounts for numerous suicidal and accidental poisonings. Acute ingestion of more than 200 mg/kg is likely to produce intoxication. Poisoning can also result from chronic overmedication; this occurs most commonly in elderly patients using salicylates for chronic pain who become confused about their dosing. Poisoning causes uncoupling of oxidative phosphorylation and disruption of normal cellular metabolism.

The first sign of salicylate toxicity is often hyperventilation and respiratory alkalosis due to medullary stimulation. Metabolic acidosis follows, and an increased anion gap results from accumulation of lactate as well as excretion of bicarbonate by the kidney to compensate for respiratory alkalosis. Arterial blood gas testing often reveals a mixed respiratory alkalosis and metabolic acidosis. Body temperature may be elevated owing to uncoupling of oxidative phosphorylation. Severe hyperthermia may occur in serious cases. Vomiting and hyperpnea as well as hyperthermia contribute to fluid loss and dehydration. With very severe poisoning, profound metabolic acidosis, seizures, coma, pulmonary edema, and cardiovascular collapse may occur. Absorption of salicylate and signs of toxicity may be delayed after very large overdoses or ingestion of enteric coated tablets.

General supportive care is essential. After massive aspirin ingestions (eg, more than 100 tablets), aggressive gut decontamination is advisable, including gastric lavage, repeated doses of activated charcoal, and consideration of whole bowel irrigation. Intravenous fluids are used to replace fluid losses caused by tachypnea, vomiting, and fever. For moderate intoxications, intravenous sodium bicarbonate is given to alkalinize the urine and promote salicylate excretion by trapping the salicylate in its ionized, polar form. For severe poisoning (eg, patients with severe acidosis, coma, and serum salicylate level >90 – 100 mg/dL), emergency hemodialysis is performed to remove the salicylate more quickly and restore acid-base balance and fluid status.

BETA BLOCKERS

In overdose, β blockers inhibit both β_1 and β_2 adrenoceptors; selectivity, if any, is lost at high dosage. The most toxic β blocker is propranolol. As little as two to three times the therapeutic dose can cause serious toxicity. This may be because propranolol in high doses may cause sodium channel-blocking effects similar to those seen with tricyclic antidepressants, and it is lipophilic, allowing it to enter the CNS (see Chapter 10).

Bradycardia and hypotension are the most common manifestations of toxicity. Agents with partial agonist activity (eg, pindolol) can cause tachycardia and hypertension. Seizures and cardiac conduction block (wide QRS complex) may be seen with propranolol overdose.

General supportive care should be provided as outlined earlier. The usual measures used to raise the blood pressure and heart rate, such as intravenous fluids, β -agonist drugs, and atropine, are generally ineffective. Glucagon is a useful antidote that—like β agonists—acts on cardiac cells to raise intracellular cAMP but does so independent of β adrenoceptors. It can improve heart rate and blood pressure when given in high doses (5–20 mg intravenously).

CALCIUM CHANNEL BLOCKERS

Calcium antagonists can cause serious toxicity or death with relatively small overdoses. These channel blockers depress sinus node automaticity and slow AV node conduction (see Chapter 12). They also reduce cardiac output and blood pressure. Serious hypotension

is mainly seen with nifedipine and related dihydropyridines, but in severe overdose all of the listed cardiovascular effects can occur with any of the calcium channel blockers.

Treatment requires general supportive care. Since most ingested calcium antagonists are in sustained-release form, it may be possible to expel them before they are completely absorbed; initiate whole bowel irrigation and oral activated charcoal as soon as possible, before calcium antagonist-induced ileus intervenes. Calcium, given intravenously in doses of 2–10 g, is a useful antidote for depressed cardiac contractility but less effective for nodal block or peripheral vascular collapse. Other treatments reported to be helpful in managing hypotension associated with calcium channel blocker poisoning include high-dose insulin (0.5–1 unit/kg/h) plus glucose supplementation to maintain euglycemia; glucagon; veno-arterial extracorporeal membrane oxygenation (ECMO-VA); and methylene blue. A few case reports have suggested benefit from administration of lipid emulsion (normally used as an intravenous dietary fat supplement) for severe verapamil overdose.

CARBON MONOXIDE & OTHER TOXIC GASES

Carbon monoxide (CO) is a colorless, odorless gas that is ubiquitous because it is created whenever carbon-containing materials are burned. Carbon monoxide poisoning is the leading cause of death due to poisoning in the USA. Most cases occur in victims of fires, but accidental and suicidal exposures are also common. The diagnosis and treatment of carbon monoxide poisoning are described in Chapter 56. Many other toxic gases are produced in fires or released in industrial accidents (Table 58–4).

CHOLINESTERASE INHIBITORS

Organophosphate and carbamate cholinesterase inhibitors (see Chapter 7) are widely used to kill insects and other pests. Most cases of serious organophosphate or carbamate poisoning result from intentional ingestion by a suicidal person, but poisoning has also occurred at work (pesticide application or packaging) or, rarely, as a result of food contamination or terrorist attack (eg, release of the chemical warfare nerve agent sarin in the Tokyo subway system in 1995).

Stimulation of muscarinic receptors causes abdominal cramps, diarrhea, excessive salivation, sweating, urinary frequency, and increased bronchial secretions (see Chapters 6 and 7). Stimulation of nicotinic receptors causes generalized ganglionic activation, which can lead to hypertension and either tachycardia or bradycardia. Muscle twitching and fasciculations may progress to weakness and respiratory muscle paralysis. CNS effects include agitation, confusion, and seizures. The mnemonic DUMBELS (diarrhea, urination, miosis and muscle weakness, bronchospasm, excitation, lacrimation, and seizures, sweating, and salivation) helps recall the common findings. Blood testing may be used to document depressed activity of red blood cell (acetylcholinesterase) and

TABLE 58–4 Characteristics of poisoning with some gases.

Gas	Mechanism of Toxicity	Clinical Features and Treatment
Irritant gases (eg, chlorine, ammonia, sulfur dioxide, nitrogen oxides)	Corrosive effect on upper and lower airways	Cough, stridor, wheezing, pneumonia <i>Treatment:</i> Humidified oxygen, bronchodilators
Carbon monoxide	Binds to hemoglobin, reducing oxygen delivery to tissues	Headache, dizziness, nausea, vomiting, seizures, coma <i>Treatment:</i> 100% oxygen; consider hyperbaric oxygen
Cyanide	Binds to cytochrome, blocks cellular oxygen use	Headache, nausea, vomiting, syncope, seizures, coma <i>Treatment:</i> Conventional antidote kit consists of nitrites to induce methemoglobinemia (which binds cyanide) and thiosulfate (which hastens conversion of cyanide to less toxic thiocyanate); a newer antidote kit (Cyanokit) consists of concentrated hydroxocobalamin, which directly converts cyanide into cyanocobalamin
Hydrogen sulfide	Similar to cyanide	Similar to cyanide. Smell of rotten eggs <i>Treatment:</i> No specific antidote; some authorities recommend the nitrite portion of the conventional cyanide antidote kit.
Oxidizing agents (eg, nitrogen oxides)	Can cause methemoglobinemia	Dyspnea, cyanosis (due to brown color of methemoglobin), syncope, seizures, coma <i>Treatment:</i> Methylene blue (which hastens conversion back to normal hemoglobin)

plasma (butyrylcholinesterase) enzymes, which provide an indirect estimate of synaptic cholinesterase activity.

General supportive care should be provided as outlined above. Precautions should be taken to ensure that rescuers and health care providers are not poisoned themselves by exposure to contaminated clothing or skin. This is especially critical for the most potent substances such as parathion or nerve gas agents. Antidotal treatment consists of atropine and pralidoxime (see Table 58–3). Atropine is an effective competitive inhibitor at muscarinic sites but has no effect at nicotinic sites. Pralidoxime given early enough may be capable of restoring the cholinesterase activity and is active at both muscarinic and nicotinic sites; however, studies are conflicting regarding its effect on clinical outcome.

CYANIDE

Cyanide (CN^-) salts and hydrogen cyanide (HCN) are highly toxic chemicals used in chemical synthesis, as rodenticides (eg, “gopher getter”), formerly as a method of execution, and as agents of suicide or homicide. Hydrogen cyanide is formed from the burning of plastics, wool, and many other synthetic and natural products. Cyanide is also released after ingestion of various plants (eg, cassava) and seeds (eg, apple, peach, and apricot).

Cyanide binds readily to cytochrome oxidase, inhibiting oxygen utilization within the cell and leading to cellular hypoxia and lactic acidosis. Symptoms of cyanide poisoning include shortness of breath, agitation, and tachycardia followed by seizures, coma, hypotension, and death. Severe metabolic acidosis is characteristic. The venous oxygen content may be elevated because oxygen is not being taken up by cells.

Treatment of cyanide poisoning includes rapid administration of activated charcoal (although charcoal binds cyanide poorly, it can reduce absorption) and general supportive care. The conventional antidote kit available in the USA includes two forms of

nitrite (amyl nitrite and sodium nitrite) and sodium thiosulfate. The nitrites induce methemoglobinemia, which binds CN^- , creating the less toxic cyanomethemoglobin; thiosulfate is a cofactor in the enzymatic conversion of CN^- to the much less toxic thiocyanate (SCN^-).

In 2006, the FDA approved a new cyanide antidote, a concentrated form of hydroxocobalamin, which is now available as the Cyanokit (EMD Pharmaceuticals, Durham, North Carolina). Hydroxocobalamin (one form of vitamin B_{12}) combines rapidly with CN^- to form nontoxic cyanocobalamin (another form of vitamin B_{12}).

DIGOXIN

Digitalis and other cardiac glycosides and cardenolides are found in many plants (see Chapter 13) and in the skin of some toads. Toxicity may occur as a result of acute overdose or from accumulation of digoxin in a patient with renal insufficiency or from taking a drug that interferes with digoxin elimination. Patients receiving long-term digoxin treatment are often also taking diuretics, which can lead to electrolyte depletion (especially potassium).

Vomiting is common in patients with digitalis overdose. Hyperkalemia may be caused by acute digitalis overdose or severe poisoning, whereas hypokalemia may be present in patients as a result of long-term diuretic treatment. (Digitalis does not cause hypokalemia.) A variety of cardiac rhythm disturbances may occur, including sinus bradycardia, AV block, atrial tachycardia with block, accelerated junctional rhythm, premature ventricular beats, bidirectional ventricular tachycardia, and other ventricular arrhythmias.

General supportive care should be provided. Atropine is often effective for bradycardia or AV block. The use of digoxin antibodies (see Chapter 13) has revolutionized the treatment of digoxin toxicity; they should be administered intravenously in the dosage

indicated in the package insert. Symptoms usually improve within 30–60 minutes after antibody administration. Digoxin antibodies may also be tried in cases of poisoning by other cardiac glycosides (eg, digitoxin, oleander), although larger doses may be needed due to incomplete cross-reactivity.

ETHANOL & SEDATIVE-HYPNOTIC DRUGS

Overdosage with ethanol and sedative-hypnotic drugs (eg, benzodiazepines, barbiturates, γ -hydroxybutyrate [GHB], carisoprodol [Soma]; see Chapters 22 and 23) occurs frequently because of their common availability and use.

Patients with ethanol or other sedative-hypnotic overdose may be euphoric and rowdy (“drunk”) or in a state of stupor or coma (“dead drunk”). Comatose patients often have depressed respiratory drive. Depression of protective airway reflexes may result in pulmonary aspiration of gastric contents, leading to pneumonia. Hypothermia may be present because of environmental exposure and depressed shivering. Ethanol blood levels greater than 300 mg/dL usually cause deep coma, but regular users are often tolerant to the effects of ethanol and may be ambulatory despite even higher levels. Patients with GHB overdose are often deeply comatose for 3–4 hours and then awaken fully in a matter of minutes.

General supportive care should be provided. With careful attention to protecting the airway (including endotracheal intubation) and assisting ventilation, most patients recover as the drug effects wear off. Hypotension usually responds to intravenous fluids, body warming if cold, and, if needed, dopamine. Patients with isolated benzodiazepine overdose may awaken after intravenous flumazenil, a benzodiazepine antagonist. However, this drug is not widely used as empiric therapy for drug overdose because it may precipitate seizures in patients who are addicted to benzodiazepines or who have ingested a convulsant drug (eg, a tricyclic antidepressant). There are no antidotes for ethanol, barbiturates, or most other sedative-hypnotics.

ETHYLENE GLYCOL & METHANOL

Ethylene glycol and methanol are alcohols that are important toxins because of their metabolism to highly toxic organic acids (see Chapter 23). They are capable of causing CNS depression and a drunken state similar to ethanol overdose. In addition, their products of metabolism—formic acid (from methanol) or hippuric, oxalic, and glycolic acids (from ethylene glycol)—cause a severe metabolic acidosis and can lead to coma and blindness (in the case of formic acid) or renal failure (from oxalic acid and glycolic acid). Initially, the patient appears drunk, but after a delay of up to several hours, a severe anion gap metabolic acidosis becomes apparent, accompanied by hyperventilation and altered mental status. Patients with methanol poisoning may have visual disturbances ranging from blurred vision to blindness.

Metabolism of ethylene glycol and methanol to their toxic products can be blocked by inhibiting the enzyme alcohol

dehydrogenase with a competing drug, such as fomepizole (4-methylpyrazole). Ethanol is also an effective antidote, but it can be difficult to achieve a safe and effective blood level.

IRON & OTHER METALS

Iron is widely used in over-the-counter vitamin preparations and is a leading cause of childhood poisoning deaths. As few as 10–12 prenatal multivitamins with iron may cause serious illness in a small child. Poisoning with other metals (lead, mercury, arsenic) is also important, especially in industry. See Chapters 33, 56, and 57 for detailed discussions of poisoning by iron and other metals.

OPIOIDS

Opioids (opium, morphine, heroin, meperidine, methadone, etc) are common drugs of abuse (see Chapters 31 and 32), and overdose is a common result of using the poorly standardized preparations sold on the street. See Chapter 31 for a detailed discussion of opioid overdose and its treatment.

RATTLESNAKE ENVENOMATION

In the USA, rattlesnakes are the most common venomous reptiles. Bites are rarely fatal, and 20% do not involve envenomation. However, about 60% of bites cause significant morbidity due to the destructive digestive enzymes found in the venom. Evidence of rattlesnake envenomation includes severe pain, swelling, bruising, hemorrhagic bleb formation, and obvious fang marks. Systemic effects include nausea, vomiting, muscle fasciculations, tingling and metallic taste in the mouth, shock, and systemic coagulopathy with prolonged clotting time and reduced platelet count.

Studies have shown that emergency field remedies such as incision and suction, tourniquets, and ice packs are far more damaging than useful. Avoidance of unnecessary motion, on the other hand, does help to limit the spread of the venom. Definitive therapy relies on intravenous antivenom (also known as antivenin), and this should be started as soon as possible.

THEOPHYLLINE

Although it has been largely replaced by inhaled β agonists, theophylline continues to be used for the treatment of bronchospasm by some patients with asthma and bronchitis (see Chapter 20). A dose of 20–30 tablets can cause serious or fatal poisoning. Chronic or subacute theophylline poisoning can also occur as a result of accidental overmedication or use of a drug that interferes with theophylline metabolism (eg, cimetidine, ciprofloxacin, erythromycin; see Chapter 4). Caffeine produces similar toxic effects and it is available in several “energy” supplements.

In addition to sinus tachycardia and tremor, vomiting is common after overdose. Hypotension, tachycardia, hypokalemia, and hyperglycemia may occur, probably owing to β_2 -adrenergic activation.

The cause of this activation is not fully understood, but the effects can be ameliorated by β blockers (see below). Cardiac arrhythmias include atrial tachycardias, premature ventricular contractions, and ventricular tachycardia. In severe poisoning (eg, acute overdose with serum level >100 mg/L), seizures often occur and are usually resistant to common anticonvulsants. Toxicity may be delayed in onset for many hours after ingestion of sustained-release tablet formulations.

General supportive care should be provided. Aggressive gut decontamination should be carried out using repeated doses of activated charcoal and whole bowel irrigation. Propranolol or other β blockers (eg, esmolol) are useful antidotes for β -mediated

hypotension and tachycardia. Phenobarbital is preferred over phenytoin for convulsions; most anticonvulsants are ineffective. Hemodialysis is indicated for serum concentrations >100 mg/L and for intractable seizures in patients with lower levels.

CASE STUDY ANSWER

Overdose of bupropion can cause seizures that are often recurrent or prolonged. Drug-induced seizures are treated with an intravenous benzodiazepine such as lorazepam or diazepam. If this is not effective, phenobarbital or another

more potent central nervous system depressant may be used. To prevent ingested drugs and poisons from being absorbed systemically, a slurry of activated charcoal is often given orally or by nasogastric tube.

SECTION X SPECIAL TOPICS

C H A P T E R

59

Special Aspects of Perinatal & Pediatric Pharmacology

Gideon Koren, MD, FRCPC, FACMT

The effects of drugs on the fetus and newborn infant are based on the general principles set forth in Chapters 1–4 of this book. However, the physiologic contexts in which these pharmacologic laws operate are different in pregnant women and in rapidly maturing infants. At present, the special pharmacokinetic factors operative in these patients are beginning to be understood, whereas information regarding pharmacodynamic differences (eg, receptor characteristics and responses) is still incomplete.

DRUG THERAPY IN PREGNANCY

Pharmacokinetics

Most drugs taken by pregnant women can cross the placenta and expose the developing embryo and fetus to their pharmacologic and teratogenic effects. Critical factors affecting placental drug transfer and drug effects on the fetus include the following: (1) the physicochemical properties of the drug; (2) the rate at which the drug crosses the placenta and the amount of drug reaching the fetus; (3) the duration of exposure to the drug; (4) distribution characteristics in different fetal tissues; (5) the stage of placental and fetal development at the time of exposure to the drug; and (6) the effects of drugs used in combination.

A. Lipid Solubility

As is true also of other biologic membranes, drug passage across the placenta is dependent on lipid solubility and the degree of drug ionization. Lipophilic drugs tend to diffuse readily across the placenta and enter the fetal circulation. For example, thiopental, a drug commonly used for cesarean sections, crosses the placenta almost immediately and can produce sedation or apnea in the newborn infant. Highly ionized drugs such as succinylcholine and tubocurarine, also used for cesarean sections, cross the placenta slowly and achieve very low concentrations in the fetus. Impermeability of the placenta to polar compounds is relative rather than absolute. If high enough maternal-fetal concentration gradients are achieved, polar compounds cross the placenta in measurable amounts. Salicylate, which is almost completely ionized at physiologic pH, crosses the placenta rapidly. This occurs because the small amount of salicylate that is not ionized is highly lipid-soluble.

B. Molecular Size and pH

The molecular weight of the drug also influences the rate of transfer and the amount of drug transferred across the placenta. Drugs with molecular weights of 250–500 can cross the placenta easily, depending upon their lipid solubility and degree of ionization;

those with molecular weights of 500–1000 cross the placenta with more difficulty; and those with molecular weights >1000 cross very poorly. An important clinical application of this property is the choice of heparin as an anticoagulant in pregnant women. Because it is a very large (and polar) molecule, heparin is unable to cross the placenta. Unlike warfarin, which is teratogenic and should be avoided during the first trimester and even beyond (as the brain continues to develop), heparin may be safely given to pregnant women who need anticoagulation. Yet the placenta contains drug transporters, which can carry larger molecules to the fetus. For example, a variety of maternal antibodies cross the placenta and may cause fetal morbidity, as in Rh incompatibility. Starting in the second trimester of pregnancy, the placenta develops transporters that allow immunoglobulins to cross from the mother to the fetus despite their large molecular size. This has important clinical implications, because an increasing number of biological drugs (eg, anti-tumor necrosis factor therapy) have been shown to cross the placenta. In addition to the detection of biologicals in cord blood, cases of severe neonatal neutropenia and fetal dissemination of bacillus Calmette-Guérin (BCG) have been reported. With an increasing number of infants exposed to immunoglobulin biologicals in utero, there is a need to address the challenges in vaccinating these infants.

Because maternal blood has a pH of 7.4, whereas the fetal blood is 7.3, basic drugs with a pK_a above 7.4 will be more ionized in the fetal compartment, leading to ion trapping and, hence, to higher fetal levels (see Chapter 1, Ionization of Weak Acids and Weak Bases).

C. Placental Transporters

During the last decade, many drug transporters have been identified in the placenta, with increasing recognition of their effects on drug transfer to the fetus. For example, the P-glycoprotein transporter encoded by the *MDR1* gene pumps back into the maternal circulation a variety of drugs, including cancer drugs (eg, vinblastine, doxorubicin) and other agents. Similarly, viral protease inhibitors, which are substrates to P-glycoprotein, achieve only low fetal concentrations—an effect that may increase the risk of vertical HIV infection from the mother to the fetus. The hypoglycemic drug glyburide has lower plasma levels in the fetus as compared with the mother. Recent work has documented that this agent is effluxed from the fetal circulation by the BCRP transporter as well as by the MRP3 transporter located in the placental brush border membrane. In addition, very high maternal protein binding of glyburide (>98.8%) also contributes to lower fetal levels as compared with maternal concentrations.

D. Protein Binding

The degree to which a drug is bound to plasma proteins (particularly albumin) may also affect the rate of transfer and the amount transferred. However, if a compound is very lipid-soluble (eg, some anesthetic gases), it will not be affected greatly by protein binding. Transfer of these more lipid-soluble drugs and their overall rates of equilibration are more dependent on (and proportionate to) placental blood flow. This is because very lipid-soluble drugs diffuse across placental membranes so rapidly that their overall rates

of equilibration do not depend on the free drug concentrations becoming equal on both sides. If a drug is poorly lipid-soluble and is ionized, its transfer is slow and will probably be impeded by its binding to maternal plasma proteins. Differential protein binding is also important since some drugs exhibit greater protein binding in maternal plasma than in fetal plasma because of a lower binding affinity of fetal proteins. This has been shown for sulfonamides, barbiturates, phenytoin, and local anesthetic agents.

E. Placental and Fetal Drug Metabolism

Two mechanisms help protect the fetus from drugs in the maternal circulation: (1) The placenta itself plays a role both as a semipermeable barrier and as a site of metabolism of some drugs passing through it. Several different types of aromatic oxidation reactions (eg, hydroxylation, *N*-dealkylation, demethylation) have been shown to occur in placental tissue. Pentobarbital is oxidized in this way. Conversely, it is possible that the metabolic capacity of the placenta may lead to creation of toxic metabolites, and the placenta may therefore augment toxicity (eg, ethanol, benzpyrenes). (2) Because of the ability of the placenta to convert prednisolone to the inactive prednisone, prednisolone can be used in pregnant patients requiring corticosteroid treatment without the risk of fetal exposure to an active corticosteroid. Drugs that have crossed the placenta enter the fetal circulation via the umbilical vein. About 40–60% of umbilical venous blood flow enters the fetal liver; the remainder bypasses the liver and enters the general fetal circulation. A drug that enters the liver may be partially metabolized there before it enters the fetal circulation. In addition, a large proportion of drug present in the umbilical artery (returning to the placenta) may be shunted through the placenta back to the umbilical vein and into the liver again. It should be noted that metabolites of some drugs may be more active than the parent compound and may affect the fetus adversely.

Pharmacodynamics

A. Maternal Drug Actions

The effects of drugs on the reproductive tissues (breast, uterus, etc) of the pregnant woman are sometimes altered by the endocrine environment appropriate for the stage of pregnancy. Drug effects on other maternal tissues (heart, lungs, kidneys, central nervous system, etc) are not changed significantly by pregnancy, although the physiologic context (cardiac output, renal blood flow, etc) may be altered, requiring the use of drugs that are not needed by the same woman when she is not pregnant. For example, cardiac glycosides and diuretics may be needed for heart failure precipitated by the increased cardiac workload of pregnancy, or insulin may be required for control of blood glucose in pregnancy-induced diabetes.

B. Therapeutic Drug Actions in the Fetus

Fetal therapeutics is an emerging area in perinatal pharmacology. This involves drug administration, mostly to the pregnant woman, with the fetus as the target of the drug. At present, corticosteroids are used to stimulate fetal lung maturation when preterm birth is expected. Phenobarbital, when given to pregnant women near

term, can induce fetal hepatic enzymes responsible for the glucuronidation of bilirubin, and the incidence of jaundice is lower in newborns when mothers are given phenobarbital than when phenobarbital is not used. Before phototherapy became the preferred mode of therapy for neonatal indirect hyperbilirubinemia, phenobarbital was used for this indication. Administration of phenobarbital to the mother was suggested recently as a means of decreasing the risk of intracranial bleeding in preterm infants. However, large randomized studies failed to confirm this effect. Antiarrhythmic drugs have also been given to mothers for treatment of fetal cardiac arrhythmias. Although their efficacy has not yet been established by controlled studies, digoxin, flecainide, procainamide, verapamil, and other antiarrhythmic agents have been shown to be effective in case series. Similarly, it has been shown that maternal use of zidovudine and other HIV drugs substantially decreases transmission of HIV from the mother to the fetus, and use of combinations of three antiretroviral agents can eliminate fetal infection almost entirely (see Chapter 49).

C. Predictable Toxic Drug Actions in the Fetus

Chronic use of opioids by the mother often produces dependence in the fetus and newborn. This dependence may be manifested after delivery as a neonatal withdrawal syndrome. A less well understood fetal drug toxicity is caused by the use of angiotensin-converting enzyme inhibitors during late pregnancy. These drugs

can result in significant and irreversible renal damage in the fetus and are therefore contraindicated in pregnant women. Adverse effects may also be delayed, as in the case of female fetuses exposed to diethylstilbestrol, who may be at increased risk for adenocarcinoma of the vagina after puberty.

D. Teratogenic Drug Actions

A single intrauterine exposure to a drug can affect the fetal structures undergoing rapid development at the time of exposure. Thalidomide is an example of a drug that may profoundly affect the development of the limbs after only brief exposure. This exposure, however, must be at a critical time in the development of the limbs. Thalidomide-induced phocomelia occurs during the fourth through the seventh weeks of gestation because it is during this time that the arms and legs develop (Figure 59–1).

1. Teratogenic mechanisms—The mechanisms by which different drugs produce teratogenic effects are poorly understood and are probably multifactorial. For example, drugs may have a direct effect on maternal tissues with secondary or indirect effects on fetal tissues. Drugs may interfere with the passage of oxygen or nutrients through the placenta and therefore have effects on the most rapidly metabolizing tissues of the fetus. Finally, drugs may have important direct actions on the processes of differentiation in developing tissues. For example, vitamin A (retinol)

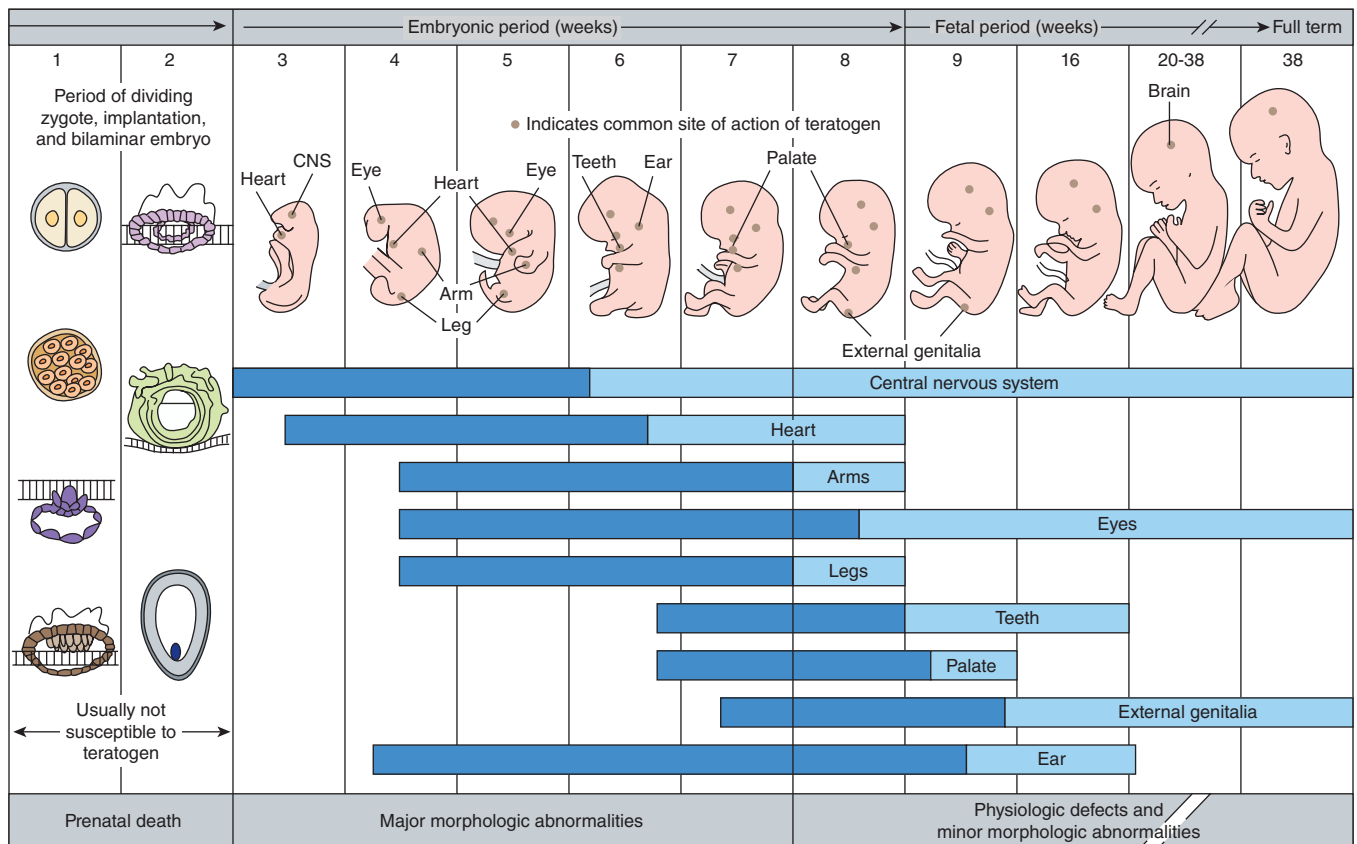

FIGURE 59–1 Schematic diagram of critical periods of human development. (Reproduced, with permission, from Moore KL: *The Developing Human: Clinically Oriented Embryology*, 4th ed. Saunders, 1988. © Elsevier.)

has been shown to have important differentiation-directing actions in normal tissues. Several vitamin A analogs (isotretinoin, etretinate) are powerful teratogens, suggesting that they alter the normal processes of differentiation. Finally, deficiency of a critical substance appears to play a role in some types of abnormalities. For example, folic acid supplementation during pregnancy appears to reduce the incidence of neural tube defects (see Box, page 599).

Continued exposure to a teratogen may produce cumulative effects or may affect several organs going through varying stages of development. Chronic consumption of high doses of ethanol during pregnancy, particularly during the first and second trimesters, may result in the fetal alcohol spectrum disorder (see Chapter 23). In this syndrome, the central nervous system, growth, and facial development may be affected.

2. Defining a teratogen—To be considered teratogenic, a candidate substance or process should (1) result in a characteristic set of malformations, indicating selectivity for certain target organs; (2) exert its effects at a particular stage of fetal development, eg, during the limited time period of organogenesis of the target organs (Figure 59–1); and (3) show a dose-dependent incidence. Some drugs with known teratogenic or other adverse effects in pregnancy are listed in Table 59–1. Teratogenic effects are not limited only to major malformations, but also include intrauterine growth restriction (eg, cigarette smoking), miscarriage (eg, alcohol), stillbirth (eg, cigarette smoke), and neurocognitive delay (eg, alcohol, valproic acid).

In addition to teratogenic drugs, teratogenicity can be induced by a large group of infectious pathogens, including viruses such as rubella, cytomegalovirus, herpes, and recently, Zika virus. Similarly, numerous chemicals, such as heavy metals (eg, mercury, lead) and environmental factors (eg, radiation, hyperthermia) can damage the fetus. It is important to consider these nondrug factors in the differential diagnosis of drug-induced adverse fetal effects.

The widely cited US Food and Drug Administration (FDA) system for teratogenic potential (Table 59–2) has been an attempt to quantify teratogenic risk from A (safe) to X (definite human teratogenic risk). This system has been criticized as inaccurate and impractical. For example, several drugs have been labeled “X” despite extensive opposite human safety data (eg, oral contraceptives). Diazepam and other benzodiazepines are labeled as “D” despite lack of positive evidence of human fetal risk. The FDA has recently changed its system from the A, B, C grading system to narrative statements that summarize evidence-based knowledge about each drug in terms of fetal risk and safety.

3. Counseling women about teratogenic risk—Since the thalidomide disaster, medicine has been practiced as if every drug were a potential human teratogen when, in fact, fewer than 30 such drugs have been identified, with hundreds of agents proved safe for the unborn. Owing to high levels of anxiety among pregnant women—and because half of the pregnancies in North America are unplanned—every year many thousands of women need counseling about fetal exposure to drugs, chemicals, and radiation. The ability of appropriate counseling to prevent unnecessary abortions has been documented. Clinicians who wish to

provide such counsel to pregnant women must ensure that their information is up-to-date and evidence-based and that the woman understands that the baseline teratogenic risk in pregnancy (ie, the risk of a neonatal abnormality in the absence of any known teratogenic exposure) is about 3%. It is also critical to address the maternal-fetal risks of the untreated condition if a medication is avoided. Recent studies show serious morbidity in women who discontinued selective serotonin reuptake inhibitor therapy for depression in pregnancy.

DRUG THERAPY IN INFANTS & CHILDREN

Physiologic processes that influence pharmacokinetic variables in the infant change significantly in the first year of life, particularly during the first few months. Therefore, special attention must be paid to pharmacokinetics in this age group. Pharmacodynamic differences between pediatric and other patients have not been explored in great detail but are probably important for those specific target tissues that mature at birth or immediately thereafter (eg, the ductus arteriosus).

Drug Absorption

Drug absorption in infants and children follows the same general principles as in adults. Unique factors that influence drug absorption include blood flow at the site of administration, as determined by the physiologic status of the infant or child; and, for orally administered drugs, gastrointestinal function, which changes rapidly during the first few days after birth. Age after birth also influences the regulation of drug absorption.

A. Blood Flow at the Site of Administration

Absorption after intramuscular or subcutaneous injection depends mainly, in neonates as in adults, on the rate of blood flow to the muscle or subcutaneous area injected. Physiologic conditions that might reduce blood flow to these areas are cardiovascular shock, vasoconstriction due to sympathomimetic agents, and heart failure. However, sick preterm infants requiring intramuscular injections may have very little muscle mass. This is further complicated by diminished peripheral perfusion to these areas. In such cases, absorption becomes irregular and difficult to predict, because the drug may remain in the muscle and be absorbed more slowly than expected. If perfusion suddenly improves, there can be a sudden and unpredictable increase in the amount of drug entering the circulation, resulting in high and potentially toxic concentrations of drug. Examples of drugs especially hazardous in such situations are cardiac glycosides, aminoglycoside antibiotics, and anticonvulsants.

B. Gastrointestinal Function

Significant biochemical and physiologic changes occur in the neonatal gastrointestinal tract shortly after birth. In full-term infants, gastric acid secretion begins soon after birth and increases gradually over several hours. In preterm infants, the secretion of gastric acid occurs more slowly, with the highest concentrations appearing on the fourth day of life.

TABLE 59–1 Drugs with significant teratogenic or other adverse effects on the fetus.

Drug	Trimester	Effect
ACE inhibitors	All, especially second and third	Renal damage, hypocalvaria
Aminopterin	First	Multiple gross anomalies
Amphetamines	All	Suspected abnormal developmental patterns, decreased school performance
Androgens	Second and third	Masculinization of female fetus
Antidepressants, tricyclic	Third	Neonatal withdrawal symptoms have been reported in a few cases with clomipramine, desipramine, and imipramine
Barbiturates	All	Chronic use can lead to neonatal dependence.
Busulfan	All	Various congenital malformations; low birth weight
Carbamazepine	First	Neural tube defects
Chlorpropamide	All	Prolonged symptomatic neonatal hypoglycemia
Clomipramine	Third	Neonatal lethargy, hypotonia, cyanosis, hypothermia
Cocaine	All	Increased risk of spontaneous abortion, abruptio placentae, and premature labor; neonatal cerebral infarction, abnormal development, and decreased school performance
Cyclophosphamide	First	Various congenital malformations
Cytarabine	First, second	Various congenital malformations
Diazepam	All	Chronic use may lead to neonatal dependence
Diethylstilbestrol	All	Vaginal adenosis, clear cell vaginal adenocarcinoma
Ethanol	All	Risk of fetal alcohol spectrum disorder
Etretinate	All	High risk of multiple congenital malformations
Heroin	All	Chronic use leads to neonatal abstinence syndrome
Iodide	All	Congenital goiter, hypothyroidism
Isotretinoin	All	Extremely high risk of central nervous system (CNS), face, ear, and other malformations
Lithium	First, third	Ebstein's anomaly, neonatal toxicity after third trimester exposure
Methadone	All	Chronic use may lead to neonatal abstinence syndrome
Methotrexate	First	Multiple congenital malformations
Methylthiouracil	All	Hypothyroidism
Misoprostol	First	Möbius sequence
Mycophenolate mofetil	First	Major malformations of the face, limbs, and other organs
Organic solvents	First	Multiple malformations
Penicillamine	First	Cutis laxa, other congenital malformations
Phencyclidine	All	Abnormal neurologic examination, poor suck reflex and feeding
Phenytoin	All	Fetal hydantoin syndrome
Propylthiouracil	All	Congenital goiter
Serotonin reuptake inhibitors	Third	Neonatal abstinence syndrome, persistent pulmonary hypertension of the newborn
Smoking (constituents of tobacco smoke)	All	Intrauterine growth restriction; prematurity; sudden infant death syndrome; perinatal complications
Tamoxifen	All	Increased risk of spontaneous abortion or fetal damage
Tetracycline	All	Discoloration and defects of teeth and altered bone growth
Thalidomide	First	Phocomelia (shortened or absent long bones of the limbs) and many internal malformations
Trimethadione	All	Multiple congenital anomalies
Topiramate	First	Oral cleft
Valproic acid	All	Neural tube defects, cardiac and limb malformations; developmental delay; possibly autism
Warfarin	First	Hypoplastic nasal bridge, chondrodysplasia punctata
	Second	CNS malformations
	Third	Risk of bleeding. Discontinue use 1 month before delivery.

TABLE 59–2 FDA teratogenic risk categories.¹

Category	Description
A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in late trimesters), and the possibility of fetal harm appears remote.
B	Either animal-reproduction studies have not demonstrated a fetal risk, but there are no controlled studies in pregnant women, or animal-reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).
C	Either studies in animals have revealed adverse effects on the fetus (teratogenic or embryocidal or other) and there are no controlled studies in women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (eg, if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).
X	Studies in animals or human beings have demonstrated fetal abnormalities or there is evidence of fetal risk based on human experience or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

¹This system has been changed as of 2014 by eliminating the A, B, C qualifications and replacing them with specific structured narratives for each drug.

Gastric emptying time is prolonged (up to 6 or 8 hours) in the first day or so after delivery. Therefore, drugs that are absorbed primarily in the stomach may be absorbed more completely than anticipated. In the case of drugs absorbed in the small intestine, therapeutic effect may be delayed. Peristalsis in the neonate is irregular and may be slow. The fraction of drug absorbed in the small intestine may therefore be unpredictable; more than the usual amount of drug may be absorbed if peristalsis is slowed, and this could result in toxicity from an otherwise standard dose. Table 59–3 summarizes data on oral bioavailability of various drugs in neonates compared with older children and adults. An increase in peristalsis, as in diarrheal conditions, tends to decrease the extent of absorption, because contact time with the large absorptive surface of the intestine is decreased.

Gastrointestinal enzyme activities tend to be lower in the newborn than in the adult. Activities of α -amylase and other pancreatic enzymes in the duodenum are low in infants up to 4 months of age. Neonates also have low concentrations of bile acids and lipase, which may decrease the absorption of lipid-soluble drugs.

TABLE 59–3 Oral drug absorption (bioavailability) of various drugs in the neonate compared with older children and adults.

Drug	Oral Absorption
Acetaminophen	Decreased
Ampicillin	Increased
Diazepam	Normal
Digoxin	Normal
Penicillin G	Increased
Phenobarbital	Decreased
Phenytoin	Decreased
Sulfonamides	Normal

Drug Distribution

As body composition changes with development, the distribution volumes of drugs are also changed. The neonate has a higher percentage of its body weight in the form of water (70–75%) than does the adult (50–60%). Differences can also be observed between the full-term neonate (70% of body weight as water) and the small preterm neonate (85% of body weight as water). Similarly, extracellular water is 40% of body weight in the neonate, compared with 20% in the adult. Most neonates will experience diuresis in the first 24–48 hours of life. Since many drugs are distributed throughout the extracellular water space, the size (volume) of the extracellular water compartment may be important in determining the concentration of drug at receptor sites. This is especially important for water-soluble drugs (such as aminoglycosides) and less crucial for lipid-soluble agents.

Preterm infants have much less fat than full-term infants. Total body fat in preterm infants is about 1% of total body weight, compared with 15% in full-term neonates. Therefore, organs that generally accumulate high concentrations of lipid-soluble drugs in adults and older children may accumulate smaller amounts of these agents in less mature infants.

Another major factor determining drug distribution is drug binding to plasma proteins. Albumin is the plasma protein with the greatest binding capacity. In general, protein binding of drugs is reduced in the neonate, as seen with local anesthetic drugs, diazepam, phenytoin, ampicillin, and phenobarbital. Therefore, the concentration of free (unbound) drug in plasma is increased initially. Because the free drug exerts the pharmacologic effect, this can result in greater drug effect or toxicity despite a normal or even low plasma concentration of total drug (bound plus unbound). As an example, consider a therapeutic dose of a drug (eg, diazepam) given to a patient. The concentration of total drug in the plasma is 300 mcg/L. If the drug is 98% protein-bound in an older child or adult, then 6 mcg/L is the concentration of free drug. Assume that this concentration of free drug produces the desired effect in the patient without producing toxicity. However, if this drug

is given to a preterm infant in a dosage adjusted for body weight and it produces a total drug concentration of 300 mcg/L—and protein binding is only 90%—then the free drug concentration will be 30 mcg/L, or five times higher. Although the higher free concentration may result in faster elimination (see Chapter 3), this concentration may be quite toxic initially.

Some drugs compete with serum bilirubin for binding to albumin. Drugs given to a neonate with jaundice can displace bilirubin from albumin. Because of the greater permeability of the neonatal blood-brain barrier, substantial amounts of bilirubin may enter the brain and cause kernicterus. This was in fact observed when sulfonamide antibiotics were given to preterm neonates as prophylaxis against sepsis. Conversely, as the serum bilirubin rises for physiologic reasons or because of a blood group incompatibility, bilirubin can displace a drug from albumin and substantially raise the free drug concentration. This may occur without altering the total drug concentration and would result in greater therapeutic effect or toxicity at normal concentrations, as has been shown with phenytoin.

Drug Metabolism

The metabolism of most drugs occurs in the liver (see Chapter 4). The drug-metabolizing activities of the cytochrome P450 superfamily and the conjugating enzymes are substantially lower (50–70% of adult values) in early neonatal life than later. The point in development at which enzymatic activity reaches adult levels depends on the specific enzyme system in question. Glucuronide formation reaches adult values (per kilogram body weight) between the third and fourth years of life. Because of the neonate's decreased ability to metabolize drugs, many drugs have slow clearance rates and prolonged elimination half-lives in early life. If drug doses and dosing schedules are not altered appropriately, this immaturity predisposes the neonate to adverse effects from drugs that are metabolized by the liver. Table 59–4 demonstrates how

neonatal and adult drug elimination half-lives can differ and how the half-lives of phenobarbital and phenytoin decrease as the neonate grows older. The process of maturation must be considered when administering drugs to this age group, especially in the case of drugs administered over long periods.

Another consideration for the neonate is whether or not the mother was receiving drugs (eg, phenobarbital) that can induce early maturation of fetal hepatic enzymes. In this case, the ability of the neonate to metabolize certain drugs will be greater than expected, and one may see less therapeutic effect and lower plasma drug concentrations when the usual neonatal dose is given. During toddlerhood (12–36 months), the metabolic rate of many drugs exceeds adult values, often necessitating larger doses per kilogram than later in life.

Drug Excretion

The glomerular filtration rate is much lower in newborns than in older infants, children, or adults, and this limitation persists during the first few days of life. Calculated on the basis of body surface area, glomerular filtration in the neonate is only 30–40% of the adult value. The glomerular filtration rate is even lower in neonates born before 34 weeks of gestation. Function improves substantially during the first week of life. At the end of the first week, the glomerular filtration rate and renal plasma flow have increased 50% from the first day. By the end of the third week, glomerular filtration is 50–60% of the adult value; by 6–12 months, it reaches adult values (per unit surface area). Subsequently, during toddlerhood, it exceeds adult values, often necessitating larger doses per kilogram than in adults, as described previously for drug-metabolic rate. Therefore, drugs that depend on renal function for elimination are cleared from the body very slowly in the first weeks of life.

Penicillins, for example, are cleared by preterm infants at 17% of the adult rate based on comparable surface area and 34% of the adult rate when adjusted for body weight. The dosage of ampicillin for a neonate less than 7 days old is 50–100 mg/kg/d in two doses at 12-hour intervals. The dosage for a neonate over 7 days old is 100–200 mg/kg/d in three doses at 8-hour intervals. A decreased rate of renal elimination in the neonate has also been observed with aminoglycoside antibiotics (kanamycin, gentamicin, neomycin, and streptomycin). The dosage of gentamicin for a neonate less than 7 days old is 5 mg/kg/d in two doses at 12-hour intervals. The dosage for a neonate over 7 days old is 7.5 mg/kg/d in three doses at 8-hour intervals. Total body clearance of digoxin is directly dependent upon adequate renal function, and accumulation of digoxin can occur when glomerular filtration is decreased. Since renal function in a sick infant may not improve at the predicted rate during the first weeks and months of life, appropriate adjustments in dosage and dosing schedules may be very difficult. In this situation, adjustments are best made on the basis of plasma drug concentrations determined at intervals throughout the course of therapy.

Although great focus is naturally concentrated on the neonate, it is important to remember that toddlers may have *shorter* elimination half-lives of drugs than older children and adults,

TABLE 59–4 Comparison of elimination half-lives of various drugs in neonates and adults.

Drug	Neonatal Age	Neonates $t_{1/2}$ (hours)	Adults $t_{1/2}$ (hours)
Acetaminophen		2.2–5	0.9–2.2
Diazepam		25–100	40–50
Digoxin		60–70	30–60
Phenobarbital	0–5 days	200	64–140
	5–15 days	100	
	1–30 months	50	
Phenytoin	0–2 days	80	12–18
	3–14 days	18	
	14–50 days	6	
Salicylate		4.5–11	10–15
Theophylline	Neonate	13–26	5–10
	Child	3–4	

due probably to *increased* renal elimination and metabolism. For example, the dose per kilogram of digoxin is much higher in toddlers than in adults. The mechanisms for these developmental changes are still poorly understood.

Special Pharmacodynamic Features in the Neonate

The appropriate use of drugs has made possible the survival of neonates with severe abnormalities who would otherwise die within days or weeks after birth. For example, administration of indomethacin (see Chapter 36) causes the rapid closure of a patent ductus arteriosus, which would otherwise require surgical closure in an infant with a normal heart. Infusion of prostaglandin E₁, on the other hand, causes the ductus to remain open, which can be lifesaving in an infant with transposition of the great vessels or tetralogy of Fallot (see Chapter 18). An unexpected effect of such infusion has been described when the drug caused antral hyperplasia with gastric outlet obstruction as a clinical manifestation in 6 of 74 infants who received it. This phenomenon appears to be dose-dependent. Neonates are also more sensitive to the central depressant effects of opioids than are older children and adults, necessitating extra caution when they are exposed to some narcotics (eg, codeine) through breast milk.

At birth, the function of drug transporters may be very low; for example, P-glycoprotein, which pumps morphine from the blood-brain barrier back to the systemic circulation. Low-level function of P-glycoprotein at birth can explain why neonates are substantially more sensitive than older children to the central nervous system depressant effects of morphine.

PEDIATRIC DOSAGE FORMS & ADHERENCE

The form in which a drug is manufactured and the way in which the parent dispenses the drug to the child determine the actual dose administered. Many drugs prepared for children are in the form of elixirs or suspensions. **Elixirs** are alcoholic solutions in which the drug molecules are dissolved and evenly distributed. No shaking is required, and unless some of the vehicle has evaporated, the first dose from the bottle and the last dose should contain equivalent amounts of drug. **Suspensions** contain undissolved particles of drug that must be distributed throughout the vehicle by shaking. If shaking is not thorough each time a dose is given, the first doses from the bottle may contain less drug than the last doses, with the result that less than the expected plasma concentration or effect of the drug may be achieved early in the course of therapy. Conversely, toxicity may occur late in the course of therapy, when it is not expected. This uneven distribution is a potential cause of inefficacy or toxicity in children taking phenytoin suspensions. It is thus essential that the prescriber know the form in which the drug will be dispensed and provide proper instructions to the pharmacist and patient or parent.

Adherence (formerly called compliance) may be more difficult to achieve in pediatric practice than otherwise, since it involves not only the parent's conscientious effort to follow directions but also such practical matters as measuring errors, spilling, and spitting out. For example, the measured volume of "teaspoons" can vary from 2.5 to 7.8 mL. The parents should obtain a calibrated medicine spoon or syringe from the pharmacy as these devices improve the accuracy of dose measurements and simplify administration of drugs to children.

When evaluating adherence, it is often helpful to ask if an attempt has been made to give a further dose after the child has spilled half of what was offered. The parents may not always be able to say with confidence how much of a dose the child actually received. The parents must be told whether or not to wake the infant for its every-6-hour dose day or night. These matters should be discussed and made clear, and no assumptions should be made about what the parents may or may not do. Nonadherence frequently occurs when antibiotics are prescribed to treat otitis media or urinary tract infections and the child feels well after 4 or 5 days of therapy. The parents may not feel there is any reason to continue giving the medicine even though it was prescribed for 10 or 14 days. This common situation should be anticipated so the parents can be told why it is important to continue giving the medicine for the prescribed period even if the child seems to be "cured."

Practical and convenient dosage forms and dosing schedules should be chosen to the extent possible. The easier it is to administer and take the medicine and the easier the dosing schedule is to follow, the more likely it is that adherence will be achieved.

Consistent with their ability to comprehend and cooperate, children should also be given some responsibility for their own health care and for taking medications. This should be discussed in appropriate terms both with the child and with the parents. Possible adverse effects and drug interactions with over-the-counter medicines or foods should also be discussed. Whenever a drug does not achieve its therapeutic effect, the possibility of nonadherence should be considered. There is ample evidence that in such cases parents' or children's reports may be grossly inaccurate. Random pill counts and measurement of serum concentrations may help disclose nonadherence. The use of computerized pill containers, which record each lid opening, has been shown to be very effective in measuring adherence.

Because many pediatric doses are calculated—eg, using body weight—rather than simply read from a list, major dosing errors may result from incorrect calculations. Typically, tenfold errors due to incorrect placement of the decimal point have been described. In the case of digoxin, for example, an intended dose of 0.1 mL containing 5 mcg of drug, when replaced by 1.0 mL—which is still a small volume—can result in a fatal overdose. Different strategies have been developed to prevent these potentially fatal errors. For drugs with narrow therapeutic windows (eg, digoxin, insulin, potassium), independent double-checking of dose and volume calculations is widely practiced. A good rule for avoiding such "decimal point" errors is to use a leading "0" plus decimal point when dealing with doses less than "1" and to avoid using a zero after a decimal point (see Chapter 65).

DRUG USE DURING LACTATION

Despite the fact that most drugs are excreted into breast milk in amounts too small to adversely affect neonatal health, thousands of women taking medications do not breast-feed because of fears of harming the baby and misperception of risk. Unfortunately, physicians often contribute to this bias. It is important to

remember that, compared with breast-feeding, formula feeding is associated with higher infant morbidity and mortality in all socioeconomic groups.

Most drugs administered to lactating women are detectable in breast milk. Fortunately, the concentration of drugs achieved in breast milk is usually low (Table 59–5). Therefore, the total amount the infant would receive in a day is substantially less than what

TABLE 59–5 Drugs often used during lactation and possible effects on the nursing infant.

Drug	Effect on Infant	Comments
Amiodarone	Significant	Large amounts in milk; follow-up of thyroid function in the baby.
Ampicillin	Minimal	No significant adverse effects; possible occurrence of diarrhea or allergic sensitization.
Aspirin	Minimal	Occasional doses are safe.
Caffeine	Minimal	Caffeine intake in moderation is safe; concentration in breast milk is low.
Chloral hydrate	Significant	May cause drowsiness if infant is fed at peak concentration in milk.
Chloramphenicol	Significant	Concentrations too low to cause gray baby syndrome; possibility of bone marrow suppression does exist; recommend not taking chloramphenicol while breast-feeding.
Chlorothiazide	Minimal	No adverse effects reported.
Chlorpromazine	Minimal	Appears insignificant.
Codeine	Variable, based on genetic polymorphism	Safe in most cases. Neonatal toxicity described when the mother is an ultra rapid 2D6 metabolizer, producing substantially more morphine from codeine.
Dicumarol	Minimal	No adverse side effects reported; may wish to follow infant's prothrombin time.
Digoxin	Minimal	Insignificant quantities enter breast milk.
Ethanol	Moderate	Moderate ingestion by mother unlikely to produce effects in infant; large amounts consumed by mother can produce alcohol effects in infant.
Heroin	Significant	Enters breast milk and can prolong neonatal narcotic dependence.
Iodine (radioactive)	Significant	Enters milk in quantities sufficient to cause thyroid suppression in infant.
Isoniazid (INH)	Minimal	Milk concentrations equal maternal plasma concentrations. Possibility of pyridoxine deficiency developing in the infant.
Kanamycin	Minimal	No adverse effects reported.
Lithium	Variable	In some cases—but not in others—large amounts enter breast milk.
Methadone	Significant	(See heroin.) Under close physician supervision, breast-feeding can be continued. Signs of opioid withdrawal in the infant may occur if mother stops taking methadone or stops breast-feeding abruptly.
Oral contraceptives	Minimal	May suppress lactation in high doses.
Penicillin	Minimal	Very low concentrations in breast milk.
Phenobarbital	Moderate	Hypnotic doses can cause sedation in the infant.
Phenytoin	Moderate	Amounts entering breast milk are not sufficient to cause adverse effects in infant.
Prednisone	Moderate	Low maternal doses (5 mg/d) probably safe. Doses 2 or more times physiologic amounts (>15 mg/d) should probably be avoided.
Propranolol	Minimal	Very small amounts enter breast milk.
Propylthiouracil	Variable	Rarely may suppress thyroid function in infant.
Radioactive nuclides	Will expose baby to radioactivity	Ensure that mother's system has cleared the radioactivity.
Spironolactone	Minimal	Very small amounts enter breast milk.
Tetracycline	Moderate	Possibility of permanent staining of developing teeth in the infant. Should be avoided during lactation.
Theophylline	Moderate	Can enter breast milk in moderate quantities but not likely to produce significant effects.
Thyroxine	Minimal	No adverse effects in therapeutic doses.
Tolbutamide	Minimal	Low concentrations in breast milk.
Warfarin	Minimal	Very small quantities found in breast milk.

would be considered a “therapeutic dose.” If the nursing mother must take medications and the drug is a relatively safe one, she should optimally take it 30–60 minutes after nursing and 3–4 hours before the next feeding. In some cases this may allow time for drugs to be partially cleared from the mother’s blood, and the concentrations in breast milk will be relatively low. Most antibiotics taken by nursing mothers can be detected in breast milk. Tetracycline concentrations in breast milk are approximately 70% of maternal serum concentrations and present a risk of permanent tooth staining in the infant. Isoniazid rapidly reaches equilibrium between breast milk and maternal blood. The concentrations achieved in breast milk are high enough so that signs of pyridoxine deficiency may occur in the infant if the mother is not given pyridoxine supplements.

Most sedatives and hypnotics achieve concentrations in breast milk sufficient to produce a pharmacologic effect in some infants. Barbiturates taken in hypnotic doses by the mother can produce lethargy, sedation, and poor suck reflexes in the infant. Chloral hydrate can produce sedation if the infant is fed at peak milk concentrations. Diazepam can have a sedative effect on the nursing infant, but, most importantly, its long half-life can result in significant drug accumulation.

Opioids such as heroin, methadone, and morphine enter breast milk in quantities potentially sufficient to prolong the state of neonatal narcotic dependence if the drug was taken chronically by the mother during pregnancy. If conditions are well controlled and there is a good relationship between the mother and the physician, an infant could be breast-fed while the mother is taking methadone. She should not, however, stop taking the drug abruptly; the infant can be tapered off the methadone as the mother’s dose is tapered. The infant should be watched for signs of narcotic withdrawal. Although codeine has been believed to be safe, a case of neonatal death from opioid toxicity revealed that the mother was an ultra rapid metabolizer of cytochrome 2D6 substrates, producing substantially higher amounts of morphine. Hence, polymorphism in maternal drug metabolism may affect neonatal exposure and safety. A subsequent case-control study has shown that this situation is not rare. The FDA has published a warning to lactating mothers to exert extra caution while using painkillers containing codeine. More recent research has also shown that blood-brain barrier levels of P-glycoprotein are lower at birth, allowing more morphine to penetrate into the brain, than later in infancy and childhood. This can explain sedation in breast-fed neonates even when there is no genetic variability in CYP2D6.

Minimal use of alcohol by the mother has not been reported to harm nursing infants. Excessive amounts of alcohol, however, can produce alcohol effects in the infant. Nicotine concentrations in the breast milk of smoking mothers are low and do not produce effects in the infant. Very small amounts of caffeine are excreted in the breast milk of coffee-drinking mothers.

Lithium enters breast milk in concentrations equal to those in maternal serum. Clearance of this drug is almost completely dependent upon renal elimination, and women who are receiving lithium may expose the infant to relatively large amounts of the drug.

Radioactive substances such as iodinated ^{125}I albumin and radioiodine can cause thyroid suppression in infants and may increase the risk of subsequent thyroid cancer as much as tenfold.

Breast-feeding is contraindicated after large doses and should be withheld for days to weeks after small doses. Similarly, breast-feeding should be avoided in mothers receiving cancer chemotherapy or being treated with cytotoxic or immunomodulating agents for collagen diseases such as lupus erythematosus or after organ transplantation.

PEDIATRIC DRUG DOSAGE

Because of differences in pharmacokinetics in infants and children, simple proportionate reduction in the adult dose may not be adequate to determine a safe and effective pediatric dose. The most reliable pediatric dose information is usually that provided by the manufacturer in the package insert. However, such information is not available for the majority of products, even when studies have been published in the medical literature, reflecting the reluctance of manufacturers to label their products for children. Recently, the FDA has moved toward more explicit expectations that manufacturers test their new products in infants and children. Still, most drugs in the common formularies, eg, *Physicians’ Desk Reference*, are not specifically approved for children, in part because manufacturers often lack the economic incentive to evaluate drugs for use in the pediatric market.

Most drugs approved for use in children have recommended pediatric doses, generally stated as milligrams per kilogram or per pound. In the absence of explicit pediatric dose recommendations, an approximation can be made by any of several methods based on age, weight, or surface area. These rules are not precise and should not be used if the manufacturer provides a pediatric dose. When pediatric doses are calculated (either from one of the methods set forth below or from a manufacturer’s dose), the pediatric dose should never exceed the adult dose.

The current epidemic proportions of childhood obesity calls for a fresh and careful look at pediatric drug dosages. Studies in adults indicate that dosing based on per-kilogram body weight may constitute overdosing, because in obese subjects, drugs are distributed based on lean body weight.

Surface Area, Age, & Weight

Calculations of dosage based on age or weight (see below) are conservative and tend to underestimate the required dose. Doses based on surface area (Table 59–6) are more likely to be adequate.

Age (Young’s rule):

$$\text{Dose} = \text{Adult dose} \times \frac{\text{Age (years)}}{\text{Age} + 12}$$

Weight (somewhat more precise is Clark’s rule):

$$\text{Dose} = \text{Adult dose} \times \frac{\text{Weight (kg)}}{70}$$

or

$$\text{Dose} = \text{Adult dose} \times \frac{\text{Weight (lb)}}{150}$$

TABLE 59–6 Determination of drug dosage from surface area.¹

Weight		Approximate Age	Surface Area (m ²)	Percent of Adult Dose
(kg)	(lb)			
3	6.6	Newborn	0.2	12
6	13.2	3 months	0.3	18
10	22	1 year	0.45	28
20	44	5.5 years	0.8	48
30	66	9 years	1	60
40	88	12 years	1.3	78
50	110	14 years	1.5	90
60	132	Adult	1.7	102
70	154	Adult	1.76	103

¹For example, if adult dose is 1 mg/kg, dose for 3-month-old infant would be 0.18 mg/kg or 1.1 mg total.

Despite these approximations, only by conducting studies in children can safe and effective doses for a given age group and condition be determined.

Special Aspects of
Geriatric Pharmacology

Bertram G. Katzung, MD, PhD

CASE STUDY

A 77-year-old man comes to your office at his wife's insistence. He has had documented moderate hypertension for 18 years but does not like to take his medications. He says he has no real complaints, but his wife remarks that he has become much more forgetful lately and has almost stopped reading the newspaper and watching television. A Mini-Mental State Examination reveals that he is oriented as to name and place but is unable to give the month or year.

He cannot remember the names of his three adult children or three random words (eg, tree, flag, chair) for more than 2 minutes. No cataracts are visible, but he is unable to read standard newsprint without a powerful magnifier. Why doesn't he take his antihypertensive medications? What therapeutic measures are available for the treatment of Alzheimer's disease? How might macular degeneration be treated?

Society has traditionally classified everyone over 65 as "elderly," but most authorities consider the field of geriatrics to apply to persons over 75—even though this too is an arbitrary definition. Furthermore, chronologic age is only one determinant of the changes pertinent to drug therapy that occur in older people. In addition to the chronic diseases of adulthood, the elderly have an increased incidence of many conditions, including Alzheimer's disease, Parkinson's disease, and vascular dementia; stroke; visual impairment, especially cataracts and macular degeneration; atherosclerosis, coronary and peripheral vascular disease, and heart failure; diabetes; arthritis, osteoporosis, and fractures; cancer; and incontinence. As a result, the need for drug treatment is great in this age group. And as the average life span approaches (and in some countries, already exceeds) 80, this need will increase dramatically.

When all confounders are accounted for, age itself is still the strongest risk factor for cardiovascular and neurodegenerative diseases and most forms of cancer. Research into the molecular basis of aging has answered a few questions and opened many more. It has long been known that caloric restriction alone can prolong the life span of animals, including mammals. Some evidence suggests

that calorically restricted mice also remain healthier for a longer time. Drugs that mimic caloric restriction have been shown to increase lifespan in the nematode *Caenorhabditis elegans*, as well as other species, including mice. **Metformin** and **rapamycin** each increase life span in these species when given alone and appear to have synergistic effects when given together. Sirtuins, a class of endogenous protein deacetylase enzymes, may be linked to life span in some species, but activators (such as resveratrol) of certain sirtuins have not been shown to prolong life in mice. Assuming that safer alternatives to metformin or rapamycin can be found, should everyone over the age of 40 or 60 years take such a drug? Few would maintain that a simple increase in the years of life—life span—is desirable unless accompanied by an increase in the years of healthy life—"health span." Provocative research suggests that variables such as telomere length on chromosomes may predict prospective life span and that proteins in the blood of young animals may "rejuvenate" older animals, but these studies provide no guidance regarding the current treatment of diseases in older patients.

Important changes in responses to some drugs occur with increasing age in many individuals. For other drugs, age-related

changes are minimal, especially in the “healthy old.” Drug usage patterns also change as a result of the increasing incidence of disease with age and the tendency to prescribe heavily for patients in nursing homes. General changes in the lives of older people have significant effects on the way drugs are used. Among these changes with advancing age are the increased incidence of several simultaneous diseases, nutritional problems, reduced financial resources, and—in some patients—decreased dosing adherence (also called compliance) for a variety of reasons. The health practitioner should be aware of the changes in pharmacologic responses that may occur in older people and should know how to deal with these changes. Finally, dependent elders are sometimes abused physically or financially by caregivers at home or in nursing homes, and the health practitioner should investigate abuse as a cause of nonadherence, as well as bruises, dehydration, and other morbidities.

PHARMACOLOGIC CHANGES ASSOCIATED WITH AGING

In the general population, measurements of functional capacity of most of the major organ systems show a decline beginning in young adulthood and continuing throughout life. As shown in Figure 60–1, there is no “middle-age plateau” but rather a linear decrease beginning no later than age 45. However, these data reflect the mean and do not apply to every person above a certain age; approximately one third of healthy subjects have no age-related decrease in, for example, creatinine clearance up to the age of 75. Some of these changes result in altered pharmacokinetics.

FIGURE 60–1 Effect of age on some physiologic functions.

(Adapted, with permission, from Kohn RR: *Principles of Mammalian Aging*. Copyright copy; 1978 by Prentice-Hall, Inc. Used by permission of Pearson Education, Inc.)

For the pharmacologist and the clinician, the most important of these is the decrease in renal function. Other changes and concurrent diseases may alter the pharmacodynamic characteristics of particular drugs in certain patients.

Pharmacokinetic Changes

A. Absorption

There is little evidence of any major alteration in drug absorption with age. However, conditions associated with age may alter the rate at which some drugs are absorbed. Such conditions include altered nutritional habits, greater consumption of nonprescription drugs (eg, antacids and laxatives), and changes in gastric emptying, which is often slower in older persons, especially in older diabetics.

B. Distribution

Compared with young adults, the elderly have reduced lean body mass, reduced body water, and increased fat as a percentage of body mass. Some of these changes are shown in Table 60–1. There is usually a decrease in serum albumin, which binds many drugs, especially weak acids. There may be a concurrent *increase* in serum orosomucoid (α -acid glycoprotein), a protein that binds many basic drugs. Thus, the ratio of bound to free drug may be significantly altered. As explained in Chapter 3, these changes may alter the appropriate loading dose of a drug. However, since both the clearance and the effects of drugs are related to the free concentration, the steady-state effects of a maintenance dosage regimen should not be altered by these factors alone. For example, the loading dose of digoxin in an elderly patient with heart failure should be reduced (if used at all) because of the decreased apparent volume of distribution. The maintenance dose may have to be reduced because of reduced clearance of the drug.

C. Metabolism

The capacity of the liver to metabolize drugs declines with age for some, but not all, drugs. Animal studies and some clinical studies have suggested that certain drugs are metabolized more slowly

TABLE 60–1 Some changes related to aging that affect pharmacokinetics of drugs.

Variable	Young Adults (20–30 years)	Older Adults (60–80 years)
Body water (% of body weight)	61	53
Lean body mass (% of body weight)	19	12
Body fat (% of body weight)	26–33 (women)	38–45
	18–20 (men)	36–38
Serum albumin (g/dL)	4.7	3.8
Kidney weight (% of young adult)	100	80
Hepatic blood flow (% of young adult)	100	55–60

TABLE 60–2 Effects of age on hepatic clearance of some drugs.

Age-Related Decrease in Hepatic Clearance Found	No Age-Related Difference Found
Alprazolam	Ethanol
Barbiturates	Isoniazid
Carbenoxolone	Lidocaine
Chlordiazepoxide	Lorazepam
Chlormethiazole	Nitrazepam
Clobazam	Oxazepam
Desmethyldiazepam	Prazosin
Diazepam	Salicylate
Flurazepam	Warfarin
Imipramine	
Meperidine	
Nortriptyline	
Phenylbutazone	
Propranolol	
Quinidine, quinine	
Theophylline	
Tolbutamide	

in the elderly; some of these drugs are listed in Table 60–2. The greatest changes are in phase I reactions, ie, those carried out by microsomal P450 systems. There are much smaller changes in the ability of the liver to carry out conjugation (phase II) reactions (see Chapter 4). Some of these changes may be caused by decreased liver blood flow (Table 60–1), an important variable in the clearance of drugs that have a high hepatic extraction ratio. In addition, there is a decline with age of the liver's ability to recover from injury, eg, that caused by alcohol or viral hepatitis. Therefore, a history of recent liver disease in an older person should lead to caution in dosing with drugs that are cleared primarily by the liver, even after apparently complete recovery from the hepatic insult. Finally, malnutrition and diseases that affect hepatic function—eg, heart failure—are more common in the elderly. Heart failure may dramatically alter the ability of the liver to metabolize drugs by reducing hepatic blood flow. Similarly, severe nutritional deficiencies, which occur more often in old age, may impair hepatic function.

D. Elimination

Because the kidney is the major organ for clearance of drugs from the body, the age-related decline of renal functional capacity is very important. A decline in creatinine clearance (Cl_{cr})—the usual measure of estimated glomerular filtration rate (eGFR)—occurs in about two thirds of the population. It is important to note that this decline is not reflected in an equivalent rise in serum creatinine because the production of creatinine is also reduced as muscle mass declines with age; therefore, serum creatinine alone is not an adequate measure of renal function. The practical result of

this change is marked prolongation of the half-life of many drugs, and the possibility of accumulation to toxic levels if dosage is not reduced in size or frequency. Dosing recommendations for the elderly often include an allowance for reduced renal clearance. If only the young adult dosage is known for a drug that requires renal clearance, a rough correction can be made by using the **Cockcroft-Gault** formula to estimate the GFR and multiplying the recommended young adult dosage by eGFR/100. The Cockcroft-Gault formula is applicable to patients age 40 through 80:

$$\begin{aligned} &\text{Estimated creatinine clearance (mL/min)} \\ &= \frac{(140 - \text{Age}) \times (\text{Weight in kg})}{72 \times \text{Serum creatinine in mg/dL}} \end{aligned}$$

For women, the result should be multiplied by 0.85 (because of reduced muscle mass). It must be emphasized that this estimate is, at best, a *population* estimate and may not apply to a particular patient. If the patient has normal renal function (up to one third of elderly patients), a dose corrected on the basis of this estimate will be too low—but a low dose is initially desirable if one is uncertain of the renal function in any patient. Simple online calculators using the more modern MDRD (Modification of Diet in Renal Disease) formula are available, eg, <http://nkdep.nih.gov/lab-evaluation/gfr-calculators.shtml>.

If a precise measure is needed, a standard 12- or 24-hour creatinine clearance determination should be obtained. As indicated above, nutritional changes alter pharmacokinetic parameters. A patient who is severely dehydrated (not uncommon in patients with stroke or other motor impairment) may have an additional marked reduction in renal drug clearance that is completely reversible by rehydration.

The lungs are important for the excretion of volatile drugs. As a result of reduced respiratory capacity (Figure 60–1) and the increased prevalence of active pulmonary disease in the elderly, the use of inhalation anesthesia is less common and intravenous agents more common in this age group. (See Chapter 25.)

Pharmacodynamic Changes

It was long believed that geriatric patients were much more “sensitive” to the action of many drugs, implying a change in the pharmacodynamic interaction of the drugs with their receptors. It is now recognized that many—perhaps most—of these apparent changes result from altered pharmacokinetics or diminished homeostatic responses. Clinical studies have supported the idea that the elderly are more sensitive to *some* sedative-hypnotics and analgesics. In addition, some data from animal studies suggest actual changes with age in the characteristics or numbers of a few receptors. The most extensive studies suggest a decrease in responsiveness to β -adrenoceptor agonists. Other examples are discussed below.

Important homeostatic control mechanisms appear to be blunted in the elderly. Since homeostatic responses are often significant contributors to the overall response to a drug, these physiologic alterations may change the pattern or intensity of drug response. In the cardiovascular system, the cardiac output

increment required by mild or moderate exercise is successfully provided until at least age 75 (in individuals without obvious cardiac disease), but the increase is the result primarily of increased stroke volume in the elderly and not tachycardia, as in young adults. Average blood pressure goes up with age (in most Western countries), but the incidence of symptomatic orthostatic *hypotension* also increases markedly. It is thus particularly important to check for orthostatic hypotension (>20 mm Hg drop in systolic blood pressure on standing) on every visit. Similarly, the average 2-hour postprandial blood glucose level increases by about 1 mg/dL for each year of age above 50. Temperature regulation is also impaired, and hypothermia is poorly tolerated by the elderly.

Behavioral & Lifestyle Changes

Major changes in the conditions of daily life accompany the aging process and have an impact on health. Some of these (eg, forgetting to take one's pills) are the result of cognitive changes associated with vascular or other pathology. One of the most important changes is the loss of a spouse. Others relate to economic stresses associated with greatly reduced income and, frequently, increased expenses due to illness.

■ MAJOR DRUG GROUPS

CENTRAL NERVOUS SYSTEM DRUGS

Sedative-Hypnotics

The half-lives of many benzodiazepines and barbiturates increase by 50–150% between ages 30 and 70. Much of this change occurs during the decade from 60 to 70. For some of the benzodiazepines, both the parent molecule and its metabolites (produced in the liver) are pharmacologically active (see Chapter 22). The age-related decline in renal function and liver disease, if present, both contribute to the reduction in elimination of these compounds. In addition, an increased volume of distribution has been reported for some of these drugs. Lorazepam and oxazepam may be less affected by these changes than the other benzodiazepines. In addition to these pharmacokinetic factors, it is generally believed that the elderly vary more in their sensitivity to the sedative-hypnotic drugs on a pharmacodynamic basis as well. Among the toxicities of these drugs, ataxia and other stability impairments lead to increased falls and fractures.

Analgesics

The opioid analgesics show variable changes in pharmacokinetics with age. However, the elderly are often markedly more sensitive to the respiratory effects of these agents because of age-related changes in respiratory function. Therefore, this group of drugs should be used with caution until the sensitivity of the particular patient has been evaluated, and the patient should then be dosed appropriately for full effect. Opioids are not as effective in chronic pain syndromes as they are for acute pain, eg, fracture pain (see Chapter 31). Unfortunately, studies show that opioids are consistently *underutilized* in patients who require strong analgesics for

chronic painful conditions such as cancer. Good pain management plans are readily available (see Morrison, 2006; Rabow and Pantilat, 2011).

Antipsychotic & Antidepressant Drugs

The traditional antipsychotic agents (phenothiazines and haloperidol) have been very heavily used (and often misused) in the management of a variety of psychiatric conditions in the elderly. There is no doubt that they are useful in the management of schizophrenia in old age, and also in the treatment of some symptoms associated with delirium, dementia, agitation, combativeness, and a paranoid syndrome that occurs in some geriatric patients (see Chapter 29). However, they are not fully satisfactory in these geriatric conditions, and dosage should not be increased on the assumption that full control is possible. There is no evidence that these drugs have any beneficial effects in Alzheimer's dementia, and on theoretical grounds the antimuscarinic effects of the phenothiazines might be expected to worsen memory impairment and intellectual dysfunction (see below).

Much of the apparent improvement produced by these drugs in agitated and combative patients may simply reflect their sedative effects. When a sedative antipsychotic is desired, a phenothiazine such as thioridazine is appropriate. If sedation is to be avoided, haloperidol or a second generation (atypical) antipsychotic is more appropriate. Haloperidol has increased extrapyramidal toxicity, however, and should be avoided in patients with preexisting extrapyramidal disease. The phenothiazines, especially older drugs such as chlorpromazine, often induce orthostatic hypotension because of their α -adrenoceptor-blocking effects. They are even more prone to do so in the elderly. Dosage of these drugs should usually be started at a fraction of that used in young adults. The second generation antipsychotic agents (clozapine, olanzapine, quetiapine, risperidone, aripiprazole) do not appear to be significantly superior to the traditional agents although they have fewer autonomic adverse effects. Evidence supporting the benefits of olanzapine is somewhat stronger than that for the other second generation agents.

Lithium is often used in the treatment of mania in the aged. Because it is cleared by the kidneys, dosages must be adjusted appropriately and blood levels monitored. Concurrent use of thiazide diuretics reduces the clearance of lithium and should be accompanied by further reduction in dosage and more frequent measurement of lithium blood levels.

Psychiatric depression is thought to be underdiagnosed and undertreated in the elderly. The suicide rate in the over-65 age group (twice the national average) supports this view. Unfortunately, the apathy, flat affect, and social withdrawal of major depression may be mistaken for senile dementia. Clinical evidence suggests that the elderly are as responsive to antidepressants (of all types) as younger patients but are more likely to experience adverse effects. This factor along with the reduced clearance of some of these drugs underlines the importance of careful dosing and strict attention to the monitoring of toxic effects. Some authorities prefer selective serotonin reuptake inhibitors (SSRIs) to tricyclic antidepressants because the SSRIs have fewer autonomic adverse effects. If a tricyclic is to be used, a drug with

reduced antimuscarinic effects should be selected, eg, nortriptyline or desipramine (see Table 30–2).

Drugs Used in Alzheimer's Disease

Alzheimer's disease (AD) is characterized by progressive memory impairment, dementia, and cognitive dysfunction, and may lead to a completely vegetative state, resulting in early death. Prevalence increases with age and may be as high as 20% in individuals over 85, although long-term epidemiologic studies suggest that the overall prevalence of dementia has *decreased* in the USA and Europe over the last 15–30 years (see Langa 2017). The annual cost of dementia in the United States is estimated at \$150–\$215 billion annually. Both familial and sporadic forms have been identified. Early onset of Alzheimer's disease is associated with several gene defects, including trisomy 21 (chromosome 21), a mutation of the gene for presenilin-1 on chromosome 14, and an abnormal allele, $\epsilon 4$, for the lipid-associated protein, ApoE, on chromosome 19. Unlike the common forms (ApoE $\epsilon 2$ and $\epsilon 3$), the $\epsilon 4$ form strongly correlates with the formation of amyloid β deposits (see below).

Pathologic changes include increased deposits of **amyloid beta ($A\beta$)** peptide in the cerebral cortex, which eventually forms extracellular plaques and cerebral vascular lesions, and intra- and interneuronal fibrillary tangles consisting of the **tau protein**

(Figure 60–2). There is a progressive loss of neurons, especially cholinergic neurons, and thinning of the cortex. An inflammatory process involving the NLRP3 inflammasome appears to contribute to this pathology, and anti-inflammatory nonsteroidal anti-inflammatory drugs (NSAIDs), eg, mefenamic acid, reverse some of the markers of Alzheimer's disease in animal models. The loss of cholinergic neurons results in a marked decrease in choline acetyltransferase and other markers of cholinergic activity. Patients with Alzheimer's disease are often exquisitely sensitive to the central nervous system toxicities of drugs with antimuscarinic effects. Some evidence implicates excess excitation by glutamate as a contributor to neuronal death. In addition, abnormalities of mitochondrial function may contribute to neuronal death.

Many methods of treatment of Alzheimer's disease have been explored (Table 60–3). Much attention has been focused on the cholinomimetic drugs because of the evidence of loss of cholinergic neurons noted earlier. Monoamine oxidase (MAO) type B inhibition with selegiline (*L*-deprenyl) has been suggested to have some beneficial effects. One drug that inhibits *N*-methyl-D-aspartate (NMDA) glutamate receptors is available (see below), and “ampakines,” substances that facilitate synaptic activity at glutamate AMPA receptors, are under intense study. Some evidence suggests that lipid-lowering statins are beneficial. So-called cerebral vasodilators are ineffective.

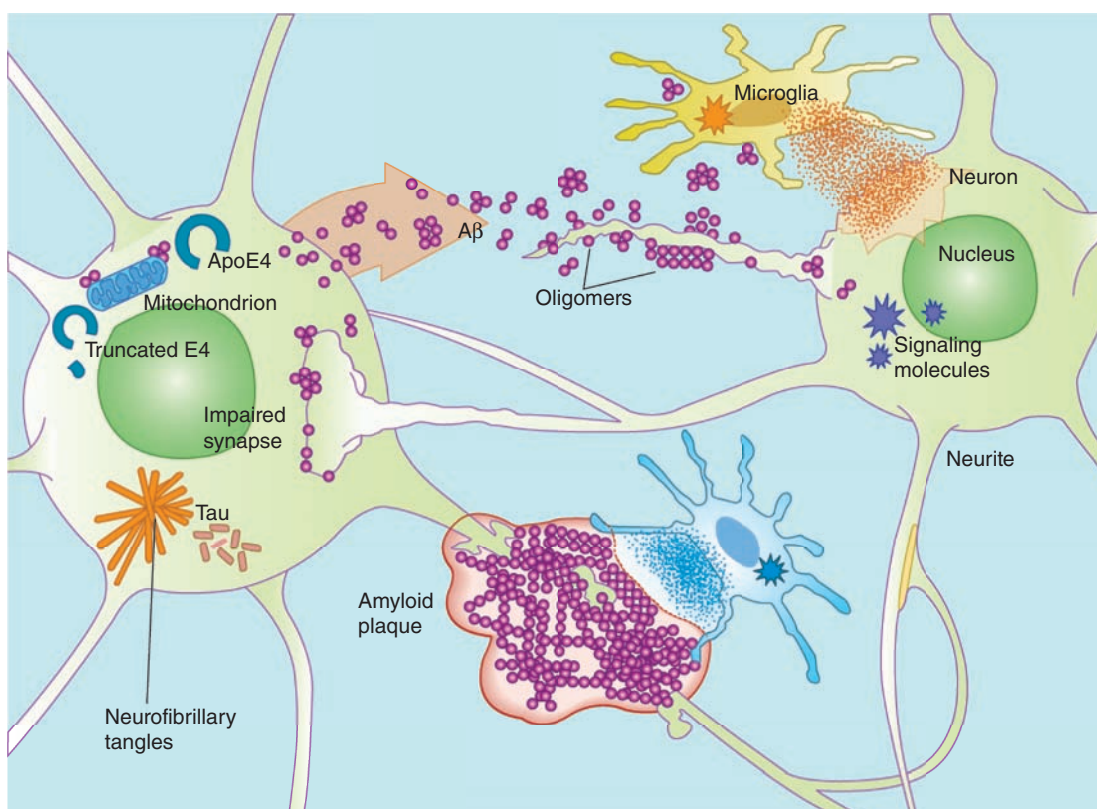

FIGURE 60–2 Some processes involved in Alzheimer's disease. From the left: Mitochondrial dysfunction, possibly involving glucose utilization; synthesis of protein tau and aggregation in filamentous tangles; synthesis of amyloid beta ($A\beta$) and secretion into the extracellular space, where it may interfere with synaptic signaling and accumulates in plaques. (Reproduced, with permission, from Roberson ED, Mucke L: 100 years and counting: Prospects for defeating Alzheimer's disease. *Science* 2006;314:781. Reprinted with permission from AAAS.)

TABLE 60–3 Some potential strategies for the prevention or treatment of Alzheimer's disease.

Therapy	Comment
Cholinesterase inhibitors	Increase cholinergic activity; 4 drugs approved
<i>N</i> -methyl-D-aspartate glutamate antagonists	Inhibit glutamate excitotoxicity; 1 drug approved
Modifiers of glucose utilization	PPAR- γ agonists
Antilipid drugs	Statins (off-label use)
Retinoid X receptor	Bexarotene transiently reduced A β in mice
NSAIDs	Disappointing results with cyclooxygenase (COX)-2 inhibitors but interest continues
Anti-amyloid vaccines	In clinical trials
Anti-amyloid antibodies	Bapineuzumab and solanezumab failed clinical trials but did modify A β kinetics; should treatment be started <i>before</i> symptoms appear?
Inhibitors of A β synthesis	γ -Secretase modulator studies in progress
Microtubule stabilizers	Drugs that inhibit disassembly of microtubules reduce accumulation of tau protein tangles in mice
Anticytokine antibodies	Anti-IL-12 and -23 antibodies reversed age-related cognitive decline and A β accumulation in mice
Antioxidants	Disappointing results
Nerve growth factor	One very small trial
PERK inhibitor GSK2606414	Preliminary study in mice

A β , amyloid beta; IL, interleukin; PERK, protein kinase RNA-like ER kinase; PPAR- γ , peroxisome proliferator-activated receptor-gamma.

Tacrine (tetrahydroaminoacridine, THA), a long-acting cholinesterase inhibitor and muscarinic modulator, was the first drug shown to have any benefit in Alzheimer's disease. Because of its hepatic toxicity, tacrine has been replaced in clinical use by newer cholinesterase inhibitors: **donepezil**, **rivastigmine**, and **galantamine**. These agents are orally active, have adequate penetration into the central nervous system, and are much less toxic than tacrine. Although evidence for the benefit of cholinesterase inhibitors (and memantine; see below) is statistically significant, the amount of benefit is modest and does not prevent the progression of the disease. The cholinesterase inhibitors cause significant adverse effects, including nausea and vomiting, diarrhea, and other peripheral cholinomimetic effects. These drugs should be used with caution in patients receiving other drugs that inhibit cytochrome P450 enzymes (eg, ketoconazole, quinidine; see Chapter 4). Preparations available are listed in Chapter 7.

Excitotoxic activation of glutamate transmission via NMDA receptors has been postulated to contribute to the pathophysiology of Alzheimer's disease. **Memantine** binds to NMDA receptor channels in a use-dependent manner and produces a noncompetitive blockade.

Its modest efficacy in moderate-to-severe Alzheimer's disease is similar to or smaller than that of the cholinesterase inhibitors. In contrast, a small study of memantine in Alzheimer's disease in persons with Down syndrome found no benefit. However, this drug may be better tolerated and less toxic than the cholinesterase inhibitors. Combination therapy with both memantine and one of the cholinesterase inhibitors has produced mixed results. Memantine is available as Namenda in 5 and 10 mg oral tablets.

Recent research has focused on amyloid beta, because the characteristic plaques consist mostly of this peptide. Unfortunately, two anti-amyloid antibodies, **solanezumab** and **bapineuzumab**, both failed to improve cognition or slow progression in recent clinical trials. **Verubecestat**, an inhibitor of beta-site amyloid precursor protein cleaving enzyme (BACE1), reduces the production of amyloid β . This drug showed safety in an early clinical trial, and longer-term phase 3 trials for efficacy are under way. Another effort suggests that the accumulation of filamentous tangles of tau protein is a critical component of neuronal damage in Alzheimer's and several other neurodegenerative conditions. Accumulation of tau appears to be associated with dissociation from microtubules in neurons, which has stimulated interest in drugs that inhibit microtubule disassembly, such as **epothilone-D**.

CARDIOVASCULAR DRUGS

Antihypertensive Drugs

Blood pressure, especially systolic pressure, increases with age in Western countries and in most cultures in which salt intake is high. In women, the increase is more marked after age 50. Although often ignored in the past, clinicians now believe that hypertension should be treated in the elderly. In fact, more aggressive treatment of hypertension is one factor that may contribute to the reported decline in the incidence of dementia.

The basic principles of therapy are not different in the geriatric age group from those described in Chapter 11, but the usual cautions regarding altered pharmacokinetics and blunted compensatory mechanisms apply. Because of its safety, nondrug therapy (weight reduction in the obese and moderate salt restriction) should be encouraged. Thiazides are a reasonable first step in drug therapy. The hypokalemia, hyperglycemia, and hyperuricemia caused by these agents are more relevant in the elderly because of the higher prevalence in these patients of arrhythmias, type 2 diabetes, and gout. Thus, use of low antihypertensive doses—rather than maximum diuretic doses—is important. Calcium channel blockers are effective and safe if titrated to the appropriate response. They are especially useful in patients who also have atherosclerotic angina (see Chapter 12). Beta blockers are potentially hazardous in patients with obstructive airway disease and are considered less useful than calcium channel blockers in older patients unless chronic heart failure is present. Angiotensin-converting enzyme inhibitors are also considered less useful in the elderly unless heart failure or diabetes is present. The most powerful drugs, such as minoxidil, are rarely needed. Every patient receiving antihypertensive drugs should be checked regularly for orthostatic hypotension because of the danger of cerebral ischemia and falls.

Positive Inotropic Agents

Heart failure is a common and particularly lethal disease in the elderly. Fear of this condition is one reason why physicians overuse cardiac glycosides in this age group. The toxic effects of digoxin are particularly dangerous in the geriatric population, since the elderly are more susceptible to arrhythmias. The clearance of digoxin is usually decreased in the older age group, and although the volume of distribution is often decreased as well, the half-life of this drug may be increased by 50% or more. Because the drug is cleared mostly by the kidneys, renal function must be considered in designing a dosage regimen. There is no evidence that there is any increase in pharmacodynamic sensitivity to the therapeutic effects of the cardiac glycosides; in fact, animal studies suggest a possible decrease in therapeutic sensitivity. On the other hand, there is probably an increase in sensitivity to the toxic arrhythmogenic actions. Hypokalemia, hypomagnesemia, hypoxemia (from pulmonary disease), and coronary atherosclerosis all contribute to the high incidence of digitalis-induced arrhythmias in geriatric patients. The less common toxicities of digitalis such as delirium, visual changes, and endocrine abnormalities (see Chapter 13) also occur more often in older than in younger patients.

Antiarrhythmic Agents

The treatment of arrhythmias in the elderly is particularly challenging because of the lack of good hemodynamic reserve, the frequency of electrolyte disturbances, and the high prevalence of significant coronary disease. The clearances of quinidine and procainamide decrease and their half-lives increase with age. Disopyramide should probably be avoided in the geriatric population because its major toxicities—antimuscarinic action, leading to voiding problems in men; and negative inotropic cardiac effects, leading to heart failure—are particularly undesirable in these patients. The clearance of lidocaine appears to be little changed, but the half-life is increased in the elderly. It is recommended that the loading dose of this drug be reduced in geriatric patients because of their greater sensitivity to its toxic effects.

Recent evidence indicates that many patients with atrial fibrillation—a very common arrhythmia in the elderly—do as well with simple control of ventricular rate as with conversion to normal sinus rhythm. Measures (such as anticoagulant drugs) must be taken to reduce the risk of thromboembolism in chronic atrial fibrillation.

ANTIMICROBIAL THERAPY

Several age-related changes contribute to the high incidence of infections in geriatric patients. A reduction in host defenses in the elderly is manifested in the increase in both serious infections and cancer. This may reflect an alteration in T-lymphocyte function. In the lungs, a major age and tobacco-dependent decrease in mucociliary clearance significantly increases susceptibility to infection. In the urinary tract, the incidence of serious infection is greatly increased by urinary retention and catheterization in men. Preventive immunizations should be maintained: influenza

vaccine should be given annually, tetanus toxoid every 10 years, and pneumococcal and zoster vaccines once.

Since 1940, the antimicrobial drugs have contributed more to the prolongation of life than any other drug group because they can compensate to some extent for this deterioration in natural defenses. The basic principles of therapy of the elderly with these agents are no different from those applicable in younger patients and have been presented in Chapter 51. The major pharmacokinetic changes relate to decreased renal function; because most of the β -lactam, aminoglycoside, and fluoroquinolone antibiotics are excreted by this route, important changes in half-life may be expected. This is particularly important in the case of the aminoglycosides, because they cause concentration- and time-dependent toxicity in the kidney and in other organs. The half-lives of gentamicin, kanamycin, and netilmicin are more than doubled. The increase may be less marked for tobramycin.

ANTI-INFLAMMATORY DRUGS

Osteoarthritis is a very common disease of the elderly. Rheumatoid arthritis is less exclusively a geriatric problem, but the same drug therapy is usually applicable to both types of disease. The basic principles laid down in Chapter 36 and the properties of the anti-inflammatory drugs described there apply fully here.

The nonsteroidal anti-inflammatory agents (NSAIDs) must be used with special care in geriatric patients because they cause toxicities to which the elderly are very susceptible. In the case of aspirin, the most important of these is gastrointestinal irritation and bleeding. In the case of the newer NSAIDs, the most important is renal damage, which may be irreversible. Because they are cleared primarily by the kidneys, these drugs accumulate more rapidly in the geriatric patient and especially in the patient whose renal function is already compromised beyond the average range for his or her age. A vicious circle is easily set up in which cumulation of the NSAID causes more renal damage, which causes more cumulation. There is no evidence that the cyclooxygenase (COX)-2 selective NSAIDs are safer with regard to renal function. Elderly patients receiving high doses of any NSAID should be carefully monitored for changes in renal function.

Corticosteroids are extremely useful in elderly patients who cannot tolerate full doses of NSAIDs. However, they consistently cause a dose- and duration-related increase in osteoporosis, an especially hazardous toxic effect in the elderly. It is not certain whether this drug-induced effect can be reduced by increased calcium and vitamin D intake, but it would be prudent to consider these agents (and bisphosphonates if osteoporosis is already present, see Qaseem reference) and to encourage frequent exercise in any patient taking corticosteroids.

OPHTHALMIC DRUGS

Drugs Used in Glaucoma

Glaucoma is more common in the elderly, but its treatment does not differ from that of glaucoma of earlier onset. Management of glaucoma is discussed in Chapter 10.

Macular Degeneration

Age-related macular degeneration (AMD) is the most common cause of blindness in the elderly in the developed world. Two forms of advanced AMD are recognized: the neovascular “wet” form, which is associated with intrusion of new blood vessels in the subretinal space, and a more common “dry” form, which is not associated with abnormal vascularization. Although the cause of AMD is not known, smoking is a documented risk factor, and oxidative stress has long been thought to play a role. On this premise, antioxidants have been used to prevent or delay the onset of AMD. Proprietary oral formulations of vitamins C and E, β -carotene, zinc oxide, and cupric oxide are available. Some include the carotenoids lutein and zeaxanthin, and omega-3 long-chain polyunsaturated fatty acids. Evidence for the efficacy of these antioxidants is modest.

In advanced neovascular AMD, treatment has been moderately successful. This form of AMD can now be treated with laser phototherapy or with antibodies against vascular endothelial growth factor (VEGF). Two antibodies are available—bevacizumab (Avastin, used off-label) and ranibizumab (Lucentis)—as well as aflibercept (Eylea, a decoy protein receptor that binds VEGF) and the oligopeptide pegaptanib (Macugen). Aflibercept is also approved for the treatment of diabetic macular degeneration. These agents are injected into the vitreous for local effect. Ranibizumab is extremely expensive. Other agents that bind VEGF are under study.

■ ADVERSE DRUG REACTIONS IN THE ELDERLY

The relation between the number of drugs taken and the incidence of adverse drug reactions (ADRs) has been well documented. In long-term care facilities, in which a high percentage of the population is elderly, the average number of prescriptions per patient varies between 6 and 8. Studies have shown that the percentage of patients with adverse reactions increases from about 10% when a single drug is being taken to nearly 100% when 10 drugs are taken. Thus, it may be expected that about half of patients in long-term care facilities will have recognized or unrecognized ADRs at some time. Patients living at home may see several different practitioners for different conditions and accumulate multiple prescriptions for drugs with overlapping actions. It is useful to conduct a “brown bag” analysis in such patients. The brown bag analysis consists of asking the patient to bring to the practitioner a bag containing *all* the medications, supplements, vitamins, etc, that he or she is currently taking. Some prescriptions will be found to be duplicates, and others unnecessary. The total number of medications taken can often be reduced by 30–50%.

The overall incidence of ADRs in geriatric patients is estimated to be at least twice that in the younger population. Reasons for this high incidence include errors in prescribing on the part of the practitioners and errors in drug usage by the patient. Practitioner errors sometimes occur because the physician does not appreciate the importance of changes in pharmacokinetics with age and age-related diseases. Some errors occur because the practitioner is

unaware of incompatible drugs prescribed by other practitioners for the same patient. For example, cimetidine, an H_2 -blocking drug heavily prescribed (or recommended in its over-the-counter form) to the elderly, causes a higher incidence of untoward effects (eg, confusion, slurred speech) in the geriatric population than in younger patients. It also inhibits the hepatic metabolism of many drugs, including phenytoin, warfarin, β blockers, and other agents. A patient who has been taking one of the latter agents without untoward effect may develop markedly elevated blood levels and severe toxicity if cimetidine is added to the regimen without adjustment of dosage of the other drugs. Additional examples of drugs that inhibit liver microsomal enzymes and lead to adverse reactions are described in Chapters 4 and 66.

Patient errors may result from nonadherence for reasons described below. In addition, they often result from use of non-prescription drugs taken without the knowledge of the physician. As noted in Chapters 63 and 64, many over-the-counter agents and herbal medications contain “hidden ingredients” with potent pharmacologic effects. For example, many antihistamines contained in over-the-counter drugs have significant sedative effects and are inherently more hazardous in patients with impaired cognitive function. Similarly, their antimuscarinic action may precipitate urinary retention in geriatric men or glaucoma in patients with a narrow anterior chamber angle. If the patient is also taking a metabolism inhibitor such as cimetidine, the probability of an adverse reaction is greatly increased. A patient taking an herbal medication containing ginkgo is more likely to experience bleeding while taking low doses of aspirin.

■ PRACTICAL ASPECTS OF GERIATRIC PHARMACOLOGY

The quality of life in elderly patients can be greatly improved and life span can be prolonged by the intelligent use of drugs. However, the prescriber must recognize several practical obstacles to compliance.

The expense of drugs can be a major disincentive in patients receiving marginal retirement incomes who are not covered or inadequately covered by health insurance. The prescriber must be aware of the cost of the prescription and of cheaper alternative therapies. For example, the monthly cost of arthritis therapy with newer NSAIDs may exceed \$100, whereas that for generic ibuprofen and naproxen, two older but equally effective NSAIDs, about \$20.

Nonadherence may result from forgetfulness or confusion, especially if the patient has several prescriptions and different dosing intervals. A survey carried out in 1986 showed that the population over 65 years of age accounted for 32% of drugs prescribed in the USA, although these patients represented only 11–12% of the population at that time. Since the prescriptions are often written by several different practitioners, there is usually no attempt to design “integrated” regimens that use drugs with similar dosing intervals for the several conditions being treated. Patients may forget instructions regarding the need to complete a fixed duration of therapy when a course of anti-infective drug is being given.

The disappearance of symptoms is often regarded as the best reason to halt drug taking, especially if the prescription was expensive.

Nonadherence may also be deliberate. A decision not to take a drug may be based on prior experience with it. There may be excellent reasons for such “intelligent” noncompliance, and the practitioner should try to elicit them. Such efforts may also improve compliance with alternative drug regimens, because enlisting the patient as a participant in therapeutic decisions increases the motivation to succeed.

Some errors in drug taking are caused by physical disabilities. Arthritis, tremor, and visual problems may all contribute. Liquid medications that are to be measured “by the spoonful” are especially inappropriate for patients with any type of tremor or motor disability. Use of a dosing syringe is essential in such cases. Because of decreased production of saliva, older patients often have difficulty swallowing large tablets. “Childproof” containers are often “elder-proof” if the patient has arthritis. Cataracts and macular degeneration occur in a large number of patients over 70. Therefore, labels on prescription bottles should be large enough for the patient with diminished vision to read or should be color-coded if the patient can see but can no longer read. Because of impaired hearing, even carefully delivered instructions regarding drug use may not be understood by the patient; written instructions may be helpful.

Drug therapy has considerable potential for both helpful and harmful effects in the geriatric patient. The balance may be tipped in the right direction by adherence to a few principles:

1. Take a careful drug history. The disease to be treated may be drug-induced, or drugs being taken may lead to interactions with drugs to be prescribed.
2. Prescribe only for a specific and rational indication. Do not prescribe omeprazole for “dyspepsia.” Expert guidelines are published regularly by national organizations and websites such as UpToDate.com.
3. Define the goal of drug therapy. Then start with small doses and titrate to the response desired. Wait at least three half-lives (adjusted for age) before increasing the dose. If the expected response does not occur at the normal adult dosage, check blood levels. If the expected response does not occur at the appropriate blood level, switch to a different drug.
4. Maintain a high index of suspicion regarding drug reactions and interactions. Know what other drugs the patient is taking, including over-the-counter and botanical (herbal) drugs.
5. Simplify the regimen as much as possible. When multiple drugs are prescribed, try to use drugs that can be taken at the same time of day. Whenever possible, reduce the number of drugs being taken.

CASE STUDY ANSWER

This patient has several conditions that warrant careful treatment. Hypertension is eminently treatable; the steps described in Chapter 11 are appropriate and effective in the elderly as well as in young patients. Patient education is critical in combating his reluctance to take his medications. Alzheimer's disease may respond to one of the anticholinesterase agents (donepezil,

rivastigmine, galantamine). Alternatively, memantine may be tried. Unfortunately, age-related macular degeneration (the most likely cause of his visual difficulties) is not readily treated, but the "wet" (neovascular) variety may respond well to one of the drugs currently available (bevacizumab, ranibizumab, pegaptanib). However, these therapies are expensive.

Dermatologic Pharmacology

Dirk B. Robertson, MD &
Howard I. Maibach, MD

CASE STUDY

A 43-year-old woman presents with a complaint of worsening rosacea. She initially responded to once-daily topical metronidazole 0.75% gel with excellent clearing of the

papulopustular component of her acne rosacea. Recently, she has noted increasing persistent facial erythema. What therapeutic options are available?

Diseases of the skin offer special opportunities to the clinician. In particular, the topical administration route is especially appropriate for skin diseases, although some dermatologic diseases respond as well or better to drugs administered systemically.

The general pharmacokinetic principles governing the use of drugs applied to the skin are the same as those involved in other routes of administration (see Chapters 1 and 3). Although often depicted as a simple three-layered structure, human skin is a complex series of diffusion barriers (Figure 61–1). Quantitation of the flux of drugs and drug vehicles through these barriers is the basis for pharmacokinetic analysis of dermatologic therapy, and techniques for making such measurements are rapidly increasing in number and sensitivity.

Major variables that determine pharmacologic response to drugs applied to the skin include the following:

1. **Regional variation in drug penetration:** For example, the scrotum, face, axilla, and scalp are far more permeable than the forearm and may require less drug for equivalent effect.
2. **Concentration gradient:** Increasing the concentration gradient increases the mass of drug transferred per unit time, just as in the case of diffusion across other barriers (see Chapter 1). Thus, resistance to topical corticosteroids can sometimes be overcome by use of higher concentrations of drug.
3. **Dosing schedule:** Because of its physical properties, skin acts as a reservoir for many drugs. As a result, the “local half-life” may be long enough to permit once-daily application of drugs

with short systemic half-lives. For example, once-daily application of corticosteroids appears to be just as effective as multiple applications in many conditions.

4. **Vehicles and occlusion:** An appropriate vehicle maximizes the ability of the drug to penetrate the outer layers of the skin. In addition, through their physical properties (moistening or drying effects), vehicles may themselves have important therapeutic effects. Occlusion (application of a plastic wrap to hold the drug and its vehicle in close contact with the skin) is extremely effective in maximizing efficacy.

■ REACTIONS TO DERMATOLOGIC MEDICATIONS

Skin reacts to many systemic medications with a variety of symptom-generating responses. In addition, some dermatologic medications themselves cause skin reactions. The major types of reactions are summarized in Table 61–1.

■ DERMATOLOGIC VEHICLES

Topical medications usually consist of active ingredients incorporated in a vehicle that facilitates cutaneous application. Important considerations in vehicle selection include solubility of the active

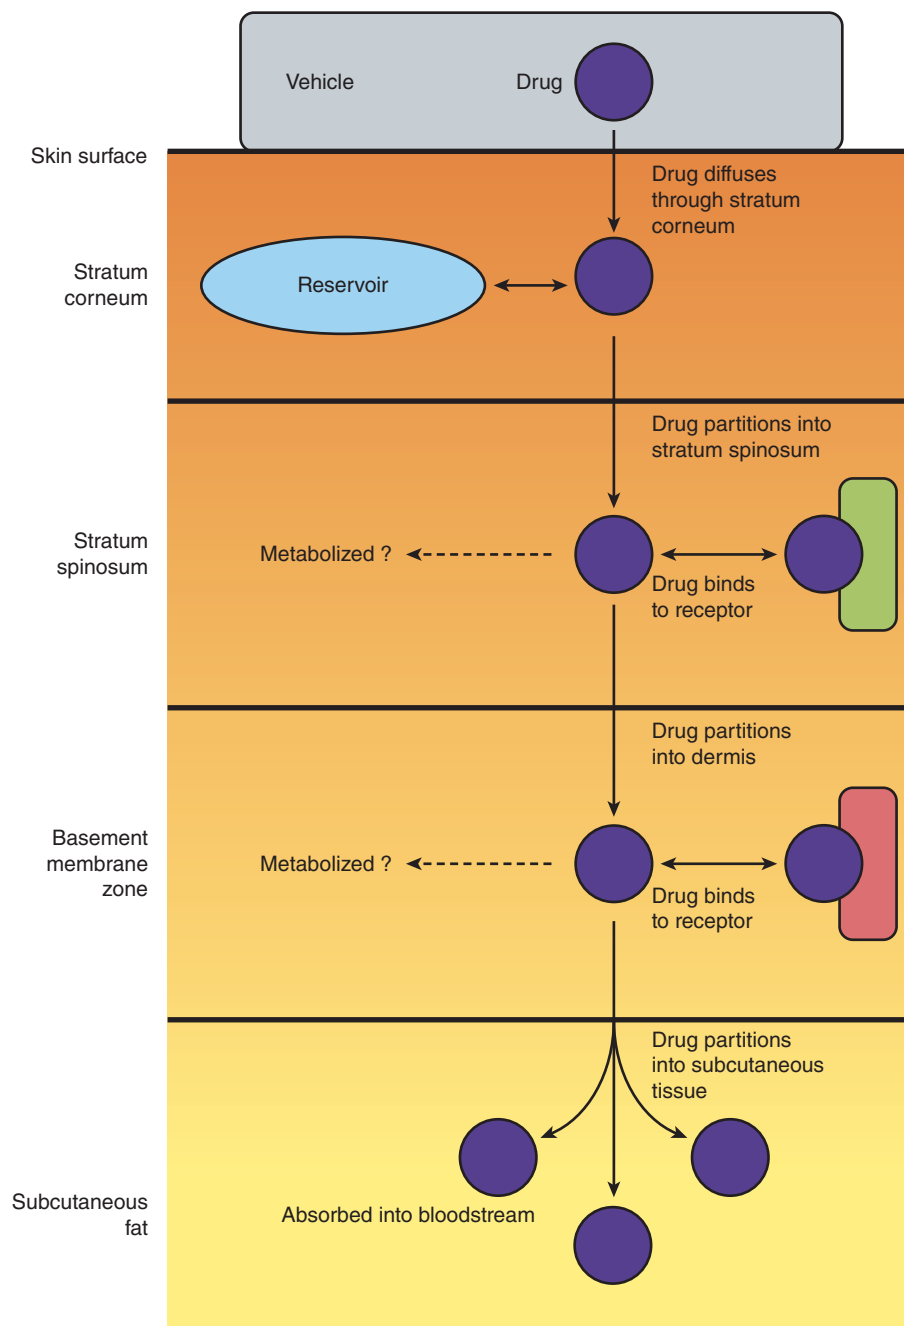

FIGURE 61–1 Schematic diagram of percutaneous absorption. (Redrawn from Orkin M, Maibach HI, Dahl MV: *Dermatology*. Appleton & Lange, 1991.)

agent in the vehicle; the rate of release of the agent from the vehicle; the ability of the vehicle to hydrate the stratum corneum, thus enhancing penetration; the stability of the therapeutic agent in the vehicle; and interactions, chemical and physical, of the vehicle, stratum corneum, and active agent.

Depending upon the vehicle, dermatologic formulations may be classified as tinctures, wet dressings, lotions, gels, aerosols, powders, pastes, creams, foams, and ointments. The ability of the vehicle to retard evaporation from the surface of the skin increases in this series, being least in tinctures and wet dressings and greatest

in ointments. In general, acute inflammation with oozing, vesiculation, and crusting is best treated with drying preparations such as tinctures, wet dressings, and lotions, whereas chronic inflammation with xerosis, scaling, and lichenification is best treated with more lubricating preparations such as creams and ointments. Tinctures, lotions, gels, foams, and aerosols are convenient for application to the scalp and hairy areas. Emulsified vanishing-type creams may be used in intertriginous areas without causing maceration.

Emulsifying agents provide homogeneous, stable preparations when mixtures of immiscible liquids such as oil-in-water creams

TABLE 61–1 Local cutaneous reactions to topical medications.

Reaction Type	Mechanism	Comment
Irritation	Nonallergic	Most common local reaction
Photoirritation	Nonallergic	Phototoxicity; usually requires UVA exposure
Allergic contact dermatitis	Allergic	Type IV delayed hypersensitivity
Photoallergic contact dermatitis	Allergic	Type IV delayed hypersensitivity; usually requires UVA exposure
Immunologic contact urticaria	Allergic	IgE-mediated type I immediate hypersensitivity; may result in anaphylaxis
Nonimmunologic contact urticaria	Nonallergic	Most common contact urticaria; occurs without prior sensitization

are compounded. Some patients develop irritation from these agents. Substituting a preparation that does not contain them or using one containing a lower concentration may resolve the problem.

■ ANTIBACTERIAL AGENTS

TOPICAL ANTIBACTERIAL PREPARATIONS

Topical antibacterial agents may be useful in preventing infections in clean wounds, in the early treatment of infected dermatoses and wounds, in reducing colonization of the nares by staphylococci, in axillary deodorization, and in the management of acne vulgaris. Efficacy of antibiotics in these topical applications is not uniform. The general pharmacology of the antimicrobial drugs is discussed in Chapters 43–51.

Some topical anti-infectives contain corticosteroids in addition to antibiotics. There is no convincing evidence that topical corticosteroids inhibit the antibacterial effect of antibiotics when the two are incorporated in the same preparation. In the treatment of secondarily infected dermatoses, which are usually colonized with streptococci, staphylococci, or both, combination therapy may prove superior to corticosteroid therapy alone. Antibiotic-corticosteroid combinations may be useful in treating diaper dermatitis, otitis externa, and impetiginized eczema.

Selection of a particular antibiotic depends upon the diagnosis and, when appropriate, in vitro culture and sensitivity studies of clinical samples. The pathogens isolated from most infected dermatoses are group A β -hemolytic streptococci, *Staphylococcus aureus*, or both. The pathogens present in surgical wounds will be those resident in the environment. Information about regional patterns of drug resistance is therefore important in selecting a therapeutic agent. Prepackaged topical antibacterial preparations that contain multiple antibiotics are available in fixed dosages well above the therapeutic threshold. These formulations offer the advantages of efficacy in mixed infections, broader coverage for

infections due to undetermined pathogens, and delayed microbial resistance to any single component antibiotic.

BACITRACIN & GRAMICIDIN

Bacitracin and gramicidin are peptide antibiotics, active against Gram-positive organisms such as streptococci, pneumococci, and staphylococci. In addition, most anaerobic cocci, neisseriae, tetanus bacilli, and diphtheria bacilli are sensitive. Bacitracin is compounded in an ointment base alone or in combination with neomycin, polymyxin B, or both. The use of bacitracin in the anterior nares may temporarily decrease colonization by pathogenic staphylococci. Microbial resistance may develop following prolonged use. Bacitracin-induced contact urticaria syndrome, including anaphylaxis, occurs rarely. Allergic contact dermatitis occurs frequently, and immunologic allergic contact urticaria rarely. Bacitracin is poorly absorbed through the skin, so systemic toxicity is rare.

Gramicidin is available only for topical use, in combination with other antibiotics such as neomycin, polymyxin, bacitracin, and nystatin. Systemic toxicity limits this drug to topical use. The incidence of sensitization following topical application is exceedingly low in therapeutic concentrations.

MUPIROCIN

Mupirocin (pseudomonic acid A) is structurally unrelated to other currently available topical antibacterial agents. Most Gram-positive aerobic bacteria, including methicillin-resistant *S aureus* (MRSA), are sensitive to mupirocin (see Chapter 50). It is effective in the treatment of impetigo caused by *S aureus* and group A β -hemolytic streptococci.

Intranasal mupirocin ointment for eliminating nasal carriage of *S aureus* may be associated with irritation of mucous membranes caused by the polyethylene glycol vehicle. Mupirocin is not appreciably absorbed systemically after topical application to intact skin.

RETAPAMULIN

Retapamulin (Altabax) is a semisynthetic pleromutilin derivative effective in the treatment of uncomplicated superficial skin infection caused by group A β -hemolytic streptococci and *S aureus*, excluding MRSA. Topical retapamulin 1% ointment is indicated for use in adult and pediatric patients, 9 months or older, for the treatment of impetigo. Recommended treatment regimen is twice-daily application for 5 days. Retapamulin is well tolerated with only occasional local irritation of the treatment site. Although uncommon, allergic contact dermatitis has been reported.

POLYMYXIN B SULFATE

Polymyxin B is a peptide antibiotic effective against Gram-negative organisms, including *Pseudomonas aeruginosa*, *Escherichia coli*, *Enterobacter*, and *Klebsiella*. Most strains of *Proteus* and *Serratia*

are resistant, as are all Gram-positive organisms. Topical preparations may be compounded in either a solution or ointment base. Numerous prepackaged antibiotic combinations contain polymyxin B. Detectable serum concentrations are difficult to achieve from topical application, but the total daily dose applied to denuded skin or open wounds should not exceed 200 mg in order to reduce the likelihood of neurotoxicity and nephrotoxicity. Allergic contact dermatitis to topically applied polymyxin B sulfate is uncommon.

NEOMYCIN & GENTAMICIN

Neomycin and gentamicin are aminoglycoside antibiotics active against Gram-negative organisms, including *E coli*, *Proteus*, *Klebsiella*, and *Enterobacter*. Gentamicin generally shows greater activity against *P aeruginosa* than neomycin. Gentamicin is also more active against staphylococci and group A β -hemolytic streptococci. Widespread topical use of gentamicin, especially in a hospital environment, should be avoided to slow the appearance of gentamicin-resistant organisms.

Neomycin is available in numerous topical formulations, alone and in combination with polymyxin, bacitracin, and other antibiotics. It is also available as a sterile powder for topical use. Gentamicin is available as an ointment or cream.

Topical application of neomycin rarely results in detectable serum concentrations. However, in the case of gentamicin, serum concentrations of 1–18 mcg/mL are possible if the drug is applied in a water-miscible preparation to large areas of denuded skin, as in burned patients. Both drugs are water-soluble and are excreted primarily in the urine. Renal failure may permit the accumulation of these antibiotics, with possible nephrotoxicity, neurotoxicity, and ototoxicity.

Neomycin frequently causes allergic contact dermatitis, particularly if applied to eczematous dermatoses or if compounded in an ointment vehicle. When sensitization occurs, cross-sensitivity to streptomycin, kanamycin, paromomycin, and gentamicin is possible.

TOPICAL ANTIBIOTICS IN ACNE

Systemic antibiotics traditionally used in the treatment of acne vulgaris have been shown effective when applied topically. Currently, two antibiotics are used topically for this indication: clindamycin phosphate and erythromycin base. Effectiveness of topical therapy is less than that achieved by its oral administration. Therefore, topical therapy is generally suitable only in mild to moderate cases of inflammatory acne.

Clindamycin

Clindamycin has in vitro activity against *Propionibacterium acnes*; this has been postulated as the mechanism of its beneficial effect in acne therapy. Approximately 10% of an applied dose is absorbed, and rare cases of bloody diarrhea and pseudomembranous colitis have been reported following topical application.

The hydroalcoholic vehicle and foam formulation (Evoclin) may cause drying and irritation of the skin, with complaints of burning and stinging. The water-based gel and lotion formulations are well tolerated and less likely to cause irritation. Allergic contact dermatitis is uncommon. Clindamycin is also available in fixed-combination topical gels with benzoyl peroxide (Acanya, BenzaClin, Duac, Onexton) and with tretinoin (Velitin, Ziana).

Erythromycin

In topical preparations, erythromycin base rather than a salt is used to facilitate penetration. The mechanism of action of topical erythromycin in inflammatory acne vulgaris is unknown but is presumed to be due to its inhibitory effects on *P acnes*. One complication of topical therapy is the development of antibiotic-resistant strains of organisms, including staphylococci. If this occurs in association with a clinical infection, topical erythromycin should be discontinued and appropriate systemic antibiotic therapy started. Adverse local reactions to erythromycin solution may include a burning sensation at application time and drying and irritation of the skin. The topical water-based gel is less drying and may be better tolerated. Allergic contact dermatitis is uncommon. Erythromycin is also available in a fixed combination preparation with benzoyl peroxide (Benzamycin) for topical treatment of acne vulgaris.

Metronidazole

Topical metronidazole is effective in rosacea treatment. The mechanism of action is unknown, but it may relate to the inhibitory effects of metronidazole on *Demodex brevis*; alternatively, the drug may act as an anti-inflammatory agent by direct effect on neutrophil cellular function. Oral metronidazole has been shown to be a carcinogen in susceptible rodent species, and topical use during pregnancy and by nursing mothers and children is therefore not recommended.

Adverse local effects of the water-based gel formulation (MetroGel) include dryness, burning, and stinging. Less drying formulations may be better tolerated (MetroCream, MetroLotion, and Noritate cream). Caution should be exercised when applying metronidazole near the eyes to avoid excessive tearing.

Ivermectin

Topical ivermectin is available as a 1% cream (Soolantra) for the treatment of inflammatory lesions of rosacea. The mechanism of action is unknown. Oral ivermectin has antiparasitic activity against *Demodex* mites and possibly an anti-inflammatory effect. Topical application is well tolerated with occasional complaints of burning and irritation.

Sodium Sulfacetamide

Topical sulfacetamide is available alone as a 10% lotion (Klaron) and as a 10% wash (Ovace), and in several preparations in combination with sulfur for the treatment of acne vulgaris and acne rosacea. The mechanism of action is thought to be inhibition of

P. acnes by competitive inhibition of *p*-aminobenzoic acid utilization. Approximately 4% of topically applied sulfacetamide is absorbed percutaneously, and its use is therefore contraindicated in patients having a known hypersensitivity to sulfonamides.

Dapsone

Topical dapsone is available as a 5% and 7.5% gel (Aczone) for the treatment of acne vulgaris. The mechanism of action is unknown. Topical use in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency has not been shown to cause clinically relevant hemolysis or anemia, but a slight decrease in hemoglobin concentration was noted in patients with G6PD deficiency, suggestive of mild hemolysis. Cases of methemoglobinemia have been reported in association with topical dapsone gel, and its use should be avoided in patients with congenital or idiopathic methemoglobinemia. Adverse local side effects include mild dryness, redness, oiliness, and skin peeling. Application of dapsone gel followed by benzoyl peroxide may result in a temporary yellow discoloration of the skin and hair.

■ ANTIFUNGAL AGENTS

The treatment of superficial fungal infections caused by dermatophytic fungi may be accomplished (1) with topical antifungal agents, eg, clotrimazole, efinaconazole, econazole, ketoconazole, luliconazole, miconazole, oxiconazole, sertaconazole, sulconazole, ciclopirox olamine, naftifine, terbinafine, butenafine, and tolnaftate; or (2) with orally administered agents, ie, griseofulvin, terbinafine, fluconazole, and itraconazole. Their mechanisms of action are described in Chapter 48. Superficial infections caused by *Candida* species may be treated with topical applications of clotrimazole, miconazole, econazole, ketoconazole, oxiconazole, ciclopirox olamine, nystatin, or amphotericin B.

TOPICAL ANTIFUNGAL PREPARATIONS

TOPICAL AZOLE DERIVATIVES

The topical imidazoles, which include clotrimazole, econazole, ketoconazole, luliconazole, miconazole, oxiconazole, sertaconazole, and sulconazole, have a wide range of activity against dermatophytes (*Epidermophyton*, *Microsporum*, and *Trichophyton*) and yeasts, including *Candida albicans* and *Pityrosporum orbiculare* (see Chapter 48).

Miconazole (Monistat, Micatin) is available for topical application as a cream or lotion and as vaginal cream or suppositories for use in vulvovaginal candidiasis. Clotrimazole (Lotrimin, Mycelex) is available for topical application to the skin as a cream or lotion and as vaginal cream and tablets for use in vulvovaginal candidiasis.

Efinaconazole (Jublia) is available as a 10% solution for the treatment of onychomycosis of the toenails. Daily application to affected toenails should be continued for 48 weeks.

Complete cure rates in clinical trials are between 15% and 18%. Econazole (Spectazole) is available as a cream for topical application. Oxiconazole (Oxistat) is available as a cream and lotion for topical use. Ketoconazole (Nizoral) is available as a cream for topical treatment of dermatophytosis and candidiasis and as a shampoo or foam for the treatment of seborrheic dermatitis. Luliconazole (Luzu) is available as a cream. Sulconazole (Exelderm) is available as a cream or solution. Sertaconazole (Ertaczo) is available as a cream. Topical antifungal-corticosteroid fixed combinations have been introduced on the basis of providing more rapid symptomatic improvement than an antifungal agent alone. Clotrimazole-betamethasone dipropionate cream (Lotrisone) is one such combination.

Once- or twice-daily application to the affected area will generally result in clearing of superficial dermatophyte infections in 2–3 weeks, although the medication should be continued until eradication of the organism is confirmed. Paronychia and intertriginous candidiasis can be treated effectively by any of these agents when applied three or four times daily. Seborrheic dermatitis should be treated with twice-daily applications of ketoconazole until clinical clearing is obtained.

Adverse local reactions to the imidazoles may include stinging, pruritus, erythema, and local irritation. Allergic contact dermatitis is uncommon.

CICLOPIROX OLAMINE

Ciclopirox olamine is a synthetic broad-spectrum antimycotic agent with inhibitory activity against dermatophytes, *Candida* species, and *P. orbiculare*. This agent inhibits the uptake of precursors of macromolecular synthesis; the site of action is probably the fungal cell membrane.

Pharmacokinetic studies indicate that 1–2% of the dose is absorbed when applied as a solution on the back under an occlusive dressing. Ciclopirox olamine is available as a 1% cream and lotion (Loprox) for the topical treatment of dermatomycosis, candidiasis, and tinea versicolor. The incidence of adverse reactions has been low. Pruritus and worsening of clinical disease have been reported. The potential for allergic contact dermatitis is small.

Topical 8% ciclopirox olamine (Penlac nail lacquer) is approved for the treatment of mild to moderate onychomycosis of fingernails and toenails. Although well tolerated with minimal side effects, the complete cure rates in clinical trials are between 5.5% and 8.5%.

TAVABOROLE

Tavaborole is the first oxaborole antifungal drug approved for the treatment of toenail onychomycosis. Tavaborole blocks fungal protein synthesis by inhibiting aminoacyl-transfer ribonucleic acid synthetase. Tavaborole is available as a 5% solution (Kerydin) that should be applied to the affected toenails once daily for 48 weeks. Complete cure rates in clinical trials are between 6.5% and 9.1%.

ALLYLAMINES: NAFTIFINE & TERBINAFINE

Naftifine hydrochloride and terbinafine (Lamisil) are allylamines that are highly active against dermatophytes but less active against yeasts. The antifungal activity derives from selective inhibition of squalene epoxidase, a key enzyme for the synthesis of ergosterol (see Figure 48–1).

They are available as 1% creams and other forms for the topical treatment of dermatophytosis, to be applied on a twice-daily dosing schedule for 1–2 weeks. Adverse reactions include local irritation, burning sensation, and erythema. Contact with mucous membranes should be avoided.

BUTENAFINE

Butenafine hydrochloride (Mentax) is a benzylamine that is structurally related to the allylamines. As with the allylamines, butenafine inhibits the epoxidation of squalene, thus blocking the synthesis of ergosterol, an essential component of fungal cell membranes. Butenafine is available as a 1% cream to be applied once daily for the treatment of superficial dermatophytosis.

TOLNAFTATE

Tolnaftate is a synthetic antifungal compound effective topically against dermatophyte infections caused by *Epidermophyton*, *Microsporum*, and *Trichophyton*. It is also active against *P. orbiculare* but not against *Candida*.

Tolnaftate (Aftate, Tinactin) is available as a cream, solution, powder, or powder aerosol for application twice daily to infected areas. Recurrences following cessation of therapy are common, and infections of the palms, soles, and nails are usually unresponsive to tolinaftate alone. The powder or powder aerosol may be used chronically following initial treatment in patients susceptible to tinea infections. Tolnaftate is generally well tolerated and rarely causes irritation or allergic contact dermatitis.

NYSTATIN & AMPHOTERICIN B

Nystatin and amphotericin B are useful in the topical therapy of *C. albicans* infections but ineffective against dermatophytes. Nystatin is limited to topical treatment of cutaneous and mucosal candida infections because of its narrow spectrum and negligible absorption from the gastrointestinal tract following oral administration. Amphotericin B has a broader antifungal spectrum and is used intravenously in the treatment of many systemic mycoses (see Chapter 48) and to a lesser extent in the treatment of cutaneous *Candida* infections.

The recommended dosage for topical preparations of nystatin in treating paronychia and intertriginous candidiasis is application two or three times a day. Oral candidiasis (thrush) is treated by holding 5 mL (infants, 2 mL) of nystatin oral suspension in the mouth for several minutes four times daily before swallowing.

An alternative therapy for thrush is to retain a vaginal tablet in the mouth until dissolved four times daily. Recurrent or recalcitrant perianal, vaginal, vulvar, and diaper area candidiasis may respond to oral nystatin, 0.5–1 million units in adults (100,000 units in children) four times daily, in addition to local therapy. Vulvo-vaginal candidiasis may be treated by insertion of 1 vaginal tablet twice daily for 14 days, then nightly for an additional 14–21 days.

Amphotericin B (Fungizone) is available for topical use in cream and lotion form. The recommended dosage in the treatment of paronychia and intertriginous candidiasis is application two to four times daily to the affected area.

Adverse effects associated with oral administration of nystatin include mild nausea, diarrhea, and occasional vomiting. Topical application is nonirritating, and allergic contact hypersensitivity is exceedingly uncommon. Topical amphotericin B is well tolerated and only occasionally locally irritating. The drug may cause a temporary yellow staining of the skin, especially when the cream vehicle is used.

ORAL ANTIFUNGAL AGENTS

ORAL AZOLE DERIVATIVES

Azole derivatives currently available for oral treatment of candida and dermatophyte infections include fluconazole (Diflucan) and itraconazole (Sporanox). As discussed in Chapter 48, imidazole derivatives act by affecting the permeability of the cell membrane of sensitive cells through alterations of the biosynthesis of lipids, especially sterols, in the fungal cell.

Fluconazole and itraconazole are effective in the therapy of cutaneous infections caused by *Epidermophyton*, *Microsporum*, and *Trichophyton* species as well as *Candida*. Tinea versicolor is responsive to short courses of oral azoles.

Fluconazole is well absorbed following oral administration, with a plasma half-life of 30 hours. In view of this long half-life, daily doses of 100 mg are sufficient to treat mucocutaneous candidiasis; alternate-day doses are sufficient for dermatophyte infections. The plasma half-life of itraconazole is similar to that of fluconazole, and detectable therapeutic concentrations remain in the stratum corneum for up to 28 days following termination of therapy. Itraconazole is effective for the treatment of onychomycosis in a dosage of 200 mg daily taken with food to ensure maximum absorption for 3 consecutive months. Recent reports of heart failure in patients receiving itraconazole for onychomycosis have resulted in recommendations that it not be given for treatment of onychomycosis in patients with ventricular dysfunction. Additionally, routine evaluation of hepatic function is recommended for patients receiving itraconazole for onychomycosis.

Administration of oral azoles with midazolam or triazolam has resulted in elevated plasma concentrations and may potentiate and prolong hypnotic and sedative effects of these agents. Administration with HMG-CoA reductase inhibitors has been shown to cause a significant risk of rhabdomyolysis. *Therefore, administration of the oral azoles with midazolam, triazolam, or HMG-CoA inhibitors is contraindicated.*

TERBINAFINE

Terbinafine (described above) is effective given orally for the treatment of onychomycosis. Recommended oral dosage is 250 mg daily for 6 weeks for fingernail infections and 12 weeks for toenail infections. Patients receiving terbinafine for onychomycosis should be monitored closely with periodic laboratory evaluations for possible hepatic dysfunction. Rare cases of liver failure have occurred with the use of oral terbinafine; therefore, its use is not recommended in patients with chronic or active liver disease.

GRISEOFULVIN

Griseofulvin, effective orally against dermatophyte infections caused by *Epidermophyton*, *Microsporum*, and *Trichophyton*, is ineffective against *Candida* and *P. orbiculare*. Griseofulvin's mechanism of antifungal action is not fully understood, but it is active only against growing cells.

Following oral administration of 1 g of microsize griseofulvin, drug can be detected in the stratum corneum 4–8 hours later. Reducing the particle size of the medication greatly increases drug absorption. Formulations that contain the smallest particle size are labeled “ultramicrosize.” Ultramicrosize griseofulvin achieves bioequivalent plasma levels with half the dose of microsize drug. In addition, solubilizing griseofulvin in polyethylene glycol enhances absorption even further. Microsized griseofulvin is available as 250 mg and 500 mg tablets, and ultramicrosized drug as 125 mg, 165 mg, 250 mg, and 330 mg tablets and as 250 mg capsules.

The usual adult dosage of the microsize form of the drug is 500 mg daily in single or divided doses with meals; occasionally, 1 g/d is indicated in the treatment of recalcitrant infections. The pediatric dosage is 10 mg/kg of body weight daily in single or divided doses with meals. An oral suspension is available for use in children.

Griseofulvin is most effective in treating tinea infections of the scalp and glabrous (nonhairy) skin. In general, infections of the scalp respond to treatment in 4–6 weeks, and infections of glabrous skin will respond in 3–4 weeks. Dermatophyte infections of the nails respond only to prolonged administration. Fingernails may respond to 6 months of therapy, whereas toenails are recalcitrant to treatment and may require 8–18 months of therapy; relapse almost invariably occurs.

Adverse effects seen with griseofulvin therapy include headaches, nausea, vomiting, diarrhea, photosensitivity, peripheral neuritis, and occasionally mental confusion. Griseofulvin is derived from a *Penicillium* mold, and cross-sensitivity with penicillin may occur. It is contraindicated in patients with porphyria or hepatic failure or those who have had hypersensitivity reactions to it in the past. Its safety in pregnant patients has not been established. Leukopenia and proteinuria have occasionally been reported. Therefore, in patients undergoing prolonged therapy, routine evaluation of the hepatic, renal, and hematopoietic systems is advisable. Coumarin anticoagulant activity may be altered by griseofulvin, and anticoagulant dosage may require adjustment.

TOPICAL ANTIVIRAL AGENTS

ACYCLOVIR, VALACYCLOVIR, PENCICLOVIR, & FAMCICLOVIR

Acyclovir, valacyclovir, penciclovir, and famciclovir are synthetic guanine analogs with inhibitory activity against members of the herpesvirus family, including herpes simplex types 1 and 2. Their mechanism of action, indications, and oral use in the treatment of cutaneous infections are discussed in Chapter 49.

Topical acyclovir (Zovirax) is available as a 5% ointment and 50 mg buccal tablet; topical penciclovir (Denavir), as a 1% cream for the treatment of recurrent orolabial herpes simplex virus infection in immunocompetent adults. Adverse local reactions to acyclovir and penciclovir may include pruritus and mild pain with transient stinging or burning.

IMMUNOMODULATORS

IMIQUIMOD

Imiquimod is available as 5% cream (Aldara) for the treatment of external genital and perianal warts in adults, actinic keratoses on the face and scalp, and biopsy-proven primary superficial basal cell carcinomas on the trunk, neck, and extremities. Creams with lower concentrations of 2.5% and 3.75% (Zyclara) are available for the treatment of face and scalp actinic keratoses. The mechanism of its action is thought to be related to imiquimod's ability to stimulate peripheral mononuclear cells to release interferon alpha and to stimulate macrophages to produce interleukins-1, -6, and -8, and tumor necrosis factor- α (TNF- α).

Imiquimod should be applied to the wart tissue three times per week and left on the skin for 6–10 hours prior to washing off with mild soap and water. Treatment should be continued until eradication of the warts is accomplished, but not for more than a total of 16 weeks. Recommended treatment of actinic keratoses consists of twice-weekly applications of the 5% cream on the contiguous area of involvement or nightly applications of the 2.5% or 3.75% cream. The cream is removed after approximately 8 hours with mild soap and water. Treatment of superficial basal cell carcinoma consists of five-times-per-week application of 5% cream to the tumor, including a 1 cm margin of surrounding skin, for a 6-week course of therapy.

Percutaneous absorption is minimal, with less than 0.9% absorbed following a single-dose application. Adverse effects consist of local inflammatory reactions, including pruritus, erythema, and superficial erosion.

TACROLIMUS & PIMECROLIMUS

Tacrolimus (Protopic) and pimecrolimus (Elidel) are macrolide immunosuppressants that have been shown to be of significant benefit in the treatment of atopic dermatitis. Both agents inhibit T-lymphocyte activation and prevent the release of inflammatory

cytokines and mediators from mast cells in vitro after stimulation by antigen-IgE complexes. Tacrolimus is available as 0.03% and 0.1% ointments, and pimecrolimus is available as a 1% cream. Both are indicated for short-term and intermittent long-term therapy for mild to moderate atopic dermatitis. Tacrolimus 0.03% ointment and pimecrolimus 1% cream are approved for use in children older than 2 years of age, although all strengths are approved for adult use. Recommended dosing of both agents is twice-daily application to affected skin until clearing is noted. Neither medication should be used with occlusive dressings. The most common side effect of both drugs is a burning sensation in the applied area that improves with continued use. The US Food and Drug Administration (FDA) mandates a black box warning regarding the long-term safety of topical tacrolimus and pimecrolimus because of animal tumorigenicity data.

■ ECTOPARASITICIDES

PERMETHRIN

Permethrin is toxic to *Pediculus humanus*, *Phthirus pubis*, and *Sarcoptes scabiei*. Less than 2% of an applied dose is absorbed percutaneously. Residual drug persists up to 10 days following application. Resistance to permethrin is becoming more widespread.

It is recommended that permethrin 1% cream rinse (Nix) be applied undiluted to affected areas of pediculosis for 10 minutes and then rinsed off with warm water. For the treatment of scabies, a single application of 5% cream (Elimite, Acticin) is applied to the body from the neck down, left on for 8–14 hours, and then washed off. Adverse reactions to permethrin include transient burning, stinging, and pruritus. Cross-sensitization to pyrethrins or chrysanthemums has been alleged but inadequately documented.

SPINOSAD

Spinosad (Natroba) suspension is approved for the topical treatment of head lice in patients 4 years of age and older. Spinosad is derived from the fermentation of a soil *Actinomyces* bacterium and is toxic to *P. humanus* with no appreciable absorption from topical application. It is recommended that the 0.9% suspension be applied to the hair and scalp for 10 minutes and then rinsed out. A repeat treatment may be applied 1 week later if live lice are present.

IVERMECTIN

Ivermectin (Sklice) 0.5% lotion is approved for head lice treatment in patients 6 months of age and older. Ivermectin is toxic to *P. humanus*, resulting in paralysis and death of the parasite. The pharmacology of ivermectin is discussed in Chapter 53. The lotion should be applied to the hair and scalp and rinsed out after 10 minutes. Ivermectin is for single use only and should not be repeated without health care provider recommendation.

LINDANE (HEXACHLOROCYCLOHEXANE)

The gamma isomer of hexachlorocyclohexane was commonly called gamma benzene hexachloride, a misnomer, since no benzene ring is present in this compound. Percutaneous absorption studies using a solution of lindane in acetone have shown that almost 10% of a dose applied to the forearm is absorbed, to be subsequently excreted in the urine over a 5-day period. After absorption, lindane is concentrated in fatty tissues, including the brain.

Lindane is available as a 1% shampoo or lotion. For pediculosis capitis or pubis, 30 mL of shampoo is applied to dry hair on the scalp or genital area for 4 minutes and then rinsed off. No additional application is indicated unless living lice are present 1 week after treatment. Then reapplication may be required.

Recent concerns about the toxicity of lindane have altered treatment guidelines for its use in scabies; the current recommendation calls for a single 60 mL application to the entire body from the neck down, left on for 8–12 hours, and then washed off. Patients should be retreated only if active mites can be demonstrated, and never within 1 week of initial treatment.

Concerns about neurotoxicity and hematotoxicity have resulted in warnings that lindane should be used with caution in infants, children, and pregnant women. The current USA package insert recommends that it not be used as a scabicide in premature infants and in patients with known seizure disorders. Local irritation may occur, and contact with the eyes and mucous membranes should be avoided.

CROTAMITON

Crotamiton, *N*-ethyl-*o*-crotonotoluidide, is a scabicide with some antipruritic properties; its mechanism of action is not known. Studies on percutaneous absorption have revealed detectable levels of crotamiton in the urine following a single application on the forearm.

Crotamiton (Eurax) is available as a 10% cream or lotion. Suggested guidelines for scabies treatment call for two applications to the entire body from the chin down at 24-hour intervals, with a cleansing bath 48 hours after the last application. Crotamiton is an effective agent that can be used as an alternative to lindane. Allergic contact dermatitis and primary irritation may occur, necessitating discontinuance of therapy. Application to acutely inflamed skin or to the eyes or mucous membranes should be avoided.

SULFUR

Sulfur has a long history as a scabicide. Although it is nonirritating, it has an unpleasant odor, is staining, and is thus disagreeable to use. It has been replaced by more aesthetic and effective scabicides in recent years, but it remains a possible alternative drug for use in infants and pregnant women. The usual formulation is 5% precipitated sulfur in petrolatum.

MALATHION

Malathion is an organophosphate cholinesterase inhibitor that is hydrolyzed and inactivated by plasma carboxylesterases much faster in humans than in insects, thereby providing a therapeutic advantage in treating pediculosis (see Chapter 7). Malathion is available as a 0.5% lotion (Ovide) that should be applied to the hair when dry; 4–6 hours later, the hair is combed to remove nits and lice.

BENZYL ALCOHOL

Benzyl alcohol (Ulesfia) is available as a 5% lotion for the treatment of head lice in patients older than 6 months. The lotion is applied to dry hair and left on for 10 minutes prior to rinsing off with water. Because the drug is not ovicidal, the treatment must be repeated after 7 days. Eye irritation and allergic contact dermatitis have been reported.

■ AGENTS AFFECTING PIGMENTATION

HYDROQUINONE, MONOBENZONE, & MEQUINOL

Hydroquinone, monobenzone (Benoquin, the monobenzyl ether of hydroquinone), and mequinol (the monomethyl ether of hydroquinone) are used to reduce hyperpigmentation of the skin. Topical hydroquinone and mequinol usually result in temporary lightening, whereas monobenzone causes irreversible depigmentation.

The mechanism of action of these compounds appears to involve inhibition of the enzyme tyrosinase, thus interfering with the biosynthesis of melanin. In addition, monobenzone may be toxic to melanocytes, resulting in permanent loss of these cells. Some percutaneous absorption of these compounds takes place, because monobenzone may cause hypopigmentation at sites distant from the area of application. Both hydroquinone and monobenzone may cause local irritation. Allergic contact dermatitis to these compounds can occur. Prescription combinations of hydroquinone, fluocinolone acetonide, and retinoic acid (Tri-Luma) and mequinol and retinoic acid (Solag ) are more effective than their individual components.

TRIOXSALEN & METHOXSALEN

Trioxsalen and methoxsalen are psoralens used for the repigmentation of depigmented macules of vitiligo. With the development of high-intensity long-wave ultraviolet fluorescent lamps, photochemotherapy with oral methoxsalen for psoriasis and with oral trioxsalen for vitiligo has been under intensive investigation.

Psoralens must be photoactivated by long-wavelength ultraviolet light in the range of 320–400 nm (ultraviolet A [UVA]) to

produce a beneficial effect. Psoralens intercalate with DNA, and with subsequent UVA irradiation, cyclobutane adducts are formed with pyrimidine bases. Both monofunctional and bifunctional adducts may be formed, the latter causing interstrand cross-links. These DNA photoproducts may inhibit DNA synthesis. The major long-term risks of psoralen photochemotherapy are cataracts and skin cancer.

■ SUNSCREENS

Topical medications useful in protecting against sunlight contain either chemical compounds that absorb ultraviolet light, called sunscreens, or opaque materials such as titanium dioxide that reflect light, called sunshades. The three classes of chemical compounds most commonly used in sunscreens are *p*-aminobenzoic acid (PABA) and its esters, the benzophenones, and the dibenzoylmethanes.

Most sunscreen preparations are designed to absorb ultraviolet light in the ultraviolet B (UVB) wavelength range from 280 to 320 nm, which is the range responsible for most of the erythema and sunburn associated with sun exposure and tanning. Chronic exposure to light in this range induces aging of the skin and photocarcinogenesis. Para-aminobenzoic acid and its esters are the most effective available absorbers in the B region. Ultraviolet in the longer UVA range, 320–400 nm, is also associated with skin aging and cancer.

The benzophenones include oxybenzone, dioxybenzone, and sulisobenzene. These compounds provide a broader spectrum of absorption from 250 to 360 nm, but their effectiveness in the UVB erythema range is less than that of PABA. The dibenzoylmethanes include Parsol and Eusolex. These compounds absorb wavelengths throughout the longer UVA range, with maximum absorption at 360 nm. Patients particularly sensitive to UVA wavelengths include individuals with polymorphous light eruption, cutaneous lupus erythematosus, and drug-induced photosensitivity. In these patients, dibenzoylmethane-containing sunscreen may provide improved photoprotection. Ecamsule (Mexoryl) appears to provide greater UVA protection than the dibenzoylmethanes and is less prone to photodegradation.

The sun protection factor (SPF) of a given sunscreen, a measure of its effectiveness in absorbing erythrogenic ultraviolet light, is determined by measuring the minimal erythema dose with and without the sunscreen in a group of normal people. The ratio of the minimal erythema dose with sunscreen to the minimal erythema dose without sunscreen is the SPF.

FDA regulations limit the claimed maximum SPF value on sunscreen labels to 50+ because data are insufficient to show that products with SPF values higher than 50 provide greater protection for users. These regulations require that sunscreens labeled “broad spectrum” pass a standard test comparing the amount of UVA radiation protection in relation to the amount of UVB protection. Broad spectrum sunscreens with SPF values of 15 or higher help protect against not only sunburn, but also skin cancer and early skin aging when used as directed. Sunscreens with an SPF value between 2 and 14 can only claim that they help prevent sunburn.

In addition, products claiming to be water resistant must indicate whether they remain effective for 40 minutes or 80 minutes while swimming or sweating, based on standard testing. These regulations are poorly enforced.

■ ACNE PREPARATIONS

RETINOIC ACID & DERIVATIVES

Retinoic acid, also known as *tretinoin* or all-*trans*-retinoic acid, is the acid form of vitamin A. It is an effective topical treatment for acne vulgaris. Several analogs of vitamin A, eg, 13-*cis*-retinoic acid (isotretinoin), have been shown to be effective in various dermatologic diseases when given orally. Vitamin A alcohol is the physiologic form of vitamin A. The topical therapeutic agent, **retinoic acid**, is formed by the oxidation of the alcohol group, with all four double bonds in the side chain in the *trans* configuration as shown.

Retinoic acid is insoluble in water but soluble in many organic solvents. Topically applied retinoic acid remains chiefly in the epidermis, with less than 10% absorption into the circulation. The small quantities of retinoic acid absorbed following topical application are metabolized by the liver and excreted in bile and urine.

Retinoic acid has several effects on epithelial tissues. It stabilizes lysosomes, increases ribonucleic acid polymerase activity, increases prostaglandin E_2 , cAMP, and cGMP levels, and increases the incorporation of thymidine into DNA. Its action in acne has been attributed to decreased cohesion between epidermal cells and increased epidermal cell turnover. This is thought to result in the expulsion of open comedones and the transformation of closed comedones into open ones.

Topical retinoic acid is applied initially in a concentration sufficient to induce slight erythema with mild peeling. The concentration or frequency of application may be decreased if too much irritation occurs. Topical retinoic acid should be applied to dry skin only, and care should be taken to avoid contact with the corners of the nose, eyes, mouth, and mucous membranes. During the first 4–6 weeks of therapy, comedones not previously evident may appear and give the impression that the acne has been aggravated by the retinoic acid. However, with continued therapy, the lesions will clear, and in 8–12 weeks optimal clinical improvement should occur. A timed-release formulation of tretinoin containing microspheres (Retin-A Micro) delivers the medication over time and may be less irritating for sensitive patients.

The effects of tretinoin on keratinization and desquamation offer benefits for patients with photo-damaged skin. Prolonged use of tretinoin promotes dermal collagen synthesis, new blood vessel formation, and thickening of the epidermis, which helps

diminish fine lines and wrinkles. Specially formulated moisturizing 0.05% cream (Renova, Refissa) is marketed for this purpose.

The most common adverse effects of topical retinoic acid are erythema and dryness that occur in the first few weeks of use, but these can be expected to resolve with continued therapy. Animal studies suggest that this drug may increase the tumorigenic potential of ultraviolet radiation. In light of this, patients using retinoic acid should be advised to avoid or minimize sun exposure and use a protective sunscreen. Allergic contact dermatitis to topical retinoic acid is rare.

Adapalene (Differin) is a derivative of naphthoic acid that resembles retinoic acid in structure and effects. It is available for daily application as a 0.1% gel, cream, or lotion and a 0.3% gel. The 0.1% gel has recently been approved by the FDA for over-the-counter sale. Unlike tretinoin, adapalene is photochemically stable and shows little decrease in efficacy when used in combination with benzoyl peroxide. Adapalene is less irritating than tretinoin and is most effective in patients with mild to moderate acne vulgaris. Adapalene is also available in a fixed-dose combination gel with benzoyl peroxide (Epiduo, Epiduo Forte).

Tazarotene (Tazorac, Fabior) is an acetylenic retinoid available as a 0.1% gel, cream, and foam for the treatment of mild to moderately severe facial acne. Topical tazarotene should be used by women of childbearing age only after contraceptive counseling. It is recommended that tazarotene should not be used by pregnant women.

ISOTRETINOIN

Isotretinoin is a synthetic retinoid currently restricted to the oral treatment of severe cystic acne that is recalcitrant to standard therapies. The precise mechanism of action of isotretinoin in cystic acne is not known, although it appears to act by inhibiting sebaceous gland size and function. The drug is well absorbed, is extensively bound to plasma albumin, and has an elimination half-life of 10–20 hours. A lipid solubilized formulation, CIP-isotretinoin (Absorica), has been approved that provides more consistent absorption and can be taken with or without food.

Most patients with cystic acne respond to 1–2 mg/kg, given in two divided doses daily for 4–5 months. If severe cystic acne persists following this initial treatment, after a period of 2 months, a second course of therapy may be initiated. Common adverse effects resemble hypervitaminosis A and include dryness and itching of the skin and mucous membranes. Less common side effects are headache, corneal opacities, pseudotumor cerebri, inflammatory bowel disease, anorexia, alopecia, and muscle and joint pains. These effects are all reversible on discontinuance of therapy. Skeletal hyperostosis has been observed in patients receiving isotretinoin with premature closure of epiphyses noted in children treated with this medication. Lipid abnormalities (triglycerides, high-density lipoproteins) are frequent; their clinical relevance is unknown at present.

Teratogenicity is a significant risk in patients taking isotretinoin; therefore, the FDA mandates that women of childbearing potential *must* use an effective form of contraception for at least 1 month before, throughout isotretinoin therapy, and for one or more menstrual cycles following discontinuance of treatment.

A negative serum pregnancy test *must* be obtained within 2 weeks before starting therapy in these patients, and therapy should be initiated only on the second or third day of the next normal menstrual period. In the USA, health care professionals, pharmacists, and patients must utilize the mandatory iPLEDGE registration and follow-up system.

BENZOYL PEROXIDE

Benzoyl peroxide, an effective topical agent in acne vulgaris treatment, penetrates the stratum corneum or follicular openings unchanged and is converted metabolically to benzoic acid within the epidermis and dermis. Less than 5% of an applied dose is absorbed from the skin in an 8-hour period. It has been postulated that the mechanism of action of benzoyl peroxide in acne is related to its antimicrobial activity against *P. acnes* and to its peeling and comedolytic effects.

To decrease the likelihood of irritation, application should be limited to a low concentration (2.5%) once daily for the first week of therapy and increased in frequency and strength if the preparation is well tolerated. Fixed-combination formulations of 5% benzoyl peroxide with 3% erythromycin base (Benzamycin) or 1% clindamycin (BenzaClin, Duac); 3.75% benzoyl peroxide with 1.2% clindamycin (Onexton); and 2.5% benzoyl peroxide with 1.2% clindamycin (Acanya) or 0.1% adapalene (Epiduo) appear to be more effective than individual agents alone.

Benzoyl peroxide is a potent contact sensitizer in experimental studies, and this adverse effect may occur in up to 1% of acne patients. Care should be taken to avoid contact with the eyes and mucous membranes. Benzoyl peroxide is an oxidant and may rarely cause bleaching of the hair or colored fabrics.

AZELAIC ACID

Azelaic acid is a straight-chain saturated dicarboxylic acid that is effective in the treatment of acne vulgaris (Azelex) and acne rosacea (Finacea, Finacea foam). Its mechanism of action has not been fully determined, but preliminary studies demonstrate antimicrobial activity against *P. acnes* as well as in vitro inhibitory effects on the conversion of testosterone to dihydrotestosterone. Initial therapy is begun with once-daily applications of the 20% cream, 15% gel, or 15% foam to the affected areas for 1 week and twice-daily applications thereafter. Most patients experience mild irritation with redness and dryness of the skin during the first week of treatment. Clinical improvement is noted in 6–8 weeks of continuous therapy.

BRIMONIDINE

Brimonidine (Mirvaso) is an α_2 -adrenergic agonist indicated for the topical treatment of persistent facial erythema of rosacea in adults 18 years of age or older. Daily topical application of brimonidine 0.33% gel may reduce erythema through direct vasoconstriction. Exacerbation of facial erythema and flushing may occur, ranging from 30 minutes to several hours after application.

Alpha₂ agonists can lower blood pressure (see Chapter 11); therefore, brimonidine should be used with caution in patients with severe, unstable, or uncontrolled cardiovascular disease.

DRUGS FOR PSORIASIS

ACITRETIN

Acitretin (Soriatane), a metabolite of the aromatic retinoid etretinate, is effective in the treatment of psoriasis, especially pustular forms. It is given orally at a dosage of 25–50 mg/d. Adverse effects attributable to acitretin therapy are similar to those seen with isotretinoin and resemble hypervitaminosis A. Elevations in cholesterol and triglycerides may be noted with acitretin, and hepatotoxicity with liver enzyme elevations has been reported. Acitretin is more teratogenic than isotretinoin in the animal species studied to date, which is of special concern in view of the drug's prolonged elimination time (more than 3 months) after chronic administration. In cases where etretinate is formed by concomitant administration of acitretin and ethanol, etretinate may be found in plasma and subcutaneous fat for many years.

Acitretin must not be used by women who are pregnant or may become pregnant while undergoing treatment or at any time for at least 3 years after treatment is discontinued. Ethanol must be strictly avoided during treatment with acitretin and for 2 months after discontinuing therapy. Patients must not donate blood during treatment and for 3 years after acitretin is stopped.

TAZAROTENE

Tazarotene (Tazorac) is a topical acetylenic retinoid prodrug that is hydrolyzed to its active form by an esterase. The active metabolite, tazarotenic acid, binds to retinoic acid receptors, resulting in modified gene expression. The precise mechanism of action in psoriasis is unknown but may relate to both anti-inflammatory and antiproliferative actions. Tazarotene is absorbed percutaneously, and teratogenic systemic concentrations may be achieved if applied to more than 20% of total body surface area. Women of childbearing potential must therefore be advised of the risk prior to initiating therapy, and adequate birth control measures must be utilized while on therapy.

Treatment of psoriasis should be limited to once-daily application of either 0.05% or 0.1% gel not to exceed 20% of total body surface area. Adverse local effects include a burning or stinging sensation (sensory irritation) and peeling, erythema, and localized edema of the skin (irritant dermatitis). Potentiation of photosensitizing medication may occur, and patients should be cautioned to minimize sunlight exposure and to use sunscreens and protective clothing.

CALCIPOTRIENE & CALCITRIOL

Calcipotriene (Dovonex, Sorilux) is a synthetic vitamin D₃ derivative (available as a 0.005% cream, scalp lotion, and foam) that is effective in the treatment of plaque-type psoriasis vulgaris of

TABLE 61–2 Biologic agents for psoriasis.

Biologic Agent	Usual Adult Dosage
Adalimumab— <i>Humira</i>	80 mg SC × 1, then 40 mg q2 weeks
Etanercept— <i>Enbrel</i>	50 mg SC twice/week × 12 weeks, then once/week
Infliximab— <i>Remicade</i>	5 mg/kg IV at 0, 2, and 6 weeks, then q8 weeks
Ixekizumab— <i>Taltz</i>	160 mg at 0 weeks and 80 mg at 2, 4, 6, 8, 10, and 12 weeks, then q4 weeks
Secukinumab— <i>Cosentyx</i>	300 mg SC at 0, 1, 2, 3, and 4 weeks, then q4 weeks
Ustekinumab— <i>Stelara</i>	Either 45 mg or 90 mg SC at 0 and 4 weeks, then q12 weeks (dose for psoriasis is 45 mg for patients weighing ≤100 kg and 90 mg for those weighing ≥100 kg)

moderate severity. Improvement of psoriasis is generally noted following 2 weeks of therapy, with continued improvement for up to 8 weeks of treatment. However, fewer than 10% of patients demonstrate total clearing while on calcipotriene as single-agent therapy. Adverse effects include burning, itching, and mild irritation, with dryness and erythema of the treatment area. Care should be taken to avoid facial contact, which may cause ocular irritation. A once-daily two-compound ointment (Taclonex) or foam (Enstilar) containing calcipotriene and betamethasone dipropionate are available. This combination is more effective than its individual ingredients and is well tolerated, with a safety profile similar to betamethasone dipropionate.

Calcitriol (Vectical) contains 1,25-dihydroxycholecalciferol, the hormonally active form of vitamin D₃. Calcitriol 3 mcg/g ointment is similar in efficacy to calcipotriene 0.005% ointment for the treatment of plaque-type psoriasis on the body and is better tolerated in intertriginous and sensitive areas of the skin. Clinical studies show comparable safety data regarding adverse cutaneous and systemic reactions between topical calcitriol and calcipotriene ointment.

BIOLOGIC AGENTS

Biologic agents useful in treating adult patients with moderate to severe chronic plaque psoriasis include the TNF- α inhibitors adalimumab, etanercept, and infliximab, and the cytokine inhibitors ixekizumab, secukinumab, and ustekinumab (Table 61–2). The pharmacology of these agents is discussed in Chapters 36 and 55.

APREMILAST

Apremilast (Otezla) is an oral phosphodiesterase 4 (PDE4) inhibitor that is effective in treating moderate to severe plaque psoriasis. Selective inhibition of PDE4 specific for cyclic adenosine monophosphate (cAMP) results in increased intracellular cAMP levels. The specific mechanism by which apremilast exerts its therapeutic effect in psoriasis is not known. Initial dosage titration from day 1 to day 5, intended to reduce the gastrointestinal symptoms associated with starting therapy, is shown in Table 61–3. Following the 5-day titration, a maintenance dose of 30 mg twice daily is started on day 6.

Treatment with apremilast is associated with an increased incidence of depression. Patients should have their weight monitored regularly due to possible weight loss associated with therapy. Use of cytochrome P450 enzyme inducers (see chapter 4) may result in a loss of efficacy and is not recommended. Apremilast is generally well tolerated with mild gastrointestinal complaints occurring early in the course of treatment that resolve with time.

FUMARIC ACID ESTERS

Fumaric acid esters (Fumaderm) are licensed in Germany for the oral treatment of psoriasis. They are considered homeopathic treatment in the USA and are not approved or regulated by the FDA for the treatment of psoriasis. Dimethyl fumarate (Tecfidera) has recently been approved by the FDA for treatment of multiple sclerosis. The mechanism of action of dimethyl fumarate in psoriasis may be due to immunomodulatory effects on lymphocytes and keratinocytes, resulting in a shift away from a psoriatic cytokine profile. Note that four cases of progressive multifocal leukoencephalopathy have been reported in psoriasis patients treated with fumaric acid esters.

■ ANTI-INFLAMMATORY AGENTS

TOPICAL CORTICOSTEROIDS

The remarkable efficacy of topical corticosteroids in the treatment of inflammatory dermatoses was noted soon after the introduction of hydrocortisone in 1952. Numerous analogs are now available that offer extensive choices of potencies, concentrations, and vehicles. The therapeutic effectiveness of topical corticosteroids is based primarily on their anti-inflammatory activity. Definitive explanations of the effects of corticosteroids on endogenous mediators of inflammation await further experimental clarification. The antimetabolic effects of corticosteroids on human epidermis may account for an additional mechanism of action in psoriasis and other dermatologic diseases associated with increased cell turnover. The general pharmacology of these endocrine agents is discussed in Chapter 39.

TABLE 61–3 Apremilast dosage titration schedule.

Day 1	Day 2		Day 3		Day 4		Day 5		Day 6 & Thereafter	
AM	AM	PM	AM	PM	AM	PM	AM	PM	AM	PM
10 mg	10 mg	10 mg	10 mg	20 mg	20 mg	20 mg	20 mg	30 mg	30 mg	30 mg

Chemistry & Pharmacokinetics

The original topical glucocorticosteroid was hydrocortisone, the natural glucocorticosteroid of the adrenal cortex. The 9 α -fluoro derivative of hydrocortisone was active topically, but its salt-retaining properties made it undesirable even for topical use. Prednisolone and methylprednisolone are as active topically as hydrocortisone (Table 61–4). The 9 α -fluorinated steroids dexamethasone and betamethasone did not have any advantage over hydrocortisone. However, triamcinolone and fluocinolone, the acetonide derivatives of the fluorinated steroids, do have a distinct efficacy advantage in topical therapy. Similarly, betamethasone is not very active topically, but attaching a 5-carbon valerate chain to the 17-hydroxyl position results in a compound over 300 times as active as hydrocortisone for topical use. Fluocinonide is the 21-acetate derivative of fluocinolone acetonide; the addition of the 21-acetate enhances the topical activity

about fivefold. Fluorination of the corticoid is not required for high potency.

Corticosteroids are only minimally absorbed following application to normal skin; for example, approximately 1% of a dose of hydrocortisone solution applied to the ventral forearm is absorbed. Long-term occlusion with an impermeable film such as plastic wrap is an effective method of enhancing penetration, yielding a tenfold increase in absorption. There is a marked regional anatomic variation in corticosteroid penetration. Compared with the absorption from the forearm, hydrocortisone is absorbed 0.14 times as well through the plantar foot arch, 0.83 times as well through the palm, 3.5 times as well through the scalp, 6 times as well through the forehead, 9 times as well through vulvar skin, and 42 times as well through scrotal skin. Penetration is increased severalfold in the inflamed skin of atopic dermatitis; and in severe exfoliative diseases, such as erythrodermic psoriasis, there appears to be little barrier to penetration.

TABLE 61–4 Relative efficacy of some topical corticosteroids in various formulations.

Concentration in Commonly Used Preparations	Drug	Concentration in Commonly Used Preparations	Drug
Lowest efficacy		Intermediate efficacy (continued)	
0.25–2.5%	Hydrocortisone	0.05%	Fluticasone propionate (Cutivate)
0.25%	Methylprednisolone acetate (Medrol)	0.05%	Desonide (Desowen)
0.1%	Dexamethasone ¹ (Decaderm)	0.025%	Halcinonide ¹ (Halog)
1.0%	Methylprednisolone acetate (Medrol)	0.05%	Desoximetasone ¹ (Topicort L.P.)
0.5%	Prednisolone (MetiDerm)	0.05%	Flurandrenolide ¹ (Cordran)
0.2%	Betamethasone ¹ (Celestone)	0.1%	Triamcinolone acetonide ¹
Low efficacy		0.025%	Fluocinolone acetonide ¹
0.01%	Fluocinolone acetonide ¹ (Fluonid, Synalar)	High efficacy	
0.01%	Betamethasone valerate ¹ (Valisone)	0.05%	Fluocinonide ¹ (Lidex)
0.025%	Fluorometholone ¹ (Oxylone)	0.05%	Betamethasone dipropionate ¹ (Diprosone, Maxivate)
0.05%	Alclometasone dipropionate (Aclovate)	0.1%	Amcinonide ¹ (Cyclocort)
0.025%	Triamcinolone acetonide ¹ (Aristocort, Kenalog, Triacet)	0.25%	Desoximetasone ¹ (Topicort)
0.1%	Clocortolone pivalate ¹ (Cloderm)	0.5%	Triamcinolone acetonide ¹
0.03%	Flumethasone pivalate ¹ (Locorten)	0.2%	Fluocinolone acetonide ¹ (Synalar-HP)
Intermediate efficacy		0.05%	Diflorasone diacetate ¹ (Florone, Maxiflor)
0.2%	Hydrocortisone valerate (Westcort)	0.1%	Halcinonide ¹ (Halog)
0.1%	Mometasone furoate (Elocon)	Highest efficacy	
0.1%	Hydrocortisone butyrate (Locoid)	0.05%	Betamethasone dipropionate in optimized vehicle (Diprolene) ¹
0.1%	Hydrocortisone probutate (Pandel)	0.05%	Diflorasone diacetate ¹ in optimized vehicle (Psorcon)
0.025%	Betamethasone benzoate ¹ (Uticort)	0.05%	Halobetasol propionate ¹ (Ultravate)
0.025%	Flurandrenolide ¹ (Cordran)	0.05%	Clobetasol propionate ¹ (Temovate)
0.1%	Betamethasone valerate ¹ (Valisone)		
0.1%	Prednicarbate (Dermatop)		

¹Fluorinated steroids.

Experimental studies on the percutaneous absorption of hydrocortisone fail to reveal a significant increase in absorption when applied on a repetitive basis and a single daily application may be effective in most conditions. Ointment bases tend to give better activity to the corticosteroid than do cream or lotion vehicles. Increasing the concentration of a corticosteroid increases the penetration but not proportionately. For example, approximately 1% of a 0.25% hydrocortisone solution is absorbed from the forearm. A tenfold increase in concentration causes only a fourfold increase in absorption. Solubility of the corticosteroid in the vehicle is a significant determinant of the percutaneous absorption of a topical steroid. Marked increases in efficacy are noted when optimized vehicles are used, as demonstrated by newer formulations of betamethasone dipropionate and diflorasone diacetate.

Table 61–4 groups topical corticosteroid formulations according to approximate relative efficacy. Table 61–5 lists major dermatologic diseases in order of their responsiveness to these drugs.

TABLE 61–5 Dermatologic disorders responsive to topical corticosteroids ranked in order of sensitivity.

Very responsive
Atopic dermatitis
Seborrheic dermatitis
Lichen simplex chronicus
Pruritus ani
Later phase of allergic contact dermatitis
Later phase of irritant dermatitis
Nummular eczematous dermatitis
Stasis dermatitis
Psoriasis, especially of genitalia and face
Less responsive
Discoid lupus erythematosus
Psoriasis of palms and soles
Necrobiosis lipoidica diabetorum
Sarcoidosis
Lichen striatus
Pemphigus
Familial benign pemphigus
Pemphigoid
Vitiligo
Granuloma annulare
Least responsive: Intralesional injection required
Keloids
Hypertrophic scars
Hypertrophic lichen planus
Alopecia areata
Acne cysts
Prurigo nodularis
Chondrodermatitis nodularis chronica helices

In the first group of diseases, low- to medium-efficacy corticosteroid preparations often produce clinical remission. In the second group, it is often necessary to use high-efficacy preparations, occlusion therapy, or both. Once a remission has been achieved, every effort should be made to maintain the improvement with a low-efficacy corticosteroid.

The limited penetration of topical corticosteroids can be overcome in certain clinical circumstances by the intralesional injection of relatively insoluble corticosteroids, eg, triamcinolone acetonide, triamcinolone diacetate, triamcinolone hexacetonide, and betamethasone acetate-phosphate. When these agents are injected into the lesion, measurable amounts remain in place and are gradually released for 3–4 weeks. This form of therapy is often effective for the lesions listed in Table 61–5 that are generally unresponsive to topical corticosteroids. The dosage of the triamcinolone salts should be limited to 1 mg per treatment site, ie, 0.1 mL of 10 mg/mL suspension, to decrease the incidence of local atrophy (see below).

Adverse Effects

All absorbable topical corticosteroids possess the potential to suppress the pituitary-adrenal axis (see Chapter 39). Although most patients with pituitary-adrenal axis suppression demonstrate only a laboratory test abnormality, cases of severely impaired stress response can occur. Iatrogenic Cushing's syndrome may occur as a result of protracted use of topical corticosteroids in large quantities. Applying potent corticosteroids to extensive areas of the body for prolonged periods, with or without occlusion, increases the likelihood of systemic effects. Fewer of these factors are required to produce adverse systemic effects in children, and growth retardation is of particular concern in the pediatric age group.

Adverse local effects of topical corticosteroids include the following: atrophy, which may present as depressed, shiny, often wrinkled "cigarette paper"-appearing skin with prominent telangiectases and a tendency to develop purpura and ecchymosis; corticoid rosacea, with persistent erythema, telangiectatic vessels, pustules, and papules in central facial distribution; perioral dermatitis, steroid acne, alterations of cutaneous infections, hypopigmentation, and hypertrichosis; increased intraocular pressure; and allergic contact dermatitis. The latter may be confirmed by patch testing with high concentrations of corticosteroids, ie, 1% in petrolatum, because topical corticosteroids are not irritating. Screening for allergic contact dermatitis potential is performed with tixocortol pivalate, budesonide, and hydrocortisone valerate or butyrate. Topical corticosteroids are contraindicated in individuals who demonstrate hypersensitivity to them. Some sensitized subjects develop a generalized flare when dosed with adrenocorticotrophic hormone or oral prednisone. Systemic corticosteroid use is discussed in Chapter 39.

CRISABOROLE

Crisaborole (Eucrisa) is a benzoxaborole, nonsteroidal, topical, anti-inflammatory PDE4 inhibitor approved as a 2% ointment for the treatment of mild-to-moderate atopic dermatitis

in patients 2 years of age and older. The most frequent adverse effect is burning or stinging at the site of application. The specific mechanism of action in atopic dermatitis is unknown. Long-term safety in clinical application remains to be determined.

TAR COMPOUNDS

Tar preparations are used mainly in the treatment of psoriasis, dermatitis, and lichen simplex chronicus. The phenolic constituents endow these compounds with antipruritic properties, making them particularly valuable in the treatment of chronic lichenified dermatitis. Acute dermatitis with vesiculation and oozing may be irritated by even weak tar preparations, which should be avoided. However, in the subacute and chronic stages of dermatitis and psoriasis, these preparations are quite useful and offer an alternative to the use of topical corticosteroids.

The most common adverse reaction to coal tar compounds is an irritant folliculitis, necessitating discontinuance of therapy to the affected areas for a period of 3–5 days. Photoirritation and allergic contact dermatitis may also occur. Tar preparations should be avoided in patients who have previously exhibited sensitivity to them.

KERATOLYTIC & DESTRUCTIVE AGENTS

SALICYLIC ACID

Salicylic acid has been extensively used in dermatologic therapy as a keratolytic agent. The mechanism by which it produces its keratolytic and other therapeutic effects is poorly understood. The drug may solubilize cell surface proteins that keep the stratum corneum intact, thereby resulting in desquamation of keratotic debris. Salicylic acid is keratolytic in concentrations of 3–6%. In concentrations greater than 6%, it can be destructive to tissues.

Salicylic acid

Salicylism and death have occurred following topical application. In an adult, 1 g of a topically applied 6% salicylic acid preparation will raise the serum salicylate level not more than 0.5 mg/dL of plasma; the threshold for toxicity is 30–50 mg/dL. Higher serum levels are possible in children, who are therefore at a greater risk for salicylism. In cases of severe intoxication, hemodialysis is the treatment of choice (see Chapter 58). It is advisable to limit both the total amount of salicylic acid applied and the frequency of application. Urticarial, anaphylactic, and erythema multiforme reactions may occur in patients who are allergic to salicylates.

Topical use may be associated with local irritation, acute inflammation, and even ulceration with the use of high concentrations of salicylic acid. Particular care must be exercised when using the drug on the extremities of patients with diabetes or peripheral vascular disease.

PROPYLENE GLYCOL

Propylene glycol is used extensively in topical preparations because it is an excellent vehicle for organic compounds. It has been used alone as a keratolytic agent in 40–70% concentrations, with plastic occlusion, or in gel with 6% salicylic acid.

Only minimal amounts of a topically applied dose are absorbed through normal stratum corneum. Percutaneously absorbed propylene glycol is oxidized by the liver to lactic acid and pyruvic acid, with subsequent utilization in general body metabolism. Approximately 12–45% of the absorbed agent is excreted unchanged in the urine.

Propylene glycol is an effective keratolytic agent for the removal of hyperkeratotic debris. It is also an effective humectant and increases the water content of the stratum corneum. The hygroscopic characteristics of propylene glycol may help it to develop an osmotic gradient through the stratum corneum, thereby increasing hydration of the outermost layers by drawing water out from the inner layers of the skin.

Propylene glycol is used under polyethylene occlusion or with 6% salicylic acid for the treatment of ichthyosis, palmar and plantar keratodermas, psoriasis, pityriasis rubra pilaris, keratosis pilaris, and hypertrophic lichen planus.

In concentrations greater than 10%, propylene glycol may act as an irritant in some patients; those with eczematous dermatitis may be more sensitive. Allergic contact dermatitis occurs with propylene glycol, and a 4% aqueous propylene glycol solution is recommended for the purpose of patch testing.

UREA

Urea in a compatible cream vehicle or ointment base has a softening and moisturizing effect on the stratum corneum. It has the ability to make creams and lotions feel less greasy, and this has been utilized in dermatologic preparations to decrease the oily feel of a preparation that otherwise might feel unpleasant. It is a white crystalline powder with a slight ammonia odor when moist.

Urea is absorbed percutaneously, although the amount absorbed is minimal. It is distributed predominantly in the extracellular space and excreted in urine. Urea is a natural product of metabolism, and systemic toxicities with topical application do not occur.

Urea increases the water content of the stratum corneum, presumably as a result of the hygroscopic characteristics of this naturally occurring molecule. Urea is also keratolytic. The mechanism of action appears to involve alterations in prekeratin and keratin, leading to increased solubilization. In addition, urea may break hydrogen bonds that keep the stratum corneum intact.

As a humectant, urea is used in concentrations of 2–20% in creams and lotions. As a keratolytic agent, it is used in 20% concentration in diseases such as ichthyosis vulgaris, hyperkeratosis of palms and soles, xerosis, and keratosis pilaris. Concentrations of 30–50% applied to the nail plate have been useful in softening the nail prior to avulsion.

PODOPHYLLUM RESIN & PODOFILOX

Podophyllum resin, an alcoholic extract of *Podophyllum peltatum*, commonly known as mandrake root or May apple, is used in the treatment of condyloma acuminatum and other verrucae. It is a mixture of podophyllotoxin, α and β peltatin, desoxypodophyllotoxin, dehydropodophyllotoxin, and other compounds. It is soluble in alcohol, ether, chloroform, and compound tincture of benzoin.

Percutaneous absorption of podophyllum resin occurs, particularly in intertriginous areas and from applications to large moist condylomas. It is soluble in lipids and therefore is distributed widely throughout the body, including the central nervous system.

The major use of podophyllum resin is in the treatment of condyloma acuminatum. Podophyllotoxin and its derivatives are active cytotoxic agents with specific affinity for the microtubule protein of the mitotic spindle. Normal assembly of the spindle is prevented, and epidermal mitoses are arrested in metaphase. A 25% concentration of podophyllum resin in compound tincture of benzoin is recommended for the treatment of condyloma acuminatum. Application should be restricted to wart tissue only, to limit the total amount of medication used and to prevent severe erosive changes in adjacent tissue. In treating cases of large condylomas, it is advisable to limit application to sections of the affected area to minimize systemic absorption. The patient is instructed to wash off the preparation 2–3 hours after the initial application, because the irritant reaction is variable. Depending on the individual patient's reaction, this period can be extended to 6–8 hours on subsequent applications. If three to five applications have not resulted in significant resolution, other methods of treatment should be considered.

Toxic symptoms associated with excessively large applications include nausea, vomiting, alterations in sensorium, muscle weakness, neuropathy with diminished tendon reflexes, coma, and even death. Local irritation is common, and inadvertent contact with the eye may cause severe conjunctivitis. Use during pregnancy is contraindicated in view of possible cytotoxic effects on the fetus.

Pure podophyllotoxin (podofilox) is approved for use as either a 0.5% solution or gel (Condylox) for application by the patient in the treatment of genital condylomas. The low concentration of podofilox significantly reduces the potential for systemic toxicity. Most men with penile warts may be treated with less than 70 μ L per application. At this dose, podofilox is not routinely detected in the serum. Treatment is self-administered in treatment cycles of twice-daily application for 3 consecutive days followed by a 4-day

drug-free period. Local adverse effects include inflammation, erosions, burning pain, and itching.

SINECATECHINS

Sinecatechins 15% ointment (Veregen) is a prescription botanical drug product of a partially purified fraction of the water extract of green tea leaves from *Camellia sinensis* containing a mixture of catechins. Sinecatechins ointment is indicated for the topical treatment of external genital and perianal warts in immunocompetent patients 18 years and older. The mechanism of action is unknown. Sinecatechins ointment should be applied three times daily to the warts until complete clearance, not to exceed 16 weeks of therapy.

FLUOROURACIL

Fluorouracil is a fluorinated pyrimidine antimetabolite that resembles uracil, with a fluorine atom substituted for the 5-methyl group. Its systemic pharmacology is described in Chapter 54. Fluorouracil is used topically for the treatment of multiple actinic keratoses.

Approximately 6% of a topically applied dose is absorbed—an amount insufficient to produce adverse systemic effects. Most of the absorbed drug is metabolized and excreted as carbon dioxide, urea, and α -fluoro- β -alanine. A small percentage is eliminated unchanged in the urine. Fluorouracil inhibits thymidylate synthetase activity, interfering with the synthesis of DNA and, to a lesser extent, RNA. These effects are most marked in atypical, rapidly proliferating cells.

Fluorouracil is available in multiple formulations containing 0.5%, 1%, 2%, 4%, and 5% concentrations (Carac, Efudex, Fluoroplex, Tolak). The response to treatment begins with erythema and progresses through vesiculation, erosion, superficial ulceration, necrosis, and finally reepithelialization. Fluorouracil should be continued until the inflammatory reaction reaches the stage of ulceration and necrosis, usually in 3–4 weeks, at which time treatment should be terminated. The healing process may continue for 1–2 months after therapy is discontinued. Local adverse reactions may include pain, pruritus, a burning sensation, tenderness, and residual postinflammatory hyperpigmentation. Excessive exposure to sunlight during treatment may increase the intensity of the reaction and should be avoided. Allergic contact dermatitis to fluorouracil has been reported, and its use is contraindicated in patients with known hypersensitivity.

INGENOL MEBUGATE

Ingenol mebugate (Picato) is derived from the sap of the *Euphorbia peplus* plant and has recently been approved for the topical treatment of actinic keratoses. The mechanism by which ingenol mebugate induces keratinocyte cell death is unknown. For the treatment of actinic keratoses on the face and scalp, the 0.015% gel should be applied once daily for 3 consecutive days. For actinic keratoses on the trunk and extremities, the 0.05% gel should be applied to the

affected area daily for 2 consecutive days. Local skin reactions are to be expected with crusting, swelling, vesiculation, and possible ulceration. Caution must be taken to prevent eye exposure. Patients must wash their hands well after applying the gel and avoid transfer of the drug to the periocular area during and after application.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

A topical 3% gel formulation of the nonsteroidal anti-inflammatory drug diclofenac (Solaraze) has shown moderate effectiveness in the treatment of actinic keratoses. The mechanism of action is unknown. As with other NSAIDs, anaphylactoid reactions may occur with diclofenac, and it should be given with caution to patients with known aspirin hypersensitivity (see Chapter 36).

AMINOLEVULINIC ACID

Aminolevulinic acid (ALA) is an endogenous precursor of photosensitizing porphyrin metabolites. When exogenous ALA is provided to the cell through topical applications, protoporphyrin IX (PpIX) accumulates in the cell. When exposed to light of appropriate wavelength and energy, the accumulated PpIX produces a photodynamic reaction resulting in the formation of cytotoxic superoxide and hydroxyl radicals. Photosensitization of actinic keratoses using ALA (Levulan Kerastick) and illumination with a blue light photodynamic therapy illuminator (BLU-U) is the basis for ALA photodynamic therapy.

Treatment consists of applying ALA 20% topical solution to individual actinic keratoses followed by blue light photodynamic illumination 14–18 hours later. Transient stinging or burning at the treatment site occurs during the period of light exposure. Patients *must* avoid exposure to sunlight or bright indoor lights for at least 40 hours after ALA application. Redness, swelling, and crusting of the actinic keratoses will occur and gradually resolve over a 3- to 4-week time course. Allergic contact dermatitis to methyl ester may occur.

■ ANTIPRURITIC AGENTS

DOXEPIN

Topical doxepin hydrochloride 5% cream (Zonalon) may provide significant antipruritic activity when utilized in the treatment of pruritus associated with atopic dermatitis or lichen simplex chronicus. The precise mechanism of action is unknown but may relate to the potent H_1 - and H_2 -receptor antagonist properties of dibenzoxepin tricyclic compounds. Percutaneous absorption is variable and may result in significant drowsiness in some patients. In view of the anticholinergic effect of doxepin, topical use is contraindicated in patients with untreated narrow-angle glaucoma or a tendency to urinary retention.

Plasma levels of doxepin similar to those achieved during oral therapy may be obtained with topical application; the usual drug interactions associated with tricyclic antidepressants may occur. Therefore, monoamine oxidase inhibitors must be discontinued at least 2 weeks prior to the initiation of doxepin cream. Topical application of the cream should be performed four times daily for up to 8 days of therapy. The safety and efficacy of chronic dosing have not been established. Adverse local effects include marked burning and stinging of the treatment site, which may necessitate discontinuation of the cream in some patients. Allergic contact dermatitis appears to be frequent, and patients should be monitored for symptoms of hypersensitivity.

PRAMOXINE

Pramoxine hydrochloride is a topical anesthetic that can provide temporary relief from pruritus associated with mild eczematous dermatoses. Pramoxine is available as a 1% cream, lotion, or gel and in combination with hydrocortisone acetate. Application to the affected area two to four times daily may provide short-term relief of pruritus. Local adverse effects include transient burning and stinging. Care should be exercised to avoid contact with the eyes.

■ ANTISEBORRHEA AGENTS

Table 61–6 lists topical formulations for the treatment of seborrheic dermatitis. These are of variable efficacy and may necessitate concomitant treatment with topical corticosteroids for severe cases.

■ TRICHOGENIC & ANTITRICHOGENIC AGENTS

MINOXIDIL

Topical minoxidil (Rogaine) is effective in reversing the progressive miniaturization of terminal scalp hairs associated with androgenic alopecia. Vertex balding is more responsive

TABLE 61–6 Antiseborrhea agents.

Active Ingredient	Typical Trade Name
Betamethasone valerate foam	Luxiq
Chloroxine shampoo	Capitol
Coal tar shampoo	Ionil-T, Pentrax, Theraplex-T, T-Gel
Fluocinolone acetonide shampoo	FS Shampoo
Ketoconazole shampoo and gel	Nizoral, Xolegel
Selenium sulfide shampoo	Selsun, Exsel
Zinc pyrithione shampoo	DHS-Zinc, Theraplex-Z

to therapy than frontal balding. The mechanism of action of minoxidil on hair follicles is unknown. Chronic dosing studies have demonstrated that the effect of minoxidil is not permanent, and cessation of treatment will lead to hair loss in 4–6 months. Percutaneous absorption of minoxidil in normal scalp is minimal, but possible systemic effects on blood pressure (see Chapter 11) should be monitored in patients with cardiac disease.

FINASTERIDE

Finasteride (Propecia) is a 5 α -reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone (see Chapter 40), the androgen responsible for androgenic alopecia in genetically predisposed men. Oral finasteride, 1 mg/d, promotes hair growth and prevents further hair loss in a significant proportion of men with androgenic alopecia. Treatment for at least 3–6 months is necessary to see increased hair growth or prevent further hair loss. Continued treatment with finasteride is necessary to sustain benefit. Reported adverse effects include decreased libido, ejaculation disorders, and erectile dysfunction, which resolve in most men who remain on therapy and in all men who discontinue finasteride.

There are no data to support the use of finasteride in women with androgenic alopecia. Pregnant women should not be exposed to finasteride either by use or by handling crushed tablets because of the risk of hypospadias developing in a male fetus.

BIMATOPROST

Bimatoprost (Latisse) is a prostaglandin analog available as a 0.03% ophthalmic solution to treat hypotrichosis of the eyelashes. Mechanism of action is unknown. Treatment consists of nightly application to the skin of the upper eyelid margins at the base of the eyelashes using a separate disposable applicator for each eyelid. Contact lenses should be removed prior to bimatoprost application. Side effects include pruritus, conjunctival hyperemia, skin pigmentation, and erythema of the eyelids. Although iris darkening has not been reported with applications confined to the upper eyelid skin, increased brown iris pigmentation, which is likely to be permanent, has occurred when bimatoprost ophthalmic solution was instilled onto the eye for glaucoma.

EFLORNITHINE

Eflornithine (Vaniqa) is an irreversible inhibitor of ornithine decarboxylase, which catalyzes the rate-limiting step in the biosynthesis of polyamines. Polyamines are required for cell division and differentiation, and inhibition of ornithine decarboxylase affects the rate of hair growth. Topical eflornithine has been shown effective in reducing facial hair growth in approximately 30% of women when applied twice daily for 6 months of therapy. Hair growth was observed to return to pretreatment levels 8 weeks

after discontinuation. Local adverse effects include stinging, burning, and folliculitis.

■ ANTINEOPLASTIC AGENTS

The treatment of melanoma is discussed in Chapter 54.

Alitretinoin (Panretin) is a topical formulation of 9-*cis*-retinoic acid that is approved for the treatment of cutaneous lesions in patients with AIDS-related Kaposi's sarcoma. Localized reactions may include intense erythema, edema, and vesiculation necessitating discontinuation of therapy. Patients who are applying alitretinoin should not concurrently use products containing DEET, a common component of insect repellent products.

Bexarotene (Targretin), a member of a subclass of retinoids that selectively binds and activates retinoid X receptor subtypes, is available both in an oral formulation and as a topical gel for the treatment of cutaneous T-cell lymphoma. Teratogenicity is a significant risk for both systemic and topical treatment with bexarotene, and women of childbearing potential must avoid becoming pregnant throughout therapy and for at least 1 month following discontinuation of the drug. Bexarotene may increase levels of triglycerides and cholesterol; therefore, lipid levels must be monitored during treatment.

Vismodegib (Erivedge) and **sonidegib** (Odomzo) are oral hedgehog pathway inhibitors for the treatment of metastatic basal cell carcinoma or locally advanced basal cell carcinoma in adults who are not candidates for surgery or radiation. They are highly effective in patients with basal cell nevus syndrome. The recommended dosage of vismodegib is 150 mg daily and sonidegib is 200 mg daily. The most common adverse effects include dysgeusia and ageusia, alopecia, fatigue, and muscle spasms.

Baseline serum creatine kinase and creatinine levels prior to initiating therapy and during treatment may be indicated for significant musculoskeletal symptoms.

Hedgehog pathway inhibitors are embryotoxic, fetotoxic, and teratogenic in animals. Pregnancy status of females of reproductive potential must be verified within 7 days prior to initiating therapy. Exposure may occur through seminal fluid.

Vorinostat (Zolinza) and **romidepsin** (Istodax) are histone deacetylase inhibitors that are approved for the treatment of cutaneous T-cell lymphoma in patients with progressive, persistent, or recurrent disease after prior systemic therapy. Adverse effects include thrombocytopenia, anemia, and gastrointestinal disturbances. Pulmonary embolism, which has occurred with vorinostat, has not been reported to date with romidepsin.

■ MISCELLANEOUS MEDICATIONS

Drugs used primarily for other conditions may also find use as oral therapeutic agents for dermatologic conditions. A few such preparations are listed in Table 61–7.

TABLE 61–7 Miscellaneous medications and the dermatologic conditions in which they are used.

Drug or Group	Conditions	For More Details, See:
Antihistamines	Pruritus (any cause), urticarial	Chapter 16

CASE STUDY ANSWER

Initiation of oral doxycycline therapy was discussed with the patient. She expressed concerns regarding possible adverse effects of prolonged systemic therapy. In light of this, daily

morning application of brimonidine 0.33% gel was added to her treatment regimen. The patient noted prompt response with significant improvement of her facial redness.

Drugs Used in the Treatment of Gastrointestinal Diseases

Kenneth R. McQuaid, MD

CASE STUDY

A 21-year-old woman comes with her parents to discuss therapeutic options for her Crohn's disease. She was diagnosed with Crohn's disease 2 years ago, and it involves her terminal ileum and proximal colon, as confirmed by colonoscopy and small bowel radiography. She was initially treated with mesalamine and budesonide with good response, but over the last 2 months, she has had a relapse of her symptoms. She is experiencing fatigue, cramping, abdominal pains, and nonbloody diarrhea up to 10 times daily, and she has had a 15-lb weight loss.

She has no other significant medical or surgical history. Her current medications are mesalamine 2.4 g/d and budesonide 9 mg/d. She appears thin and tired. Abdominal examination reveals tenderness without guarding in the right lower quadrant; no masses are palpable. On perianal examination, there is no tenderness, fissure, or fistula. Her laboratory data are notable for anemia and elevated C-reactive protein. What are the options for immediate control of her symptoms and disease? What are the long-term management options?

INTRODUCTION

Many of the drug groups discussed elsewhere in this book have important applications in the treatment of diseases of the gastrointestinal tract and other organs. Other groups are used almost exclusively for their effects on the gut; these are discussed in the following text according to their therapeutic uses.

■ DRUGS USED IN ACID-PEPTIC DISEASES

Acid-peptic diseases include gastroesophageal reflux, peptic ulcer (gastric and duodenal), and stress-related mucosal injury. In all these conditions, mucosal erosions or ulceration arise when the caustic effects of aggressive factors (acid, pepsin, bile) overwhelm the defensive factors of the gastrointestinal mucosa (mucus and

bicarbonate secretion, prostaglandins, blood flow, and the processes of restitution and regeneration after cellular injury). Over 90% of peptic ulcers are caused by infection with the bacterium *Helicobacter pylori* or by use of nonsteroidal anti-inflammatory drugs (NSAIDs). Drugs used in the treatment of acid-peptic disorders may be divided into two classes: agents that reduce intragastric acidity and agents that promote mucosal defense.

AGENTS THAT REDUCE INTRAGASTRIC ACIDITY

PHYSIOLOGY OF ACID SECRETION

The parietal cell contains receptors for gastrin (CCK-B), histamine (H₂), and acetylcholine (muscarinic, M₃) (Figure 62-1). When acetylcholine (from vagal postganglionic nerves) and gastrin (released from antral G cells into the blood) bind to the parietal

FIGURE 62-1 Schematic model for physiologic control of hydrogen ion (acid) secretion by the parietal cells of the gastric fundic glands. Parietal cells are stimulated to secrete acid (H^+) by gastrin (acting on gastrin/CCK-B receptor), acetylcholine (M_3 receptor), and histamine (H_2 receptor). Acid is secreted across the parietal cell canalicular membrane by the H^+/K^+ -ATPase proton pump into the gastric lumen. Gastrin is secreted by antral G cells into blood vessels in response to intraluminal dietary peptides. Within the gastric body, gastrin passes from the blood vessels into the submucosal tissue of the fundic glands, where it binds to gastrin-CCK-B receptors on parietal cells and enterochromaffin-like (ECL) cells. The vagus nerve stimulates postganglionic neurons of the enteric nervous system to release acetylcholine (ACh), which binds to M_3 receptors on parietal cells and ECL cells. Stimulation of ECL cells by gastrin (CCK-B receptor) or acetylcholine (M_3 receptor) stimulates release of histamine. Within the gastric antrum, vagal stimulation of postganglionic enteric neurons enhances gastrin release directly by stimulation of antral G cells (through gastrin-releasing peptide, GRP) and indirectly by inhibition of somatostatin secretion from antral D cells. Acid secretion must eventually be turned off. Antral D cells are stimulated to release somatostatin by the rise in intraluminal H^+ concentration and by CCK that is released into the bloodstream by duodenal I cells in response to proteins and fats (not shown). Binding of somatostatin to receptors on adjacent antral G cells inhibits further gastrin release. ATPase, H^+/K^+ -ATPase proton pump; CCK, cholecystokinin; M_3 -R, muscarinic receptors.

cell receptors, they cause an increase in cytosolic calcium, which in turn stimulates protein kinases that stimulate acid secretion from a H^+/K^+ -ATPase (the proton pump) on the canalicular surface.

In close proximity to the parietal cells are gut endocrine cells called **enterochromaffin-like (ECL) cells**. ECL cells also have receptors for gastrin and acetylcholine, which stimulate histamine release. Histamine binds to the H_2 receptor on the parietal cell, resulting in activation of adenyl cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP) and activates protein kinases that stimulate acid secretion by the H^+/K^+ -ATPase. In humans, it is believed that the major effect of gastrin upon acid

secretion is mediated indirectly through the release of histamine from ECL cells rather than through direct parietal cell stimulation. In contrast, acetylcholine provides potent direct parietal cell stimulation.

ANTACIDS

Antacids have been used for centuries in the treatment of patients with dyspepsia and acid-peptic disorders. They were the mainstay of treatment for acid-peptic disorders until the advent

of H_2 -receptor antagonists and proton-pump inhibitors (PPIs). They continue to be used commonly by patients as nonprescription remedies for the treatment of intermittent heartburn and dyspepsia.

Antacids are weak bases that react with gastric hydrochloric acid to form a salt and water. Their principal mechanism of action is reduction of intragastric acidity. After a meal, approximately 45 mEq/h of hydrochloric acid is secreted. A single dose of 156 mEq of antacid given 1 hour after a meal effectively neutralizes gastric acid for up to 2 hours. However, the acid-neutralization capacity among different proprietary formulations of antacids is highly variable, depending on their rate of dissolution (tablet versus liquid), water solubility, rate of reaction with acid, and rate of gastric emptying.

Sodium bicarbonate (eg, baking soda, Alka Seltzer) reacts rapidly with hydrochloric acid (HCl) to produce carbon dioxide and sodium chloride. Formation of carbon dioxide results in gastric distention and belching. Unreacted alkali is readily absorbed, potentially causing metabolic alkalosis when given in high doses or to patients with renal insufficiency. Sodium chloride absorption may exacerbate fluid retention in patients with heart failure, hypertension, and renal insufficiency. **Calcium carbonate** (eg, Tums, Os-Cal) is less soluble and reacts more slowly than sodium bicarbonate with HCl to form carbon dioxide and calcium chloride ($CaCl_2$). Like sodium bicarbonate, calcium carbonate may cause belching or metabolic alkalosis. Calcium carbonate is used for a number of other indications apart from its antacid properties (see Chapter 42). Excessive doses of either sodium bicarbonate or calcium carbonate with calcium-containing dairy products can lead to hypercalcemia, renal insufficiency, and metabolic alkalosis (milk-alkali syndrome).

Formulations containing **magnesium hydroxide** or **aluminum hydroxide** react slowly with HCl to form magnesium chloride or aluminum chloride and water. Because no gas is generated, belching does not occur. Metabolic alkalosis is also uncommon because of the efficiency of the neutralization reaction. Because unabsorbed magnesium salts may cause an osmotic diarrhea and aluminum salts may cause constipation, these agents are commonly administered together in proprietary formulations (eg, Gelusil, Maalox, Mylanta) to minimize the impact on bowel function.

Both magnesium and aluminum are absorbed and excreted by the kidneys. Hence, patients with renal insufficiency should not take these agents long-term.

All antacids may affect the absorption of other medications by binding the drug (reducing its absorption) or by increasing intragastric pH so that the drug's dissolution or solubility (especially weakly basic or acidic drugs) is altered. Therefore, antacids should not be given within 2 hours of doses of tetracyclines, fluoroquinolones, itraconazole, and iron.

H_2 -RECEPTOR ANTAGONISTS

From their introduction in the 1970s until the early 1990s, H_2 -receptor antagonists (commonly referred to as H_2 blockers) were the most commonly prescribed drugs in the world (see Clinical Uses). With the recognition of the role of *H. pylori* in ulcer disease (which may be treated with appropriate antibacterial therapy) and the advent of PPIs, the use of prescription H_2 blockers has declined markedly.

Chemistry & Pharmacokinetics

Four H_2 antagonists are in clinical use: cimetidine, ranitidine, famotidine, and nizatidine. All four agents are rapidly absorbed from the intestine. Cimetidine, ranitidine, and famotidine undergo first-pass hepatic metabolism resulting in a bioavailability of approximately 50%. Nizatidine has little first-pass metabolism. The serum half-lives of the four agents range from 1.1 to 4 hours; however, duration of action depends on the dose given (Table 62-1). H_2 antagonists are cleared by a combination of hepatic metabolism, glomerular filtration, and renal tubular secretion. Dose reduction is required in patients with moderate to severe renal (and possibly severe hepatic) insufficiency. In the elderly, there is a decline of up to 50% in drug clearance as well as a significant reduction in volume of distribution.

Cimetidine

TABLE 62-1 Clinical comparisons of H_2 -receptor blockers.

Drug	Relative Potency	Dose to Achieve >50% Acid Inhibition for 10 Hours	Usual Dose for Acute Duodenal or Gastric Ulcer	Usual Dose for Gastroesophageal Reflux Disease	Usual Dose for Prevention of Stress- Related Bleeding
Cimetidine	1	400–800 mg	800 mg HS or 400 mg bid	800 mg bid	50 mg/h continuous infusion
Ranitidine	4–10	150 mg	300 mg HS or 150 mg bid	150 mg bid	6.25 mg/h continuous infusion or 50 mg IV every 6–8 h
Nizatidine	4–10	150 mg	300 mg HS or 150 mg bid	150 mg bid	Not available
Famotidine	20–50	20 mg	40 mg HS or 20 mg bid	20 mg bid	20 mg IV every 12 h

bid, twice daily; HS, bedtime.

Pharmacodynamics

The H_2 antagonists exhibit competitive inhibition at the parietal cell H_2 receptor and suppress basal and meal-stimulated acid secretion (Figure 62–2) in a linear, dose-dependent manner. They are highly selective and do not affect H_1 or H_3 receptors (see Chapter 16). The volume of gastric secretion and the concentration of pepsin are also reduced.

H_2 antagonists reduce acid secretion stimulated by histamine as well as by gastrin and cholinomimetic agents through two mechanisms. First, histamine released from ECL cells by gastrin or vagal stimulation is blocked from binding to the parietal cell H_2 receptor. Second, direct stimulation of the parietal cell by gastrin or acetylcholine has a diminished effect on acid secretion in the presence of H_2 -receptor blockade.

The potencies of the four H_2 -receptor antagonists vary over a 50-fold range (Table 62–1). When given in usual prescription doses, however, all inhibit 60–70% of total 24-hour acid secretion. H_2 antagonists are especially effective at inhibiting nocturnal acid secretion (which depends largely on histamine), but they have a modest impact on meal-stimulated acid secretion (which is stimulated by gastrin and acetylcholine as well as histamine). Therefore, nocturnal and fasting intragastric pH is raised to 4–5, but the impact on the daytime, meal-stimulated pH profile is less. Recommended prescription doses maintain greater than 50% acid inhibition for 10 hours; hence, these drugs are commonly given twice daily. At doses available in over-the-counter formulations, the duration of acid inhibition is 6–10 hours.

Clinical Uses

H_2 -receptor antagonists continue to be prescribed, but PPIs (see below) are more commonly prescribed than H_2 antagonists for most clinical indications. The over-the-counter preparations of the H_2 antagonists are heavily used by the public.

1. Gastroesophageal reflux disease (GERD)—Patients with infrequent heartburn or dyspepsia (fewer than three times per week) may take either antacids or intermittent H_2 antagonists. Because antacids provide rapid acid neutralization, they afford faster symptom relief than H_2 antagonists. However, the effect of antacids is short-lived (1–2 hours) compared with H_2 antagonists (6–10 hours). H_2 antagonists may be taken prophylactically before meals in an effort to reduce the likelihood of heartburn. Frequent heartburn is better treated with twice-daily H_2 antagonists (Table 62–1) or PPIs. In patients with erosive esophagitis (approximately 50% of patients with GERD), H_2 antagonists afford healing in less than 50% of patients; hence PPIs are preferred because of their superior acid inhibition.

2. Peptic ulcer disease—PPIs have largely replaced H_2 antagonists in the treatment of acute peptic ulcer disease. Nevertheless, H_2 antagonists are still sometimes used. Nocturnal acid suppression by H_2 antagonists affords effective ulcer healing in most patients with uncomplicated gastric and duodenal ulcers. Hence, all the agents may be administered once daily at bedtime, resulting in ulcer healing rates >80–90% after 6–8 weeks of therapy.

FIGURE 62–2 Twenty-four-hour median intragastric acidity pretreatment (red) and after 1 month of treatment with either ranitidine, 150 mg twice daily (blue, H_2 block), or omeprazole, 20 mg once daily (green, PPI). Note that H_2 -receptor antagonists have a marked effect on nocturnal acid secretion but only a modest effect on meal-stimulated secretion. Proton-pump inhibitors (PPIs) markedly suppress meal-stimulated and nocturnal acid secretion. (Data from Lanzon-Miller S et al: Twenty-four-hour intragastric acidity and plasma gastrin concentration before and during treatment with either ranitidine or omeprazole. *Aliment Pharmacol Ther* 1987;1:239.)

For patients with ulcers caused by aspirin or other NSAIDs, the NSAID should be discontinued. If the NSAID must be continued for clinical reasons despite active ulceration, a PPI should be given instead of an H_2 antagonist to more reliably promote ulcer healing. For patients with acute peptic ulcers caused by *H. pylori*, H_2 antagonists no longer play a significant therapeutic role. *H. pylori* should be treated with a 10- to 14-day course of therapy including a PPI and two or three antibiotics (see below).

3. Nonulcer dyspepsia— H_2 antagonists are commonly used as over-the-counter agents and prescription agents for treatment of intermittent dyspepsia not caused by peptic ulcer. However, benefit compared with placebo has never been convincingly demonstrated.

4. Prevention of bleeding from stress-related gastritis—Clinically important bleeding from upper gastrointestinal erosions or ulcers occurs in 1–5% of critically ill patients as a result of impaired mucosal defense mechanisms caused by poor perfusion. Although most critically ill patients have normal or decreased acid secretion, numerous studies have shown that agents that increase intragastric pH (H_2 antagonists or PPIs) reduce the incidence of clinically significant bleeding and should be administered to patients who are at high risk of gastrointestinal bleeding. However, the optimal agent is uncertain. For patients who are unable to receive enteral medications, either intravenous H_2 antagonists or PPIs may be administered. Continuous infusions of H_2 antagonists are generally preferred to bolus infusions because they achieve more consistent, sustained elevation of intragastric pH.

Adverse Effects

H_2 antagonists are extremely safe drugs. Adverse effects occur in less than 3% of patients and include diarrhea, headache, fatigue, myalgias, and constipation. Some studies suggest that intravenous H_2 antagonists (or PPIs) may increase the risk of nosocomial pneumonia in critically ill patients.

Mental status changes (confusion, hallucinations, agitation) may occur with administration of intravenous H_2 antagonists, especially in patients in the intensive care unit who are elderly or who have renal or hepatic dysfunction. These events may be more common with cimetidine. Mental status changes rarely occur in ambulatory patients.

Cimetidine inhibits binding of dihydrotestosterone to androgen receptors, inhibits metabolism of estradiol, and increases serum prolactin levels. When used long-term or in high doses, it may cause gynecomastia or impotence in men and galactorrhea in women. These effects are specific to cimetidine and do not occur with the other H_2 antagonists.

Although there are no known harmful effects on the fetus, H_2 antagonists cross the placenta. Therefore, they should not be administered to pregnant women unless absolutely necessary. The H_2 antagonists are secreted into breast milk and may therefore affect nursing infants.

H_2 antagonists may rarely cause blood dyscrasias. Blockade of cardiac H_2 receptors may cause bradycardia, but this is rarely of clinical significance. Rapid intravenous infusion may cause

bradycardia and hypotension through blockade of cardiac H_2 receptors; therefore, intravenous infusions should be given over 30 minutes. H_2 antagonists rarely cause reversible abnormalities in liver chemistry.

Drug Interactions

Cimetidine interferes with several important hepatic cytochrome P450 drug metabolism pathways, including those catalyzed by CYP1A2, CYP2C9, CYP2D6, and CYP3A4 (see Chapter 4). Hence, the half-lives of drugs metabolized by these pathways may be prolonged. Ranitidine binds 4–10 times less avidly than cimetidine to cytochrome P450. Negligible CYP interaction occurs with nizatidine and famotidine.

H_2 antagonists compete with creatinine and certain drugs (eg, procainamide) for renal tubular secretion. All of these agents except famotidine inhibit gastric first-pass metabolism of ethanol, especially in women. Although the importance of this is debated, increased bioavailability of ethanol could lead to increased blood ethanol levels.

PROTON-PUMP INHIBITORS (PPIs)

Since their introduction in the late 1980s, these efficacious acid inhibitory agents have assumed the major role for the treatment of acid-peptic disorders. PPIs are now among the most widely prescribed drugs worldwide.

Chemistry & Pharmacokinetics

Six PPIs are available for clinical use: **omeprazole**, **esomeprazole**, **lansoprazole**, **dexlansoprazole**, **rabeprazole**, and **pantoprazole**. All are substituted benzimidazoles that resemble H_2 antagonists in structure (Figure 62–3) but have a completely different mechanism of action. Omeprazole and lansoprazole are racemic mixtures of *R*- and *S*-isomers. Esomeprazole is the *S*-isomer of omeprazole and dexlansoprazole the *R*-isomer of lansoprazole. All are available in oral formulations. Esomeprazole and pantoprazole are also available in intravenous formulations (Table 62–2).

PPIs are administered as inactive prodrugs. To protect the acid-labile prodrug from rapid destruction within the gastric lumen, oral products are formulated for delayed release as acid-resistant, enteric-coated capsules or tablets. After passing through the stomach into the alkaline intestinal lumen, the enteric coatings dissolve and the prodrug is absorbed. For children or patients with dysphagia or enteral feeding tubes, capsule formulations (but not tablets) may be opened and the microgranules mixed with apple or orange juice or mixed with soft foods (eg, applesauce). Esomeprazole, omeprazole, and pantoprazole are also available as oral suspensions. Lansoprazole is available as a tablet formulation that disintegrates in the mouth, and rabeprazole is available in a formulation that may be sprinkled on food. Omeprazole is also available as a powder formulation (capsule or packet) that contains sodium bicarbonate (1100–1680 mg $NaHCO_3$; 304–460 mg of sodium) to protect the naked (non-enteric-coated) drug from acid degradation. When administered on an empty stomach by

FIGURE 62-3 Molecular structure of the proton-pump inhibitors: omeprazole, lansoprazole, pantoprazole, and the sodium salt of rabeprazole. Omeprazole and esomeprazole have the same chemical structure (see text).

mouth or enteral tube, this “immediate-release” suspension results in rapid omeprazole absorption ($T_{\max} < 30$ minutes) and onset of acid inhibition.

The PPIs are lipophilic weak bases (pK_a 4–5) and, after intestinal absorption, diffuse readily across lipid membranes into acidified compartments (eg, the parietal cell canaliculus). The prodrug rapidly becomes protonated within the canaliculus and is concentrated more than 1000-fold by Henderson-Hasselbalch trapping (see Chapter 1). There, it rapidly undergoes a molecular conversion to the active form, a reactive thiophilic sulfenamide cation, which forms a covalent disulfide bond with the H^+/K^+ -ATPase, irreversibly inactivating the enzyme.

The pharmacokinetics of available PPIs are shown in Table 62-2. Immediate-release omeprazole has a faster onset of acid inhibition than other oral formulations. Although differences in pharmacokinetic profiles may affect speed of onset and duration of acid inhibition in the first few days of therapy, they are of little clinical importance with continued daily administration.

The bioavailability of all agents is decreased approximately 50% by food; hence, the drugs should be administered on an empty stomach. In a fasting state, only 10% of proton pumps are actively secreting acid and susceptible to inhibition. PPIs should be administered approximately 1 hour before a meal (usually breakfast), so that the peak serum concentration coincides with the maximal activity of proton-pump secretion. The drugs have a short serum half-life of about 1.5 hours, but acid inhibition lasts up to 24 hours owing to the irreversible inactivation of the proton pump. At least 18 hours are required for synthesis of new H^+/K^+ -ATPase pump molecules. Because not all proton pumps are inactivated with the first dose of medication, up to 3–4 days of daily medication are required before the full acid-inhibiting potential is reached. Similarly, after stopping the drug, it takes 3–4 days for full acid secretion to return.

PPIs undergo rapid first-pass and systemic hepatic metabolism and have negligible renal clearance. Dose reduction is not needed for patients with renal insufficiency or mild to moderate

TABLE 62-2 Pharmacokinetics of proton pump inhibitors.

Drug	pK_a	Bioavailability (%)	$t_{1/2}$ (h)	T_{\max} (h)	Usual Dosage for Peptic Ulcer or GERD
Omeprazole	4	40–65	0.5–1.0	1–3	20–40 mg qd
Esomeprazole	4	>80	1.5	1.6	20–40 mg qd
Lansoprazole	4	>80	1.0–2.0	1.7	30 mg qd
Dexlansoprazole	4	NA	1.0–2.0	5.0	30–60 mg qd
Pantoprazole	3.9	77	1.0–1.9	2.5–4.0	40 mg qd
Rabeprazole	5	52	1.0–2.0	3.1	20 mg qd

GERD, gastroesophageal reflux disease; NA, data not available.

liver disease but should be considered in patients with severe liver impairment. Although other proton pumps exist in the body, the H^+/K^+ -ATPase appears to exist only in the parietal cell and is distinct structurally and functionally from other H^+ -transporting enzymes.

The intravenous formulations of esomeprazole and pantoprazole have characteristics similar to those of the oral drugs. When given to a fasting patient, they inactivate acid pumps that are actively secreting, but they have no effect on pumps in quiescent, nonsecreting vesicles. Because the half-life of a single injection of the intravenous formulation is short, acid secretion returns several hours later as pumps move from the tubulovesicles to the canalicular surface. Thus, to provide maximal inhibition during the first 24–48 hours of treatment, the intravenous formulations must be given as a continuous infusion or as repeated bolus injections. The optimal dosing of intravenous PPIs to achieve maximal blockade in fasting patients is not yet established.

From a pharmacokinetic perspective, PPIs are ideal drugs: they have a short serum half-life, they are concentrated and activated near their site of action, and they have a long duration of action.

Pharmacodynamics

In contrast to H_2 antagonists, PPIs inhibit both fasting and meal-stimulated secretion because they block the final common pathway of acid secretion, the proton pump. In standard doses, PPIs inhibit 90–98% of 24-hour acid secretion (Figure 62–2). When administered at equivalent doses, the different agents show little difference in clinical efficacy. In a crossover study of patients receiving long-term therapy with five PPIs, the mean 24-hour intragastric pH varied from 3.3 (pantoprazole, 40 mg) to 4.0 (esomeprazole, 40 mg), and the mean number of hours the pH was higher than 4 varied from 10.1 (pantoprazole, 40 mg) to 14.0 (esomeprazole, 40 mg). Although dexlansoprazole has a delayed-release formulation that results in a longer T_{max} and greater AUC than other PPIs, it appears comparable to other agents in the ability to suppress acid secretion. This is because acid suppression is more dependent upon irreversible inactivation of the proton pump than the pharmacokinetics of different agents.

Clinical Uses

1. Gastroesophageal reflux disease—PPIs are the most effective agents for the treatment of erosive reflux disease, esophageal complications of reflux disease (peptic stricture or Barrett's esophagus), and extraesophageal manifestations of reflux disease. Once-daily dosing provides effective symptom relief and tissue healing in 85–90% of patients; up to 15% of patients require twice-daily dosing.

GERD symptoms recur in over 80% of patients within 6 months after discontinuation of a PPI. For patients with erosive esophagitis or esophageal complications, long-term daily maintenance therapy with a full-dose or half-dose PPI is usually needed. Many patients with nonerosive GERD may be treated successfully with intermittent courses of PPIs or H_2 antagonists taken as needed (“on demand”) for recurrent symptoms.

In current clinical practice, many patients with symptomatic GERD are treated empirically with medications without prior endoscopy, ie, without knowledge of whether the patient has erosive or nonerosive reflux disease. Empiric treatment with PPIs provides sustained symptomatic relief in 70–80% of patients, compared with 50–60% with H_2 antagonists. Because of recent cost reductions, PPIs are used increasingly as first-line therapy for patients with symptomatic GERD. Due to recent safety concerns, however, initial empiric treatment with an H_2 antagonist should be considered.

Sustained acid suppression with twice-daily PPIs for at least 3 months is used to treat extraesophageal complications of reflux disease (asthma, chronic cough, laryngitis, and noncardiac chest pain).

2. Peptic ulcer disease—Compared with H_2 antagonists, PPIs afford more rapid symptom relief and faster ulcer healing for duodenal ulcers and, to a lesser extent, gastric ulcers. All the pump inhibitors heal more than 90% of duodenal ulcers within 4 weeks and a similar percentage of gastric ulcers within 6–8 weeks.

a. *H pylori*-associated ulcers—For *H pylori*-associated ulcers, there are two therapeutic goals: to heal the ulcer and to eradicate the organism. The most effective regimens for *H pylori* eradication are combinations of two antibiotics and a PPI. PPIs promote eradication of *H pylori* through several mechanisms: direct antimicrobial properties (minor) and—by raising intragastric pH—lowering the minimal inhibitory concentrations of antibiotics against *H pylori*. Until recently, the most commonly recommended treatment regimen consisted of a 14-day regimen of “triple therapy”: a PPI twice daily; clarithromycin, 500 mg twice daily; and either amoxicillin, 1 g twice daily, or metronidazole, 500 mg twice daily. Due to increasing treatment failures attributable to rising clarithromycin resistance, “quadruple therapy” is now recommended as first-line treatment for patients who likely have clarithromycin resistance due to prior exposure or to residence in regions with high clarithromycin resistance. Two 14-day treatment regimens currently are recommended. Each includes a PPI twice daily with either: (a) bismuth subsalicylate 524 mg, metronidazole 500 mg, and tetracycline 500 mg, all given four times daily; or (b) amoxicillin 1 g, clarithromycin 500 mg, and metronidazole 500 mg, all given twice daily. After completion of antibiotic therapy, the PPI should be continued once daily for a total of 4–6 weeks to ensure complete ulcer healing.

b. NSAID-associated ulcers—For patients with ulcers caused by aspirin or other NSAIDs, either H_2 antagonists or PPIs provide rapid ulcer healing so long as the NSAID is discontinued; however, continued use of the NSAID impairs ulcer healing. In patients with NSAID-induced ulcers who require continued NSAID therapy, treatment with a PPI more reliably promotes ulcer healing.

Asymptomatic peptic ulceration develops in 10–20% of people taking frequent NSAIDs, and ulcer-related complications (bleeding, perforation) develop in 1–2% of persons per year. PPIs taken once daily are effective in reducing the incidence of ulcers and ulcer complications in patients taking aspirin or other NSAIDs.

c. Prevention of rebleeding from peptic ulcers—In patients with acute gastrointestinal bleeding due to peptic ulcers, the risk of rebleeding from ulcers that have a visible vessel or adherent clot is increased. Rebleeding of this subset of high-risk ulcers is reduced significantly with PPIs administered for 3–5 days either as high-dose oral therapy (eg, omeprazole, 40 mg orally twice daily) or as a continuous intravenous infusion. It is believed that an intragastric pH higher than 6 may enhance coagulation and platelet aggregation. The optimal dose of intravenous PPI needed to achieve and maintain this level of near-complete acid inhibition is unknown; however, initial bolus administration of esomeprazole or pantoprazole (80 mg) followed by constant infusion (8 mg/h) is commonly recommended.

3. Nonulcer dyspepsia—PPIs have modest efficacy for treatment of nonulcer dyspepsia, benefiting 10–20% more patients than placebo. Despite their use for this indication, superiority to H₂ antagonists (or even placebo) has not been conclusively demonstrated.

4. Prevention of stress-related mucosal bleeding—As discussed previously (see H₂-Receptor Antagonists), PPIs (given orally, by nasogastric tube, or by intravenous infusions) may be administered to reduce the risk of clinically significant stress-related mucosal bleeding in critically ill patients. The only PPI approved by the US Food and Drug Administration (FDA) for this indication is an oral immediate-release omeprazole formulation, which is administered by nasogastric tube twice daily on the first day, then once daily. Although not FDA approved for this indication, other PPI suspension formulations (esomeprazole, omeprazole, pantoprazole) may also be used. For patients with nasogastric tubes, PPI suspensions may be preferred to intravenous H₂ antagonists or PPIs because of comparable efficacy, lower cost, and ease of administration.

For patients without a nasogastric tube or with significant ileus, intravenous H₂ antagonists are preferred to intravenous PPIs because of their proven efficacy. Although PPIs are increasingly used, there are no controlled trials demonstrating efficacy or optimal dosing.

5. Gastrinoma and other hypersecretory conditions—Patients with isolated gastrinomas are best treated with surgical resection. In patients with metastatic or unresectable gastrinomas, massive acid hypersecretion results in peptic ulceration, erosive esophagitis, and malabsorption. With PPIs, excellent acid suppression can be achieved in all patients. Dosage is titrated to reduce basal acid output to less than 5–10 mEq/h. Typical doses of omeprazole are 60–120 mg/d.

Adverse Effects

1. General—Although PPIs have been considered to be extremely safe, a number of recent safety concerns have been raised. As with most drugs, PPIs should be prescribed at the lowest effective dose and the risks versus benefits of long-term use carefully weighed. Diarrhea, headache, and abdominal pain are reported in 1–5% of patients, although the frequency of

these events is only slightly increased compared with placebo. In large observational studies, PPIs have been associated with an increased risk of acute interstitial nephritis and chronic kidney disease compared to nonusers or users of H₂-receptor antagonists. A mechanism by which kidney damage might occur has not been determined. Some epidemiologic studies have also detected an increased risk of dementia in long-term PPI users, although causality has not been established. PPIs are not teratogenic in animal models; however, safety during pregnancy has not been established.

2. Nutrition—Acid is important in releasing vitamin B₁₂ from food. A minor reduction in oral cyanocobalamin absorption occurs during proton-pump inhibition, potentially leading to subnormal B₁₂ levels with prolonged therapy. Acid also promotes absorption of food-bound minerals (non-heme iron, insoluble calcium salts, magnesium). Meta-analyses of cohort and case-control studies have detected a modest increase in the risk of hip fracture in patients taking long-term PPIs. Although a causal relationship is unproven, PPIs may reduce calcium absorption or inhibit osteoclast function. All PPIs carry an FDA-mandated warning of a possible increased risk of hip, spine, and wrist fractures. Patients who require long-term PPIs—especially those with risk factors for osteoporosis—should have monitoring of bone density and should be provided calcium supplements. Cases of severe, life-threatening hypomagnesemia with secondary hypocalcemia due to PPIs have been reported, possibly due to decreased intestinal absorption.

3. Respiratory and enteric infections—Gastric acid is an important barrier to colonization and infection of the stomach and intestine from ingested bacteria. Increases in gastric bacterial concentrations are detected in patients taking PPIs, which is of unknown clinical significance. Some studies have reported an increased risk of both community-acquired respiratory infections and nosocomial pneumonia among patients taking PPIs.

There is a two- to threefold increased risk for hospital- and community-acquired *Clostridium difficile* infection in patients taking PPIs. There also is a small increased risk of other enteric infections (eg, *Salmonella*, *Shigella*, *Escherichia coli*, *Campylobacter*), which should be considered particularly when traveling in underdeveloped countries.

4. Potential problems due to increased serum gastrin—Gastrin levels are regulated by intragastric acidity. Acid suppression alters normal feedback inhibition so that median serum gastrin levels rise 1.5- to twofold in patients taking PPIs. Although gastrin levels remain within normal limits in most patients, they exceed 500 pg/mL (normal, <100 pg/mL) in 3%. Upon stopping the drug, the levels normalize within 4 weeks. The rise in serum gastrin levels may stimulate hyperplasia of ECL and parietal cells, which may cause transient rebound acid hypersecretion with increased dyspepsia or heartburn after drug discontinuation, which abate within 2–4 weeks after gastrin and acid secretion normalize. In female rats given PPIs for prolonged periods, hypergastrinemia caused gastric carcinoid tumors that developed in areas of ECL hyperplasia. Although humans who take PPIs for a

long time also may exhibit ECL hyperplasia, carcinoid tumor formation has not been documented. At present, routine monitoring of serum gastrin levels is not recommended in patients receiving prolonged PPI therapy.

5. Other potential problems due to decreased gastric acidity—Among patients infected with *H pylori*, long-term acid suppression leads to increased chronic inflammation in the gastric body and decreased inflammation in the antrum. Concerns have been raised that increased gastric inflammation may accelerate gastric gland atrophy (atrophic gastritis) and intestinal metaplasia—known risk factors for gastric adenocarcinoma. A special FDA Gastrointestinal Advisory Committee concluded that there is no evidence that prolonged PPI therapy produces the kind of atrophic gastritis (multifocal atrophic gastritis) or intestinal metaplasia that is associated with increased risk of adenocarcinoma. Routine testing for *H pylori* is not recommended in patients who require long-term PPI therapy. Long-term PPI therapy is associated with the development of small benign gastric fundic-gland polyps in a small number of patients, which may disappear after stopping the drug and are of uncertain clinical significance.

Drug Interactions

Decreased gastric acidity may alter absorption of drugs for which intragastric acidity affects drug bioavailability, eg, ketoconazole, itraconazole, digoxin, and atazanavir. All PPIs are metabolized by hepatic P450 cytochromes, including CYP2C19 and CYP3A4. Because of the short half-lives of PPIs, clinically significant drug interactions are rare. Omeprazole may inhibit the metabolism of clopidogrel, warfarin, diazepam, and phenytoin. Esomeprazole also may decrease metabolism of diazepam. Lansoprazole may enhance clearance of theophylline. Rabeprazole and pantoprazole have no significant drug interactions.

The FDA has issued a warning about a potentially important adverse interaction between clopidogrel and PPIs. Clopidogrel is a prodrug that requires activation by the hepatic P450 CYP2C19 isoenzyme, which also is involved to varying degrees in the metabolism of PPIs (especially omeprazole, esomeprazole, lansoprazole, and dexlansoprazole). Thus, PPIs could reduce clopidogrel activation (and its antiplatelet action) in some patients. Several large retrospective studies have reported an increased incidence of serious cardiovascular events in patients taking clopidogrel and a PPI. In contrast, three smaller prospective randomized trials have not detected an increased risk. When PPIs are prescribed to patients taking clopidogrel, agents with minimal CYP2C19 inhibition (pantoprazole or rabeprazole) may be preferred.

MUCOSAL PROTECTIVE AGENTS

The gastroduodenal mucosa has evolved a number of defense mechanisms to protect itself against the noxious effects of acid and pepsin. Both mucus and epithelial cell-cell tight junctions restrict back diffusion of acid and pepsin. Epithelial bicarbonate secretion establishes a pH gradient within the mucous layer

in which the pH ranges from 7 at the mucosal surface to 1–2 in the gastric lumen. Blood flow carries bicarbonate and vital nutrients to surface cells. Areas of injured epithelium are quickly repaired by restitution, a process in which migration of cells from gland neck cells seals small erosions to reestablish intact epithelium. Mucosal prostaglandins appear to be important in stimulating mucus and bicarbonate secretion and mucosal blood flow. A number of agents that potentiate these mucosal defense mechanisms are available for the prevention and treatment of acid-peptic disorders.

SUCRALFATE

Chemistry & Pharmacokinetics

Sucralfate is a salt of sucrose complexed to sulfated aluminum hydroxide. In water or acidic solutions it forms a viscous, tenacious paste that binds selectively to ulcers or erosions for up to 6 hours. Sucralfate has limited solubility, breaking down into sucrose sulfate (strongly negatively charged) and an aluminum salt. Less than 3% of intact drug and aluminum is absorbed from the intestinal tract; the remainder is excreted in the feces.

Pharmacodynamics

A variety of beneficial effects have been attributed to sucralfate, but the precise mechanism of action is unclear. It is believed that the negatively charged sucrose sulfate binds to positively charged proteins in the base of ulcers or erosion, forming a physical barrier that restricts further caustic damage and stimulates mucosal prostaglandin and bicarbonate secretion.

Clinical Uses

Sucralfate is administered in a dosage of 1 g four times daily on an empty stomach (at least 1 hour before meals). At present, its clinical uses are limited. Sucralfate (administered as a slurry through a nasogastric tube) reduces the incidence of clinically significant upper gastrointestinal bleeding in critically ill patients hospitalized in the intensive care unit, although it is slightly less effective than intravenous H₂ antagonists. Sucralfate is still used by many clinicians for prevention of stress-related bleeding because of concerns that acid inhibitory therapies (antacids, H₂ antagonists, and PPIs) may increase the risk of nosocomial pneumonia.

Adverse Effects

Because it is not absorbed, sucralfate is virtually devoid of systemic adverse effects. Constipation occurs in 2% of patients due to the aluminum salt. Because a small amount of aluminum is absorbed, it should not be used for prolonged periods in patients with renal insufficiency.

Drug Interactions

Sucralfate may bind to other medications, impairing their absorption.

PROSTAGLANDIN ANALOGS

Chemistry & Pharmacokinetics

The human gastrointestinal mucosa synthesizes a number of prostaglandins (see Chapter 18); the primary ones are prostaglandins E and F. **Misoprostol**, a methyl analog of PGE₁, has been approved for gastrointestinal conditions. After oral administration, it is rapidly absorbed and metabolized to a metabolically active free acid. The serum half-life is less than 30 minutes; hence, it must be administered 3–4 times daily. It is excreted in the urine; however, dose reduction is not needed in patients with renal insufficiency.

Misoprostol has both acid inhibitory and mucosal protective properties. It is believed to stimulate mucus and bicarbonate secretion and enhance mucosal blood flow. Misoprostol can reduce the incidence of NSAID-induced ulcers to less than 3% and the incidence of ulcer complications by 50%. It is approved for prevention of NSAID-induced ulcers in high-risk patients; however, misoprostol has never achieved widespread use owing to its high adverse-effect profile and need for multiple daily dosing.

BISMUTH COMPOUNDS

Chemistry & Pharmacokinetics

Two bismuth compounds are available: **bismuth subsalicylate**, a nonprescription formulation containing bismuth and salicylate, and **bismuth subcitrate potassium**. In the USA, bismuth subcitrate is available only as a combination prescription product that also contains metronidazole and tetracycline for the treatment of *H. pylori*. Bismuth subsalicylate undergoes rapid dissociation within the stomach, allowing absorption of salicylate. Over 99% of the bismuth appears in the stool. Although minimal (<1%), bismuth is absorbed; it is stored in many tissues and has slow renal excretion. Salicylate (like aspirin) is readily absorbed and excreted in the urine.

Pharmacodynamics

The precise mechanisms of action of bismuth are unknown. Bismuth coats ulcers and erosions, creating a protective layer against acid and pepsin. It may also stimulate prostaglandin, mucus, and bicarbonate secretion. Bismuth subsalicylate reduces stool frequency and liquidity in acute infectious diarrhea, due to salicylate inhibition of intestinal prostaglandin and chloride secretion. Bismuth has direct antimicrobial effects and binds enterotoxins, accounting for its benefit in preventing and treating traveler's diarrhea. Bismuth compounds have direct antimicrobial activity against *H. pylori*.

Clinical Uses

Despite the lack of comparative trials, nonprescription bismuth compounds (eg, Pepto-Bismol, Kaopectate) are widely used by patients for the nonspecific treatment of dyspepsia and acute diarrhea. Bismuth subsalicylate also is used for the prevention of traveler's diarrhea (30 mL or two tablets four times daily).

Bismuth compounds are used in four-drug regimens for the eradication of *H. pylori* infection (see earlier discussion of *H. pylori*-associated ulcers). One regimen consists of a PPI twice daily combined with bismuth subsalicylate (two tablets; 262 mg each), tetracycline (250–500 mg), and metronidazole (500 mg) four times daily for 10–14 days. Another regimen consists of a PPI twice daily combined with three capsules of a combination prescription formulation (each capsule containing bismuth subcitrate 140 mg, metronidazole 125 mg, and tetracycline 125 mg) taken four times daily for 10–14 days.

Adverse Effects

All bismuth formulations have excellent safety profiles. Bismuth causes harmless blackening of the stool, which may be confused with gastrointestinal bleeding. Liquid formulations may cause harmless darkening of the tongue. Bismuth agents should be used for short periods only and should be avoided in patients with renal insufficiency. Prolonged usage of some bismuth compounds may rarely lead to bismuth toxicity, resulting in encephalopathy (ataxia, headaches, confusion, seizures). However, such toxicity is not reported with bismuth subsalicylate or bismuth citrate. High dosages of bismuth subsalicylate may lead to salicylate toxicity.

■ DRUGS STIMULATING GASTROINTESTINAL MOTILITY

Drugs that can selectively stimulate gut motor function (**prokinetic** agents) have significant potential clinical usefulness. Agents that increase lower esophageal sphincter pressures may be useful for GERD. Drugs that improve gastric emptying may be helpful for gastroparesis and postsurgical gastric emptying delay. Agents that stimulate the small intestine may be beneficial for postoperative ileus or chronic intestinal pseudo-obstruction. Finally, agents that enhance colonic transit may be useful in the treatment of constipation. Unfortunately, only a limited number of agents in this group are available for clinical use at this time.

Physiology of the Enteric Nervous System

The enteric nervous system (see also Chapter 6) is composed of interconnected networks of ganglion cells and nerve fibers mainly located in the submucosa (submucosal plexus) and between the circular and longitudinal muscle layers (myenteric plexus). These networks give rise to nerve fibers that connect with the mucosa and muscle. Although extrinsic sympathetic and parasympathetic nerves project onto the submucosal and myenteric plexuses, the enteric nervous system can independently regulate gastrointestinal motility and secretion. Extrinsic primary afferent neurons project via the dorsal root ganglia or vagus nerve to the central nervous system (Figure 62–4). Release of serotonin (5-HT) from intestinal mucosa enterochromaffin (EC) cells stimulates 5-HT₃ receptors on the extrinsic afferent nerves, stimulating nausea, vomiting, or

FIGURE 62–4 Release of serotonin (5-HT) by enterochromaffin (EC) cells from gut distention stimulates submucosal intrinsic primary afferent neurons (IPANs) via 5-HT_{1P} receptors and extrinsic primary afferent neurons via 5-HT₃ receptors (5-HT_{1P}R, 5-HT₃R). Submucosal IPANs activate the enteric neurons responsible for peristaltic and secretory reflex activity. Stimulation of 5-HT₄ receptors (5-HT₄R) on presynaptic terminals of IPANs enhances release of acetylcholine (ACh) and calcitonin gene-related peptide (CGRP), promoting reflex activity. CNS, central nervous system; ENS, enteric nervous system. (Data from Gershon MD: Serotonin and its implication for the management of irritable bowel syndrome. *Rev Gastroenterol Dis* 2003;3[Suppl 2]:S25.)

abdominal pain. Serotonin also stimulates submucosal 5-HT_{1P} receptors of the intrinsic primary afferent nerves (IPANs), which contain calcitonin gene-related peptide (CGRP) and acetylcholine and project to myenteric plexus interneurons. 5-HT₄ receptors on the presynaptic terminals of the IPANs appear to enhance release of CGRP or acetylcholine. The myenteric interneurons are important in controlling the peristaltic reflex, promoting release of excitatory mediators proximally and inhibitory mediators distally. Motilin may stimulate excitatory neurons or muscle cells directly. Dopamine acts as an inhibitory neurotransmitter in the gastrointestinal tract, decreasing the intensity of esophageal and gastric contractions.

Although there are at least 14 serotonin receptor subtypes, 5-HT drug development for gastrointestinal applications to date has focused on **5-HT₃-receptor antagonists** and **5-HT₄-receptor agonists**. These agents—which have effects on gastrointestinal motility and visceral afferent sensation—are discussed under

Drugs Used in the Treatment of Irritable Bowel Syndrome and Antiemetic Agents. Other drugs acting on 5-HT receptors are discussed in Chapters 16, 29, and 30.

CHOLINOMIMETIC AGENTS

Cholinomimetic agonists such as bethanechol stimulate muscarinic M₃ receptors on muscle cells and at myenteric plexus synapses (see Chapter 7). Bethanechol was used in the past for the treatment of GERD and gastroparesis. Owing to multiple cholinergic effects and the advent of less toxic agents, it is now seldom used. The acetylcholinesterase inhibitor neostigmine can enhance gastric, small intestine, and colonic emptying. Intravenous **neostigmine** is used for the treatment of hospitalized patients with acute large bowel distention (known as acute colonic pseudo-obstruction or Ogilvie's syndrome). Administration of 2 mg results in prompt colonic evacuation of flatus and feces in the majority of patients. Cholinergic effects include excessive salivation, nausea, vomiting, diarrhea, and bradycardia.

METOCLOPRAMIDE & DOMPERIDONE

Metoclopramide and domperidone are dopamine D₂-receptor antagonists. Within the gastrointestinal tract, activation of dopamine receptors inhibits cholinergic smooth muscle stimulation; blockade of this effect is believed to be the primary prokinetic mechanism of action of these agents. These agents increase esophageal peristaltic amplitude, increase lower esophageal sphincter pressure, and enhance gastric emptying but have no effect on small intestine or colonic motility. Metoclopramide and domperidone also block dopamine D₂ receptors in the chemoreceptor trigger zone of the medulla (area postrema), resulting in potent antiemetic and anti-nausea action.

Clinical Uses

1. Gastroesophageal reflux disease—Metoclopramide is available for clinical use in the USA; domperidone is available in many other countries. These agents are sometimes used in the treatment of symptomatic GERD but are not effective in patients with erosive esophagitis. Because of the superior efficacy and safety of antisecretory agents in the treatment of heartburn, prokinetic agents are used mainly in combination with antisecretory agents in patients with regurgitation or refractory heartburn.

2. Impaired gastric emptying—These agents are widely used in the treatment of patients with delayed gastric emptying due to postsurgical disorders (vagotomy, antrectomy) and diabetic gastroparesis. Metoclopramide is sometimes administered in hospitalized patients to promote advancement of nasogastric feeding tubes from the stomach into the duodenum.

3. Nonulcer dyspepsia—These agents lead to symptomatic improvement in a small number of patients with chronic dyspepsia.

4. Prevention of vomiting—Because of their potent antiemetic action, metoclopramide and domperidone are used for the prevention and treatment of emesis.

5. Postpartum lactation stimulation—Domperidone is sometimes recommended to promote postpartum lactation (see also Adverse Effects).

Adverse Effects

The most common adverse effects of metoclopramide involve the central nervous system. Restlessness, drowsiness, insomnia, anxiety, and agitation occur in 10–20% of patients, especially the elderly. Extrapyramidal effects (dystonias, akathisia, parkinsonian features) due to central dopamine receptor blockade occur acutely in 25% of patients given high doses and in 5% of patients receiving long-term therapy. Tardive dyskinesia, sometimes irreversible, has developed in patients treated for a prolonged period with metoclopramide. For this reason, long-term use should be avoided unless absolutely necessary, especially in the elderly. Elevated prolactin levels (caused by both metoclopramide and domperidone) can cause galactorrhea, gynecomastia, impotence, and menstrual disorders.

Domperidone is extremely well tolerated. Because it does not cross the blood-brain barrier to a significant degree, neuropsychiatric and extrapyramidal effects are rare.

MACROLIDES

Macrolide antibiotics such as **erythromycin** directly stimulate motilin receptors on gastrointestinal smooth muscle and promote the onset of a migrating motor complex. Intravenous erythromycin (3 mg/kg) is beneficial in some patients with gastroparesis; however, tolerance rapidly develops. It may be used in patients with acute upper gastrointestinal hemorrhage to promote gastric emptying of blood before endoscopy.

LAXATIVES

The overwhelming majority of people do not need laxatives; yet they are self-prescribed by a large portion of the population. For most people, intermittent constipation is best prevented with a high-fiber diet, adequate fluid intake, regular exercise, and the heeding of nature's call. Patients not responding to dietary changes or fiber supplements should undergo medical evaluation before initiating long-term laxative treatment. Laxatives may be classified by their major mechanism of action, but many work through more than one mechanism.

BULK-FORMING LAXATIVES

Bulk-forming laxatives are indigestible, hydrophilic colloids that absorb water, forming a bulky, emollient gel that distends the colon and promotes peristalsis. Common preparations include natural plant products (**psyllium**, **methylcellulose**) and synthetic

fibers (**polycarbophil**). Bacterial digestion of plant fibers within the colon may lead to increased bloating and flatus.

STOOL SURFACTANT AGENTS (SOFTENERS)

These agents soften stool material, permitting water and lipids to penetrate. They may be administered orally or rectally. Common agents include **docusate** (oral or enema) and **glycerin suppository**. In hospitalized patients, docusate is commonly prescribed to prevent constipation and minimize straining. **Mineral oil** is a clear, viscous oil that lubricates fecal material, retarding water absorption from the stool. It is used to prevent and treat fecal impaction in young children and debilitated adults. It is not palatable but may be mixed with juices. Aspiration can result in a severe lipid pneumonitis. Long-term use can impair absorption of fat-soluble vitamins (A, D, E, K).

OSMOTIC LAXATIVES

The colon can neither concentrate nor dilute fecal fluid: fecal water is isotonic throughout the colon. Osmotic laxatives are soluble but nonabsorbable compounds that result in increased stool liquidity due to an obligate increase in fecal fluid.

Nonabsorbable Sugars or Salts

These agents may be used for the treatment of acute constipation or the prevention of chronic constipation. **Magnesium hydroxide (milk of magnesia)** is a commonly used osmotic laxative. It should not be used for prolonged periods in patients with renal insufficiency due to the risk of hypermagnesemia. **Sorbitol** and **lactulose** are nonabsorbable sugars that can be used to prevent or treat chronic constipation. These sugars are metabolized by colonic bacteria, producing severe flatus and cramps.

High doses of osmotically active agents produce prompt bowel evacuation (purgation) within 1–3 hours. The rapid movement of water into the distal small bowel and colon leads to a high volume of liquid stool followed by bowel evacuation. Several purgatives are available, which may be used for the treatment of acute constipation or to cleanse the bowel prior to medical procedures (eg, colonoscopy). These include **magnesium citrate**, **sulfate solution**, and a proprietary combination of magnesium oxide, sodium picosulfate, and citrate (Prepopik). When taking these purgatives, it is very important that patients maintain adequate hydration by taking increased oral liquids to compensate for fecal fluid loss. **Sodium phosphate** also is available—by prescription—as a tablet formulation but is infrequently used due to the risk of hyperphosphatemia, hypocalcemia, hypernatremia, and hypokalemia. Although these electrolyte abnormalities are clinically insignificant in most patients, they may lead to cardiac arrhythmias or acute renal failure due to tubular deposition of calcium phosphate (nephrocalcinosis). Sodium phosphate preparations should not be used in patients who are frail or elderly, have renal insufficiency, have significant cardiac disease, or are unable to maintain adequate hydration during bowel preparation.

Balanced Polyethylene Glycol

Lavage solutions containing **polyethylene glycol (PEG)** are commonly used for complete colonic cleansing before gastrointestinal endoscopic procedures. These balanced, isotonic solutions contain an inert, nonabsorbable, osmotically active sugar (PEG) with sodium sulfate, sodium chloride, sodium bicarbonate, and potassium chloride. The solution is designed so that no significant intravascular fluid or electrolyte shifts occur. Therefore, they are safe for all patients. For optimal bowel cleansing, 1–2 L of solution should be ingested rapidly (over 1–2 hours) on the evening before the procedure and again 4–6 hours before the procedure. For treatment or prevention of chronic constipation, smaller doses of PEG powder may be mixed with water or juices (17 g/8 oz) and ingested daily. In contrast to sorbitol or lactulose, PEG does not produce significant cramps or flatus.

STIMULANT LAXATIVES

Stimulant laxatives (cathartics) induce bowel movements through a number of poorly understood mechanisms. These include direct stimulation of the enteric nervous system and colonic electrolyte and fluid secretion. There has been concern that long-term use of cathartics could lead to dependence and destruction of the myenteric plexus, resulting in colonic atony and dilation. More recent research suggests that long-term use of these agents probably is safe in most patients. Cathartics may be required on a long-term basis, especially in patients who are neurologically impaired and in bed-bound patients in long-term care facilities.

Anthraquinone Derivatives

Aloe, **senna**, and **cascara** occur naturally in plants. These laxatives are poorly absorbed and after hydrolysis in the colon, produce a bowel movement in 6–12 hours when given orally and within 2 hours when given rectally. Chronic use leads to a characteristic brown pigmentation of the colon known as “melanosis coli.” There has been some concern that these agents may be carcinogenic, but epidemiologic studies do not suggest a relation to colorectal cancer.

Diphenylmethane Derivatives

Bisacodyl is available in tablet and suppository formulations for the treatment of acute and chronic constipation. It also is used in conjunction with PEG solutions for colonic cleansing prior to colonoscopy. It induces a bowel movement within 6–10 hours when given orally and 30–60 minutes when taken rectally. It has minimal systemic absorption and appears to be safe for acute and long-term use.

CHLORIDE SECRETION ACTIVATORS

Lubiprostone is a prostanoid acid derivative labeled for use in chronic constipation and irritable bowel syndrome (IBS) with predominant constipation. It acts by stimulating the type 2 chloride

channel (ClC-2) in the small intestine. This increases chloride-rich fluid secretion into the intestine, which stimulates intestinal motility and shortens intestinal transit time. Over 50% of patients experience a bowel movement within 24 hours of taking one dose. A dose of 24 mcg orally twice daily is the recommended dose for treatment of chronic constipation. There appears to be no loss of efficacy with long-term therapy. After discontinuation of the drug, constipation may return to its pretreatment severity. Lubiprostone has minimal systemic absorption but is designated category C for pregnancy because of increased fetal loss in guinea pigs. Lubiprostone may cause nausea in up to 30% of patients due to delayed gastric emptying.

Linacotide and **plecanatide** are minimally absorbed, short amino acid peptides that stimulate intestinal chloride secretion through a different mechanism by binding to and activating guanylate cyclase-C on the luminal surface. This leads to increased intracellular and extracellular cyclic guanosine monophosphate (cGMP) with activation of the cystic fibrosis transmembrane conductance regulator (CFTR), followed by chloride-rich secretion and acceleration of intestinal transit. Both agents are approved for the treatment of chronic constipation (linacotide 145 mcg orally once daily; plecanatide 3 mg orally once daily); linacotide is also approved for the treatment of irritable bowel syndrome with constipation (290 mcg orally once daily). These agents result in an average increase of 1–2 bowel movements per week that usually occurs within the first week of treatment. Upon discontinuation of the drug, bowel movement frequency returns to normal within 1 week. The most common side effect is diarrhea, which occurs in up to 20% of patients, with severe diarrhea in 2%. These drugs have negligible absorption at standard doses. Both drugs are contraindicated in pediatric patients because of reports of increased mortality in juvenile mice from dehydration. (**Crofelemer** is a small molecule with the opposite effect: it is an *inhibitor* of the CFTR channel and has recently been approved for the treatment of HIV-drug-induced diarrhea.)

OPIOID RECEPTOR ANTAGONISTS

Acute and chronic therapy with opioids may cause constipation by decreasing intestinal motility, which results in prolonged transit time and increased absorption of fecal water (see Chapter 31). Use of opioids after surgery for treatment of pain as well as endogenous opioids also may prolong the duration of postoperative ileus. These effects are mainly mediated through intestinal μ -opioid receptors. Two selective antagonists of the μ -opioid receptor are commercially available: **methylnaltrexone** bromide and **alvimopan**. Because these agents do not readily cross the blood-brain barrier, they inhibit peripheral μ -opioid receptors without impacting analgesic effects within the central nervous system. Methylnaltrexone is approved for the treatment of opioid-induced constipation in patients receiving palliative care for advanced illness who have had inadequate response to other agents. It is administered as a subcutaneous injection (0.15 mg/kg) every 2 days. Alvimopan is approved for short-term use to

shorten the period of postoperative ileus in hospitalized patients who have undergone small or large bowel resection. Alvimopan (12 mg capsule) is administered orally within 5 hours before surgery and twice daily after surgery until bowel function has recovered, but for no more than 7 days. Because of possible cardiovascular toxicity, alvimopan currently is restricted to short-term use in hospitalized patients only.

SEROTONIN 5-HT₄-RECEPTOR AGONISTS

Stimulation of 5-HT₄ receptors on the presynaptic terminal of submucosal intrinsic primary afferent nerves enhances the release of their neurotransmitters, including calcitonin gene-related peptide, which stimulates second-order enteric neurons to promote the peristaltic reflex (Figure 62–4). These enteric neurons stimulate proximal bowel contraction (via acetylcholine and substance P) and distal bowel relaxation (via nitric oxide and vasoactive intestinal peptide).

Tegaserod is a serotonin 5-HT₄ partial agonist that has high affinity for 5-HT₄ receptors but no appreciable binding to 5-HT₃ or dopamine receptors. Tegaserod was approved for the treatment of patients with chronic constipation and IBS with predominant constipation. It has since been withdrawn. **Prucalopride** is a high-affinity 5-HT₄ agonist that is available in Europe (but not in the USA) for the treatment of chronic constipation in women. In contrast to cisapride and tegaserod, it does not appear to have significant affinities for either hERG K⁺ channels or 5-HT_{1B} receptors. In three 12-week clinical trials of patients with severe chronic constipation, it resulted in a significant increase in bowel movements compared with placebo. The long-term efficacy and safety of this agent require further study.

■ ANTIDIARRHEAL AGENTS

Antidiarrheal agents may be used safely in patients with mild to moderate acute diarrhea. However, these agents should not be used in patients with bloody diarrhea, high fever, or systemic toxicity because of the risk of worsening the underlying condition. They should be discontinued in patients whose diarrhea is worsening despite therapy. Antidiarrheals are also used to control chronic diarrhea caused by such conditions as IBS or inflammatory bowel disease (IBD).

OPIOID AGONISTS

As previously noted, opioids have significant constipating effects (see Chapter 31). They increase colonic phasic segmenting activity through inhibition of presynaptic cholinergic nerves in the submucosal and myenteric plexuses and lead to increased colonic transit time and fecal water absorption. They also decrease mass colonic movements and the gastrocolic reflex. Although all opioids have antidiarrheal effects, central nervous system effects and potential for addiction limit the usefulness of most.

Loperamide is a nonprescription opioid agonist that does not cross the blood-brain barrier and has no analgesic properties or potential for addiction. Tolerance to long-term use has not been reported. It is typically administered in doses of 2 mg taken one to four times daily. **Diphenoxylate** is a prescription opioid agonist that has no analgesic properties in standard doses; however, higher doses have central nervous system effects, and prolonged use can lead to opioid dependence. Commercial preparations commonly contain small amounts of atropine to discourage overdosage (2.5 mg diphenoxylate with 0.025 mg atropine). The anticholinergic properties of atropine may contribute to the antidiarrheal action.

Eluxadoline is a prescription opioid agonist with high affinity for the mu receptor (as well as low affinity for the delta receptor). When taken orally, eluxadoline binds to gut opioid receptors, resulting in slower colonic transit and increased fecal fluid absorption. Eluxadoline is approved for the treatment of patients with diarrhea-predominant IBS at a dose of 75–100 mg twice daily. In two randomized placebo-controlled trials, eluxadoline 100 mg twice daily led to significant improvement in abdominal pain and diarrhea in 30% of patients compared with 16% with placebo. Constipation may occur in 8% of patients. Approximately 1% of patients may experience sphincter of Oddi spasm (usually within the first week of therapy) resulting in abdominal pain, pancreatitis, and/or elevated pancreatic or liver enzymes. Eluxadoline should not be used in patients with a history of pancreatitis, alcoholism, or known sphincter of Oddi disease. Caution is advised in patients with prior cholecystectomy, in whom there is up to a 5% risk of complications due to sphincter of Oddi spasm. Eluxadoline 75 mg twice daily is recommended for patients with prior cholecystectomy, mild to moderate liver disease, or side effects at the higher dose.

COLLOIDAL BISMUTH COMPOUNDS

See the section under Mucosal Protective Agents in earlier text.

BILE SALT-BINDING RESINS

Conjugated bile salts are normally absorbed in the terminal ileum. Disease of the terminal ileum (eg, Crohn's disease) or surgical resection leads to malabsorption of bile salts, which may cause colonic secretory diarrhea. The bile salt-binding resins **cholestyramine**, **colestipol**, or **colesevelam**, may decrease diarrhea caused by excess fecal bile acids (see Chapter 35). These products come in a variety of powder and pill formulations that may be taken one to three times daily before meals. Adverse effects include bloating, flatulence, constipation, and fecal impaction. In patients with diminished circulating bile acid pools, further removal of bile acids may lead to an exacerbation of fat malabsorption. Cholestyramine and colestipol bind a number of drugs and reduce their absorption; hence, they should not be given within 2 hours of other drugs. Colesevelam does not appear to have significant effects on absorption of other drugs.

OCTREOTIDE

Somatostatin is a 14-amino-acid peptide that is released in the gastrointestinal tract and pancreas from paracrine cells, D cells, and enteric nerves as well as from the hypothalamus (see Chapter 37). Somatostatin is a key regulatory peptide that has many physiologic effects:

1. It inhibits the secretion of numerous hormones and transmitters, including gastrin, cholecystokinin, glucagon, growth hormone, insulin, secretin, pancreatic polypeptide, vasoactive intestinal peptide, and 5-HT.
2. It reduces intestinal fluid secretion and pancreatic secretion.
3. It slows gastrointestinal motility and inhibits gallbladder contraction.
4. It reduces portal and splanchnic blood flow.
5. It inhibits secretion of some anterior pituitary hormones.

The clinical usefulness of somatostatin is limited by its short half-life in the circulation (3 minutes) when it is administered by intravenous injection. **Octreotide** is a synthetic octapeptide with actions similar to somatostatin. When administered intravenously, it has a serum half-life of 1.5 hours. It also may be administered by subcutaneous injection, resulting in a 6- to 12-hour duration of action. A longer-acting formulation is available for once-monthly depot intramuscular injection.

Clinical Uses

1. Inhibition of endocrine tumor effects—Two gastrointestinal neuroendocrine tumors (carcinoid, VIPoma) cause secretory diarrhea and systemic symptoms such as flushing and wheezing. For patients with advanced symptomatic tumors that cannot be completely removed by surgery, octreotide decreases secretory diarrhea and systemic symptoms through inhibition of hormonal secretion and may slow tumor progression.

2. Other causes of diarrhea—Octreotide inhibits intestinal secretion and has dose-related effects on bowel motility. In low doses (50 mcg subcutaneously), it stimulates motility, whereas at higher doses (eg, 100–250 mcg subcutaneously), it inhibits motility. Octreotide is effective in higher doses for the treatment of diarrhea due to vagotomy or dumping syndrome as well as for diarrhea caused by short bowel syndrome or AIDS. Octreotide has been used in low doses (50 mcg subcutaneously) to stimulate small bowel motility in patients with small bowel bacterial overgrowth or intestinal pseudo-obstruction secondary to scleroderma.

3. Other uses—Because it inhibits pancreatic secretion, octreotide may be of value in patients with pancreatic fistula. The role of octreotide in the treatment of pituitary tumors (eg, acromegaly) is discussed in Chapter 37. Octreotide is sometimes used in gastrointestinal bleeding (see below).

Adverse Effects

Impaired pancreatic secretion may cause steatorrhea, which can lead to fat-soluble vitamin deficiency. Alterations in gastrointestinal

motility cause nausea, abdominal pain, flatulence, and diarrhea. Because of inhibition of gallbladder contractility and alterations in fat absorption, long-term use of octreotide can cause formation of sludge or gallstones in over 50% of patients, which rarely results in the development of acute cholecystitis. Because octreotide alters the balance among insulin, glucagon, and growth hormone, hyperglycemia or, less frequently, hypoglycemia (usually mild) can occur. Prolonged treatment with octreotide may result in hypothyroidism. Octreotide also can cause bradycardia.

■ DRUGS USED IN THE TREATMENT OF IRRITABLE BOWEL SYNDROME

IBS is an idiopathic chronic, relapsing disorder characterized by abdominal discomfort (pain, bloating, distention, or cramps) in association with alterations in bowel habits (diarrhea, constipation, or both). With episodes of abdominal pain or discomfort, patients note a change in the frequency or consistency of their bowel movements.

Pharmacologic therapies for IBS are directed at relieving abdominal pain and discomfort and improving bowel function. For patients with predominant diarrhea, antidiarrheal agents, especially loperamide, are helpful in reducing stool frequency and fecal urgency. For patients with predominant constipation, fiber supplements may lead to softening of stools and reduced straining; however, increased gas production may exacerbate bloating and abdominal discomfort. Consequently, osmotic laxatives, especially milk of magnesia, are commonly used to soften stools and promote increased stool frequency.

For chronic abdominal pain, low doses of tricyclic antidepressants (eg, amitriptyline or desipramine, 10–50 mg/d) appear to be helpful (see Chapter 30). At these doses, these agents have no effect on mood but may alter central processing of visceral afferent information. The anticholinergic properties of these agents also may have effects on gastrointestinal motility and secretion, reducing stool frequency and liquidity. Finally, tricyclic antidepressants may alter receptors for enteric neurotransmitters such as serotonin, affecting visceral afferent sensation.

Several other agents are available that are specifically intended for the treatment of IBS.

ANTISPASMODICS (ANTICHOLINERGICS)

Some agents are promoted as providing relief of abdominal pain or discomfort through antispasmodic actions. However, small or large bowel spasm has not been found to be an important cause of symptoms in patients with IBS. Antispasmodics work primarily through anticholinergic activities. Commonly used medications in this class include **dicyclomine** and **hyoscyamine** (see Chapter 8). These drugs inhibit muscarinic cholinergic receptors in the enteric plexus and on smooth muscle. The efficacy of antispasmodics for relief of abdominal symptoms has never been convincingly demonstrated. At low doses, they have minimal autonomic effects.

However, at higher doses they exhibit significant additional anticholinergic effects, including dry mouth, visual disturbances, urinary retention, and constipation. For these reasons, antispasmodics are infrequently used.

SEROTONIN 5-HT₃-RECEPTOR ANTAGONISTS

5-HT₃ receptors in the gastrointestinal tract activate visceral afferent pain sensation via extrinsic sensory neurons from the gut to the spinal cord and central nervous system. Inhibition of afferent gastrointestinal 5-HT₃ receptors may reduce unpleasant visceral afferent sensation, including nausea, bloating, and pain. Blockade of central 5-HT₃ receptors also reduces the central response to visceral afferent stimulation. In addition, 5-HT₃-receptor blockade on the terminals of enteric cholinergic neurons inhibits colonic motility, especially in the left colon, increasing total colonic transit time.

Alosetron is a 5-HT₃ antagonist that has been approved for the treatment of patients with severe IBS with diarrhea (Figure 62–5). Four other 5-HT₃ antagonists (ondansetron,

granisetron, dolasetron, and palonosetron) have been approved for the prevention and treatment of nausea and vomiting (see Antiemetics); however, their efficacy in the treatment of IBS has not been determined. The differences between these 5-HT₃ antagonists that determine their pharmacodynamic effects have not been well studied.

Pharmacokinetics & Pharmacodynamics

Alosetron is a highly potent and selective antagonist of the 5-HT₃ receptor. It is rapidly absorbed from the gastrointestinal tract with a bioavailability of 50–60% and has a plasma half-life of 1.5 hours but a much longer duration of effect. It undergoes extensive hepatic cytochrome P450 metabolism with renal excretion of most metabolites. Alosetron binds with higher affinity and dissociates more slowly from 5-HT₃ receptors than other 5-HT₃ antagonists, which may account for its long duration of action.

Clinical Uses

Alosetron is approved for the treatment of women with severe IBS in whom diarrhea is the predominant symptom

FIGURE 62–5 Chemical structure of serotonin; the 5-HT₃ antagonists ondansetron, granisetron, dolasetron, and alosetron; and the 5-HT₄ partial agonist tegaserod.

(“diarrhea-predominant IBS”). Its efficacy in men has not been established. In a dosage of 1 mg once or twice daily, it reduces IBS-related lower abdominal pain, cramps, urgency, and diarrhea. Approximately 50–60% of patients report adequate relief of pain and discomfort with alosetron compared with 30–40% of patients treated with placebo. It also leads to a reduction in the mean number of bowel movements per day and improvement in stool consistency. Alosetron has not been evaluated for the treatment of other causes of diarrhea.

Adverse Events

In contrast to the excellent safety profile of other 5-HT₃-receptor antagonists, alosetron is associated with rare but serious gastrointestinal toxicity. Constipation occurs in up to 30% of patients with diarrhea-predominant IBS, requiring discontinuation of the drug in 10%. Serious complications of constipation requiring hospitalization or surgery have occurred in 1 of every 1000 patients. Episodes of ischemic colitis—some fatal—have been reported in up to 3 per 1000 patients. Given the seriousness of these adverse events, alosetron is restricted to women with severe diarrhea-predominant IBS who have not responded to conventional therapies and who have been educated about the relative risks and benefits.

Drug Interactions

Despite being metabolized by a number of CYP enzymes, alosetron does not appear to have clinically significant interactions with other drugs.

CHLORIDE CHANNEL ACTIVATORS

As discussed previously, **lubiprostone** is a prostanoid acid derivative that stimulates the type 2 chloride channel (ClC-2) in the small intestine. Lubiprostone is approved for the treatment of women with IBS with predominant constipation. Its efficacy for men with IBS is unproven. The approved dose for IBS is 8 mcg twice daily (compared with 24 mcg twice daily for chronic constipation). In clinical trials, lubiprostone resulted in modest clinical benefit—only 8% more patients than with placebo. Lubiprostone is listed as category C for pregnancy and should be avoided in women of child-bearing age.

Also discussed previously, **linaclotide** is a guanylyl cyclase-C agonist that leads to activation of the CFTR in the small intestine with stimulation of chloride-rich intestinal secretion. It is approved for treatment of adults with IBS with constipation at an approved dose of 290 mcg once daily (compared with 145 mcg once daily for chronic constipation). In clinical trials, up to 25% more patients treated with linaclotide than with placebo demonstrated significant clinical improvement. Linaclotide is listed as category C for pregnancy and is contraindicated for pediatric patients.

Due to their high cost and lack of information about long-term safety and efficacy, the role of these agents in the treatment of IBS with constipation is uncertain. Neither agent has been compared with other less expensive laxatives (eg, milk of magnesia).

ANTIEMETIC AGENTS

Nausea and vomiting may be manifestations of a wide variety of conditions, including adverse effects from medications; systemic disorders or infections; pregnancy; vestibular dysfunction; central nervous system infection or increased pressure; peritonitis; hepatobiliary disorders; radiation or chemotherapy; and gastrointestinal obstruction, dysmotility, or infections.

PATHOPHYSIOLOGY

The brainstem “vomiting center” is a loosely organized neuronal region within the lateral medullary reticular formation and coordinates the complex act of vomiting through interactions with cranial nerves VIII and X and neural networks in the nucleus tractus solitarius that control respiratory, salivatory, and vasomotor centers. High concentrations of muscarinic M₁, histamine H₁, neurokinin 1 (NK₁), and serotonin 5-HT₃ receptors have been identified in the vomiting center (Figure 62–6).

There are four important sources of afferent input to the vomiting center:

1. The “chemoreceptor trigger zone” or area postrema is located at the caudal end of the fourth ventricle. This is outside the blood-brain barrier and is accessible to emetogenic stimuli in the blood or cerebrospinal fluid. The chemoreceptor trigger zone is rich in dopamine D₂ receptors and opioid receptors, and possibly serotonin 5-HT₃ receptors and NK₁ receptors.
2. The vestibular system is important in motion sickness via cranial nerve VIII. It is rich in muscarinic M₁ and histamine H₁ receptors.
3. Vagal and spinal afferent nerves from the gastrointestinal tract are rich in 5-HT₃ receptors. Irritation of the gastrointestinal mucosa by chemotherapy, radiation therapy, distention, or acute infectious gastroenteritis leads to release of mucosal serotonin and activation of these receptors, which stimulate vagal afferent input to the vomiting center and chemoreceptor trigger zone.
4. The central nervous system plays a role in vomiting due to psychiatric disorders, stress, and anticipatory vomiting prior to cancer chemotherapy.

Identification of the different neurotransmitters involved with emesis has allowed development of a diverse group of antiemetic agents that have affinity for various receptors. Combinations of antiemetic agents with different mechanisms of action are often used, especially in patients with vomiting due to chemotherapeutic agents.

SEROTONIN 5-HT₃ ANTAGONISTS

Pharmacokinetics & Pharmacodynamics

Selective 5-HT₃-receptor antagonists have potent antiemetic properties that are mediated in part through central 5-HT₃-receptor blockade in the vomiting center and chemoreceptor

FIGURE 62-6 Neurologic pathways involved in pathogenesis of nausea and vomiting (see text). (Adapted, with permission, from Krakauer EL et al: Case records of the Massachusetts General Hospital. N Engl J Med 2005;352:817. Copyright copy; 2005 Massachusetts Medical Society. Reprinted, with permission, from Massachusetts Medical Society.)

trigger zone but mainly through blockade of peripheral 5-HT₃ receptors on extrinsic intestinal vagal and spinal afferent nerves. The antiemetic action of these agents is restricted to emesis attributable to vagal stimulation (eg, postoperative) and chemotherapy; other emetic stimuli such as motion sickness are poorly controlled.

Four agents are available in the USA: **ondansetron**, **granisetron**, **dolasetron**, and **palonosetron**. (**Tropisetron** is available outside the USA.) The first three agents (ondansetron, granisetron, and dolasetron, Figure 62-5) have a serum half-life of 4–9 hours and may be administered once daily by oral or intravenous routes. All three drugs have comparable efficacy and tolerability when administered at equipotent doses. Palonosetron is a newer intravenous agent that has greater affinity for the 5-HT₃ receptor and a long serum half-life of 40 hours. All four drugs undergo extensive hepatic metabolism and are eliminated by renal and hepatic excretion. However, dose reduction is not required in geriatric patients or patients with renal insufficiency. For patients with hepatic insufficiency, dose reduction may be required with ondansetron.

5-HT₃-receptor antagonists do not inhibit dopamine or muscarinic receptors. They do not have effects on esophageal or gastric motility but may slow colonic transit.

Clinical Uses

1. Chemotherapy-induced nausea and vomiting—5-HT₃-receptor antagonists are the primary agents for the prevention of acute chemotherapy-induced nausea and emesis. When used alone, these drugs have little or no efficacy for the prevention of delayed nausea and vomiting (ie, occurring >24 hours after chemotherapy). The drugs are most effective when given as a single dose by intravenous injection 30 minutes prior to administration of chemotherapy in the following doses: ondansetron, 8 mg; granisetron, 1 mg; dolasetron, 100 mg; or palonosetron, 0.25 mg. A single oral dose given 1 hour before chemotherapy may be equally effective in the following regimens: ondansetron 8 mg twice daily or 24 mg once; granisetron, 2 mg; dolasetron, 100 mg. Although 5-HT₃-receptor antagonists are effective as single agents for the prevention of chemotherapy-induced nausea and vomiting, their efficacy is enhanced by combination therapy with a corticosteroid (dexamethasone), NK₁-receptor antagonist, and a dopamine D₂ antagonist (antipsychotics; see below).

2. Postoperative and postradiation nausea and vomiting—5-HT₃-receptor antagonists are used to prevent or treat postoperative nausea and vomiting. Because of adverse effects and increased restrictions on the use of other antiemetic agents,

5-HT₃-receptor antagonists are increasingly used for this indication. They are also effective in the prevention and treatment of nausea and vomiting in patients undergoing radiation therapy to the whole body or abdomen.

Adverse Effects

The 5-HT₃-receptor antagonists are well-tolerated agents with excellent safety profiles. The most commonly reported adverse effects are headache, dizziness, and constipation. All four agents cause a small but statistically significant prolongation of the QT interval, but this is most pronounced with dolasetron. Although cardiac arrhythmias have not been linked to dolasetron, it should not be administered to patients with prolonged QT or in conjunction with other medications that may prolong the QT interval (see Chapter 14). Serotonin syndrome has been reported in patients taking 5-HT₃-receptor antagonists in combination with other serotonergic drugs (selective serotonin reuptake inhibitors [SSRIs] and serotonin-norepinephrine reuptake inhibitors [SNRIs]; see Chapter 30).

Drug Interactions

No significant drug interactions have been reported with 5-HT₃-receptor antagonists. All four agents undergo some metabolism by the hepatic cytochrome P450 system, but they do not appear to affect the metabolism of other drugs. However, other drugs may reduce hepatic clearance of the 5-HT₃-receptor antagonists, altering their half-life.

CORTICOSTEROIDS

Corticosteroids (dexamethasone, methylprednisolone) have antiemetic properties, but the basis for these effects is unknown. The pharmacology of this class of drugs is discussed in Chapter 39. These agents appear to enhance the efficacy of 5-HT₃-receptor antagonists for prevention of acute and delayed nausea and vomiting in patients receiving moderately to highly emetogenic chemotherapy regimens. Although a number of corticosteroids have been used, dexamethasone, 8–20 mg intravenously before chemotherapy, followed by 8 mg/d orally for 2–4 days, is commonly administered.

NEUROKININ RECEPTOR ANTAGONISTS

Neurokinin 1 (NK₁)-receptor antagonists have antiemetic properties that are mediated through central blockade in the area postrema. **Aprepitant**, **netupitant**, and **rolapitant** (all oral formulations) are highly selective NK₁-receptor antagonists that cross the blood-brain barrier and occupy brain NK₁ receptors. They have no affinity for serotonin, dopamine, or corticosteroid receptors. Netupitant (300 mg) is available only as a combination product with palonosetron (0.5 mg). **Fosaprepitant** is an intravenous formulation that is converted within 30 minutes after infusion to aprepitant.

Pharmacokinetics

The oral bioavailability of aprepitant is 65%, and the serum half-life is 12 hours. Netupitant and rolapitant have longer half-lives (90 and 180 hours, respectively), allowing single-dose administration. All three agents are metabolized by the liver, primarily by the CYP3A4 pathway.

Clinical Uses

NK₁-receptor antagonists are used in combination with 5-HT₃-receptor antagonists and corticosteroids for the prevention of acute and delayed nausea and vomiting from highly emetogenic chemotherapeutic regimens. Combined therapy with an NK₁-receptor antagonist, a 5-HT₃-receptor antagonist, and dexamethasone prevents acute emesis in 80–90% of patients compared with less than 70% of patients treated without an NK₁ antagonist. Prevention of delayed emesis occurs in more than 70% of patients receiving combined therapy versus 30–50% treated without an NK₁ antagonist. Oral NK₁-receptor antagonists may be administered as follows: aprepitant 125 mg given 1 hour before chemotherapy, followed by oral aprepitant 80 mg/d for 2 days after chemotherapy; rolapitant 180 mg; or netupitant 300 mg/palonosetron 0.5 mg given as a single dose 1–2 hours before chemotherapy. For patients unable to tolerate oral therapy, intravenous fosaprepitant 115 mg may be given as a single intravenous dose 1 hour before chemotherapy. The addition of the antipsychotic agent olanzapine 10 mg on days 1–4 further decreases the incidence of acute and delayed nausea and vomiting with highly emetogenic chemotherapeutic regimens by 15–30%.

Adverse Effects & Drug Interactions

The NK₁-receptor antagonists are well tolerated with a low incidence of fatigue and dizziness. The drugs are metabolized by CYP3A4 and may inhibit the metabolism of other drugs metabolized by the CYP3A4 pathway. Several chemotherapeutic agents are metabolized by CYP3A4, including docetaxel, paclitaxel, etoposide, irinotecan, imatinib, vinblastine, and vincristine. Drugs that inhibit CYP3A4 metabolism may significantly increase aprepitant plasma levels (eg, ketoconazole, ciprofloxacin, clarithromycin, nefazodone, ritonavir, nelfinavir, verapamil, and quinidine). Aprepitant decreases the international normalized ratio (INR) in patients taking warfarin.

ANTI-PSYCHOTIC AGENTS (PHENOTHIAZINES, BUTYROPHENONES, & THIENOBENZODIAZEPINES)

Several classes of antipsychotic agents can be used for their antiemetic and sedative properties (see Chapter 29). The antiemetic properties of phenothiazines are mediated through inhibition of dopamine and muscarinic receptors. Sedative properties are due to their antihistamine activity. The agents most commonly used as antiemetics are **prochlorperazine**, **promethazine**, and **thiethylperazine**. The antiemetic properties of **olanzapine**

(a thienobenzodiazepine) may be attributable to inhibition of dopamine D_2 and serotonin 5-HT_{1c} and 5-HT_3 receptors.

Antipsychotic butyrophenones also possess antiemetic properties due to their central dopaminergic blockade (see Chapter 29). The main agent used is **droperidol**, which can be given by intramuscular or intravenous injection. In antiemetic doses, droperidol is extremely sedating. Previously, it was used extensively for postoperative nausea and vomiting, in conjunction with opiates and benzodiazepines for sedation for surgical and endoscopic procedures, for neuroleptanalgesia, and for induction and maintenance of general anesthesia. Extrapyramidal effects and hypotension may occur. Droperidol may prolong the QT interval, rarely resulting in fatal episodes of ventricular tachycardia including torsades de pointes. Therefore, droperidol should not be used in patients with QT prolongation and should be used only in patients who have not responded adequately to alternative agents.

SUBSTITUTED BENZAMIDES

Substituted benzamides include **metoclopramide** (discussed previously) and **trimethobenzamide**. Their primary mechanism of antiemetic action is believed to be dopamine-receptor blockade. Trimethobenzamide also has weak antihistaminic activity. For prevention and treatment of nausea and vomiting, metoclopramide may be given in the relatively high dosage of 10–20 mg orally or intravenously every 6 hours. The usual dose of trimethobenzamide is 300 mg orally, or 200 mg by intramuscular injection. The principal adverse effects of these central dopamine antagonists are extrapyramidal: restlessness, dystonias, and parkinsonian symptoms.

H₁ ANTIHISTAMINES & ANTICHOLINERGIC DRUGS

The pharmacology of anticholinergic agents is discussed in Chapter 8 and that of H₁ antihistaminic agents in Chapter 16. As single agents, these drugs have weak antiemetic activity, although they are particularly useful for the prevention or treatment of motion sickness. Their use may be limited by dizziness, sedation, confusion, dry mouth, cycloplegia, and urinary retention. **Diphenhydramine** and one of its salts, **dimenhydrinate**, are first-generation histamine H₁ antagonists that also have significant anticholinergic properties. Because of its sedating properties, diphenhydramine is commonly used in conjunction with other antiemetics for treatment of emesis due to chemotherapy. **Meclizine** is an H₁ antihistaminic agent with minimal anticholinergic properties that also causes less sedation. It is used for the prevention of motion sickness and the treatment of vertigo due to labyrinth dysfunction.

Hyoscine (scopolamine), a prototypic muscarinic receptor antagonist, is one of the best agents for the prevention of motion sickness. However, it has a very high incidence of anticholinergic effects when given orally or parenterally. It is better tolerated as a transdermal patch. Superiority to dimenhydrinate has not been proved.

BENZODIAZEPINES

Benzodiazepines such as lorazepam or diazepam are used before the initiation of chemotherapy to reduce anticipatory vomiting or vomiting caused by anxiety. The pharmacology of these agents is presented in Chapter 22.

CANNABINOIDS

Dronabinol is Δ^9 -tetrahydrocannabinol (THC), the major psychoactive chemical in marijuana (see Chapter 32). After oral ingestion, the drug is almost completely absorbed but undergoes significant first-pass hepatic metabolism. Its metabolites are excreted slowly over days to weeks in the feces and urine. Like crude marijuana, dronabinol is a psychoactive agent that is used medically as an appetite stimulant and as an antiemetic, but the mechanisms for these effects are not understood. Because of the availability of more effective agents, dronabinol now is uncommonly used for the prevention of chemotherapy-induced nausea and vomiting. Combination therapy with phenothiazines provides synergistic antiemetic action and appears to attenuate the adverse effects of both agents. Dronabinol is usually administered in a dosage of 5 mg/m² just prior to chemotherapy and every 2–4 hours as needed. Adverse effects include euphoria, dysphoria, sedation, hallucinations, dry mouth, and increased appetite. It has some autonomic effects that may result in tachycardia, conjunctival injection, and orthostatic hypotension. Dronabinol has no significant drug-drug interactions but may potentiate the clinical effects of other psychoactive agents.

Nabilone is a closely related THC analog that has been available in other countries and is now approved for use in the USA.

■ DRUGS USED TO TREAT INFLAMMATORY BOWEL DISEASE (IBD)

IBD comprises two distinct disorders: ulcerative colitis and Crohn's disease. The etiology and pathogenesis of these disorders remain unknown. For this reason, pharmacologic treatment of inflammatory bowel disorders often involves drugs that belong to different therapeutic classes and have different but nonspecific mechanisms of anti-inflammatory action. Drugs used in IBD are chosen on the basis of disease severity, responsiveness, and drug toxicity (Figure 62–7).

AMINOSALICYLATES

Chemistry & Formulations

Drugs that contain **5-aminosalicylic acid (5-ASA)** have been used successfully for decades in the treatment of IBDs (Figure 62–8). 5-ASA differs from salicylic acid only by the addition of an amino group at the 5 (meta) position. Aminosaliclates are believed to

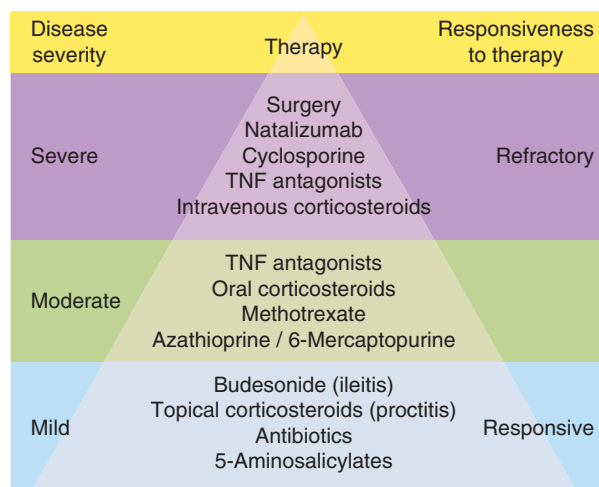

FIGURE 62-7 Therapeutic pyramid approach to inflammatory bowel diseases. Treatment choice is predicated on both the severity of the illness and the responsiveness to therapy. Agents at the bottom of the pyramid are less efficacious but carry a lower risk of serious adverse effects. Drugs may be used alone or in various combinations. Patients with mild disease may be treated with 5-aminosalicylates (with ulcerative colitis or Crohn's colitis), topical corticosteroids (ulcerative colitis), antibiotics (Crohn's colitis or Crohn's perianal disease), or budesonide (Crohn's ileitis). Patients with moderate disease or patients who fail initial therapy for mild disease may be treated with oral corticosteroids to promote disease remission; immunomodulators (azathioprine, mercaptopurine, methotrexate) to promote or maintain disease remission; or anti-TNF antibodies. Patients with moderate disease who fail other therapies or patients with severe disease may require intravenous corticosteroids, anti-TNF antibodies, or surgery. Natalizumab is reserved for patients with severe Crohn's disease who have failed immunomodulators and TNF antagonists. Cyclosporine is used primarily for patients with severe ulcerative colitis who have failed a course of intravenous corticosteroids. TNF, tumor necrosis factor.

work topically (not systemically) in areas of diseased gastrointestinal mucosa. Up to 80% of unformulated, aqueous 5-ASA is absorbed from the small intestine and does not reach the distal small bowel or colon in appreciable quantities. To overcome the rapid absorption of 5-ASA from the proximal small intestine, a number of formulations have been designed to deliver 5-ASA to various distal segments of the small bowel or the colon. These include **sulfasalazine**, **olsalazine**, **balsalazide**, and various forms of **mesalamine**.

1. Azo compounds—Sulfasalazine, balsalazide, and olsalazine contain 5-ASA bound by an azo ($N=N$) bond to an inert compound or to another 5-ASA molecule (Figure 62-8). In sulfasalazine, 5-ASA is bound to sulfapyridine; in balsalazide, 5-ASA is bound to 4-aminobenzoyl- β -alanine; and in olsalazine, two 5-ASA molecules are bound together. The azo structure markedly reduces absorption of the parent drug from the small intestine. In the terminal ileum and colon, resident bacteria cleave the azo bond by means of an azoreductase enzyme, releasing the active 5-ASA. Consequently, high concentrations of active drug are made available in the terminal ileum or colon.

2. Mesalamine compounds—Other proprietary formulations have been designed that package 5-ASA itself in various ways to deliver it to different segments of the small or large bowel. These 5-ASA formulations are known generically as **mesalamine**. **Pentasa** is a mesalamine formulation that contains timed-release microgranules that release 5-ASA throughout the small intestine (Figure 62-9). **Asacol** and **Apriso** have 5-ASA coated in a pH-sensitive resin that dissolves at pH 6–7 (the pH of the distal ileum and proximal colon). **Lialda** also uses a pH-dependent resin that encases a multimatrix core. On dissolution of the pH-sensitive resin in the colon, water slowly penetrates its hydrophilic and lipophilic core, leading to slow release of mesalamine throughout

FIGURE 62-8 Chemical structures and metabolism of aminosaliclates. Azo compounds (balsalazide, olsalazine, sulfasalazine) are converted by bacterial azoreductase to 5-aminosalicylic acid (mesalamine), the active therapeutic moiety.

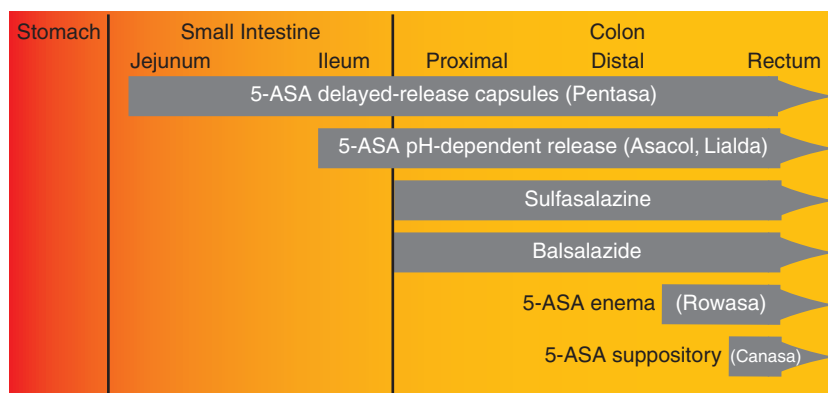

FIGURE 62-9 Sites of 5-aminosalicylic acid (5-ASA) release from different formulations in the small and large intestines.

the colon. 5-ASA also may be delivered in high concentrations to the rectum and sigmoid colon by means of enema formulations (**Rowasa**) or suppositories (**Canasa**).

Pharmacokinetics & Pharmacodynamics

Although unformulated 5-ASA is readily absorbed from the small intestine, absorption of 5-ASA from the colon is extremely low. In contrast, approximately 20–30% of 5-ASA from current oral mesalamine formulations is systemically absorbed in the small intestine. Absorbed 5-ASA undergoes *N*-acetylation in the gut epithelium and liver to a metabolite that does not possess significant anti-inflammatory activity. The acetylated metabolite is excreted by the kidneys.

Of the azo compounds, 10% of sulfasalazine and less than 1% of balsalazide are absorbed as native compounds. After azoreductase breakdown of sulfasalazine, over 85% of the carrier molecule sulfapyridine is absorbed from the colon. Sulfapyridine undergoes hepatic metabolism (including acetylation) followed by renal excretion. By contrast, after azoreductase breakdown of balsalazide, over 70% of the carrier peptide is recovered intact in the feces and only a small amount of systemic absorption occurs.

The mechanism of action of 5-ASA is not certain. The primary action of salicylate and other NSAIDs is due to blockade of prostaglandin synthesis by inhibition of cyclooxygenase. However, the aminosaliclates have variable effects on prostaglandin production. It is thought that 5-ASA modulates inflammatory mediators derived from both the cyclooxygenase and lipoxygenase pathways. Other potential mechanisms of action of the 5-ASA drugs relate to their ability to interfere with the production of inflammatory cytokines. 5-ASA inhibits the activity of nuclear factor- κ B (NF- κ B), an important transcription factor for proinflammatory cytokines. 5-ASA may also inhibit cellular functions of natural killer cells, mucosal lymphocytes, and macrophages, and it may scavenge reactive oxygen metabolites.

Clinical Uses

5-ASA drugs induce and maintain remission in ulcerative colitis and are considered to be the first-line agents for treatment of mild to moderate active ulcerative colitis. Their efficacy in Crohn's

disease is unproven, although many clinicians use 5-ASA agents as first-line therapy for mild to moderate disease involving the colon or distal ileum.

The effectiveness of 5-ASA therapy depends in part on achieving high drug concentration at the site of active disease. Thus, 5-ASA suppositories or enemas are useful in patients with ulcerative colitis or Crohn's disease confined to the rectum (proctitis) or distal colon (proctosigmoiditis). In patients with ulcerative colitis or Crohn's colitis that extends to the proximal colon, both the azo compounds and mesalamine formulations are useful. For the treatment of Crohn's disease involving the small bowel, mesalamine compounds, which release 5-ASA in the small intestine, have a theoretic advantage over the azo compounds.

Adverse Effects

Sulfasalazine has a high incidence of adverse effects, most of which are attributable to systemic effects of the sulfapyridine molecule. Slow acetylators of sulfapyridine have more frequent and more severe adverse effects than fast acetylators. Up to 40% of patients cannot tolerate therapeutic doses of sulfasalazine. The most common problems are dose-related and include nausea, gastrointestinal upset, headaches, arthralgias, myalgias, bone marrow suppression, and malaise. Hypersensitivity to sulfapyridine (or, rarely, 5-ASA) can result in fever, exfoliative dermatitis, pancreatitis, pneumonitis, hemolytic anemia, pericarditis, or hepatitis. Sulfasalazine has also been associated with oligospermia, which reverses upon discontinuation of the drug. Sulfasalazine impairs folate absorption and processing; hence, dietary supplementation with 1 mg/d folic acid is recommended.

In contrast to sulfasalazine, other aminosaliclate formulations are well tolerated. In most clinical trials, the frequency of drug adverse events is similar to that in patients treated with placebo. For unclear reasons, olsalazine may stimulate a secretory diarrhea—which should not be confused with active IBD—in 10% of patients. Rare hypersensitivity reactions may occur with all aminosaliclates but are much less common than with sulfasalazine. Careful studies have documented subtle changes indicative of renal tubular damage in patients receiving high doses of aminosaliclates. Rare cases of interstitial nephritis are reported, particularly in association with high doses of mesalamine formulations; this may be

attributable to the higher serum 5-ASA levels attained with these drugs. Sulfasalazine and other aminosalicylates rarely cause worsening of colitis, which may be misinterpreted as refractory colitis.

GLUCOCORTICOIDS

Pharmacokinetics & Pharmacodynamics

In gastrointestinal practice, **prednisone** and **prednisolone** are the most commonly used oral glucocorticoids. These drugs have an intermediate duration of biologic activity allowing once-daily dosing.

Hydrocortisone enemas, foam, or suppositories are used to maximize colonic tissue effects and minimize systemic absorption via topical treatment of active IBD in the rectum and sigmoid colon. Absorption of hydrocortisone is reduced with rectal administration, although 15–30% of the administered dosage is still absorbed.

Budesonide is a potent synthetic analog of prednisolone that has high affinity for the glucocorticoid receptor but is subject to rapid first-pass hepatic metabolism (in part by CYP3A4), resulting in low oral bioavailability. Two pH-controlled delayed-release oral formulations of budesonide are available that release the drug either in the distal ileum and colon (pH > 5.5, Entocort) or in the colon (pH > 7, Uceris), where it is absorbed. The bioavailability of controlled-release budesonide capsules is approximately 10%.

As in other tissues, glucocorticoids inhibit production of inflammatory cytokines (tumor necrosis factor [TNF]- α , interleukin [IL]-1) and chemokines (IL-8); reduce expression of inflammatory cell adhesion molecules; and inhibit gene transcription of nitric oxide synthase, phospholipase A₂, cyclooxygenase-2, and NF- κ B.

Clinical Uses

Glucocorticoids are commonly used in the treatment of patients with moderate to severe active IBD. Active disease is commonly treated with an initial oral dosage of 40–60 mg/d of prednisone or prednisolone. Higher doses have not been shown to be more efficacious but have significantly greater adverse effects. Once a patient responds to initial therapy (usually within 1–2 weeks), the dosage is tapered to minimize development of adverse effects. In severely ill patients, the drugs are usually administered intravenously.

For the treatment of IBD involving the rectum or sigmoid colon, rectally administered glucocorticoids are preferred because of their lower systemic absorption.

The oral controlled-release budesonide (9 mg/d) formulations described above are used in the treatment of mild to moderate Crohn's disease involving the ileum and proximal colon (Entocort) and ulcerative colitis (Uceris). They are slightly less effective than prednisolone in achieving clinical remission but have significantly less adverse systemic effects.

Corticosteroids are not useful for maintaining disease remission. Other medications such as aminosalicylates or immunosuppressive agents should be used for this purpose.

Adverse Effects

Oral controlled-release budesonide formulations are metabolized extensively in the liver by CYP3A4. Potent inhibitors of CYP3A4 can increase budesonide plasma levels several-fold, increasing the likelihood of adverse effects. General adverse effects of glucocorticoids are reviewed in Chapter 39.

PURINE ANALOGS: AZATHIOPRINE & 6-MERCAPTOPURINE

Pharmacokinetics & Pharmacodynamics

Azathioprine and 6-mercaptopurine (6-MP) are purine antineoplastic agents that have immunosuppressive properties (see Chapters 54 and 55).

The bioavailability of azathioprine (80%) is superior to 6-MP (50%). After absorption, azathioprine is rapidly converted by a nonenzymatic process to 6-MP. 6-Mercaptopurine subsequently undergoes a complex biotransformation via competing catabolic enzymes (xanthine oxidase and thiopurine methyltransferase) that produce inactive metabolites and anabolic pathways that produce active thioguanine nucleotides. Azathioprine and 6-MP have a serum half-life of less than 2 hours; however, the active 6-thioguanine nucleotides are concentrated in cells resulting in a prolonged half-life of days. The prolonged kinetics of 6-thioguanine nucleotide results in a median delay of 17 weeks before onset of therapeutic benefit from oral azathioprine or 6-MP is observed in patients with IBD.

Clinical Uses

Azathioprine and 6-MP are important agents in the induction and maintenance of remission of ulcerative colitis and Crohn's disease. Although the optimal dose is uncertain, most patients with normal thiopurine-S-methyltransferase (TPMT) activity (see below) are treated with 6-MP, 1–1.5 mg/kg/d, or azathioprine, 2–2.5 mg/kg/d. After 3–6 months of treatment, 50–60% of patients with active disease achieve remission. These agents help maintain remission in up to 80% of patients. Among patients who depend on long-term glucocorticoid therapy to control active disease, purine analogs allow dose reduction or elimination of steroids in the majority.

Adverse Effects

Dose-related toxicities of azathioprine or 6-MP include nausea, vomiting, bone marrow depression (leading to leukopenia, macrocytosis, anemia, or thrombocytopenia), and hepatic toxicity. Routine laboratory monitoring with complete blood count and liver function tests is required in all patients. Leukopenia or elevations in liver chemistries usually respond to medication dose reduction. Severe leukopenia may predispose to opportunistic infections; leukopenia may respond to therapy with granulocyte stimulating factor. Catabolism of 6-MP by TPMT is low in 11% and absent in 0.3% of the population, leading to increased production of active 6-thioguanine metabolites and increased risk of

bone marrow depression. TPMT levels can be measured before initiating therapy. These drugs should not be administered to patients with no TPMT activity and should be initiated at lower doses in patients with intermediate activity. Hypersensitivity reactions to azathioprine or 6-MP occur in 5% of patients. These include fever, rash, pancreatitis, diarrhea, and hepatitis.

As with transplant recipients receiving long-term 6-MP or azathioprine therapy, there appears to be an increased risk of lymphoma among patients with IBD, some of which may be related to Epstein-Barr virus infection. The drugs are also associated with an increased risk of nonmelanoma skin cancers. These drugs cross the placenta; however, there are many reports of successful pregnancies in women taking these agents, and the risk of teratogenicity appears to be small.

Drug Interactions

Allopurinol markedly reduces xanthine oxidase catabolism of the purine analogs, potentially increasing active 6-thioguanine nucleotides that may lead to severe leukopenia. Allopurinol should not be given to patients taking 6-MP or azathioprine except in carefully monitored situations.

METHOTREXATE

Pharmacokinetics & Pharmacodynamics

Methotrexate is another antimetabolite that has beneficial effects in a number of chronic inflammatory diseases, including Crohn's disease and rheumatoid arthritis (see Chapter 36), and in cancer (see Chapter 54). Methotrexate may be given orally, subcutaneously, or intramuscularly. Reported oral bioavailability is 50–90% at doses used in chronic inflammatory diseases. Intramuscular and subcutaneous methotrexate exhibit nearly complete bioavailability.

The principal mechanism of action is inhibition of dihydrofolate reductase, an enzyme important in the production of thymidine and purines. At the high doses used for chemotherapy, methotrexate inhibits cellular proliferation. However, at the low doses used in the treatment of IBD (12–25 mg/wk), the antiproliferative effects may not be evident. Methotrexate may interfere with the inflammatory actions of IL-1. It may also stimulate increased release of adenosine, an endogenous anti-inflammatory autacoid. Methotrexate may also stimulate apoptosis and death of activated T lymphocytes.

Clinical Uses

Methotrexate is used to induce and maintain remission in patients with Crohn's disease. Its efficacy in ulcerative colitis is uncertain. To induce remission, patients are treated with 15–25 mg of methotrexate once weekly by subcutaneous injection. If a satisfactory response is achieved within 8–12 weeks, the dose is reduced to 15 mg/wk.

Adverse Effects

At higher dosage, methotrexate may cause bone marrow depression, megaloblastic anemia, alopecia, and mucositis. At the doses

used in the treatment of IBD, these events are uncommon but warrant dose reduction if they do occur. Folate supplementation reduces the risk of these events without impairing the anti-inflammatory action.

In patients with psoriasis treated with methotrexate, hepatic damage is common; however, among patients with IBD and rheumatoid arthritis, the risk is significantly lower. Renal insufficiency may increase risk of hepatic accumulation and toxicity.

ANTITUMOR NECROSIS FACTOR THERAPY

Pharmacokinetics & Pharmacodynamics

A dysregulation of the helper T cell type 1 (Th1) response and regulatory T cells (Tregs) is present in IBD, especially Crohn's disease. One of the key proinflammatory cytokines in IBD is tumor necrosis factor (TNF). TNF is produced by the innate immune system (eg, dendritic cells, macrophages), the adaptive immune system (especially Th1 cells), and nonimmune cells (fibroblasts, smooth muscle cells). TNF exists in two biologically active forms: soluble TNF and membrane-bound TNF. The biologic activity of soluble and membrane-bound TNF is mediated by binding to TNF receptors (TNFR) that are present on some cells (especially Th1 cells, innate immune cells, and fibroblasts). Binding of TNF to TNFR initially activates components including NF- κ B that stimulate transcription, growth, and expansion. Biologic actions ascribed to TNFR activation include release of proinflammatory cytokines from macrophages, T-cell activation and proliferation, fibroblast collagen production, up-regulation of endothelial adhesion molecules responsible for leukocyte migration, and stimulation of hepatic acute phase reactants. Activation of TNFR may later lead to apoptosis (programmed cell death) of activated cells.

Four monoclonal antibodies to human TNF are approved for the treatment of IBD: infliximab, adalimumab, golimumab, and certolizumab (Table 62–3). Infliximab, adalimumab, and golimumab are antibodies of the IgG₁ subclass. Certolizumab is a recombinant antibody that contains an Fab fragment that is conjugated to polyethylene glycol (PEG) but lacks an Fc portion. The Fab portion of infliximab is a chimeric mouse-human antibody, but adalimumab, certolizumab, and golimumab are fully humanized. Infliximab is administered as an intravenous infusion. At therapeutic doses of 5–10 mg/kg, the half-life of infliximab is approximately 8–10 days, resulting in plasma disappearance of antibodies over 8–12 weeks. Adalimumab, golimumab, and certolizumab are administered by subcutaneous injection. Their half-lives are approximately 2 weeks.

All four agents bind to soluble and membrane-bound TNF with high affinity, preventing the cytokine from binding to its receptors. Binding of all three antibodies to membrane-bound TNF also causes reverse signaling that suppresses cytokine release. When infliximab, adalimumab, or golimumab bind to membrane-bound TNF, the Fc portion of the human IgG₁ region promotes antibody-mediated apoptosis, complement activation, and cellular cytotoxicity of activated T lymphocytes and macrophages. Certolizumab, without an Fc portion, lacks these properties.

TABLE 62–3 Anti-TNF antibodies used in inflammatory bowel disease.

	Infliximab	Adalimumab	Certolizumab	Golimumab
Class	Monoclonal antibody	Monoclonal antibody	Monoclonal antibody	Monoclonal antibody
% Human	75%	100%	95%	100%
Structure	IgG ₁	IgG ₁	Fab fragment attached to PEG (lacks Fc portion)	IgG ₁
Route of administration	Intravenous	Subcutaneous	Subcutaneous	Subcutaneous
Half-life	8–10 days	10–20 days	14 days	14 days
Neutralizes soluble TNF	Yes	Yes	Yes	Yes
Neutralizes membrane-bound TNF	Yes	Yes	Yes	Yes
Induces apoptosis of cells expressing membrane-bound TNF	Yes	Yes	No	Yes
Complement-mediated cytotoxicity of cells expressing membrane-bound TNF	Yes	Yes	No	Yes
Induction dose	5 mg/kg at 0, 2, and 6 weeks	160 mg, 80 mg, and 40 mg at 0, 2, and 4 weeks	400 mg at 0, 2, and 4 weeks	200 mg, 100 mg at 0, 2 weeks
Maintenance dose	5 mg/kg every 8 weeks	40 mg every 2 weeks	400 mg every 4 weeks	100 mg every 4 weeks

TNF, tumor necrosis factor.

Clinical Uses

Infliximab, adalimumab, and certolizumab are approved for the acute and chronic treatment of patients with moderate to severe Crohn's disease who have had an inadequate response to conventional therapies. Infliximab, adalimumab, and golimumab are approved for the acute and chronic treatment of moderate to severe ulcerative colitis. With induction therapy, these approved agents lead to symptomatic improvement in 60% and disease remission in 30% of patients with moderate to severe Crohn's disease, including patients who have been dependent on glucocorticoids or who have not responded to 6-MP or methotrexate. The median time to clinical response is 2 weeks. Induction therapy is generally given as follows: infliximab 5 mg/kg intravenous infusion at 0, 2, and 6 weeks; adalimumab 160 mg (in divided doses) initially and 80 mg subcutaneous injection at 2 weeks; and certolizumab 400 mg subcutaneous injection at 0, 2, and 4 weeks. Patients who respond may be treated with chronic maintenance therapy, as follows: infliximab 5 mg/kg intravenous infusion every 8 weeks; adalimumab 40 mg subcutaneous injection every 2 weeks; certolizumab 400 mg subcutaneous injection every 4 weeks. With chronic, regularly scheduled therapy, clinical response is maintained in more than 60% of patients and disease remission in 40%. However, one-third of patients eventually lose response despite higher doses or more frequent injections. Loss of response in many patients may be due to the development of antibodies to the TNF antibody or to other mechanisms.

Infliximab is approved for the treatment of patients with moderate to severe ulcerative colitis who have had inadequate response to mesalamine or corticosteroids. After induction therapy of 5–10 mg/wk at 0, 2, and 6 weeks, 70% of patients have a clinical response and one third achieve a clinical remission. With continued maintenance infusions every 8 weeks, approximately 50% of

patients have continued clinical response. Adalimumab and golimumab also are approved for the treatment of moderate to severe ulcerative colitis but appear to be less effective than intravenous infliximab. After induction therapy, less than 55% of patients have a clinical response and less than 20% achieve remission. The reason why subcutaneous anti-TNF formulations are less effective than intravenous infliximab is uncertain.

Adverse Effects

Serious adverse events occur in up to 6% of patients with anti-TNF therapy. The most important adverse effect of these drugs is infection due to suppression of the Th1 inflammatory response. This may lead to serious infections such as bacterial sepsis, tuberculosis, invasive fungal organisms, reactivation of hepatitis B, listeriosis, and other opportunistic infections. Reactivation of latent tuberculosis, with dissemination, has occurred. Before administering anti-TNF therapy, all patients must undergo testing with tuberculin skin tests or interferon gamma release assays. Prophylactic therapy for tuberculosis is warranted for patients with positive test results before beginning anti-TNF therapy. More common but usually less serious infections include upper respiratory infections (sinusitis, bronchitis, and pneumonia) and cellulitis. The risk of serious infections is increased markedly in patients taking concomitant corticosteroids.

Antibodies to the antibody (ATA) may develop with all four agents. These antibodies may attenuate or eliminate the clinical response and increase the likelihood of developing acute or delayed infusion or injection reactions. Antibody formation is much more likely in patients given episodic anti-TNF therapy than regular scheduled injections. In patients on chronic maintenance therapy, the prevalence of ATA with infliximab is 10%, with certolizumab 8%, and with adalimumab or golimumab 3%.

Antibody development also is less likely in patients who receive concomitant therapy with immunomodulators (ie, 6-MP or methotrexate). Concomitant treatment with anti-TNF agents and immunomodulators may increase the risk of lymphoma.

Infliximab intravenous infusions result in acute adverse infusion reactions in up to 10% of patients, but discontinuation of the infusion for severe reactions is required in less than 2%. Infusion reactions are more common with the second or subsequent infusions than with the first. Early mild reactions include fever, headache, dizziness, urticaria, or mild cardiopulmonary symptoms that include chest pain, dyspnea, or hemodynamic instability. Reactions to subsequent infusions may be reduced with prophylactic administration of acetaminophen, diphenhydramine, or corticosteroids. Severe acute reactions include significant hypotension, shortness of breath, muscle spasms, and chest discomfort; such reactions may require treatment with oxygen, epinephrine, and corticosteroids.

A delayed serum sickness-like reaction may occur 1–2 weeks after anti-TNF therapy in 1% of patients. These reactions consist of myalgia, arthralgia, jaw tightness, fever, rash, urticaria, and edema and usually require discontinuation of that agent. Positive antinuclear antibodies and anti-double-stranded DNA develop in a small number of patients. Development of a lupus-like syndrome is rare and resolves after discontinuation of the drug.

Rare but serious adverse effects of all anti-TNF agents also include severe hepatic reactions leading to acute hepatic failure, demyelinating disorders, hematologic reactions, and new or worsened congestive heart failure in patients with underlying heart disease. Anti-TNF agents may cause a variety of psoriatic skin rashes, which usually resolve after drug discontinuation.

Lymphoma appears to be increased in patients with untreated IBD. Anti-TNF agents may further increase the risk of lymphoma in this population, although the relative risk is uncertain. An increased number of cases of hepatosplenic T-cell lymphoma, a rare but usually fatal disease, have been noted in children and young adults, virtually all of whom have been on combined therapy with immunomodulators, anti-TNF agents, or corticosteroids. Anti-TNF agents may also be associated with an increased risk of nonmelanoma skin cancers.

ANTI-INTEGRIN THERAPY

Integrins are a family of adhesion molecules on the surface of leukocytes that may interact with another class of adhesion molecules on the surface of the vascular endothelium known as selectins, allowing circulating leukocytes to adhere to the vascular endothelium and subsequently move through the vessel wall into the tissue. Integrins consist of heterodimers that contain two subunits, alpha and beta. Two monoclonal antibodies directed against integrins are available for the treatment of inflammatory bowel disease: **natalizumab** and **vedolizumab**. Both are administered intravenously. Natalizumab is a humanized IgG₄ monoclonal antibody targeted only against the $\alpha 4$ subunit; thus, it blocks several integrins on circulating inflammatory cells and prevents binding to the vascular adhesion molecules and subsequent migration

into surrounding tissues, including the bowel and central nervous system. Unfortunately, patients treated with natalizumab may develop progressive multifocal leukoencephalopathy (PML) due to central nervous system reactivation of a human polyomavirus (JC virus), which is present in latent form in over 80% of adults. Patients who are positive for JC virus antibody have a mean risk of PML of 3.9 per 1000 patients; however, the risk is markedly increased in patients treated for more than 24 months or receiving other immunosuppressants.

Vedolizumab is a monoclonal antibody with activity directed specifically against the $\alpha 4/\beta 7$ integrin, thereby blocking interaction of leukocytes with gut vascular endothelial cell adhesion molecules. Because lymphocytes trafficking to the brain are unaffected, the risk of reactivation of JC virus and PML is believed to be extremely low. With the advent of vedolizumab, natalizumab is almost never used for the treatment of IBD. Vedolizumab is increasingly used as a second-line treatment for patients with moderate to severe ulcerative colitis or Crohn's disease who cannot take anti-TNF agents due to side effects, lack of efficacy, or loss of response. After intravenous induction therapy of 300 mg at 0, 2, and 6 weeks, patients with a clinical response are treated with intravenous maintenance therapy every 8 weeks. Vedolizumab appears to have a very low incidence of serious side effects. Neutralizing antibodies may develop in 2–10% of patients.

■ PANCREATIC ENZYME SUPPLEMENTS

Exocrine pancreatic insufficiency is most commonly caused by cystic fibrosis, chronic pancreatitis, or pancreatic resection. When secretion of pancreatic enzymes falls below 10% of normal, fat and protein digestion is impaired and can lead to steatorrhea, azotorrhea, vitamin malabsorption, and weight loss. Pancreatic enzyme supplements, which contain a mixture of amylase, lipase, and proteases, are the mainstay of treatment for pancreatic enzyme insufficiency. Two major types of preparations in use are **pancreatin** and **pancrelipase**. Pancreatin is an alcohol-derived extract of hog pancreas with relatively low concentrations of lipase and proteolytic enzymes, whereas pancrelipase is an enriched preparation. On a per-weight basis, pancrelipase has approximately 12 times the lipolytic activity and more than 4 times the proteolytic activity of pancreatin. Consequently, pancreatin is no longer in common clinical use. Only pancrelipase is discussed here.

Pancrelipase is available worldwide in both non-enteric-coated and enteric-coated preparations. Formulations are available in sizes containing varying amounts of lipase, amylase, and protease. However, manufacturers' listings of enzyme content do not always reflect true enzymatic activity. Pancrelipase enzymes are rapidly and permanently inactivated by gastric acids. Viokace is a non-enteric-coated tablet that should be given concomitantly with acid suppression therapy (PPI or H₂ antagonist) to reduce acid-mediated destruction within the stomach. Enteric-coated formulations are more commonly used because they do not require concomitant acid suppression therapy. At present, five

enteric-coated, delayed-release formulations are approved for use (Creon, Pancreaze, Zenpep, Ultresa, and Pertyze).

Pancrelipase preparations are administered with each meal and snack. Enzyme activity may be listed in international units (IU) or USP units. One IU is equal to 2–3 USP units. Dosing should be individualized according to the age and weight of the patient, the degree of pancreatic insufficiency, and the amount of dietary fat intake. Therapy is initiated at a dose that provides 60,000–90,000 USP units (20,000–30,000 IU) of lipase activity in the prandial and postprandial period—a level that is sufficient to reduce steatorrhea to a clinically insignificant level in most cases. Suboptimal response to enteric-coated formulations may be due to poor mixing of granules with food or slow dissolution and release of enzymes. Gradual increase of dose, change to a different formulation, or addition of acid suppression therapy may improve response. For patients with feeding tubes, microspheres may be mixed with enteral feeding prior to administration.

Pancreatic enzyme supplements are well tolerated. The capsules should be swallowed, not chewed, because pancreatic enzymes may cause oropharyngeal mucositis. Excessive doses may cause diarrhea and abdominal pain. The high purine content of pancreas extracts may lead to hyperuricosuria and renal stones. Several cases of colonic strictures were reported in patients with cystic fibrosis who received high doses of pancrelipase with high lipase activity. These high-dose formulations have since been removed from the market.

■ GLUCAGON-LIKE PEPTIDE 2 ANALOG FOR SHORT-BOWEL SYNDROME

Extensive surgical resection or disease of the small intestine may result in short-bowel syndrome with malabsorption of nutrients and fluids. Patients with less than 200 cm of small intestine (with or without colon resection) usually are dependent on partial or complete parenteral nutritional support to maintain hydration and nutrition. **Teduglutide** is a glucagon-like peptide 2 analog that binds to enteric neurons and endocrine cells, stimulating release of a number of trophic hormones (including insulin-like growth factor) that stimulate mucosal epithelial growth and enhance fluid absorption. In clinical trials, 54% of patients treated with teduglutide (0.05 mg/kg once daily by subcutaneous injection) reduced their need for parenteral support by at least 1 day/wk compared with 23% treated with placebo. Teduglutide may be associated with an increased risk of neoplasia, including colorectal polyps.

■ BILE ACID AGENTS

Ursodiol (ursodeoxycholic acid) is a naturally occurring bile acid that makes up less than 5% of the circulating bile salt pool in humans and a much higher percentage in bears. After oral administration, it is absorbed, conjugated in the liver with glycine

or taurine, and excreted in the bile. Conjugated ursodiol undergoes extensive enterohepatic recirculation. The serum half-life is approximately 100 hours. With long-term daily administration, ursodiol constitutes 30–50% of the circulating bile acid pool. A small amount of unabsorbed conjugated or unconjugated ursodiol passes into the colon, where it is either excreted or undergoes dehydroxylation by colonic bacteria to lithocholic acid, a substance with potential hepatic toxicity.

Pharmacodynamics

The solubility of cholesterol in bile is determined by the relative proportions of bile acids, lecithin, and cholesterol. Although prolonged ursodiol therapy expands the bile acid pool, this does not appear to be the principal mechanism of action for dissolution of gallstones. Ursodiol decreases the cholesterol content of bile by reducing hepatic cholesterol secretion. Ursodiol also appears to stabilize hepatocyte canalicular membranes, possibly through a reduction in the concentration of other endogenous bile acids or through inhibition of immune-mediated hepatocyte destruction.

Clinical Use

Ursodiol is used for dissolution of small cholesterol gallstones in patients with symptomatic gallbladder disease who refuse cholecystectomy or who are poor surgical candidates. At a dosage of 10 mg/kg/d orally for 12–24 months, dissolution occurs in up to 50% of patients with small (<5–10 mm) noncalcified gallstones. It is also effective for the prevention of gallstones in obese patients undergoing rapid weight loss therapy.

Ursodiol is also the first-line agent used for the treatment of early primary biliary cirrhosis (PBC). As a nontoxic bile acid, ursodiol is believed to reduce liver injury by replacement of more toxic endogenous bile acids and through anti-inflammatory effects. At a dose of 13–15 mg/kg/d, ursodiol improves liver biochemical abnormalities, slows the rate of clinical and histologic progression, reduces the need for liver transplantation, and improves long-term survival. Approximately 35% of patients with PBC do not respond to ursodiol.

Adverse Effects

Ursodiol is practically free of serious adverse effects. Bile salt-induced diarrhea is uncommon. Unlike its predecessor, chenodeoxycholate, ursodiol has not been associated with hepatotoxicity.

Obeticholic acid is a synthetic derivative of the naturally occurring bile acid chenodeoxycholate. Like ursodiol, it is a nontoxic bile acid and is believed to reduce liver injury by decreasing hepatic concentrations of more toxic endogenous bile acids. It also is a ligand for the nuclear farnesoid X receptor, which modulates hepatic inflammation, fibrosis, gluconeogenesis, lipid synthesis, and insulin sensitivity. Obeticholic acid was recently approved for the treatment of PBC at a dose of 5–10 mg/d orally in combination with ursodiol in patients who have had an inadequate response to ursodiol monotherapy. In a randomized, double-blind, placebo-controlled, 12-month trial, almost 50% of patients treated with combination therapy had a clinical response

compared with 10% treated with ursodiol alone. Obeticholic acid causes severe pruritus in up to 25% of patients (especially at the 10 mg dose), leading to discontinuation in up to 10% of patients.

■ DRUGS USED TO TREAT VARICEAL HEMORRHAGE

Portal hypertension most commonly occurs as a consequence of chronic liver disease. Portal hypertension is caused by increased blood flow within the portal venous system and increased resistance to portal flow within the liver. Splanchnic blood flow is increased in patients with cirrhosis due to low arteriolar resistance that is mediated by increased circulating vasodilators and decreased vascular sensitivity to vasoconstrictors. Intrahepatic vascular resistance is increased in cirrhosis due to fixed fibrosis within the spaces of Disse and hepatic veins as well as reversible vasoconstriction of hepatic sinusoids and venules. Among the consequences of portal hypertension are ascites, hepatic encephalopathy, and the development of portosystemic collaterals—especially gastric or esophageal varices. Varices can rupture, leading to massive upper gastrointestinal bleeding.

Several drugs are available that reduce portal pressures. These may be used in the short term for the treatment of active variceal hemorrhage or long term to reduce the risk of hemorrhage.

SOMATOSTATIN & OCTREOTIDE

The pharmacology of octreotide is discussed above under Antidiarrheal Agents. In patients with cirrhosis and portal hypertension, intravenous somatostatin (250 mcg/h) or octreotide (50 mcg/h) reduces portal blood flow and variceal pressures; the mechanism by which they do so is poorly understood. They do not appear to induce direct contraction of vascular smooth muscle. Their activity may be mediated through inhibition of release of glucagon and other gut peptides that alter mesenteric blood flow. Although data from clinical trials are conflicting, these agents are probably effective in promoting initial hemostasis from bleeding esophageal varices. They are generally administered for 3–5 days.

VASOPRESSIN & TERLIPRESSIN

Vasopressin (antidiuretic hormone) is a polypeptide hormone secreted by the hypothalamus and stored in the posterior pituitary. Its pharmacology is discussed in Chapters 17 and 37. Although its

primary physiologic role is to maintain serum osmolality, it is also a potent arterial vasoconstrictor. When administered intravenously by continuous infusion, vasopressin causes splanchnic arterial vasoconstriction that leads to reduced splanchnic perfusion and lowered portal venous pressures. Before the advent of octreotide, vasopressin was commonly used to treat acute variceal hemorrhage. However, because of its high adverse-effect profile, it is no longer used for this purpose. In contrast, for patients with acute gastrointestinal bleeding from small bowel or large bowel vascular ectasias or diverticulosis, vasopressin may be infused—to promote vasospasm—into one of the branches of the superior or inferior mesenteric artery through an angiographically placed catheter. Adverse effects with systemic vasopressin are common. Systemic and peripheral vasoconstriction can lead to hypertension, myocardial ischemia or infarction, or mesenteric infarction. These effects may be reduced by coadministration of nitroglycerin, which may further reduce portal venous pressures (by reducing portohepatic vascular resistance) and may also reduce the coronary and peripheral vascular vasospasm caused by vasopressin. Other common adverse effects are nausea, abdominal cramps, and diarrhea (due to intestinal hyperactivity). Furthermore, the antidiuretic effects of vasopressin promote retention of free water, which can lead to hyponatremia, fluid retention, and pulmonary edema.

Terlipressin is a vasopressin analog that appears to have similar efficacy to vasopressin with fewer adverse effects. Although this agent is available in other countries, it has never been approved for use in the USA.

BETA-RECEPTOR-BLOCKING DRUGS

The pharmacology of β -receptor-blocking agents is discussed in Chapter 10. Beta-receptor antagonists reduce portal venous pressures via a decrease in portal venous inflow. This decrease is due to a decrease in cardiac output (β_1 blockade) and to splanchnic vasoconstriction (β_2 blockade) caused by the unopposed effect of systemic catecholamines on α receptors. Thus, nonselective β blockers such as propranolol and nadolol are more effective than selective β_1 blockers in reducing portal pressures. Among patients with cirrhosis and esophageal varices who have not previously had an episode of variceal hemorrhage, the incidence of bleeding among patients treated with nonselective β blockers is 15% compared with 25% in control groups. Among patients with a history of variceal hemorrhage, the likelihood of recurrent hemorrhage is 80% within 2 years. Nonselective β blockers significantly reduce the rate of recurrent bleeding, although a reduction in mortality is unproved.

SUMMARY Drugs Used Primarily for Gastrointestinal Conditions

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
DRUGS USED IN ACID-PEPTIC DISEASES				
<ul style="list-style-type: none"> Proton-pump inhibitors (PPIs), eg, omeprazole, lansoprazole 	Irreversible blockade of H^+ /K ⁺ -ATPase pump in active parietal cells of stomach	Long-lasting reduction of stimulated and nocturnal acid secretion	Peptic ulcer, gastroesophageal reflux disease, erosive gastritis	Half-lives much shorter than duration of action • low toxicity • reduction of stomach acid may reduce absorption of some drugs and increase that of others
<ul style="list-style-type: none"> <i>H₂-receptor blockers, eg, cimetidine: Effective reduction of nocturnal acid but less effective against stimulated secretion; very safe, available over the counter (OTC). Cimetidine, but not other H₂ blockers, is a weak antiandrogenic agent and a potent CYP enzyme inhibitor</i> <i>Sucralfate: Polymerizes at site of tissue damage (ulcer bed) and protects against further damage; very insoluble with no systemic effects; must be given four times daily</i> <i>Antacids: Popular OTC medication for symptomatic relief of heartburn; not as useful as PPI and H₂ blockers in peptic diseases</i> 				
DRUGS STIMULATING MOTILITY				
<ul style="list-style-type: none"> Metoclopramide 	D ₂ -receptor blocker • removes inhibition of acetylcholine neurons in enteric nervous system	Increases gastric emptying and intestinal motility	Gastric paresis (eg, in diabetes) • antiemetic (see below)	Parkinsonian symptoms due to block of central nervous system (CNS) D ₂ receptors
<ul style="list-style-type: none"> <i>Domperidone: Like metoclopramide, but less CNS effect; not available in USA</i> <i>Cholinomimetics: Neostigmine often used for colonic pseudo-obstruction in hospitalized patients</i> <i>Macrolides: Erythromycin useful in diabetic gastroparesis but tolerance develops</i> 				
LAXATIVES				
<ul style="list-style-type: none"> Magnesium hydroxide, other nonabsorbable salts and sugars 	Osmotic agents increase water content of stool	Usually causes evacuation within 4–6 h, sooner in large doses	Simple constipation; bowel prep for endoscopy (especially polyethylene glycol [PEG] solutions)	Magnesium may be absorbed and cause toxicity in renal impairment
<ul style="list-style-type: none"> <i>Bulk-forming laxatives: Methylcellulose, psyllium, etc: increase volume of colon contents, stimulate evacuation</i> <i>Stimulants: senna, cascara; stimulate activity; may cause cramping</i> <i>Stool surfactants: Docusate, mineral oil; lubricate stool, ease passage</i> <i>Chloride channel activators: Lubiprostone, prostanoic acid derivative, stimulates chloride secretion into intestine, increasing fluid content; linaclotide, guanylyl cyclase-C agonist, stimulates chloride secretion by CFTR</i> <i>Opioid receptor antagonists: Alvimopan, methyl naloxone; block intestinal μ-opioid receptors but do not enter CNS, so analgesia is maintained</i> 				
ANTI-DIARRHEAL DRUGS				
<ul style="list-style-type: none"> Loperamide 	Activates μ -opioid receptors in enteric nervous system	Slows motility in gut with negligible CNS effects	Nonspecific, noninfectious diarrhea	Mild cramping but little or no CNS toxicity
<ul style="list-style-type: none"> <i>Diphenoxylate: Similar to loperamide, but high doses can cause CNS opioid effects and toxicity</i> <i>Colloidal bismuth compounds: Subsalicylate and citrate salts available. OTC preparations popular and have some value in travelers' diarrhea due to adsorption of toxins</i> <i>Kaolin + pectin: Adsorbent compounds available OTC in some countries</i> 				
DRUGS FOR IRRITABLE BOWEL SYNDROME (IBS)				
<ul style="list-style-type: none"> Alosetron 	5-HT ₃ antagonist of high potency and duration of binding	Reduces smooth muscle activity in gut	Approved for severe diarrhea-predominant IBS in women	Rare but serious constipation • ischemic colitis • infarction
<ul style="list-style-type: none"> <i>Anticholinergics: Nonselective action on gut activity, usually associated with typical antimuscarinic toxicity</i> <i>Chloride channel activator: Lubiprostone (see above); useful in constipation-predominant IBS in women; linaclotide (see above): useful in adults with constipation-predominant IBS</i> 				

(continued)

Subclass, Drug	Mechanism of Action	Effects	Clinical Applications	Pharmacokinetics, Toxicities, Interactions
ANTIEMETIC DRUGS				
<ul style="list-style-type: none"> Ondansetron, other 5-HT₃ antagonists 	5-HT ₃ blockade in gut and CNS with shorter duration of binding than alosetron	Extremely effective in preventing chemotherapy-induced and postoperative nausea and vomiting	First-line agents in cancer chemotherapy; also useful for postop emesis	Usually given IV but orally active in prophylaxis • 4–9 h duration of action • very low toxicity but may slow colonic transit
<ul style="list-style-type: none"> Aprepitant 	NK ₁ -receptor blocker in CNS	Interferes with vomiting reflex • no effect on 5-HT, dopamine, or steroid receptors	Effective in reducing both early and delayed emesis in cancer chemotherapy	Given orally • IV fosaprepitant available • fatigue, dizziness, diarrhea • CYP interactions
<ul style="list-style-type: none"> <i>Corticosteroids: Mechanism not known but useful in antiemetic IV cocktails</i> <i>Antimuscarinics (scopolamine): Effective in emesis due to motion sickness; not other types</i> <i>Antihistaminics: Moderate efficacy in motion sickness and chemotherapy-induced emesis</i> <i>Phenothiazines: Act primarily through block of D₂ and muscarinic receptors</i> <i>Cannabinoids: Dronabinol is available for use in chemotherapy-induced nausea and vomiting, but is associated with CNS marijuana effects</i> 				
DRUGS USED IN INFLAMMATORY BOWEL DISEASE (IBD)				
<ul style="list-style-type: none"> 5-Aminosalicylates, eg, mesalamine in many formulations Sulfasalazine 	Mechanism uncertain • may be inhibition of eicosanoid inflammatory mediators	Topical therapeutic action • systemic absorption may cause toxicity	Mild to moderately severe Crohn's disease and ulcerative colitis	Sulfasalazine causes sulfonamide toxicity and may cause GI upset, myalgias, arthralgias, myelosuppression • other aminosalicylates much less toxic
<ul style="list-style-type: none"> Purine analogs and antimetabolites, eg, 6-mercaptopurine, methotrexate 	Mechanism uncertain • may promote apoptosis of immune cells • Methotrexate blocks dihydrofolate reductase	Generalized suppression of immune processes	Moderately severe to severe Crohn's disease and ulcerative colitis	GI upset, mucositis • myelosuppression • purine analogs may cause hepatotoxicity, but rare with methotrexate at the low doses used
<ul style="list-style-type: none"> Anti-TNF antibodies, eg, infliximab, others 	Bind tumor necrosis factor and prevent it from binding to its receptors	Suppression of several aspects of immune function, especially T _H 1 lymphocytes	Infliximab: Moderately severe to severe Crohn's disease and ulcerative colitis • others approved in Crohn's disease	Infusion reactions • reactivation of latent tuberculosis • increased risk of dangerous systemic fungal and bacterial infections
<ul style="list-style-type: none"> <i>Corticosteroids: Generalized anti-inflammatory effect; see Chapter 39</i> 				
PANCREATIC SUPPLEMENTS				
<ul style="list-style-type: none"> Pancrelipase 	Replacement enzymes from animal pancreatic extracts	Improves digestion of dietary fat, protein, and carbohydrate	Pancreatic insufficiency due to cystic fibrosis, pancreatitis, pancreatectomy	Taken with every meal • may increase incidence of gout
<ul style="list-style-type: none"> <i>Pancreatin: Similar pancreatic extracts but much lower potency; rarely used</i> 				
BILE ACID THERAPY FOR GALLSTONES AND PRIMARY BILIARY CIRRHOSIS				
<ul style="list-style-type: none"> Ursodiol 	Reduces cholesterol secretion into bile and concentration of endogenous hepatocyte bile salts	Dissolves gallstones • reduces hepatic inflammation and fibrosis	Gallstones in patients refusing or not eligible for surgery • early primary biliary cirrhosis	May cause diarrhea
<ul style="list-style-type: none"> Obeticholic acid 	Binds to hepatocyte nuclear farnesoid X receptor	Reduces hepatic inflammation and fibrosis	Treatment of primary biliary cirrhosis in patients with inadequate response to ursodiol	Severe pruritus
DRUGS USED TO TREAT VARICEAL HEMORRHAGE				
<ul style="list-style-type: none"> Octreotide 	Somatostatin analog • mechanism not certain	May alter portal blood flow and variceal pressures	Patients with bleeding varices or at high risk of repeat bleeding	Reduced endocrine and exocrine pancreatic activity • other endocrine abnormalities • GI upset
<ul style="list-style-type: none"> <i>Beta blockers: Reduce cardiac output and splanchnic blood flow; see Chapter 10</i> 				

PREPARATIONS AVAILABLE

GENERIC NAME	AVAILABLE AS	GENERIC NAME	AVAILABLE AS
ANTACIDS		SELECTED ANTI-INFLAMMATORY DRUGS USED IN GASTROINTESTINAL DISEASE (SEE ALSO CHAPTER 55)	
Aluminum hydroxide gel*	Generic, Alternagel, others	Adalimumab	Humira
Calcium carbonate*	Generic, Tums, others	Balsalazide	Colazal
Combination aluminum hydroxide and magnesium hydroxide preparations*	Generic, Maalox, Mylanta, Gaviscon, Gelusil, others	Budesonide	Entocort, Uceris
H₂ HISTAMINE RECEPTOR BLOCKERS		Certolizumab	Cimzia
Cimetidine	Generic, Tagamet, Tagamet HB*	Golimumab	Symponi
Famotidine	Generic, Pepcid, Pepcid AC,* Pepcid Complete*	Hydrocortisone	Cortenema, Cortifoam, Proctofoam-HC
Nizatidine	Generic, Axid, Axid AR*	Infliximab	Remicade
Ranitidine	Generic, Zantac, Zantac 75*	Mesalamine	5-ASA
SELECTED ANTICHOLINERGIC DRUGS		Oral:	Asacol
Atropine	Generic	Rectal:	Rowasa, Canasa
Belladonna alkaloids tincture	Generic	Methylprednisolone	Medrol Enpack
Dicyclomine	Generic, Bentyl, others	Olsalazine	Dipentum
Glycopyrrolate	Generic, Robinul	Sulfasalazine	Generic, Azulfidine
Hyoscyamine	Anaspaz, Levsin, others	Vedolizumab	Entyvio
Scopolamine	Generic, Transderm Scop	SELECTED ANTIDIARRHEAL DRUGS	
PROTON-PUMP INHIBITORS		Bismuth subsalicylate*	Pepto-Bismol, others
Esomeprazole magnesium	Nexium*	Difenoxin	Motofen
Esomeprazole strontium		Diphenoxylate	Generic, Lomotil, others
Omeprazole	Generic, Prilosec, Prilosec OTC*	Eluxadoline	Viberzi
Omeprazole-sodium bicarbonate	Zegerid	Loperamide*	Generic, Imodium
Lansoprazole	Generic, Prevacid*	BULK-FORMING LAXATIVES*	
Dexlansoprazole	Dexilant	Methylcellulose	Generic, Citrucel
Pantoprazole	Generic, Protonix	Psyllium	Generic, Serutan, Metamucil, others
Rabeprazole	Generic, Aciphex	OTHER SELECTED LAXATIVE DRUGS	
MUCOSAL PROTECTIVE AGENTS		Alvimopan	Entereg
Sucralfate	Generic, Carafate	Bisacodyl*	Generic, Dulcolax, others
DIGESTIVE ENZYMES		Cascara sagrada*	Generic
Pancrelipase	Creon, Pancrease, Zenpep, Pertyze, Ultresa	Docosate*	Generic, Colace, others
DRUGS FOR MOTILITY DISORDERS & SELECTED ANTIEMETICS		Lactulose	Generic, Chronulac, Cephulac, others
5-HT₃-RECEPTOR ANTAGONISTS		Linacotide	Linzess
Alosetron	Lotronex	Lubiprostone	Amitiza
Dolasetron	Anzemet	Magnesium hydroxide (milk of magnesia, Epsom Salt)*	Generic
Granisetron	Generic, Kytril	Methylnaltrexone bromide	Relistor
Ondansetron	Generic, Zofran	Polycarbophil*	Equalactin, Mitrolan, FiberCon, Fiber-Lax
Palonosetron	Aloxi	Polyethylene glycol electrolyte solution	Co-Lyte, GoLYTELY, HalfLyte, Moviprep, others
OTHER MOTILITY AND ANTIEMETIC AGENTS		Senna*	Senokot, ExoLax, others
Aprepitant	Emend	Sodium Phosphate	Fleets Phospho-soda, OsmoPrep, Visicol
Dronabinol	Generic, Marinol	DRUGS THAT DISSOLVE GALLSTONES	
Fosaprepitant	Emend, Emend IV	Obeticholic acid	Ocaliva
Metoclopramide	Generic, Reglan, others	Ursodiol	Generic, Actigall, URSO
Nabilone	Cesamet		
Netupitant/palonosetron	Akynzeo		
Prochlorperazine	Generic, Compazine		
Promethazine	Generic, Phenergan, others		
Rolapitant	Varubi		

*Over-the-counter formulations.

CASE STUDY ANSWER

The immediate goals of therapy are to improve this young woman's symptoms of abdominal pain, diarrhea, weight loss, and fatigue. Equally important goals are to reduce the intestinal inflammation in hopes of preventing progression to intestinal stenosis, fistulization, and need for surgery. One option now is to step up her therapy by giving her a slow, tapering course of systemic corticosteroids (eg, prednisone) for 8–12 weeks in order to quickly bring her symptoms and inflammation under control while also initiating therapy

with an immunomodulator (eg, azathioprine or mercaptopurine) in hopes of achieving long-term disease remission. If satisfactory disease control is not achieved within 3–6 months, therapy with an anti-TNF agent would then be recommended. Alternatively, patients with moderate-to-severe Crohn's disease who have failed mesalamine may be treated upfront with *both* an anti-TNF agent and immunomodulators, which achieves higher remission rates than either agent alone and may improve long-term outcomes.

Therapeutic & Toxic Potential of Over-the-Counter Agents

Valerie B. Clinard, PharmD, &
Robin L. Corelli, PharmD

CASE STUDY

KH, a 55-year-old woman, presents to the emergency department with nausea, vomiting, and complaints of new-onset flu symptoms over the past several days. Her past medical history is significant for allergic rhinitis and chronic lower back pain secondary to a work-related fall 2 years ago. Her current medications include Norco 5/325 (hydrocodone 5 mg/acetaminophen 325 mg per tablet; two tablets four times daily for pain) and loratadine (10 mg daily). The patient also reported recent use of several over-the-counter (OTC) medications over the past 3 days to treat the new-onset flu symptoms, including Alka-Seltzer Plus Severe Cold + Flu (two tablets every 4 hours during the day) and Tylenol PM (two tablets at bedtime).

Her social history is significant for alcohol use (three to four glasses of wine/night). Her vital signs include the following: temperature 99.8°F, blood pressure 132/64 mm Hg, pulse 78 bpm, and respiratory rate 15/min. On physical examination, she had left upper abdominal tenderness with evidence of hepatomegaly and mild scleral icterus. Laboratory data revealed the following: alanine aminotransferase, 527 IU/L (normal 10–35 IU/L); aspartate aminotransferase, 425 IU/L (normal < 35 IU/L); and bilirubin, 2.9 mg/dL (normal 0.1–0.3 mg/dL). What medications do OTC cold and flu preparations typically contain? Which of the OTC medications might have contributed to the patient's current symptoms?

In the USA, medications are divided by law into two classes: those restricted to sale by prescription only and those for which directions for safe use by the public can be written. The latter category constitutes the nonprescription, or over-the-counter (OTC), medications. This category does not include supplements (vitamins, minerals, herbals, and botanicals), which are subject to different regulatory requirements (see Chapter 64, Dietary Supplements & Herbal Medications). In 2016, the American public spent approximately \$34 billion on OTC products to self-manage a wide variety of acute and chronic medical conditions.

It is apparent that many OTC medications are comparable products advertised to consumers in ways that suggest significant differences between them. For example, there are over 100

different systemic analgesic products, almost all of which contain aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen, or a combination of these agents as primary ingredients. They are made different from one another by the addition of questionable ingredients such as caffeine or antihistamines; by brand names chosen to suggest a specific use or strength (eg, “women’s,” “migraine,” “arthritis,” “maximum”); or by special dosage formulations (eg, enteric-coated tablets, gel tabs, liquids, orally disintegrating strips and tablets, sustained-release products, powders, seltzers). Generally, a price is attached to all of these features, and in most cases, a less expensive generic product can be equally effective. It is probably safe to assume that the public is generally overwhelmed and confused by the wide

array of products presented and will likely use those that are most heavily advertised.

Since 1972, the US Food and Drug Administration (FDA) has been engaged in a methodical review of OTC ingredients for both safety and efficacy. There have been two major outcomes of this review: (1) Ingredients designated as ineffective or unsafe for their claimed therapeutic use are being eliminated from OTC product formulations (eg, antimuscarinic agents have been eliminated from OTC sleep aids; attapulgite and polycarbophil can no longer be marketed as OTC antidiarrheal products); and (2) agents previously available by prescription only have been made available for OTC use because they were judged by the review panel to be generally safe and effective for consumer use without medical supervision (Table 63–1). The prescription-to-OTC switch process has significantly enhanced and expanded self-care options for US consumers. More than 100 OTC active ingredients or dosages are on the market today that were previously available only by prescription. Other OTC ingredients previously available in low doses only are now available in original prescription strength formulations (eg, ranitidine 150 mg, famotidine 20 mg). Examples of other prescription medications with the potential for future OTC reclassification include oral contraceptives, nicotine replacement therapy (oral inhaler, nasal spray) for smoking cessation, proton-pump inhibitors (pantoprazole) for heartburn, and second-generation nonsedating antihistamines (desloratadine) for relief of allergy and cold symptoms. The prescription-to-OTC reclassification process is both costly and rigorous, and only select prescription medications are appropriate candidates for a switch (eg, a consumer can self-diagnose and safely treat the condition). For example, the cholesterol-lowering agents lovastatin and pravastatin were denied OTC status on the basis that these

agents could not be used safely and effectively in an OTC setting. The nonprescription drug advisory committee believed that diagnosis and ongoing management by a health care professional was necessary for the management of hyperlipidemia, a chronic, asymptomatic condition with potentially life-threatening consequences. In a similar recommendation, oral acyclovir for OTC use in the treatment of recurrent genital herpes was not approved because of concerns about misdiagnosis and inappropriate use leading to increased viral resistance.

There are three reasons why it is essential for clinicians to be familiar with the OTC class of products. First, many OTC medications are effective in treating common ailments, and it is important to be able to help the patient select a safe, effective product. Because health care insurance practices encourage clinicians to reduce costs, many providers will recommend effective OTC treatments, since these medications are rarely paid for by health plans. Second, many of the active ingredients contained in OTC medications may worsen existing medical conditions or interact with prescription medications (see Chapter 66, Important Drug Interactions & Their Mechanisms). Finally, the misuse or abuse of OTC products may actually produce significant medical complications. Phenylpropanolamine, for example, a sympathomimetic previously found in many cold, allergy, and weight control products, was withdrawn from the US market by the FDA based on reports that the drug increased the risk of hemorrhagic stroke. Dextromethorphan, an antitussive found in many cough and cold preparations, has been increasingly abused in high doses (eg, >5–10 times the recommended antitussive dose) by adolescents as a hallucinogen. Although severe complications associated with dextromethorphan as a single agent in overdose are uncommon, many dextromethorphan-containing products

TABLE 63–1 Selected agents switched from prescription to over-the-counter status by the US Food and Drug Administration (2006–2017).

Ingredient	Indication (Pharmacologic Category)	Year Ingredient First Switched	Single-Ingredient Product Examples
Adapalene	Acne (topical retinoid)	2016	Differin Gel
Budesonide	Allergic rhinitis (topical glucocorticoid)	2015	Rhinocort Allergy Spray
Cetirizine	Hay fever/upper respiratory allergies (antihistamine)	2007	Zyrtec
Esomeprazole	Acid reducer (proton-pump inhibitor)	2014	Nexium 24 hour
Fexofenadine	Hay fever/upper respiratory allergies (antihistamine)	2011	Allegra 12 hour, Allegra 24 hour
Fluticasone	Allergic rhinitis (topical glucocorticoid)	2014	Flonase Allergy Relief, Flonase Sensimist Allergy-Relief
Ketotifen	Itchy eyes (ophthalmic antihistamine)	2006	Alaway, Zaditor
Lansoprazole	Acid reducer (proton-pump inhibitor)	2009	Prevacid 24 hour
Levocetirizine	Hay fever/upper respiratory allergies (antihistamine)	2017	Xyzal
Levonorgestrel	Emergency contraceptive (progestin)	2006	Plan B One-Step
Orlistat	Weight loss aid (lipase inhibitor)	2007	Alli
Oxybutynin	Overactive bladder (transdermal anticholinergic)	2013	Oxytrol for Women
Polyethylene glycol	Constipation (osmotic laxative)	2006	MiraLAX
Triamcinolone	Allergic rhinitis (topical glucocorticoid)	2013	Nasacort Allergy 24 hour

are formulated with other ingredients (acetaminophen, antihistamines, and sympathomimetics) that can be fatal in overdose. Loperamide is sometimes used in large doses to create an opioid-like high or to self-treat opioid withdrawal symptoms. In large doses, loperamide may cross the blood-brain barrier and cause altered mental status and respiratory depression; additionally, loperamide may induce ventricular arrhythmias in supratherapeutic doses. Pseudoephedrine, a decongestant contained in numerous OTC cold preparations, has been used in the illicit manufacture

of methamphetamine. A general awareness of these products and their formulations will enable clinicians to more fully appreciate the potential for OTC medication-related problems in their patients.

Table 63–2 lists examples of OTC products that may be used effectively to treat common medical problems. The selection of one ingredient over another may be important in patients with certain medical conditions or in patients taking other medications. These are discussed in detail in other chapters.

TABLE 63–2 Ingredients of known efficacy for selected over-the-counter (OTC) classes.

OTC Category	Generic Name (Brand Example)	Labeled Use	Warnings	Considerations
Acid reducers (H₂ antagonists)	Cimetidine (Tagamet HB)	Relief and prevention of heartburn associated with acid indigestion.	Avoid use: in children <12 years of age; if patient has trouble or pain swallowing food, vomiting with blood, or bloody or black stools; with other acid reducers; if symptoms include heartburn with lightheadedness, sweating, dizziness, or chest pain; for treatment durations >14 days. Adverse effects include: nausea, agitation, headache, dizziness, agitation, and gynecomastia (cimetidine; rare).	<ul style="list-style-type: none"> To prevent symptoms, take 30–60 minutes before consuming food or beverages that cause heartburn. Cimetidine may increase the serum concentrations of theophylline, warfarin, and phenytoin.
	Famotidine (Pepcid AC) Ranitidine (Zantac 75, Zantac 150)			
Acid reducers (proton-pump inhibitors [PPI])	Esomeprazole (Nexium 24 hour)	Treatment of frequent heartburn (occurs 2 or more days a week).	Avoid use: in children <18 years of age; if patient has trouble or pain swallowing food, vomiting with blood, or bloody or black stools; if symptoms include heartburn with lightheadedness, sweating, dizziness, or chest pain; for treatment durations >14 days. Adverse effects include: headache, abdominal pain, nausea, diarrhea, and flatulence.	<ul style="list-style-type: none"> Not intended for immediate relief (products take 1–4 days for full effect). Take with water before eating in the morning. Patients may repeat a 2-week course of therapy every 4 months. PPI therapy can increase risk of <i>Clostridium difficile</i>-associated diarrhea and risk of fracture. Esomeprazole, lansoprazole, and omeprazole may interact with warfarin, clopidogrel, cilostazol, antifungal medications, diazepam, digoxin, tacrolimus, and HIV antiretrovirals.
	Lansoprazole (Prevacid 24 hour) Omeprazole (Prilosec OTC)			
Allergy preparations	Chlorpheniramine (Chlor-Trimeton)	Temporary relief of the following symptoms due to hay fever or upper respiratory allergies: sneezing, runny nose, itchy, watery eyes, itching of nose or throat.	Avoid use: in children <2 years of age; in combination with other sedatives and alcohol as sedative effects may be potentiated. Use caution when driving or operating machinery. Adverse effects include: drowsiness, dizziness, fatigue, nausea, and urinary retention. Antihistamines are contained in many OTC preparations in combination with analgesics, decongestants, and expectorants. See the warnings section for each formulation.	<ul style="list-style-type: none"> Diphenhydramine is the most sedating antihistamine. Consult product labeling before use in children ages 2–11 years. First-generation antihistamines (chlorpheniramine, clemastine, diphenhydramine) may cause excitability in children. Second-generation antihistamines (cetirizine, fexofenadine, levocetirizine, loratadine) have minimal anticholinergic effects and are associated with lower chances of sedation.
	Clemastine (Tavist Allergy) Cetirizine (Zyrtec) Diphenhydramine (Benadryl Allergy) Fexofenadine (Allegra 12 hour, Allegra 24 hour) Levocetirizine (Xyzal) Loratadine (Alavert, Claritin)			

(continued)

TABLE 63–2 Ingredients of known efficacy for selected over-the-counter (OTC) classes. (Continued)

OTC Category	Generic Name (Brand Example)	Labeled Use	Warnings	Considerations
Analgesics and antipyretics	Acetaminophen (Tylenol)	Temporary reduction of fever and temporary relief of minor aches, pains, and headaches.	<i>Acetaminophen</i> Avoid use: in combination with other drugs containing acetaminophen; in patients drinking 3 or more alcoholic beverages daily due to an increased risk of severe liver damage.	<i>Acetaminophen</i> • Maximum recommended adult dose for OTC use is 3000 mg/24 h (4000 mg/24 h under medical supervision). • Many products may include acetaminophen, which can lead to unintentional overdose.
	<i>Nonsteroidal anti-inflammatory drugs (NSAIDs)</i>			
	Aspirin (Ecotrin)			<i>Aspirin and other NSAIDs</i>
	Ibuprofen (Advil, Motrin IB)		Adverse effects include: drowsiness, hepatotoxicity (dose related), nephrotoxicity (with chronic overdose), and hypersensitivity reactions (rare).	• Use can increase risk of severe gastrointestinal hemorrhage in individuals: age 60 or older; with peptic ulcer disease or coagulation abnormalities; taking anticoagulants, corticosteroids, or other NSAIDs; who consume ≥ 3 alcoholic beverages daily; who take the products for a longer time than directed.
	Naproxen (Aleve)		<i>Aspirin and other NSAIDs</i> Avoid use in patients with: underlying gastrointestinal bleeding disorders; heart failure; renal insufficiency; hepatic insufficiency; in children or teenagers with chickenpox or flu-like symptoms due to an increased risk of Reye's syndrome (aspirin only). Adverse effects include: dyspepsia, nausea, gastric ulceration, duodenal ulceration, renal insufficiency, hypersensitivity reactions (rare), and tinnitus (dose-related with aspirin).	• Maximum recommended adult daily dose for OTC use: aspirin (3900 mg); ibuprofen (1200 mg); naproxen (660 mg). • May reduce the effectiveness of medications used to treat high blood pressure. • Long-term continuous use of ibuprofen may increase the risk of myocardial infarction and stroke. • Frequent or regular use of ibuprofen may interfere with the cardioprotective effect of aspirin.
Antacids	Aluminum hydroxide (generic only)	Temporary relief of upset stomach with heartburn, acid indigestion, and sour stomach. Products containing simethicone are used for relief of bloating, pressure, or gas symptoms.	Avoid use in patients with: severe renal impairment (aluminum- and sodium-containing products); heart failure or high blood pressure (sodium-containing products).	• Combinations of magnesium and aluminum hydroxide are less likely to cause constipation or diarrhea and offer high neutralizing capacity. • With prolonged use, antacids may cause "acid rebound" (paradoxical acid hypersecretory state associated with increased gastrin levels). • Antacids can significantly reduce the absorption of many prescription drugs.
	Calcium carbonate (Tums)			
	Magnesium hydroxide (Milk of Magnesia)		Adverse effects include: diarrhea (magnesium preparations) and constipation (aluminum preparations).	
	Sodium bicarbonate/citric acid (Alka-Seltzer Heartburn)			
	Aluminum hydroxide/magnesium hydroxide/simethicone (Maalox, Mylanta)			
Antidiarrheal agents	Bismuth subsalicylate (Kaopectate, Pepto-Bismol)	To control symptoms of diarrhea (including traveler's diarrhea). Bismuth-containing products are also used to relieve upset stomach symptoms (indigestion, heartburn, nausea, gas, belching).	<i>Bismuth-containing products</i> Avoid use in patients: taking salicylate products; with allergies to aspirin; with bleeding disorders; with peptic ulcer disease; with bloody or black stool; in children or teenagers with chickenpox or flu-like symptoms due to an increased risk of Reye's syndrome.	• Antidiarrheal agents should not be used if diarrhea occurs with fever $>100^{\circ}\text{F}$ or if blood or mucus present in stool. • Bismuth-containing products may be used as part of combination therapy for <i>Helicobacter pylori</i> eradication therapy. • Loperamide, a synthetic opioid, is not considered a controlled substance but is sometimes abused in high doses for euphoric opioid-like effects.
	Loperamide (Imodium A-D)			

(continued)

TABLE 63-2 Ingredients of known efficacy for selected over-the-counter (OTC) classes. (Continued)

OTC Category	Generic Name (Brand Example)	Labeled Use	Warnings	Considerations
Antidiarrheal agents (cont.)			<p>Adverse effects include: fecal discoloration (black, tarry), tongue discoloration (darkening), and tinnitus (dose-related and more likely when coadministered with aspirin).</p> <p><i>Loperamide</i></p> <p>Avoid use in: children <12 years of age; patients with bloody or black stools.</p> <p>Adverse effects include: abdominal pain, nausea, constipation, drowsiness, dizziness, and dry mouth.</p>	
Antifungal preparations (topical)	<p>Butenafine (Lotrimin Ultra)</p> <p>Clotrimazole (Lotrimin Antifungal)</p> <p>Miconazole (Desenex, Lotrimin AF)</p> <p>Terbinafine (Lamisil AT)</p> <p>Tolnaftate (Tinactin)</p>	Relieves itching, burning, scaling, chafing, and discomfort associated with tinea pedis (athlete's foot), tinea cruris (jock itch), and tinea corporis (ringworm).	<p>For external use only. Avoid contact with eyes, nose, mouth, or other mucous membranes. Avoid use: in children <2 years of age (clotrimazole, miconazole, tolnaftate) or children <12 years of age (butenafine, terbinafine).</p> <p>Adverse effects include: erythema, irritation, itching, and burning.</p>	<ul style="list-style-type: none"> For treatment of athlete's foot, apply product to spaces between toes and change shoes and socks daily.
Antifungal preparations (vaginal)	<p>Clotrimazole (Gyne-Lotrimin)</p> <p>Miconazole (Monistat-1, Monistat-3, Monistat-7, Vagistat-3)</p> <p>Tioconazole (Monistat-1 1-Day, Vagistat-1)</p>	Treatment of vaginal yeast (candidiasis) infections and for the relief of external vulvar itching and irritation associated with vaginal yeast infections.	<p>For vaginal use only. Avoid use: in children <12 years of age; if patient has lower abdominal, back, or shoulder pain, or fever, chills, nausea, vomiting, or foul-smelling vaginal discharge; in combination with tampons, douches, spermicides, or other vaginal products.</p> <p>Adverse effects include: vaginal itching, burning, vaginal soreness, and swelling.</p>	<ul style="list-style-type: none"> Topical vaginal antifungals should only be used for treatment of recurrent vulvovaginal candidiasis in healthy, nonpregnant women who were previously diagnosed by a clinician. Therapy should be discontinued if symptoms do not improve within 3 days or if symptoms persist after 7 days of treatment. Vaginal products (7-day therapy preferred) can be used for treatment in pregnant women. Products with similar brand names may contain different antifungal products; read labels and instructions for use carefully. Condoms and diaphragms may be damaged by the products and fail to prevent pregnancy or sexually transmitted disease.
Antitussives	Dextromethorphan (Delsym, Robitussin Cough, Vicks 44)	Temporary relief of cough due to minor throat and bronchial irritation with the common cold or inhaled irritants.	<p>Avoid use: in patients taking a monoamine oxidase inhibitor (MAOI), or for 2 weeks after discontinuation of an MAOI.</p> <p>Use with caution in patients with a chronic cough that occurs with smoking, asthma, and emphysema and in patients with cough with production of mucus.</p> <p>Adverse effects include: confusion, excitement, irritability, nervousness, and serotonin syndrome (uncommon).</p>	<ul style="list-style-type: none"> Dextromethorphan is a nonopioid congener of levorphanol without analgesic or addictive properties. Health care providers should be alert for problems of abuse or misuse. Often used with antihistamines, decongestants, and expectorants in combination products. Notify provider if symptoms do not improve in 7 days or are accompanied by fever, rash, or persistent headache.

(continued)

TABLE 63-2 Ingredients of known efficacy for selected over-the-counter (OTC) classes. (Continued)

OTC Category	Generic Name (Brand Example)	Labeled Use	Warnings	Considerations
Decongestants, topical (intranasal)	Oxymetazoline (Afrin, Mucinex Full Force, Vicks Sinex) Phenylephrine (Neo-Synephrine)	Temporary relief of nasal congestion due to common cold, hay fever, upper respiratory allergies, or sinus congestion and pressure.	Avoid use for >3 days. Use with caution in patients with: heart disease; high blood pressure; thyroid disease; diabetes; trouble urinating due to an enlarged prostate. Adverse effects include: sneezing, burning, stinging, dryness, and rhinorrhea.	<ul style="list-style-type: none"> Long-acting agents (oxymetazoline-containing products) are generally preferred. Topical decongestants should not exceed 3 days to prevent rebound nasal congestion (eg, worsening or recurrence of congestion symptoms).
Decongestants, systemic	Phenylephrine (Sudafed PE) Pseudoephedrine (Sudafed)	Temporary relief of sinus congestion and pressure. Temporarily relieves nasal congestion due to the common cold, hay fever, or other upper respiratory allergies.	Avoid use: in patients taking an MAOI or for 2 weeks after stopping the MAOI. Use with caution in patients with heart disease; high blood pressure; diabetes; thyroid disease; trouble urinating due to an enlarged prostate gland. Adverse effects include: arrhythmias, tachycardia, high blood pressure, anxiety, headache, dizziness, tremor, and insomnia.	<ul style="list-style-type: none"> May be found in combination with antihistamine, antitussives, expectorants, and analgesic products. Extended-release pseudoephedrine products should not be used in children <12 years of age. Federal regulations established to discourage the illicit manufacture of methamphetamine specify that all drug products containing pseudoephedrine must be stored in locked cabinets or behind the pharmacy counter and can only be sold in limited quantities to consumers after they provide photo identification and are entered into a registry.
Emergency contraceptive	Levonorgestrel (Plan B One-Step)	To prevent pregnancy following unprotected intercourse or possible contraceptive failure.	Avoid use in the case of known or suspected pregnancy. Adverse effects include: heavier menstrual bleeding, nausea, lower abdominal pain, fatigue, headache, dizziness, and breast tenderness.	<ul style="list-style-type: none"> Available only by prescription for women <17 years of age. Should be taken as soon as possible within 72 hours after unprotected intercourse. If vomiting occurs within 2 hours of taking the tablet, the dose may need to be repeated. Use backup contraceptive after administration. Patients taking oral contraceptives regularly should also use backup contraception, such as condom, until next period cycle starts.
Expectorants	Guaifenesin (Mucinex)	Used to help loosen phlegm (mucus) and thin bronchial secretions to make cough more productive.	Avoid use in children <2 years of age. Adverse effects include: nausea, vomiting, stomach pain, and dizziness.	<ul style="list-style-type: none"> The only OTC expectorant recognized as safe and effective by the FDA. Often used with antihistamines, decongestants, and antitussives in combination products. Administer with a large quantity of fluids for best results. When used for self-care, do not use extended-release tablets in children <12 years of age.
Laxatives	<i>Bulk formers</i> Polycarbophil, psyllium, and methylcellulose preparations (Citrucel, Fibercon, Metamucil)	Temporary relief of occasional constipation and irregularity.	<i>Bulk formers</i> Avoid use in patients with difficulty swallowing. <i>Polyethylene glycol 3350</i> Avoid use in patients with kidney disease.	<ul style="list-style-type: none"> The safest laxatives for chronic use include bulk formers and stool softeners. The bulk formers in powder formulation must be taken with adequate fluid for optimal effect and to avoid choking.

(continued)

TABLE 63-2 Ingredients of known efficacy for selected over-the-counter (OTC) classes. (Continued)

OTC Category	Generic Name (Brand Example)	Labeled Use	Warnings	Considerations
Laxatives (cont.)	<i>Hyperosmotics</i>		Adverse effects include: nausea, abdominal bloating, cramping, and flatulence.	
	Glycerin (Fleet Glycerin suppositories)		<i>Stool softeners</i>	
	Polyethylene glycol 3350 (Miralax)		Avoid use in patients taking mineral oil.	
	<i>Stool softeners</i>		<i>Stimulants</i>	
	Docusate sodium (Colace, Dulcolax)		Adverse effects include: stomach discomfort, rectal burning, and mild cramps.	
	Docusate calcium (Surfak)		<i>Saline laxatives</i>	
	<i>Stimulant laxatives</i>		Do not use more than one enema in a 24-hour period.	
	Bisacodyl (Dulcolax, Ex-Lax)		Use with caution in patients on a sodium-restricted diet; in patients with kidney disease.	
	Senna (Senokot)			
	<i>Saline laxatives</i>		<i>All laxatives</i>	
	Sodium phosphate (Fleet enema)		Use with caution in patients with a sudden change in bowel habits that persist for 2 weeks; in patients with abdominal pain, nausea, or vomiting.	
Overactive bladder treatment	Oxybutynin transdermal system (Oxytrol for women)	Treatment of overactive bladder for women with symptoms of urge incontinence and urinary urgency and frequency for at least 3 months.	Avoid use in: men; women <18 years of age; patients with symptoms of a urinary tract infection (pain or burning when urinating, blood in urine, unexplained lower back pain, urine that is cloudy or foul smelling). Adverse effects include: sleepiness, dizziness, confusion, dry mouth, constipation, and blurred vision.	<ul style="list-style-type: none"> • Women should consult with their physician about symptoms before using this product. • Women who only experience accidental urine loss when coughing, sneezing, or laughing may have stress incontinence; this product is not effective for this condition. • The OTC patch formulation contains the same dosage as the prescription product. • One patch should be applied to abdomen, hips, or buttocks every 4 days; alternating sites.
Pediculicides (lice treatment)	Permethrin (Nix) Pyrethrins combined with piperonyl butoxide (RID)	Treatment of head lice (permethrin-containing products); and pubic and body lice (piperonyl butoxide-containing products).	For external use only. Avoid use: if allergic to ragweed; in children <2 years of age; near the eyes; inside the nose, mouth, or vagina; on lice in eyebrows or eyelashes. Adverse effects include: itching and redness at the application sites.	<ul style="list-style-type: none"> • Proper use requires careful inspection and thorough application of the products (10 minutes) to the affected areas. • Following application, lice and nits (eggs) should be removed with a fine-tooth comb. • Kills live lice (neurotoxic), but is not effective for eggs (nits). Therefore, repeat process in 7-10 days to kill newly hatched nits. • Clothing, bed linens, and other items that the infested person wore or used during the 2 days before treatment should be washed using the hot water (130°F) cycle and dried using the high heat cycle.

(continued)

TABLE 63–2 Ingredients of known efficacy for selected over-the-counter (OTC) classes. (Continued)

OTC Category	Generic Name (Brand Example)	Labeled Use	Warnings	Considerations
Sleep aids	Diphenhydramine (Nytol, Sominex) Doxylamine (Unisom)	Reduces difficulty in falling asleep.	Avoid use in: children <12 years of age; combination with alcohol, other antihistamines, or sedatives; individuals with angle-closure glaucoma; men with trouble urinating due to an enlarged prostate gland. Use caution when driving or operating machinery. Adverse effects include: dizziness, constipation, and dry mouth.	<ul style="list-style-type: none"> Insomnia persisting for >2 weeks may be a sign of a serious underlying medical condition.
Smoking cessation aids	Nicotine polacrilex gum (Nicorette) Nicotine polacrilex lozenge (Nicorette) Nicotine transdermal patch (Nicoderm CQ)	Reduces withdrawal symptoms (including nicotine craving) associated with quitting smoking.	<p>Avoid use in: children <18 years of age; women who are pregnant or breastfeeding; individuals with temporomandibular joint disease (gum only); individuals with allergies to adhesive tape (patch only). Use patch with caution in patients with a history of dermatologic conditions (eczema, psoriasis, ectopic dermatitis).</p> <p><i>Gum</i> Adverse effects include: jaw soreness, hiccups, dyspepsia, throat and mouth irritation, nausea, vomiting, lightheadedness.</p> <p><i>Lozenge</i> Adverse effects include: mouth irritation, nausea, hiccups, cough, heartburn, headache, sore throat, dizziness.</p> <p><i>Transdermal patch</i> Adverse effects include: local skin reactions (erythema, itching, burning), headache, and sleep disturbances (insomnia, abnormal/vivid dreams).</p>	<ul style="list-style-type: none"> Nicotine replacement products in addition to behavioral support approximately double the long-term cessation rates compared with placebo. Nicotine replacement products can be used in combination to improve long-term abstinence rates. The patch may aid in improved adherence (once-daily dosing). Do not use lozenge if allergic to soya (soy beans).

The recommendations listed in Table 63–2 are based on the efficacy of the ingredients and on the principles set forth in the following paragraphs.

1. Select the product that is simplest in formulation; in general, single-ingredient products are preferred. Combination products may contain effective doses of some ingredients and subtherapeutic doses of others. Furthermore, there may be differing durations of action among the ingredients, and there is always a possibility that the clinician or patient is unaware of the presence of certain active ingredients in the product.
2. Select a product that contains a therapeutically effective dose.
3. Consumers and providers should carefully read the “Drug Facts” label (Figure 63–1) to determine which ingredients are

appropriate based on the patient’s symptoms, underlying health conditions, and whatever is known about the medications the patient is already taking. Many products with the same brand name contain different ingredients that are labeled for different uses. For example, multiple products (with different active ingredients) carry the Allegra name, including Allegra Allergy (fexofenadine), Allegra-D (fexofenadine and pseudoephedrine), and Allegra Anti-Itch Cream (allantoin and diphenhydramine).

4. Recommend a generic product if one is available.
5. Be wary of claims of specific superiority over similar products.
6. For children, the dose, dosage form, and palatability of the product are prime considerations.

Certain ingredients in OTC products should be avoided or used with caution in selected patients because they may exacerbate existing medical problems or interact with other medications the patient is taking. The presence of many of the more potent OTC ingredients may be unexpectedly hidden in products (Table 63–3). Although OTC medications have standardized label formatting and content requirements (Figure 63–1), many consumers do not carefully read or comprehend this information. Lack of awareness of the ingredients in OTC products and the belief by many patients and providers that OTC products are ineffective and harmless may cause diagnostic confusion and compromise therapeutic management. For example, innumerable OTC products, including analgesics and allergy, cough, and cold preparations, contain sympathomimetics. These agents should be avoided or used cautiously by patients with type 1 diabetes and patients with hypertension, angina, or hyperthyroidism. Aspirin should not be used in children and adolescents for viral infections (with or without fever) because of an increased risk of Reye’s syndrome. Aspirin and other NSAIDs should be avoided by individuals with active peptic ulcer disease, certain platelet disorders and patients taking oral anticoagulants. Cimetidine, an H₂ antagonist, is a well-known inhibitor of hepatic drug metabolism and can

increase the blood levels and toxicity of agents such as phenytoin, theophylline, and warfarin.

Overuse or misuse of OTC products may cause significant medical problems. A prime example is rhinitis medicamentosa or “rebound rhinitis,” a condition that manifests as nasal congestion without rhinorrhea, associated with the regular use of topical decongestant nasal sprays for more than 3 days. The improper and long-term use of some antacids (eg, aluminum hydroxide) may cause constipation and even impaction in the elderly, as well as hypophosphatemia. Long-term laxative use can result in abdominal cramping and fluid and electrolyte disturbances. A condition known as laxative abuse syndrome is often observed in women with anorexia nervosa. Insomnia, nervousness, and restlessness can result from the use of sympathomimetics or caffeine present in many OTC products (Table 63–3). The long-term use of analgesics containing caffeine may trigger rebound headaches upon discontinuation. OTC products containing aspirin, other salicylates, acetaminophen, ibuprofen, or naproxen may increase the risk of hepatotoxicity and gastrointestinal hemorrhage in individuals who consume three or more alcoholic drinks daily, and long-term use of these products has been associated with interstitial nephritis. Acute ingestion of large amounts of

Drug Facts

Active ingredient (in each tablet) Chlorpheniramine maleate 2 mg	Purpose Antihistamine
--	---------------------------------

Uses temporarily relieves these symptoms due to hay fever or other upper respiratory allergies:
■ Sneezing ■ Runny nose ■ Itchy, watery eyes ■ Itchy throat

Warnings
Ask a doctor before use if you have
■ Glaucoma ■ A breathing problem such as emphysema or chronic bronchitis
■ Trouble urinating due to an enlarged prostate gland

Ask a doctor or pharmacist before use if you are taking tranquilizers or sedatives

When using this product
■ You may get drowsy ■ Avoid alcoholic drinks
■ Alcohol, sedatives, and tranquilizers may increase drowsiness
■ Be careful when driving a motor vehicle or operating machinery
■ Excitability may occur, especially in children

If pregnant or breast-feeding, ask a health professional before use.
Keep out of reach of children. In case of overdose, get medical help or contact a Poison Control Center right away.

Directions	
Adults and children 12 years and over	Take 2 tablets every 4 to 6 hours; not more than 12 tablets in 24 hours
Children 6 years to under 12 years	Take 1 tablet every 4 to 6 hours; not more than 6 tablets in 24 hours
Children under 6 years	Ask a doctor

Other information store at 20–25°C (68–77°F) ■ Protect from excessive moisture

Inactive ingredients D&C yellow no. 10, lactose, magnesium stearate, microcrystalline cellulose, pregelatinized starch

FIGURE 63–1 Typical FDA-required labeling for an over-the-counter antihistamine. The label must contain, in the following order: active ingredient(s), including the amount in each dosage unit; purpose of product (pharmacologic action); use(s) for product (indication); specific warnings, including when the product should not be used and pregnancy information; when the patient should seek care of a health care provider; side effects and substances or activities to avoid; dosage instructions (when, how, and how often to take medication); and inactive ingredients. Additional requirements include, but are not limited to, the following: type size must be large enough to be easily read, >6-point font type for information in drug facts section; bullets must be solid square or circle 5-point type; and directions in table format for dosage instructions when presented for three or more age groups or populations. Image from <http://www.fda.gov/Drugs/ResourcesForYou/Consumers/ucm143551.htm>

TABLE 63–3 Hidden ingredients in over-the-counter (OTC) products.

Hidden Drug or Drug Class	OTC Class Containing Drug	Selected Product Examples
Alcohol (percent ethanol)	Cough syrups, cold preparations	Theraflu Nighttime (10%); Vicks NyQuil Cold & Flu Liquid (10%); Vicks NyQuil Cough (10%)
	Mouthwashes	Listerine (27%); Cepacol (14%)
Antihistamines	Analgesics	Advil PM; Excedrin PM; Goody's PM Pain Relief Powder; Tylenol PM
	Menstrual products	Midol Complete; Pamprin
	Sleep aids	Nytol; Simply Sleep; Sominex; Unisom
Aspirin and other salicylates	Antacids	Alka-Seltzer Original; Alka-Seltzer Extra Strength
	Antidiarrheals	Pepto-Bismol (bismuth subsalicylate); Kaopectate (bismuth subsalicylate)
	Menstrual products	Pamprin Max
	Cold/allergy preparations	Alka-Seltzer Plus Formulation: Cold; Cold and Cough; Night Cold
Caffeine (mg/tablets or as stated)	Analgesics	Anacin Advanced Headache (65); Excedrin Extra Strength (65); Excedrin Migraine (65); Goody's Headache Relief Shot (65/60 mL)
	Menstrual products	Midol Complete (60); Pamprin Max (65)
	Stimulants	NoDoz Maximum Strength (200); Vivarin (200)
Local anesthetics (usually benzocaine)	Antitussives/lozenges	Cepacol Sore Throat Lozenges; Chloraseptic Sore Throat
	Dermatologic preparations	Bactine; Dermoplast; Solarcaine
	Hemorrhoidal products	Americaine Ointment; Tronolane
	Toothache, cold sore, and teething products	Anbesol; Kank-A; Zilactin-B
Sodium (mg/tablet or as stated)	Analgesics/antacids	Alka-Seltzer Original Effervescent Tablet (567); Alka-Seltzer Extra Strength Effervescent Tablet (588); Alka-Seltzer Gold (309)
	Cold/cough preparations	Alka-Seltzer Plus Formulations: Day and Night Cold (416); Cold & Cough (415); Severe Cold & Flu (416); Night Cold (474); Cold Sparkling Original (476)
	Laxatives	Fleets Enema (4439 mg, of which 275–400 mg/enema is absorbed)
Sympathomimetics (ephedrine, phenylephrine)	Analgesics	Sine-Off; Tylenol Sinus
	Asthma products	Bronkaid; Primatene Tablets
	Cold/cough/allergy preparations	Advil Cold & Sinus; Alka-Seltzer Plus (many); Dimetapp (many); PediaCare (many); Robitussin (many); Sudafed (many); Theraflu (many); Tylenol Cold (many); Tylenol Allergy (many)
	Hemorrhoidal products	Preparation H (cream, ointment, suppository)

acetaminophen by adults or children can cause serious, and often fatal, hepatotoxicity (see Chapter 4). Antihistamines may cause sedation or drowsiness, especially when taken concurrently with sedative-hypnotics, tranquilizers, alcohol, or other central nervous system depressants.

Finally, use of OTC cough and cold preparations in the pediatric population has been under scrutiny by the FDA based on a lack of efficacy data in children less than 12 years of age and reports of serious toxicity in children. Following a thorough review, the FDA recommends that OTC cough and cold agents (eg, products containing antitussives, expectorants, decongestants, and antihistamines) not be used in infants and children younger than 2 years

old due to serious and potentially life-threatening adverse events associated with accidental overdose including arrhythmias, hallucinations, and encephalopathy. Drug information sources for OTC products include the *Handbook of Nonprescription Drugs*, the most comprehensive resource for OTC medications. It evaluates ingredients contained in major OTC drug classes and lists the ingredients included in many OTC products. *Facts and Comparisons Answers* is an online reference that is updated monthly; it provides detailed OTC product information and patient counseling instructions. Any health care provider who seeks more specific information regarding OTC products may find useful the references listed below.

CASE STUDY ANSWER

Combination OTC “cold and flu” medications typically contain analgesics (eg, acetaminophen, aspirin), antihistamines (eg, chlorpheniramine, diphenhydramine), antitussives (eg, dextromethorphan), expectorants (eg, guaifenesin), and nasal decongestants (eg, phenylephrine, pseudoephedrine). KH’s chronic prescription medications include a narcotic analgesic combination product that provides 2600 mg of acetaminophen and 40 mg of hydrocodone. Over the past few days, KH has added two different OTC acetaminophen-containing products including Alka-Seltzer Plus Severe Cold + Flu (650 mg acetaminophen/2 tablets) every 4 hours and Tylenol PM (1000 mg acetaminophen/2 tablets) at bedtime. The clinician should obtain a detailed medication history to determine the actual total dose of acetaminophen consumed, but it is likely that KH has ingested more than 6 g of acetaminophen

daily over the past 72 hours. This cumulative dosage, coupled with KH’s chronic ethanol consumption (three to four glasses of wine daily), significantly potentiates the risk for acetaminophen hepatotoxicity. In the USA, unintentional acetaminophen overdose is a leading cause of acute liver failure. The warnings section on all OTC acetaminophen-containing products clearly state that severe liver damage may occur when consumers: (1) take dosages >4000 mg in 24 hours; (2) use acetaminophen in combination with other drugs containing acetaminophen; or (3) take acetaminophen and drink three or more alcoholic beverages daily. Unfortunately, many consumers do not carefully read OTC medication labels, and many do not appreciate the amount of acetaminophen “hidden” in combination prescription and OTC products.

Dietary Supplements & Herbal Medications*

Cathi E. Dennehy, PharmD, &
Candy Tsourounis, PharmD

CASE STUDY

A 53-year-old woman with a history of knee osteoarthritis, high cholesterol, type 2 diabetes, and hypertension presents with new onset of hot flashes and a question about a dietary supplement. She is obese (body mass index [BMI] 33), does not exercise, and spends a good portion of her work day in a seated position. She eats a low-sugar diet and regularly eats packaged frozen meals for dinner because she doesn't have time to cook regularly. Her most recent laboratory values include a low-density lipoprotein (LDL) cholesterol that is above goal at 160 mg/dL (goal < 100 mg/dL) and a hemoglobin A_{1c} that is well controlled at 6%. Her blood pressure

is high at 160/100 mm Hg. Her prescription medications include simvastatin, metformin, and benazepril. She also takes over-the-counter ibuprofen for occasional knee pain and a multivitamin supplement once daily. She has heard good things about natural products and asks you if taking a garlic supplement daily could help to bring her blood pressure and cholesterol under control. She's also very interested in St. John's wort after a friend told her that it helped alleviate her hot flashes and could also help improve mood. How should you advise her? Are there any supplements that could increase bleeding risk if taken with ibuprofen?

The medical use of plants in their natural and unprocessed form undoubtedly began when the first intelligent animals noticed that certain food plants altered particular body functions. While there is a great deal of historical information about the use of plant-based supplements, there is also much unreliable information as a result of unknown or poor-quality natural product formulations, poorly designed clinical studies that do not account for randomization errors, confounders, and—most importantly—a placebo effect that can contribute 30–50% of the observed response. Since the literature surrounding dietary supplements is evolving, reputable evidence-based resources should be used to evaluate claims and guide treatment decisions. An unbiased and regularly updated compendium of basic and clinical information regarding botanicals is *Natural Medicines* by Therapeutic Research Center (see References), which includes content review by an international,

multidisciplinary, collaborative review committee of experts. The recommendations in this database are limited by the quality of the existing research and the quality of the dietary supplement used at the time of the report. As a result, all statements regarding positive benefits should be regarded as preliminary, and conclusions regarding safety should be considered tentative at this time.

For legal purposes, “dietary supplements” are distinguished from “prescription drugs” derived from plants (morphine, digitalis, atropine, etc) by virtue of being available without a prescription and, unlike “over-the-counter medications,” are legally considered dietary supplements rather than drugs. This distinction eliminates the need for proof of efficacy and safety prior to marketing and also places the burden of proof on the FDA to prove that a supplement is harmful before it can be removed from the market or its use can be restricted. Furthermore, marketed dietary supplements are not tested for dose-response relationships or toxicity, and there is a lack of adequate testing

*The US Food and Drug Administration (FDA) recognizes “herbal medication” and “botanical medication” as “dietary supplements.” For the purposes of this chapter, they are identical.

for mutagenicity, carcinogenicity, and teratogenicity. Although manufacturers are prohibited from marketing unsafe or ineffective products, the FDA has met significant challenges from the supplement industry largely due to the strong lobbying effort by supplement manufacturers and the variability in interpretation of the **Dietary Supplement Health and Education Act (DSHEA)**. The DSHEA defines dietary supplements as vitamins, minerals, herbs or other botanicals, amino acids or dietary supplements used to supplement the diet by increasing dietary intake, or concentrates, metabolites, constituents, extracts, or any combination of these ingredients. For the purposes of this chapter, plant-based substances and certain synthetic purified chemicals will be referred to as dietary supplements. Among the purified chemicals, glucosamine, coenzyme Q10, and melatonin are of significant pharmacologic interest. Ephedrine, the active principle in Ma-huang, is discussed in Chapter 9.

This chapter provides some historical perspective and describes the evidence provided by randomized, double-blind, placebo-controlled trials, meta-analyses, and systematic reviews involving several of the most commonly used agents in this class. Health care providers should adhere to the principles of “do no harm” but also, because patients are strongly influenced by popular opinion and media reports, be open to therapies that support “integrative health” safely and responsibly. Unproven therapies that are marketed as “alternatives” to conventional medicine should be viewed with caution, but therapies that are supported by evidence-based medicine and have been assessed for benefits and risks when used in combination with conventional medicine can be viewed favorably, especially if a patient expresses an interest in, and a desire to utilize, dual treatment approaches.

HISTORICAL & REGULATORY FACTORS

Under the DSHEA, dietary supplements are not considered over-the-counter drugs in the USA but rather food supplements used for health maintenance. Legally, dietary supplements are intended to supplement the diet, but consumers may use them in the same fashion as drugs and even use them in place of drugs or in combination with drugs.

In 1994, the US Congress, influenced by growing “consumerism” as well as strong manufacturer lobbying efforts, passed the DSHEA. The DSHEA required the establishment of Good Manufacturing Practice (GMP) standards for the supplement industry; however, it was not until 2007 that the FDA issued a final rule on the proposed GMP standards. This 13-year delay allowed supplement manufacturers to self-regulate the manufacturing process and resulted in many instances of adulteration, misbranding, and contamination. For example, a study using DNA barcoding to confirm botanical content evaluated 44 botanicals containing 30 plant species and found product substitutions in 32% of samples (see Newmaster reference). Therefore, much of the criticism regarding the dietary supplement industry involves problems with botanical misidentification, a lack of product purity, and variations in potency and purification, which continue to be problematic even with GMP

standards in place. When the new GMP standards are met, dietary supplement manufacturers should be in compliance with this legislation. However, the FDA has limited resources to investigate and oversee compliance with manufacturing standards, particularly since many ingredient suppliers are based overseas. Furthermore, the dietary supplement ingredient supply chain is complex, and federal regulators are not able to inspect all manufacturing facilities in a timely and efficient manner. Finally, the financial incentive to maximize sales (\$32 billion in supplement sales in the USA in 2012) is very great, regardless of lack of evidence of product safety or efficacy.

Because of the problems that resulted from self-regulation, another law, the Dietary Supplement and Non-Prescription Drug Consumer Protection Act, was approved in 2006. This law requires manufacturers, packers, or distributors of supplements to submit reports of serious adverse events to the FDA. Serious adverse events are defined as death, a life-threatening event, hospitalization, a persistent or significant disability or incapacity, congenital anomaly or birth defect, or an adverse event that requires medical or surgical intervention to prevent such outcomes based on reasonable medical judgment. These reports are intended to identify trends in adverse effects and would help to alert the public to safety issues.

CLINICAL ASPECTS OF THE USE OF BOTANICALS

Many US consumers have embraced the use of dietary supplements as a “natural” approach to their health care. Unfortunately, misconceptions regarding safety and efficacy of the agents are common, and the fact that a substance can be called “natural” does not of course guarantee its safety. In fact, botanicals may be inherently inert or toxic. If a manufacturer does not follow GMP, this can also result in intentional or unintentional plant species substitutions (eg, misidentification), adulteration with pharmaceuticals, or contamination.

Adverse effects have been documented for a variety of dietary supplements; however, underreporting of adverse effects is likely since consumers do not routinely report, and do not know how to report an adverse effect if they suspect that the event was caused by consumption of a supplement. Furthermore, chemical analysis is rarely performed on the products involved, including those products that are described in the literature as being linked to an adverse event. This leads to confusion about whether the primary ingredient or an adulterant caused the adverse effect. In some cases, the chemical constituents of the herb can clearly lead to toxicity. Some of the herbs that should be used cautiously or not at all are listed in Table 64–1.

An important risk factor in the use of dietary supplements is the lack of adequate testing for drug interactions. Since botanicals may contain hundreds of active and inactive ingredients, it is very difficult and costly to study potential drug interactions when they are combined with other medications. This may present significant risks to patients.

TABLE 64–1 Various supplements and some associated risks.

Commercial Name, Scientific Name, Plant Parts	Intended Use	Toxic Agents, Effects	Comments
Aconite <i>Aconitum</i> species	Analgesic	Alkaloid, cardiac and central nervous system effects	Avoid
Aristolochic acid <i>Aristolochia</i> species	Traditional Chinese medicine; various uses	Carcinogen, nephrotoxicity	Avoid
Black cohosh <i>Cimicifuga racemosa</i>	Menopausal symptoms	Hepatotoxicity	Avoid ¹
Borage <i>Borago officinalis</i> Tops, leaves	Anti-inflammatory; diuretic	Pyrrolizidine alkaloids, hepatotoxicity	Avoid
Chaparral <i>Larrea tridentata</i> Twigs, leaves	Anti-infective; antioxidant; anticancer	Hepatotoxicity	Avoid
Coltsfoot <i>Tussilago farfara</i> Leaves, flower	Upper respiratory tract infections	Pyrrolizidine alkaloids, hepatotoxicity	Avoid ingestion of any parts of plant; leaves may be used topi- cally for anti-inflammatory effects for up to 4–6 weeks
Comfrey <i>Symphytum</i> species Leaves and roots	Internal digestive aid; topical for wound healing	Pyrrolizidine alkaloids, hepatotoxicity	Avoid ingestion; topical use should be limited to 4–6 weeks
Ephedra, Ma-huang <i>Ephedra</i> species	Diet aid; stimulant; bronchodilator	Central nervous system toxicity, cardiac toxicity	Avoid in patients at risk for stroke, myocardial infarction, arrhythmia, hypertension, seizures, general anxiety disorder
Germander <i>Teucrium chamaedrys</i> Leaves, tops	Diet aid	Hepatotoxicity	Avoid
Gland-derived extracts (thymus, adrenal, thyroid)	Hormone replacement	Risk of bacterial, viral, or prion transmission; variable hormone content	Avoid
Human placenta derivatives	Antirheumatic; anti-inflammatory	Risk of bacterial, viral, or prion transmission	Avoid
Jin Bu Huan	Analgesic; sedative	Hepatotoxicity	Avoid
Kava-kava	Anxiety	Hepatotoxicity	Avoid
Pennyroyal Extract of <i>Mentha pulegium</i> or <i>Hedeoma pulegioides</i>	Digestive aid; induction of menstrual flow; abortifacient	Pulegone and pulegone metabolite, liver failure, renal failure	Avoid
Poke root <i>Phytolacca americana</i>	Antirheumatic	Hemorrhagic gastritis	Avoid
Royal jelly of <i>Apis mellifera</i> (honeybee)	Tonic	Bronchospasm, anaphylaxis	Avoid in patients with chronic allergies or respiratory diseases; asthma, chronic obstructive pulmonary disease, emphysema, atopy
Sassafras <i>Sassafras albidum</i> root, bark	Blood thinner	Safrole oil, hepatocarcinogen in animals	Avoid

¹Cases of hepatotoxicity have occurred; these cases are rare given the widespread use of black cohosh.

BOTANICAL SUBSTANCES

ECHINACEA (*ECHINACEA PURPUREA*)

Chemistry

The three most widely used species of *Echinacea* are *Echinacea purpurea*, *E pallida*, and *E angustifolia*. The chemical constituents include flavonoids, lipophilic constituents (eg, alkamides, polyacetylenes), water-soluble polysaccharides, and water-soluble caffeoyl conjugates (eg, echinacoside, cichoric acid, caffeic acid). Within any marketed echinacea formulation, the relative amounts of these components are dependent upon the species used, the method of manufacture, and the plant parts used. *E purpurea*, the purple coneflower, has been the most widely studied in clinical trials. Although the active constituents of echinacea are not completely known, cichoric acid from *E purpurea* and echinacoside from *E pallida* and *E angustifolia*, as well as alkamides and polysaccharides, are most often noted as having immune-modulating properties. Most commercial formulations, however, are not standardized for any particular constituent.

Pharmacologic Effects

1. Immune modulation—The effect of echinacea on the immune system is controversial. In vivo human studies using commercially marketed formulations of *E purpurea* have shown increased phagocytosis, total circulating monocytes, neutrophils, and natural killer cells, indicative of general immune modulation. In vitro, a standardized ethanol extract of the aerial (above-ground) parts of *E purpurea*, known as Echinaforce, inhibited the rise in pro-inflammatory cytokines and interleukins-6 and -8, and also inhibited mucin secretion caused by exposure to rhinovirus type 1A in a 3D tissue model of human airway epithelium. This type of model is intended to mimic what would be seen in vivo. The extract had no effect on cytokine actions.

2. Anti-inflammatory effects—Certain echinacea constituents have demonstrated anti-inflammatory properties in vitro. Inhibition of cyclooxygenase, 5-lipoxygenase, and hyaluronidase may be involved. In animals, application of *E purpurea* prior to application of a topical irritant reduced both paw and ear edema. Despite these preclinical findings, randomized, controlled clinical trials involving echinacea for wound healing have not been performed in humans.

3. Antibacterial, antifungal, antiviral, and antioxidant effects—In vitro studies have reported some antibacterial, antifungal, antiviral, and antioxidant activity with echinacea constituents. For example, Echinaforce demonstrated virucidal activity ($MIC_{100} < 1$ mcg/mL) against influenza and herpes simplex viruses and bactericidal activity against *Streptococcus pyogenes*, *Haemophilus influenzae*, and *Legionella pneumophila* in human bronchial cells. In vitro, Echinaforce inactivated both avian influenza virus (H5N1, H7N7) and swine-origin influenza virus (H1N1) at doses consistent with recommended oral consumption. The extract blocked key steps (ie, viral hemagglutination

activity and neuraminidase activity in vitro) involved in early virus replication and cellular entry. It was less effective against intracellular virus. Newer in vitro research in human skin fibroblasts also suggests bactericidal activity and inhibition of secretion of inflammatory cytokines produced by *Propionibacterium acnes* with Echinaforce.

Clinical Trials

Echinacea is most often used to enhance immune function in individuals who have colds and other respiratory tract infections. Two reviews have assessed the efficacy of echinacea for this primary indication. A review by the Cochrane Collaboration involved 24 randomized, double-blind trials with 33 comparisons of echinacea mono-preparations, which are single-ingredient echinacea preparations, and placebo. Trials were included if they involved echinacea for cold treatment or prevention, where the primary efficacy outcome was cold incidence in prevention trials and duration of symptoms in treatment trials. Overall, the review did not find significant evidence of benefit for echinacea (among all species) in treating colds. Preparations made from the aerial parts of *E purpurea* plants and prepared as alcoholic extracts or pressed juices were discussed as possibly being preferred to other formulations for cold treatment in adults, but still having a weak overall treatment effect. In prevention trials, pooling results suggested a small relative risk reduction of 10–20%, but no statistically significant benefit within individual trials.

A separate meta-analysis involving 14 randomized, placebo-controlled trials of echinacea for cold treatment or prevention was published in *Lancet*. In this review, echinacea decreased the risk of developing clear signs and symptoms of a cold by 58% and decreased symptom duration by 1.25 days. This review, however, was confounded by the inclusion of four clinical trials involving multi-ingredient echinacea preparations, as well as three studies using rhinovirus inoculation versus natural cold development.

Echinacea has been used investigational to enhance hematologic recovery following chemotherapy. It has also been used as an adjunct in the treatment of urinary tract and vaginal fungal infections. These indications require further research before they can be accepted in clinical practice. *E purpurea* is ineffective in treating recurrent genital herpes.

Adverse Effects

Adverse effects with oral commercial formulations are minimal and most often include unpleasant taste, gastrointestinal upset, or allergic reactions (eg, rash). In one large clinical trial, pediatric patients using an oral echinacea product were significantly more likely to develop a rash than those taking placebo. In a small Norwegian mother and child cohort study, 0.5% of women reported taking any formulation of echinacea during early-stage (conception up to pregnancy week 17) or late-stage pregnancy and had no adverse pregnancy outcomes compared to pregnant women who did not use echinacea. Herbal supplements, and particularly those made from alcoholic extracts, should only be used in pregnancy

and lactation after consultation with the primary health care provider.

Drug Interactions & Precautions

Until the role of echinacea in immune modulation is better defined, this agent should be avoided in patients with immune deficiency disorders (eg, AIDS, cancer) or autoimmune disorders (eg, multiple sclerosis, rheumatoid arthritis). Although there are no well-documented herb-drug interactions for echinacea, in theory, it should also be avoided in persons taking immunosuppressant medications (eg, organ transplant recipients). Co-administration of an echinacea product containing *E purpurea* and *E angustifolia* root had no effect on warfarin pharmacodynamics, platelet aggregation, or baseline clotting in healthy subjects. Human studies have shown no effect of varied *E purpurea* preparations on the pharmacokinetics of lopinavir, ritonavir, etravirine, and darunavir.

Dosage

It is recommended to follow the dosing on the package label, as there may be variations in dose based on the procedure used in product manufacture. Standardized preparations made from the aerial parts of *E purpurea* (Echinaforce, Echinaguard) as an alcoholic extract or fresh pressed juice may be preferred in adults for common cold treatment if taken within the first 24 hours of cold symptoms. It should not be used on a continuous basis for longer than 10–14 days.

GARLIC (*ALLIUM SATIVUM*)

Chemistry

The pharmacologic activity of garlic involves a variety of organosulfur compounds. Dried and powdered formulations contain many of the compounds found in raw garlic and will usually be standardized to allicin or alliin content. Allicin is responsible for the characteristic odor of garlic, and alliin is its chemical precursor. Dried powdered formulations are often enteric-coated to protect the enzyme allinase (the enzyme that converts alliin to allicin) from degradation by stomach acid. Aged garlic extract (AGE) has also been studied in clinical trials but to a lesser degree than dried, powdered garlic (GP). AGE contains no alliin or allicin and is odor-free. Its primary constituents are water-soluble organosulfur compounds, and packages may carry standardization to the compound *S*-allylcysteine.

Pharmacologic Effects

1. Cardiovascular effects—In vitro, allicin and related compounds inhibit HMG-CoA reductase, which is involved in cholesterol biosynthesis (see Chapter 35), and exhibit antioxidant properties. Several clinical trials have investigated the lipid-lowering potential of garlic. The most recent meta-analysis (Ried et al, 2013) involved 39 randomized, double-blind, placebo-controlled trials with approximately 2300 patients. The investigators studied the effect of garlic mono-preparations on lipid

parameters and found a moderate and significant reduction in both total serum cholesterol (-17 ± 6 mg/dL) and LDL cholesterol (-9 ± 6 mg/dL) when garlic was taken for 2 or more months by patients with elevated baseline cholesterol (>200 mg/dL). Subgroup analysis showed a greater effect on cholesterol reduction when AGE preparations were used than when GP preparations were used. While the benefit of garlic in lowering total cholesterol and LDL cholesterol is clinically relevant, optimal prescription drug therapy is far more efficacious (see Chapter 35).

Clinical trials report antiplatelet effects (possibly through inhibition of thromboxane synthesis or stimulation of nitric oxide synthesis) following garlic ingestion. A majority of human studies also suggest enhancement of fibrinolytic activity. These effects in combination with antioxidant effects (eg, increased resistance to LDL oxidation) and reductions in total cholesterol might be beneficial in patients with atherosclerosis. A randomized, controlled trial among persons with advanced coronary artery disease who consumed GP for 4 years showed significant reductions in secondary markers (plaque accumulation in the carotid and femoral arteries) as compared with patients on placebo, but primary end points (death, stroke, myocardial infarction) were not assessed. AGE preparations have similarly shown favorable effects in three small (<100 patients) randomized, double-blind, placebo-controlled trials in reducing coronary artery calcification (CAC) progression over 1 year. All trials involved patients with known coronary artery disease (CAD) or who were considered medium to high risk for CAD at baseline.

Garlic constituents may affect blood vessel elasticity and blood pressure. Several mechanisms have been proposed. Twenty placebo-controlled studies using single-ingredient preparations of GP (13 studies), AGE (5 studies), or other preparations (2 studies) were included in a meta-analysis. Significant reductions in systolic blood pressure (SBP) and diastolic blood pressure (DBP) were present when all trials were considered. Benefits were most pronounced in subjects with baseline hypertension (mean SBP reduction of 8.6 ± 2.2 mm Hg and DBP reduction of 6.1 ± 1.3 mm Hg), and no significant effect was observed in subjects who had normal or prehypertensive blood pressures ($<140/90$ mm Hg) at baseline. A Cochrane review on the effect of garlic monotherapy for prevention of cardiovascular morbidity and mortality in hypertensive patients also identified a significant reduction in systolic and diastolic pressure compared with placebo. A separate Cochrane review of the effect of garlic on peripheral occlusive disease found insufficient support for this indication.

2. Endocrine effects—The effect of garlic on glucose homeostasis does not appear to be significant in persons with diabetes. Certain organosulfur constituents in garlic, however, have demonstrated hypoglycemic effects in nondiabetic animal models.

3. Antimicrobial effects—The antimicrobial effect of garlic has not been extensively studied in clinical trials. Allicin has been reported to have in vitro activity against some gram-positive and gram-negative bacteria as well as fungi (*Candida albicans*), protozoa (*Entamoeba histolytica*), and certain viruses. The primary mechanism involves the inhibition of thiol-containing enzymes

needed by these microbes. A Cochrane review studying the effect of garlic on cold prevention and treatment found a significant reduction in total number of colds using a garlic supplement (with 180 mg allicin content) once daily for 12 weeks. Limited conclusions can be drawn regarding the effects observed, however, because only one trial met inclusion criteria. Given the availability of safe and effective prescription antimicrobials, the usefulness of garlic in this area appears limited.

4. Antineoplastic effects—In rodent studies, garlic inhibits procarcinogens for colon, esophageal, lung, breast, and stomach cancer, possibly by detoxification of carcinogens and reduced carcinogen activation. Several epidemiologic case-control studies demonstrate a reduced incidence of stomach, esophageal, and colorectal cancers in persons with high dietary garlic consumption. Current anticancer studies are focused on specific organosulfur garlic compounds in *in vivo* animal models of cancer and *in vitro* effects on human cancer cell lines.

Adverse Effects

Following oral ingestion, adverse effects of garlic products may include nausea (6%), hypotension (1.3%), allergy (1.1%), and bleeding (rare). Breath and body odor have been reported with an incidence of 20–40% at recommended doses using enteric-coated powdered garlic formulations. Contact dermatitis may occur with the handling of raw garlic.

Drug Interactions & Precautions

Because of reported antiplatelet effects, patients using anticoagulating medications (eg, warfarin, aspirin, ibuprofen) should use garlic cautiously. Additional monitoring of blood pressure and signs and symptoms of bleeding is warranted. Garlic may reduce the bioavailability of saquinavir, an antiviral protease inhibitor, but it does not appear to affect the bioavailability of ritonavir.

Dosage

Dried, powdered garlic products should be standardized to contain 1.3% alliin (the allicin precursor) or have an allicin-generating potential of 0.6%. Enteric-coated formulations are recommended to minimize degradation of the active substances. A daily dose of 600–900 mg/d of powdered garlic is most common. This is equivalent to one clove of raw garlic (2–4 g) per day. A garlic bulb can contain up to 1.8% alliin. Doses of AGE most often range from 600 to 1800 mg/d, but doses up to 7200 mg daily have been safely used in clinical trials for up to 6 months.

GINKGO (GINKGO BILOBA)

Chemistry

Ginkgo biloba extract is prepared from the leaves of the ginkgo tree. The most common formulation is prepared by concentrating 50 parts of the crude leaf to prepare one part of extract.

The active constituents in ginkgo are flavone glycosides and terpenoids including ginkgolides A, B, C, and J, and bilobalide.

Pharmacologic Effects

1. Cardiovascular effects—In animal models and some human studies, ginkgo has been shown to increase blood flow, reduce blood viscosity, and promote vasodilation, thus enhancing tissue perfusion. Enhancement of endogenous nitric oxide effects (see Chapter 19) and antagonism of platelet-activating factor have been observed in animal models.

Ginkgo biloba has been studied for its effects on mild to moderate occlusive peripheral arterial disease. Among 11 randomized, placebo-controlled studies involving 477 participants using standardized ginkgo leaf extract (EGb761) for up to 6 months, a nonsignificant trend toward improvements in pain-free walking distance (increase of 64.5 meters) was observed ($P = .06$). The authors concluded that the standardized extract lacked benefit for this indication.

The Ginkgo Evaluation of Memory (GEM) study and the recently published GuidAge study evaluated cardiovascular outcomes as well as incidence and mean time to Alzheimer's dementia associated with the long-term use of ginkgo for 5–6 years in approximately 3000 elderly (age ≥ 70) adults with normal cognition or mild cognitive impairment. Daily use of 240 mg/d EGb761 did not affect the incidence of hypertension or reduce blood pressure among persons with hypertension or prehypertension. No significant effects in cardiovascular disease mortality, ischemic stroke or events, or hemorrhagic stroke were observed.

2. Metabolic effects—Antioxidant and radical-scavenging properties have been observed for the flavonoid fraction of ginkgo as well as some of the terpene constituents. *In vitro*, ginkgo has been reported to have superoxide dismutase-like activity and superoxide anion- and hydroxyl radical-scavenging properties. The flavonoid fraction has also been observed to have antiapoptotic properties. In some studies, it has also demonstrated a protective effect in limiting free radical formation in animal models of ischemic injury and in reducing markers of oxidative stress in patients undergoing coronary artery bypass surgery.

3. Central nervous system effects—In aged animal models, chronic administration of ginkgo for 3–4 weeks led to modifications in central nervous system receptors and neurotransmitters. Receptor densities increased for muscarinic, α_2 , and 5-HT_{1a} receptors, and decreased for β adrenoceptors. Increased serum levels of acetylcholine and norepinephrine and enhanced synaptosomal reuptake of serotonin and dopamine have also been reported. Additional possible effects include inhibition of amyloid-beta fibril formation and protective effects of EGb761 on hippocampal neurons against cell death induced by beta-amyloid.

Ginkgo has been used to treat cerebral insufficiency and dementia of the Alzheimer type. The term *cerebral insufficiency*, however, includes a variety of manifestations ranging from poor concentration and confusion to anxiety and depression as well as physical complaints such as hearing loss and headache. For this

reason, studies evaluating cerebral insufficiency tend to be more inclusive and difficult to assess than trials evaluating dementia. A meta-analysis of ginkgo for cognitive impairment or dementia was performed by the Cochrane Collaboration. They reviewed 36 randomized, double-blind, placebo-controlled trials ranging in length from 3 to 52 weeks. Significant improvements in cognition and activities of daily living were observed at 12 but not 24 weeks. Significant improvements in clinical global assessment however, were observed at 24 but not 12 weeks. The authors concluded that the effects of ginkgo in the treatment of cognitive impairment and dementia were unpredictable and unlikely to be clinically relevant. However, recent meta-analyses of randomized controlled trials, 22–26 weeks in duration, using EGb761 that limited inclusion criteria to patients with dementia of the Alzheimer type (in eight studies), vascular or mixed dementia type (in six studies), or dementia with neuropsychiatric features (in four studies) showed favorable results. Significant improvements in cognition and activities of daily living were observed for ginkgo compared to placebo. Clinical global assessment of improvement also was significantly improved when EGb761 doses of 240 mg/d were used, but not doses of 120 mg/d. Because of the stricter inclusion criteria used, the overall methodologic quality of the studies was higher than that of the Cochrane review, when determining a benefit in patients with dementia. This suggests that patients with a diagnosis of dementia are more likely to benefit than patients with more mild cognitive impairment. In the GEM and GuidAge studies that included persons with normal or mild cognitive impairment, the effects of ginkgo as a prophylactic agent to prevent progression to dementia were assessed. No benefit was observed with 5–6 years of ginkgo treatment.

4. Miscellaneous effects—Ginkgo has been studied for its effects in schizophrenia, tardive dyskinesia, allergic and asthmatic bronchoconstriction, short-term memory in healthy, nondemented adults, erectile dysfunction, tinnitus and hearing loss, and macular degeneration. Preliminary data from eight randomized, double-blind, placebo-controlled trials suggest that EGb761 can significantly reduce the symptoms of chronic schizophrenia when used in combination with standard treatment (eg, clozapine, haloperidol, olanzapine). These trials were conducted in China, so firm conclusions about benefit in a broader population are lacking. There is insufficient evidence to warrant clinical use for the other conditions listed.

Adverse Effects

Adverse effects of ginkgo have been reported with a frequency comparable to that of placebo. These include nausea, headache, stomach upset, diarrhea, allergy, anxiety, and insomnia. A few case reports noted bleeding complications in patients using ginkgo. In some of these cases, the patients were also using either aspirin or warfarin.

Drug Interactions & Precautions

Ginkgo may have antiplatelet properties and should not be used in combination with antiplatelet or anticoagulant medications. Other single case reports noted virologic failure when ginkgo

was combined with efavirenz, sedation when combined with trazodone, priapism when combined with risperidone, and seizure when combined with valproic acid and phenytoin; all warrant further pharmacokinetic studies before firm conclusions can be drawn. Seizures have been reported as a toxic effect of ginkgo, most likely related to seed contamination in the leaf formulations. Uncooked ginkgo seeds are epileptogenic due to the presence of ginkgotoxin. Ginkgo formulations should be avoided in individuals with preexisting seizure disorders.

Dosage

Ginkgo biloba dried leaf extract is usually standardized to contain 24% flavone glycosides and 6% terpene lactones. The daily dose most commonly studied and associated with a benefit in clinical trials of dementia is 240 mg daily of the dried extract in two divided doses.

GINSENG

Chemistry

Ginseng may be derived from any of several species of the genus *Panax*. Of these, crude preparations or extracts of *Panax ginseng*, the Chinese or Korean variety, and *P. quinquefolium*, the American variety, are most often available to consumers in the United States. The active principles appear to be the triterpenoid saponin glycosides called ginsenosides or panaxosides, of which there are approximately 30 different types. It is recommended that commercial *P. ginseng* formulations be standardized to contain 4–10% ginsenosides.

Other plant materials are commonly sold under the name ginseng but are not from *Panax* species. These include Siberian ginseng (*Eleutherococcus senticosus*) and Brazilian ginseng (*Pfaffia paniculata*). Of these, Siberian ginseng may be more widely available in the USA. Siberian ginseng contains eleutherosides but no ginsenosides. Currently, there is no recommended standardization for eleutheroside content in Siberian ginseng products.

Pharmacologic Effects

An extensive literature exists on the potential pharmacologic effects of ginsenosides. Unfortunately, the studies differ widely in the species of *Panax* used, the ginsenosides studied, the degree of purification applied to the extracts, the animal species studied, the doses or concentrations involved, and the measurements used to evaluate the responses. Reported beneficial pharmacologic effects include modulation of immune function (induced mRNA expression for interleukins-2 and -10, interferon- γ , and granulocyte-macrophage colony-stimulating factor; activated B and T cells, natural killer cells, and macrophages). Central nervous system effects included increased proliferating ability of neural progenitors and increased central levels of acetylcholine, serotonin, norepinephrine, and dopamine in the cerebral cortex. Miscellaneous effects included antioxidant activity; anti-inflammatory effects (inhibited tumor necrosis factor- α , interleukin-1 β , and vascular and intracellular cell adhesion molecules); antistress activity

(ie, stimulated pituitary-adrenocortical system, agonist at glucocorticoid receptor); analgesia (inhibited substance P); vasoregulatory effects (increased endothelial nitric oxide, inhibited prostacyclin production); cardioprotective activity (reduced ventricular remodeling and cardiac hypertrophy in animal models of myocardial ischemia); antiplatelet activity; improved glucose homeostasis (reduced cell death in pancreatic beta cells; increased insulin release, number of insulin receptors, and insulin sensitivity); and anticancer properties (reduced tumor angiogenesis, increased tumor cell apoptosis). Such extensive claims naturally evoke skepticism and require careful replication.

Clinical Trials

Ginseng is most often claimed to help improve physical and mental performance or to function as an “adaptogen,” an agent that helps the body to return to normal when exposed to stressful or noxious stimuli. However, the clinical trials evaluating ginseng for these indications have shown few, if any, benefits. Some randomized controlled trials evaluating “quality of life” and “cognition” have claimed significant benefits in some subscale measures of behavior, cognitive function, or quality of life but rarely in overall composite scores using *P. ginseng*. Better results have been observed with *P. quinquefolium* and *P. ginseng* in lowering postprandial glucose indices in subjects with and without diabetes. This was the subject of a systematic review in which 15 studies (13 randomized and 2 nonrandomized) were evaluated. Nine of the studies reported significant reductions in blood glucose. Some randomized, placebo-controlled trials have reported immunomodulating benefits of *P. quinquefolium* and *P. ginseng* in preventing upper respiratory tract infections. Use of ginseng for 2–4 months in healthy seniors may reduce the risk of acquiring the common cold as well as the duration of symptoms. Because of heterogeneity in these trials, however, the findings are insufficient to warrant a recommendation of ginseng for cold prevention. To assess effects on cardiovascular health, a systematic review and meta-analysis of 17 randomized controlled trials involving predominantly *P. ginseng* (12 studies) and *P. quinquefolium* (5 studies) species in persons with and without hypertension was performed. Over a mean time period of 9 weeks, no significant effect was observed of ginseng on SBP, DBP, and mean arterial pressure compared with controls. Finally, two case-control studies and a cohort study suggest a non-organ-specific cancer-preventive effect with long-term administration of *P. ginseng*. Significant benefits in some cancer-related fatigue symptoms have been observed in both a dose-finding study and a multisite, double-blind, randomized trial using *P. quinquefolium*, 2 g daily, versus placebo over a 2-month period. In summary, the strongest support for use of *P. ginseng* or *P. quinquefolium* currently relates to its effects in cold prevention, lowering postprandial glucose, nonspecific cancer prevention, and alleviating cancer-related fatigue.

Adverse Effects

Vaginal bleeding and mastalgia have been described in case reports, suggesting possible estrogenic effects. Central nervous system stimulation (eg, insomnia, nervousness) and hypertension

have been reported in patients using high doses (>3 g/d) of *P. ginseng*. Methylxanthines found in the ginseng plant may contribute to this effect. Vasoregulatory effects have not been found to be clinically significant.

Drug Interactions & Precautions

Irritability, sleeplessness, and manic behavior have been reported in psychiatric patients using ginseng in combination with other medications (phenelzine, lithium, neuroleptics). Ginseng should be used cautiously in patients taking any psychiatric, estrogenic, or hypoglycemic medications. Ginseng has antiplatelet properties and should not be used in combination with warfarin. Cytokine stimulation has been claimed for both *P. ginseng* and *P. quinquefolium* in vitro and in animal models. In a randomized, double-blind, placebo-controlled study, *P. ginseng* significantly increased natural killer cell activity versus placebo with 8 and 12 weeks of use. Immunocompromised individuals, those taking immune stimulants, and those with autoimmune disorders should use ginseng products with caution.

Dosage

A dose of 1–2 g/d of the crude *P. ginseng* root or its equivalent is considered standard dosage. Two hundred milligrams of standardized *P. ginseng* extract are equivalent to 1 g of the crude root. The trademarked preparation Ginsana has been used as a standardized extract in some clinical trials and is available in the USA.

MILK THISTLE (*SILYBUM MARIANUM*)

Chemistry

The fruit and seeds of the milk thistle plant contain a lipophilic mixture of flavonolignans known as silymarin. Silymarin comprises 2–3% of the dried herb and is composed of three primary isomers: silybin (also known as silybinin or silibinin), silychristin (silychristin), and silydianin (silydianin). Silybin is the most prevalent and potent of the three isomers and accounts for 50–70% of the silymarin complex. Products should be standardized to contain 70–80% silymarin.

Pharmacologic Effects

1. Liver disease—In animal models, milk thistle purportedly limits hepatic injury associated with a variety of toxins, including *Amanita* mushrooms, galactosamine, carbon tetrachloride, acetaminophen, radiation, cold ischemia, and ethanol. In vitro studies and some in vivo studies indicate that silymarin reduces lipid peroxidation, scavenges free radicals, and enhances glutathione and superoxide dismutase levels. This may contribute to membrane stabilization and reduce toxin entry.

Milk thistle appears to have anti-inflammatory properties. In vitro, silybin strongly and noncompetitively inhibits lipoxygenase activity and reduces leukotriene formation. Inhibition of leukocyte migration has been observed in vivo and may be a factor when acute inflammation is present. Silymarin inhibits nuclear factor

kappa B (NF- κ B), an inflammatory response mediator. One of the most unusual mechanisms claimed for milk thistle involves an increase in RNA polymerase I activity in nonmalignant hepatocytes but not in hepatoma or other malignant cell lines. By increasing this enzyme's activity, enhanced protein synthesis and cellular regeneration might occur in healthy but not malignant cells. In an animal model of cirrhosis, it reduced collagen accumulation, and in an in vitro model it reduced expression of the fibrogenic cytokine transforming growth factor- β . If confirmed, milk thistle may have a role in the treatment of hepatic fibrosis.

In animal models, silymarin has a dose-dependent stimulatory effect on bile flow that could be beneficial in cases of cholestasis. To date, however, there is insufficient evidence to warrant the use of milk thistle for these indications.

2. Chemotherapeutic effects—Preliminary in vitro and animal studies of the effects of silymarin and silybinin have been carried out with several cancer cell lines. In murine models of skin cancer, silybinin and silymarin were said to reduce tumor initiation and promotion. Induction of apoptosis has also been reported using silymarin in a variety of malignant human cell lines (eg, melanoma, prostate, colon, leukemia cells, bladder transitional-cell papilloma cells, cervical and hepatoma cells). Inhibition of cell growth and proliferation by inducing a G₁ cell cycle arrest has also been claimed in cultured human breast and prostate cancer cell lines. The use of milk thistle in the clinical treatment of cancer has not yet been adequately studied but preliminary trials in patients undergoing chemotherapy show that it may improve liver function (ie, reduced liver transaminase concentrations in blood). There are insufficient data to support use in patients with cancer. The antioxidant potential of milk thistle should be taken into consideration prior to administration with chemotherapeutic agents that may be affected by antioxidant compounds.

3. Lactation—Historically, milk thistle has been used by herbalists and midwives to induce lactation in pregnant or postpartum women. In female rats, milk thistle increases prolactin production. As such, it is possible that it could have an effect on human breast milk production. Clinical trial data are lacking, however, for this indication, as are safety data on nursing mothers and infants. Until further data become available, milk thistle should not be used for this indication.

Clinical Trials

Oral milk thistle has been used to treat acute and chronic viral hepatitis, alcoholic liver disease, and toxin-induced liver injury in human patients. A systematic review of 13 randomized trials involving 915 patients with alcoholic liver disease or hepatitis B or C found no significant reductions in all-cause mortality, liver histopathology, or complications of liver disease with 6 months of use. A significant reduction in liver-related mortality was claimed using the data from all the surveyed trials, but not when the data were limited to trials of better design and controls. It was concluded that the effects of oral milk thistle in improving liver function or mortality from liver disease are currently poorly substantiated. A recent multicenter, double-blind, placebo-controlled

clinical trial in patients with hepatitis C refractory to interferon treatment failed to show a benefit with 24 weeks of milk thistle, 420 mg/d and 700 mg/d, on reduction of serum alanine aminotransferase levels. Milk thistle also had no effect on mean serum hepatitis C virus (HCV) RNA levels at 24 weeks. In contrast, the intravenous use of silybinin succinate has shown some benefit in reducing HCV RNA levels and alanine aminotransferase levels in patients with treatment-resistant hepatitis C infection. Prospective pilot studies have also shown benefits with intravenous silybinin before and after liver transplantation treatment in patients with HCV cirrhosis. Potent antiviral activity was demonstrated with significant reductions in HCV-RNA levels during treatment compared to placebo or nontreated controls when given for at least 14 days before transplantation and 7 days after liver transplantation. HCV-RNA relapsed, however, after silybinin withdrawal. This suggests that formulation and poor oral bioavailability may influence treatment outcomes.

Although milk thistle has not been confirmed as an antidote following acute exposure to liver toxins in humans, intravenous silybinin is marketed and used in Europe (Legalon SIL) as an antidote in *Amanita phalloides* mushroom poisoning. This use is based on favorable outcomes reported in case-control studies.

Adverse Effects

Milk thistle has rarely been reported to cause adverse effects when used at recommended doses. In clinical trials, the incidence of adverse effects (eg, gastrointestinal upset, dermatologic, headaches) was comparable to that of placebo. At high doses (>1500 mg), it can have a laxative effect caused by stimulation of bile flow and secretion.

Drug Interactions, Precautions, & Dosage

Milk thistle does not significantly alter the pharmacokinetics of other drugs transported by the P-glycoprotein transporter or metabolized by cytochrome enzymes. In a recent review, the impact of the herb was listed as “posing no risk for drug interactions in humans.” Recommended oral dosage is 280–420 mg/d, calculated as silybin, in three divided doses.

ST. JOHN'S WORT (*HYPERICUM PERFORATUM*)

Chemistry

St. John's wort, also known as hypericum, contains a variety of constituents that might contribute to its claimed pharmacologic activity in the treatment of depression. Hypericin, a marker of standardization for currently marketed products, was thought to be the primary antidepressant constituent. Recent attention has focused on hyperforin, but a combination of several compounds is probably involved. Commercial formulations are usually prepared by soaking the dried chopped flowers in methanol to create a hydroalcoholic extract that is then dried.

Pharmacologic Effects

1. Antidepressant action—The hypericin fraction was initially reported to have MAO-A and -B inhibitor properties. Later studies found that the concentration required for this inhibition was higher than that achieved with recommended dosages. In vitro studies using the commercially formulated hydroalcoholic extract have shown inhibition of nerve terminal reuptake of serotonin, norepinephrine, and dopamine. While the hypericin constituent did not show reuptake inhibition for any of these systems, the hyperforin constituent did. Chronic administration of the commercial extract has also been reported to significantly down-regulate the expression of cortical β adrenoceptors and up-regulate the expression of serotonin receptors (5-HT₂) in a rodent model.

Other effects observed in vitro include sigma receptor binding using the hypericin fraction and GABA receptor binding using the commercial extract. Interleukin-6 production is also reduced in the presence of the extract.

a. Clinical trials for depression—The most recent systematic review and meta-analysis involved 29 randomized, double-blind, controlled trials (18 compared St. John's wort with placebo, 5 with tricyclic antidepressants, and 12 with selective serotonin reuptake inhibitors [SSRIs]). Only studies meeting defined classification criteria for major depression were included. St. John's wort was reported to be more efficacious than placebo and equivalent to prescription reference treatments including the SSRIs for mild to moderate major depressive disorder but with fewer side effects. Most trials used 900 mg/d of St. John's wort for 4–12 weeks. Depression severity was mild to moderate in 19 trials, moderate to severe in 9 trials, and not stated in 1 trial. In a longer but uncontrolled trial, the use of the herb for up to 52 weeks was reported to reduce depression scores in patients with mild to moderate major depression. These data and the mechanism of action data reported above suggest a potential role for St. John's wort in relieving symptoms of mild to moderate major depression. Due to the short study duration of these clinical trials, efficacy beyond 12 weeks still requires further study.

b. Other mood-related conditions—St. John's wort has been studied for several other indications related to mood, including premenstrual dysphoric disorder, climacteric complaints, somatoform disorders, and anxiety. For most of these indications, studies are too few in number to draw any firm conclusions regarding efficacy. Evidence for climacteric complaints was the subject of a recent meta-analysis. Six trials were included where two used mono-preparations of St. John's wort and four used combinations of St. John's wort and black cohosh, *Cimicifuga racemosa* (note black cohosh warning in Table 64-1). St. John's wort significantly reduced hot flashes (severity, duration, and frequency) compared to placebo when used for up to 16 weeks. Heterogeneity in these trials limits drawing firm conclusions on efficacy for this indication.

2. Antiviral and anticarcinogenic effects—The hypericin constituent of St. John's wort is photolabile and can be activated by exposure to certain wavelengths of visible or ultraviolet A light.

Parenteral formulations of hypericin (photoactivated just before administration) have been used investigatively to treat HIV infection (given intravenously) and basal and squamous cell carcinoma (given by intralesional injection). In vitro, photoactivated hypericin inhibits a variety of enveloped and nonenveloped viruses as well as the growth of some neoplastic cells. Inhibition of protein kinase C and inhibition of singlet oxygen radical generation have been proposed as possible mechanisms. The latter could inhibit cell growth or cause cell apoptosis. These studies were carried out using the isolated hypericin constituent of St. John's wort; the usual hydroalcoholic extract of St. John's wort has not been studied for these indications and should not be recommended for patients with viral illness or cancer.

Adverse Effects

Photosensitization is related to the hypericin and pseudohypericin constituents in St. John's wort. Consumers should be instructed to wear sunscreen and eye protection while using this product when exposed to the sun. Rarely, mild gastrointestinal symptoms, fatigue, sedation, restlessness, dizziness, headache, and dry mouth have been observed. Hypomania, mania, and autonomic arousal have also been reported in patients using St. John's wort. When compared to SSRIs, St. John's wort appears to be better tolerated when used to support medical treatment of major depression.

Drug Interactions & Precautions

Inhibition of reuptake of various amine transmitters has been highlighted as a potential mechanism of action for St. John's wort. Drugs with similar mechanisms (ie, antidepressants, stimulants) should be used cautiously or avoided in patients using St. John's wort due to the risk of serotonin syndrome (see Chapters 16 and 30). The hyperforin constituent of St. John's wort has been shown to activate the pregnane X receptor (PXR), which ultimately leads to many drug interactions by inducing hepatic CYP enzymes (3A4, 2C9, 1A2) and the P-glycoprotein drug transporter. Another constituent, hypericin, which may not be present in all commercial formulations, does not have any effect on PXR, CYP, or P-glycoprotein. Case reports involving the use of St. John's wort have suggested the herb resulted in subtherapeutic levels of numerous drugs, including digoxin, birth control drugs (and subsequent pregnancy), cyclosporine, HIV protease and nonnucleoside reverse transcriptase inhibitors, warfarin, irinotecan, theophylline, and anticonvulsants. Without knowing which constituent is present in a St. John's wort formulation, indiscriminate combined use with other medicines should be avoided.

Dosage

The most common commercial formulation of St. John's wort is the dried hydroalcoholic extract. Products should be standardized to 2–5% hyperforin, although most still bear the older standardized marker of 0.3% hypericin. The recommended dosing for mild to moderate depression is 900 mg of the dried extract per day in three divided doses. Onset of effect may take 2–4 weeks. Long-term benefits beyond 12 weeks have not been studied.

SAW PALMETTO (*SERENOA REPENS* OR *SABAL SERRULATA*)

Chemistry

The active constituents in saw palmetto berries are not well defined. Phytosterols (eg, β -sitosterol), aliphatic alcohols, poly-prenic compounds, and flavonoids are all present. Marketed preparations are dried lipophilic extracts that are generally standardized to contain 85–95% fatty acids and sterols.

Pharmacologic Effects

Saw palmetto is most often promoted for the treatment of benign prostatic hyperplasia (BPH). Enzymatic conversion of testosterone to dihydrotestosterone (DHT) by 5α -reductase is inhibited by saw palmetto in vitro. Specifically, saw palmetto shows a noncompetitive inhibition of isoforms I and II of this enzyme, thereby reducing DHT production. In vitro, saw palmetto also inhibits the binding of DHT to androgen receptors. Additional effects observed in vitro include inhibition of prostatic growth factors, blockade of α_1 adrenoceptors, and inhibition of inflammatory mediators produced by the 5-lipoxygenase pathway.

The clinical pharmacology of saw palmetto in humans is not well defined. One week of treatment in healthy volunteers failed to influence 5α -reductase activity, DHT concentration, or testosterone concentration. Six months of treatment in patients with BPH also failed to affect prostate-specific antigen (PSA) levels, a marker that is typically reduced by enzymatic inhibition of 5α -reductase. In contrast, other researchers have reported a reduction in epidermal growth factor, DHT levels, and antagonist activity at the nuclear estrogen receptor in the prostate after 3 months of treatment with saw palmetto in patients with BPH. Recent reports suggest that daily saw palmetto, as compared to daily tamsulosin (see Chapter 10), has greater anti-inflammatory activity on infiltrating prostatic cells in men with BPH-related lower urinary tract symptoms at 3 months. The anti-inflammatory effects on infiltrating prostatic cells may serve as a link between hormonal changes and the remodeling process promoted by growth factors. The anti-inflammatory effects of saw palmetto also raise questions as to the value of early initiation of BPH therapy as well as the value of early combination therapy with 5α -reductase inhibitors (see Chapter 40).

Clinical Trials

The most recent review involved 32 randomized controlled trials in 5666 men with symptoms consistent with BPH. Seventeen trials compared saw palmetto monotherapy with placebo and found no significant improvement in most urologic symptoms (eg, international prostate symptom scores, peak flow, prostate size).

Adverse Effects

Adverse effects are reported with an incidence of 1–3%. The most common include abdominal pain, nausea, diarrhea, fatigue, headache, decreased libido, and rhinitis. Saw palmetto has been

associated with a few rare case reports of pancreatitis, liver damage, and increased bleeding risk, but due to confounding factors, causality remains uncertain. In comparison to tamsulosin and finasteride, saw palmetto was claimed to be less likely to affect sexual function (eg, ejaculation).

Drug Interactions, Precautions, & Dosage

No drug-drug interactions have been reported for saw palmetto. Because saw palmetto has no effect on the PSA marker, it will not interfere with prostate cancer screening using this test. Recommended dosage of a standardized dried extract (containing 85–95% fatty acids and sterols) is 160 mg orally twice daily. The lack of positive results as noted in the review of randomized controlled studies cited above indicates that the use of saw palmetto in prostate disease cannot be recommended.

■ PURIFIED NUTRITIONAL SUPPLEMENTS

COENZYME Q10

Coenzyme Q10, also known as CoQ, CoQ10, and ubiquinone, is found in the mitochondria of many organs, including the heart, kidney, liver, and skeletal muscle. After ingestion, the reduced form of coenzyme Q10, ubiquinol, predominates in the systemic circulation. Coenzyme Q10 is a potent antioxidant and has been heavily promoted for this reason. It may have a role in maintaining healthy muscle function, although the clinical significance of this effect is unknown. Reduced serum levels have been reported in Parkinson's disease.

Clinical Uses

1. Hypertension—In clinical trials, small but significant reductions in systolic and diastolic blood pressure were reported after 8–10 weeks of coenzyme Q10 supplementation. The exact mechanism is unknown but might be related to the antioxidant and vasodilating properties of coenzyme Q10. In three randomized, placebo-controlled trials, coenzyme Q10 was reported to significantly lower systolic and diastolic blood pressure by 11 mm Hg and 7 mm Hg, respectively, compared with no change in the placebo groups. However, an exaggerated treatment effect may have occurred as adequate randomization, blinding, and concealment of allocation have been questioned for these studies. Whether coenzyme Q10 can be used to lower blood pressure remains unclear.

2. Heart failure—Low endogenous coenzyme Q10 levels have been associated with worse heart failure outcomes, but this association is likely because low levels are a marker for more advanced heart failure, rather than a predictor of disease. Despite these findings, coenzyme Q10 is often advocated to improve heart muscle function in patients with heart failure. According to the most recent meta-analysis, coenzyme Q10 was shown to improve ejection fraction

by 3.7% when used short term (2–28 weeks). It is unclear whether improvements in ejection fraction are applicable to all patients with heart failure, including those receiving the current standard of care for heart failure management. More research is required to assess the role of coenzyme Q10 in heart failure and its impact on disease severity, particularly with concomitant prescription medications.

3. Ischemic heart disease—The effects of coenzyme Q10 on coronary artery disease and chronic stable angina are modest but appear promising. A theoretical basis for such benefit could be metabolic protection of the ischemic myocardium by reducing proinflammatory markers (including interleukin-6 and C-reactive protein) that contribute to oxidative stress. Double-blind, placebo-controlled trials have suggested that coenzyme Q10 supplementation improved a number of clinical measures in patients with a history of acute myocardial infarction (AMI). Improvements have been observed in lipoprotein (a), high-density lipoprotein cholesterol, exercise tolerance, and time to development of ischemic changes on the electrocardiogram during stress tests. In addition, very small reductions in cardiac deaths and rate of reinfarction in patients with previous AMI have been reported (absolute risk reduction 1.5%).

4. Prevention of statin-induced myopathy—Statins reduce cholesterol by inhibiting the HMG-CoA reductase enzyme (see Chapter 35). This enzyme is also required for synthesis of coenzyme Q10. Initiating statin therapy has been shown to reduce endogenous coenzyme Q10 levels, which may block steps in muscle cell energy generation, possibly leading to statin-related myopathy. It is unknown whether a reduction in intramuscular coenzyme Q10 levels leads to statin myopathy or if the myopathy causes cellular damage that reduces intramuscular coenzyme Q10 levels. A meta-analysis evaluating the effect of coenzyme Q10 on statin-induced myopathy as measured by muscle pain and plasma creatine kinase activity found that coenzyme Q10 supplementation (30 days to 3 months) did not demonstrate any benefit in reducing myopathy. More information is needed to determine which patients, if any, with statin-related myopathy might benefit from coenzyme Q10 supplementation, especially as it relates to the specific statin, the dose, and the duration of therapy.

Adverse Effects

Coenzyme Q10 is well tolerated, rarely leading to any adverse effects at doses as high as 3000 mg/d. In clinical trials, gastrointestinal upset, including diarrhea, nausea, heartburn, and anorexia, has been reported with an incidence of less than 1%. Cases of maculopapular rash and thrombocytopenia have very rarely been observed. Other rare adverse effects include irritability, dizziness, and headache.

Drug Interactions

Coenzyme Q10 shares a structural similarity with vitamin K, and an interaction has been observed between coenzyme Q10 and warfarin. Coenzyme Q10 supplements may decrease the effects of warfarin therapy. This combination should be avoided or very carefully monitored.

Dosage

As a dietary supplement, 30 mg/d of coenzyme Q10 is adequate to replace low endogenous levels. For cardiac effects, typical dosages are 100–600 mg/d given in two or three divided doses. These doses increase endogenous levels to 2–3 mcg/mL (normal for healthy adults, 0.7–1 mcg/mL).

GLUCOSAMINE

Glucosamine is found in human tissue, is a substrate for the production of articular cartilage, and serves as a cartilage nutrient. Glucosamine is commercially derived from crabs and other crustaceans. As a dietary supplement, glucosamine is primarily used for pain associated with knee osteoarthritis. Sulfate and hydrochloride forms are available, but recent research has shown the hydrochloride form to be ineffective.

Pharmacologic Effects & Clinical Uses

Endogenous glucosamine is used for the production of glycosaminoglycans and other proteoglycans in articular cartilage. In osteoarthritis, the rate of production of new cartilage is exceeded by the rate of degradation of existing cartilage. Supplementation with glucosamine is thought to increase the supply of the necessary glycosaminoglycan building blocks, leading to better maintenance and strengthening of existing cartilage.

Many clinical trials have been conducted on the effects of both oral and intra-articular administration of glucosamine. Early studies reported significant improvements in overall mobility, range of motion, and strength in patients with osteoarthritis. More recent studies have reported mixed results, with both positive and negative outcomes. One of the largest and best-designed clinical trials, which compared glucosamine, chondroitin sulfate, the combination, celecoxib, and placebo, found no benefit for glucosamine therapy in mild to moderate disease. Unfortunately the investigators studied the glucosamine hydrochloride formulation, which has been shown to be inferior to the sulfate formulation. The formulation of glucosamine appears to play a critical role with regard to efficacy, and this may be a factor contributing to the variability observed across published studies. Research suggests that use of a crystalline formulation of glucosamine sulfate leads to less pain, functional improvements in knee osteoarthritis, and an improvement in joint space narrowing at 3 years. Currently, national orthopedic and rheumatic societies do not recommend glucosamine for knee osteoarthritis primarily because of formulation variability and study heterogeneity. More research is needed to better define the ideal glucosamine formulation and patient populations that stand to benefit from glucosamine sulfate.

Adverse Effects

Oral glucosamine sulfate is very well tolerated. In clinical trials, mild diarrhea, abdominal cramping, and nausea were occasionally reported. Cross-allergenicity in people with shellfish allergies is a potential concern; however, this is unlikely if the formulation has been properly manufactured and purified.

Drug Interactions & Precautions

Glucosamine sulfate may increase the international normalized ratio (INR) in patients taking warfarin, increasing the risk for bruising and bleeding. The mechanism is not well understood and may be dose-related as increases in INR have occurred when the glucosamine dose was increased. Until more is known, the combination should be avoided or very carefully monitored.

Dosage

The oral dosage used most often in clinical trials is 500 mg three times daily or 1500 mg once daily. Glucosamine does not have direct analgesic effects, and improvements in function, if any, may not be observed for 1–2 months.

MELATONIN

Melatonin, a serotonin derivative produced by the pineal gland and some other tissues (see also Chapter 16), is believed to be responsible for regulating sleep-wake cycles. Release coincides with darkness; it typically begins around 9 PM and lasts until about 4 AM. Melatonin release is suppressed by daylight. Melatonin has also been studied for a number of other functions, including contraception, protection against endogenous oxidants, prevention of aging, treatment of depression, HIV infection, and a variety of cancers. Currently, melatonin is most often used to prevent jet lag and to induce sleep.

Pharmacologic Effects & Clinical Uses

1. Jet lag—Jet lag, a disturbance of the sleep-wake cycle, occurs when there is a disparity between the external time, ie, hours of daylight or darkness, and the traveler's endogenous circadian clock (internal time). The internal time regulates not only daily sleep rhythms but also body temperature and many metabolic systems. The synchronization of the circadian clock relies on light as the most potent “zeitgeber” (time giver).

Jet lag is especially common among frequent travelers and airplane cabin crews. Typical symptoms of jet lag may include daytime drowsiness, insomnia, frequent awakenings, and gastrointestinal upset. Clinical studies of melatonin have reported subjective reduction in daytime fatigue, improved mood, and a quicker recovery time (return to normal sleep patterns, energy, and alertness). These outcomes are also supported by a systematic review that showed melatonin was better than placebo in helping patients fall asleep faster and to sleep better at their destination. When traveling across five or more time zones, jet lag symptoms are reduced when taking melatonin close to the target bedtime (10 PM to midnight) at the new destination. The benefit of melatonin is thought to be greater as more time zones are crossed. In addition, melatonin appears more effective for eastbound travel than for westward travel. Finally, maximizing exposure to daylight on arrival at the new destination can also aid in resetting the internal clock.

2. Insomnia—Melatonin has been studied in the treatment of various sleep disorders, including insomnia and delayed

sleep-phase syndrome. It has been reported to improve sleep onset, duration, and quality when administered to healthy volunteers, suggesting a pharmacologic hypnotic effect. Melatonin has also been shown to increase rapid eye movement (REM) sleep. These observations have been applied to the development of ramelteon, a prescription hypnotic that is an agonist at melatonin receptors (see Chapter 22).

Clinical studies in patients with primary insomnia have shown that oral melatonin supplementation may alter sleep architecture. Melatonin appears effective in some patients who develop insomnia from β blockers. Subjective and objective improvements in sleep quality and improvements in sleep onset and sleep duration have been reported. Specifically, melatonin taken at the desired bedtime, with bedroom lights off, has been shown to improve morning alertness and quality of sleep as compared with placebo. These effects have been observed in both young and older adults (18–80 years of age). Interestingly, baseline endogenous melatonin levels were not predictive of exogenous melatonin efficacy.

3. Pre- and postoperative anxiety in adults—Melatonin given as a premedication has been shown to reduce preoperative anxiety in adults. Melatonin may be as effective as midazolam in reducing anxiety before a surgical procedure (measured 50–100 minutes after administration). The effect of melatonin on postoperative anxiety in adults is mixed, but studies support an overall reduction in anxiety as compared to preoperative anxiety levels.

4. Female reproductive function—The presence of melatonin within the female reproductive system appears widespread in mammals, and research suggests it plays a role in reducing oxidative stress. Melatonin receptors have been identified in ovarian granulosa cell membranes, and significant amounts of melatonin have been detected in follicular fluid. Some studies suggest it can be used as an adjunctive therapy in the treatment of infertility during in vitro fertilization by reducing oxidative stress and thereby improving the quality of oocytes and embryos during ovulation induction and egg retrieval. Melatonin requirements increase during pregnancy, and researchers are evaluating the role of melatonin in preeclampsia and neonatal neurologic morbidity. Importantly, melatonin has been shown to lack teratogenic effects when taken during pregnancy. Melatonin supplementation may decrease prolactin release in women and therefore should be used cautiously or not at all while nursing.

5. Male reproductive function—Melatonin receptors have been identified on spermatozoa, suggesting melatonin may play a role in sperm function. When melatonin was added to semen samples, sperm motility was increased and early apoptosis was inhibited. These findings suggest that melatonin may be important in male fertility; however, more research is needed.

Adverse Effects

Melatonin appears to be well tolerated and is often used in preference to over-the-counter “sleep-aid” drugs. Although melatonin is associated with few adverse effects, some next-day drowsiness has been reported as well as fatigue, dizziness, headache, and irritability.

Transient depressive symptoms and dysphoria have been reported rarely. Melatonin may affect blood pressure as both increases and decreases in blood pressure have been observed. Careful monitoring is recommended, particularly in patients initiating melatonin therapy while taking antihypertensive medications.

Drug Interactions

Melatonin drug interactions have not been formally studied. Various studies, however, suggest that melatonin concentrations are altered by a variety of drugs, including nonsteroidal anti-inflammatory drugs, antidepressants, β -adrenoceptor agonists and antagonists, scopolamine, and sodium valproate. The relevance of these effects is unknown. Melatonin is metabolized by CYP450 1A2 and may interact with other drugs that either inhibit or induce the 1A2 isoenzyme, including fluvoxamine. Melatonin may decrease prothrombin time and may theoretically decrease the effects of warfarin therapy. A dose-response relationship between the plasma concentration of melatonin and coagulation activity has been suggested according to one in vitro analysis. If combination therapy is desired, careful monitoring is recommended especially if melatonin is being used on a short-term basis. Melatonin may interact with nifedipine, possibly leading to increased blood pressure and heart rate. The exact mechanism is unknown.

Dosage

1. Jet lag—Daily doses of 0.5–5 mg appear to be equally effective for jet lag; however, the 5 mg dose resulted in a faster onset of sleep and better sleep quality than lower doses. The immediate-release formulation is preferred and should be given at the desired sleep time (10 PM–midnight) upon arrival at the new destination and for 1–3 nights after arrival. A dark room environment is important when taking melatonin and when possible, room lights should be turned off. The value of extended-release formulations remains unknown, as evidence suggests the short-acting, high-peak effect of the immediate-release formulation to be more effective. Exposure to daylight at the new time zone is also important to regulate the sleep-wake cycle.

2. Insomnia—Doses of 0.3–10 mg of the immediate-release formulation given orally once nightly have been used. The lowest effective dose should be used first and may be repeated in 30 minutes up to a maximum of 10–20 mg. Sustained-release formulations are effective and may be used but, as noted above, may be inferior to immediate-release formulations. Sustained-release formulations are also more costly.

CASE STUDY ANSWER

Garlic has shown significant benefits in lowering total cholesterol, LDL, and systolic and diastolic blood pressure, but the effects are moderate and unlikely to be large enough to lower this patient's values into the normal range. While this patient's diabetes is under control, her hypertension places her at risk for microvascular complications of diabetes, thus making it necessary to reevaluate her current medication adherence, doses of benazepril for hypertension and simvastatin for hyperlipidemia, and duration of therapy. She would benefit from meeting with a nutritionist because packaged frozen dinners can be high in sodium, and this may be elevating her blood pressure. Adding exercise to her weekly routine could also help with weight control and overall cardiovascular health. The data supporting benefits of St. John's wort in patients with hot

flashes are preliminary but show promise. Good data support use of the herb to alleviate symptoms of mild to moderate depression when used for up to 1 year. However, this patient is not a good candidate for St. John's wort (a cytochrome P450 1A2, 2C9, 3A4 inducer) because of her prescription drug use and the potential for herb-drug interactions. Several dietary supplements reviewed in this chapter (garlic, ginkgo, and ginseng) may have antiplatelet effects that could be additive with ibuprofen. If this patient were also taking warfarin, additional interactions could occur with coenzyme Q10 (vitamin K-like structure), St. John's wort, and melatonin (in vitro decreased prothrombin time), leading to a decreased warfarin effect, or with glucosamine (increased international normalized ratio), leading to an increased warfarin effect.

65

Rational Prescribing & Prescription Writing

Paul W. Lofholm, PharmD, &
Bertram G. Katzung, MD, PhD

Once a patient with a clinical problem has been evaluated and a diagnosis has been reached, the practitioner can often select from a variety of therapeutic approaches. Medication, surgery, psychiatric treatment, radiation, physical therapy, health education, counseling, further consultation (second opinions), and no therapy are some of the options available. Of these options, drug therapy is by far the one most frequently chosen. In most cases, this requires the writing of a prescription. A written prescription is the prescriber's order to prepare or dispense a specific treatment—usually medication—for a specific patient. When a patient comes for an office visit, the physician or other authorized health professional prescribes medications 67% of the time, and an average of one prescription is written per office visit because more than one prescription may be written at a single visit.

In this chapter, a plan for prescribing is presented. The physical form of the prescription, common prescribing errors, and legal requirements that govern various features of the prescribing process are then discussed. Finally, some of the social and economic factors involved in prescribing and drug use are described.

RATIONAL PRESCRIBING

Like any other process in health care, writing a prescription should be based on a series of rational steps as follows:

1. **Make a specific diagnosis:** Prescriptions based merely on a desire to satisfy the patient's psychological need for some type of therapy are often unsatisfactory and may result in adverse effects. A specific diagnosis, even if it is tentative, is required to move to the next step. For example, in a patient with a probable diagnosis of rheumatoid arthritis, the diagnosis and the reasoning underlying it should be clear and should be shared with the patient.
2. **Consider the pathophysiologic implications of the diagnosis:** If the disorder is well understood, the prescriber is in a much better position to offer effective therapy.

For example, increasing knowledge about the mediators of inflammation makes possible more effective use of nonsteroidal anti-inflammatory drugs (NSAIDs) and other agents used in rheumatoid arthritis. The patient should be provided with the appropriate level and amount of information about the pathophysiology. Many pharmacies, websites, and disease-oriented public and private agencies (eg, Arthritis Foundation, American Heart Association, American Cancer Society, etc) provide information sheets suitable for patients.

3. **Select a specific therapeutic objective:** A therapeutic objective should be chosen for each of the pathophysiologic processes defined in the preceding step. In a patient with rheumatoid arthritis, relief of pain by reduction of the inflammatory process is one of the major therapeutic goals that identifies the drug groups that should be considered. Arresting the course of the disease process in rheumatoid arthritis is a different therapeutic goal, which might lead to consideration of additional drug groups and prescriptions.
4. **Select a drug of choice:** One or more drug groups will be suggested by each of the therapeutic goals specified in the preceding step. Selection of a drug of choice from among these groups follows from a consideration of the specific characteristics of the patient and the clinical presentation, a selection process that has been emphasized as part of "precision medicine." For certain drugs, characteristics such as age, other diseases, and other drugs being taken (because of the risk of duplicative therapy or drug-drug interactions) are extremely important in determining the most suitable drug for management of the present complaint. As the tools of precision medicine provide more detailed information (eg, mutations of drug metabolizing enzymes—pharmacogenomics), the selection process will become more focused. In the example of the patient with probable rheumatoid arthritis, it would be important to know whether the patient has a history of aspirin intolerance or ulcer disease, whether the cost of medication is an

especially important factor and the nature of the patient's insurance coverage, and whether there is a need for once-daily dosing. Based on this information, a drug would probably be selected from the NSAID group. If the patient does not have ulcer disease but does have a need for low-cost treatment, ibuprofen or naproxen would be a rational choice.

5. **Determine the appropriate dosing regimen:** The dosing regimen is determined primarily by the pharmacokinetics of the drug in that patient. If the patient is known to have disease of the organs required for elimination of the drug selected, adjustment of the average regimen is needed. For a drug such as ibuprofen, which is eliminated mainly by the kidneys, renal function should be assessed. If renal function is normal, the half-life of ibuprofen (about 2 hours) requires administration three or four times daily. The dose suggested in this book, drug handbooks, and the manufacturer's literature is 400–800 mg four times daily.
6. **Devise a plan for monitoring the drug's action and determine an end point for therapy:** The prescriber should be able to describe to the patient the kinds of drug effects that will be monitored and in what way, including laboratory tests (if necessary) and signs and symptoms that the patient should report. For conditions that call for a limited course of therapy (eg, most infections), the duration of therapy should be made clear so that the patient does not stop taking the drug prematurely and understands why the prescription probably need not be renewed. For the patient with rheumatoid arthritis, the need for prolonged—perhaps indefinite—therapy should be explained, including how to obtain refills. The prescriber should also specify any changes in the patient's condition that would call for changes in therapy. For example, in the patient with rheumatoid arthritis, development of gastrointestinal bleeding would require an immediate change in drug therapy and a prompt workup of the bleeding. Major toxicities that require immediate attention should be explained clearly to the patient.
7. **Plan a program of patient education:** The prescriber and other members of the health team should be prepared to repeat, extend, and reinforce the information transmitted to the patient as often as necessary. The more toxic the drug prescribed, the greater the importance of this educational program. The importance of informing and involving the patient in each of the above steps must be recognized, as shown by experience with teratogenic drugs (see Chapter 59). Many pharmacies routinely provide this type of information with each prescription filled, but the prescriber must not assume that this will occur.

THE PRESCRIPTION

Although a prescription can be written on any piece of paper (as long as all of the legal elements are present), it usually takes a specific form. A typical printed prescription form for outpatients is shown in Figure 65–1.

In the traditional hospital setting, drugs have been prescribed on a particular page of the patient's hospital chart called the **physician's order sheet (POS)** or **chart order**. In the electronic medical

FIGURE 65–1 Common form of outpatient prescription. Circled numbers are explained in the text.

records environment, prescriptions are executed via electronic order entry. The contents of that prescription are specified in the medical staff rules by the hospital's Pharmacy and Therapeutics Committee or similar authority. The patient's name is typed or written on the form; the orders consist of the name and strength of the medication, the dose, the route and frequency of administration, the date, other pertinent information, and the signature of the prescriber. If the duration of therapy or the number of doses is not specified (which is often the case), the medication is continued until the prescriber discontinues the order or until it is terminated as a matter of policy routine, eg, a stop-order policy.

A typical chart order might be as follows:

3/12/16

10:30 A.M.

(1) Ampicillin 500 mg IV q6h 5 days

(2) Aspirin 0.6 g per rectum q6h prn temp over 101

[Signed] Janet B. Doe, MD

Thus, the elements of the hospital chart order are equivalent to the central elements (5, 8–11, 15) of the outpatient prescription.

ELEMENTS OF THE PRESCRIPTION

The first four elements (see circled numerals in Figure 65–1) of the outpatient prescription establish the identity of the prescriber: name, license classification (ie, professional degree), address, and office telephone number. Before dispensing a prescription, the pharmacist must establish the prescriber's bona fides and should be able to contact the prescriber by telephone if any questions arise.

Element [5] is the date on which the prescription was written. It should be near the top of the prescription form or at the beginning (left margin) of the chart order. Since the order has legal significance and usually has some temporal relationship to the date of the patient-prescriber interview, a pharmacist should refuse to fill a prescription without verification by telephone if too much time has elapsed since its writing.

Elements [6] and [7] identify the patient by name and address. The patient's name and full address should be clearly spelled out.

The body of the prescription contains the elements [8] to [11] that specify the medication, the strength and quantity to be dispensed, the dosage, and complete directions for use. When writing the drug name (element [8]), either the brand name (proprietary name) or the generic name (nonproprietary name) may be used. Reasons for using one or the other are discussed below. The strength of the medication [9] should be written in metric units. However, the prescriber should be familiar with both systems now in use: metric and apothecary. For practical purposes, the following approximate conversions are useful:

1 grain (gr) = 0.065 grams (g), often rounded to 60 milligrams (mg)

15 gr = 1 g

1 ounce (oz) by volume = 30 milliliters (mL)

1 teaspoonful (tsp) = 5 mL

1 tablespoonful (tbsp) = 15 mL

1 quart (qt) = 1000 mL

1 minim = 1 drop (gtt)

20 drops = 1 mL

2.2 pounds (lb) = 1 kilogram (kg)

The strength of a solution is usually expressed as the quantity of solute in sufficient solvent to make 100 mL; for instance, 20% potassium chloride solution is 20 grams of KCl per deciliter (g/dL) of final solution. Both the concentration and the volume should be explicitly written out.

The quantity of medication prescribed should reflect the anticipated duration of therapy, the cost, the need for continued contact with the clinic or physician, the potential for abuse, and the potential for toxicity or overdose. Consideration should be given also to the standard sizes in which the product is available and whether this is the initial prescription of the drug or a repeat prescription or refill. If 10 days of therapy are required to effectively cure a streptococcal infection, an appropriate quantity for the full course should be prescribed. Birth control pills are often prescribed for 1 year or until the next examination is due; however, some patients may not be able to afford a year's supply at one time; therefore, a 3-month supply might be ordered, with refill instructions to renew three times or for 1 year (element [12]). Some third-party (insurance) plans limit the amount of medicine that can be dispensed—often to only one month's supply. Finally, when first prescribing medications that are to be used for the treatment of a chronic disease, the initial quantity should be small, with refills for larger quantities. The purpose of beginning treatment with a small quantity of drug is to reduce the cost if the patient cannot tolerate it. Once it is determined that intolerance is not a problem, a larger quantity purchased less frequently is sometimes less expensive.

The directions for use (element [11]) must be both drug-specific and patient-specific. The simpler the directions, the better; and the fewer the number of doses (and drugs) per day, the better. Patient noncompliance (also known as nonadherence, failure to adhere to the drug regimen) is a major cause of treatment failure. To help patients remember to take their medications, prescribers often give an instruction that medications be taken at or around mealtimes and at bedtime. However, it is important to inquire about the patient's eating habits and other lifestyle patterns, because many patients do not eat three regularly spaced meals a day.

The instructions on how and when to take medications, the duration of therapy, and the purpose of the medication must be explained to each patient both by the prescriber and by the pharmacist. (Neither should assume that the other will do it.) Furthermore, the drug name, the purpose for which it is given, and the duration of therapy should be written on each label so that the drug may be identified easily in case of overdose. An instruction to "take as directed" may save the time it takes to write the orders out but often leads to noncompliance, patient confusion, and medication error. The directions for use must be clear and concise to prevent toxicity and to obtain the greatest benefits from therapy.

Although directions for use are no longer written in Latin, many Latin apothecary abbreviations (and some others included below) are still in use. Knowledge of these abbreviations is essential for the dispensing pharmacist and often useful for the prescriber. Some of the abbreviations still used are listed in Table 65-1.

Note: It is always safer to write out the direction without abbreviating.

Elements [12] to [14] of the prescription include refill information, waiver of the requirement for childproof containers, and additional labeling instructions (eg, warnings such as "may cause drowsiness," "do not drink alcohol"). Pharmacists put the name of the medication on the label unless directed otherwise by the prescriber, and some medications have the name of the drug stamped or imprinted on the tablet or capsule. Pharmacists must place the expiration date for the drug on the label. If the patient or prescriber does not request waiver of childproof containers, the pharmacist or dispenser must place the medication in such a container. Pharmacists may not refill a prescription medication without authorization from the prescriber. Prescribers may grant authorization to renew prescriptions at the time of writing the prescription or over the telephone or electronically. Elements [15] to [17] are the prescriber's signature and other identification data such as National Provider Identification (NPI), Drug Enforcement Administration (DEA) number, or State License number.

PREScribing ERRORS

Unfortunately, prescribing errors are common. Several groups provide online information regarding practices designed to reduce or document such errors, eg, Institute for Safe Medication Practices (ISMP; <http://www.ismp.org/>) and National Coordinating Council for Medication Error Reporting and Prevention Program (MERP; <http://www.nccmerp.org/about-medication-errors>).

TABLE 65-1 Abbreviations used in prescriptions and chart orders.

Abbreviation	Explanation	Abbreviation	Explanation
ā	before	PO	by mouth
ac	before meals	PR	per rectum
agit	shake, stir	prn	when needed
Aq	water	q	every
Aq dest	distilled water	qam, om	every morning
bid	twice a day	qd (do not use)	every day (write "daily")
ċ	with	qh, q1h	every hour
cap	capsule	q2h, q3h, etc	every 2 hours, every 3 hours, etc
D5W, D ₅ W	dextrose 5% in water	qhs	every night at bedtime
dil	dissolve dilute	qid	four times a day
disp, dis	dispense	qod (do not use)	every other day
elix	elixir	qs	sufficient quantity
ext	extract	rept, repet	may be repeated
g	gram	Rx	take
gr	grain	̄	without
gtt	drops	SC, SQ	subcutaneous
h	hour	sid (veterinary)	once a day
hs	at bedtime	Sig, S	label
IA	intra-arterial	sos	if needed
IM	intramuscular	̄̄, ss	one-half
IV	intravenous	stat	at once
IVPB	IV piggyback	sup, supp	suppository
kg	kilogram	susp	suspension
mcg, µg (do not use)	microgram (always write out "microgram")	tab	tablet
mEq, meq	milliequivalent	tbsp, T (do not use)	tablespoon (always write out "15 mL")
mg	milligram	tid	three times a day
no	number	Tr, tinct	tincture
non rep	do not repeat	tsp (do not use)	teaspoon (always write out "5 mL")
OD	right eye	U (do not use)	units (always write out "units")
OS, OL	left eye	vag	vaginal
OTC	over-the-counter	i, ii, iii, iv, etc	one, two, three, four, etc
OU	both eyes	℥ (do not use)	dram (in fluid measure 3.7 mL)
̄	after	℥ (do not use)	ounce (in fluid measure 29.6 mL)
pc	after meals		

All prescription orders should be legible, unambiguous, dated (and timed in the case of a chart order), and signed clearly for optimal communication between prescriber, pharmacist, and nurse. Furthermore, a good prescription or chart order should contain sufficient information to permit the pharmacist or nurse to discover possible errors before the drug is dispensed or administered.

Certain types of prescribing errors are particularly common. These include errors involving omission of needed information; poor writing perhaps leading to errors of drug dose or timing; and prescription of drugs that are inappropriate for the specific situation.

OMISSION OF INFORMATION

Errors of omission are common in hospital orders and may include instructions to "resume pre-op meds," which assumes that a full and accurate record of the "pre-op meds" is available; "continue present IV fluids," which fails to state exactly what fluids are to be given, in what volume, and over what time period; or "continue eye drops," which omits mention of which eye is to be treated as well as the drug, concentration, and frequency of administration. Chart orders may also fail to discontinue a prior medication when a new one is begun; may fail to state whether a regular or

long-acting form is to be used; may fail to specify a strength or notation for long-acting forms; or may authorize “as needed” (prn) use that fails to state what conditions will justify the need.

POOR PRESCRIPTION WRITING

Poor prescription writing is traditionally exemplified by illegible handwriting. However, other types of poor writing are common and often more dangerous. One of the most important is the misplaced or ambiguous decimal point. Thus “.1” is easily misread as “1,” a tenfold overdose, if the decimal point is not unmistakably clear. This danger is easily avoided by always preceding the decimal point with a zero. On the other hand, appending an unnecessary zero after a decimal point increases the risk of a tenfold overdose, because “1.0 mg” is easily misread as “10 mg,” whereas “1 mg” is not. The slash or virgule (“/”) was traditionally used as a substitute for a decimal point. This should be abandoned because it is too easily misread as the numeral “1.” Similarly, the abbreviation “U” for units should never be used because “10 U” is easily misread as “100”; the word “units” should *always* be written out. Doses in micrograms should always have this unit written out because the abbreviated form (“μg”) is very easily misread as “mg,” a 1000-fold overdose! Orders for drugs specifying only the number of dosage units and not the total dose required should not be filled if more than one size dosage unit exists for that drug. For example, ordering “one ampule of furosemide” is unacceptable because furosemide is available in ampules that contain 20, 40, or 100 mg of the drug. The abbreviation “OD” should be used (if at all) only to mean “the right eye”; it has been used for “every day” and has caused inappropriate administration of drugs into the eye. Similarly, “Q.D.” or “QD” should not be used because it is often read as “QID,” resulting in four daily doses instead of one. Acronyms and abbreviations such as “ASA” (aspirin), “5-ASA” (5-aminosalicylic acid), “6MP” (6-mercaptopurine), etc, should not be used; drug names should be written out. Unclear handwriting can be lethal when drugs with similar names but very different effects are available, eg, acetazolamide and acetohexamide, methotrexate and metolazone. In this situation, errors are best avoided by noting the indication for the drug in the body of the prescription, eg, “acetazolamide, for glaucoma.” Pharmacy and Therapeutics committees have developed some additional principles to lessen errors, such as a High-Alert Medication list and using a comma (in the USA) when the dose exceeds 999.

INAPPROPRIATE DRUG PRESCRIPTIONS

Prescribing an inappropriate drug for a particular patient often results from failure to recognize contraindications imposed by other diseases the patient may have, failure to obtain information about other drugs the patient is taking (including over-the-counter drugs), or failure to recognize possible physicochemical incompatibilities between drugs that may react with each other. Contraindications to drugs in the presence of other diseases or pharmacokinetic characteristics are listed in the discussions of the drugs described in this book. The manufacturer’s package insert usually contains similar information. Many of the important drug

interactions are listed in Chapter 66 of this book as well as in package inserts.

Physicochemical incompatibilities are of particular concern when parenteral administration is planned. For example, certain insulin preparations should not be mixed. Similarly, the simultaneous administration of antacids or products high in metal content may compromise the absorption of many drugs in the intestine, eg, tetracyclines. The package insert and the *Handbook on Injectable Drugs* (see References) are good sources for this information.

E-PRESCRIBING

Seventy percent of prescriptions in the USA are now E-prescribed. Congress has passed legislation related to E-prescribing, including Medicare Improvement for Patients and Providers Act (MIPPA) and the Medicare and Medicaid Electronic Health Record Incentive Program or the “meaningful use program.” E-prescribing provides an electronic flow of information between the prescriber, intermediary, pharmacy, and health plan. The health plan can provide information on patient eligibility, formulary, benefits, costs, and sometimes, a medication history. The prescriber selects the medication, strength, dosage form, quantity, and directions for use and the prescription is transmitted to the pharmacy where the appropriate data fields are populated. The pharmacist reviews the order and, if appropriate, dispenses the prescription. The electronic system must be Health Insurance Portability and Accountability Act (HIPAA)-compliant, and there is often a business association agreement between the parties involved.

Prescribers can obtain decision support information such as disease-drug and drug-drug interaction information or cost information prior to prescribing as part of the health plan information. Prescriptions can be clear in their writing, but pull-down drug lists can create new errors. Prescription renewals can be processed electronically and drug misuse or abuse may be identifiable. Theoretically, time to process prescription orders should be reduced and patients would have their medication ready when they arrive at the pharmacy.

The DEA has issued rules for e-prescribing of controlled substances. Currently, only registered prescribers can e-prescribe, and there will be several independent identification proofing sources required: a unique pin number, or retinal scan, or a finger print. The objective is to prevent drug diversion. DEA registrants, including pharmacies and physicians, can order controlled drugs via computer using a specific form once they are certified (Controlled Substances Ordering System, CSOS).

COMPLIANCE

Compliance (also called adherence) is the extent to which patients follow treatment instructions. There are four types of noncompliance leading to medication errors and increased health care costs as given below:

1. The patient fails to obtain the medication. Some studies suggest that one third of patients never have their prescriptions filled. Patients usually leave the hospital without obtaining

their discharge medications because the hospital is not reimbursed for them by the insurer; others leave the hospital without having their prehospitalization medications resumed. In many cases, patients cannot afford the medications prescribed.

2. The patient fails to take the medication as prescribed. Examples include wrong dosage, wrong frequency of administration, improper timing or sequencing of administration, wrong route or technique of administration, or taking medication for the wrong purpose. This usually results from inadequate communication between the patient, the prescriber, and the pharmacist.
3. The patient prematurely discontinues the medication. This can occur, for instance, if the patient incorrectly assumes that the medication is no longer needed because the bottle is empty or symptomatic improvement has occurred.
4. The patient (or another person) takes medication inappropriately. For example, the patient may share a medication with others for any of several reasons.

Several factors encourage noncompliance. Some diseases cause no symptoms (eg, hypertension); patients with these diseases therefore have no symptoms to remind them to take their medications. Patients with painful conditions such as arthritis may continually change medications in the hope of finding a better one. Characteristics of the therapy itself can limit the degree of compliance; patients taking a drug once a day are much more likely to be compliant than those taking a drug four times a day. Various patient factors also play a role in compliance. Patients living alone are much less likely to be compliant than married patients of the same age. Packaging may also be a deterrent to compliance—elderly arthritic patients often have difficulty opening their medication containers. Lack of transportation as well as various cultural or personal beliefs about medications are likewise barriers to compliance. For example, some parents refuse to allow their children to be vaccinated because of a misguided fear of autism.

Strategies for improving compliance include enhanced communication between the patient and health care team members; assessment of personal, social, and economic conditions (often reflected in the patient's lifestyle); development of a routine for taking medications (eg, at mealtimes if the patient has regular meals); provision of systems to assist taking medications (ie, containers that separate drug doses by day of the week, or medication alarm clocks that remind patients to take their medications); and mailing of refill reminders by the pharmacist to patients taking drugs chronically. The patient who is likely to discontinue a medication because of a perceived drug-related problem should receive instruction about how to monitor and understand the effects of the medication. Compliance can often be improved by enlisting the patient's active participation in the treatment.

LEGAL FACTORS (USA)

The United States government recognizes two classes of drugs: (1) over-the-counter (OTC) drugs and (2) those that require a prescription from a licensed prescriber (Rx Only). OTC drugs are those

that can be safely self-administered by the layman for self-limiting conditions and for which appropriate labels can be written for lay comprehension (see Chapter 63). Half of all drug doses consumed by the American public are OTC drugs. In 2014 in the USA, \$373.9 billion was spent on prescription drugs and \$30.7 billion was spent on OTC drugs, more than any other country.

Physicians, dentists, podiatrists, and veterinarians—and, in many states, specialized pharmacists, nurses, physician's assistants, and optometrists—are granted authority to prescribe certain drugs (those bearing the federal legend statement, "Rx Only") on the basis of their training in diagnosis and treatment (see Box: Who May Prescribe?). Depending on the state, mid-level practitioners may prescribe/furnish prescriptions. Pharmacists are authorized to dispense prescriptions pursuant to a prescriber's order provided that the medication order is appropriate and rational for the patient. Nurses are authorized to administer medications to patients subject to a prescriber's order.

Because of the multiplicity of third-party payers (health insurers) and Medicare and Medicaid claimants, the concept of electronic processing of prescriptions ("e-prescribing") has become urgent. (Further information about e-prescribing may be found at <http://www.cms.gov/Medicare/E-Health/Eprescribing/>.) To further standardize electronic prescription transmission and billing, the Centers for Medicare and Medicaid (CMS) issued regulations effective in 2008 requiring all US health care providers to obtain a National Provider Identification (NPI) number. This 10-digit identifier is issued by the National Plan and Provider Enumeration System (NPPES) at <https://NPPES.cms.hhs.gov>. The purpose of the NPI is to identify all health care transactions (and associated costs) incurred by a particular practitioner with a single number.

In addition to a health care provider's unique identification number, some states require that prescriptions for controlled substances be written on tamper-resistant security prescription forms. The purpose of this legislation is to prevent forgeries and to tighten the control of prescription order forms.

The concept of a "secure" prescription form was expanded by the federal government in 2008 to all prescriptions written for Medicaid patients. Any prescription for a Medicaid patient must be written on a security form if the pharmacist is to be compensated for the prescription service. In turn, the use of "triplicate" prescription forms was eliminated and replaced with an online electronic transmission system whereby orders for Schedule II, Schedule III, and Schedule IV prescriptions are transmitted to a company that acts as a repository for these transactions. In California, it is called the CURES program (Controlled Substances Utilization Review and Evaluation System). Prescribers are provided with a record of who prescribed which controlled drug to which patient. Additional information about CURES may be found at <http://oag.ca.gov/cures-pdmp>.

In the USA, prescription drugs are controlled by the US Food and Drug Administration (FDA) as described in Chapter 1. The federal legend statement as well as the package insert are part of the packaging requirements for all prescription drugs. The package insert is the official brochure setting forth the indications, contraindications, warnings, and dosing for the drug.

The prescriber, by writing and signing a prescription order, controls who may obtain prescription drugs. The pharmacist may

Who May Prescribe?

The right to prescribe drugs has traditionally been the responsibility of the physician, dentist, podiatrist, or veterinarian. Prescribing now includes—in a number of states and in varying degrees—pharmacists, nurse practitioners, nurse midwives, physician's assistants, and optometrists (see below; Table 65–2). In the future, physical therapists may be licensed to prescribe drugs relevant to their practice. The development of large health maintenance organizations has greatly strengthened this expansion of prescribing rights because it offers these extremely powerful economic bodies a way to reduce their expenses.

The primary organizations controlling the privilege of prescribing in the USA are the state boards, under the powers delegated to them by the state legislatures. Many state boards have attempted to reserve some measure of the primary responsibility for prescribing to physicians by requiring that the ancillary professional work with or under a physician according to a specific protocol. In the state of California, this protocol must include a statement of the training, supervision, and documentation requirements of the arrangement and must specify

referral requirements, limitations to the list of drugs that may be prescribed (ie, a formulary), and a method of evaluation by the supervising physician. The protocol must be in writing and must be periodically updated.

The following rules govern prescribing by nonphysicians in the various states at the time of this writing.

In almost all states, nurse practitioners (NPs) and physician assistants (PAs) may prescribe with or without physician supervision depending on the state. Likewise, optometrists may prescribe selected formulary drugs for ophthalmologic indications.

Pharmacists can initiate prescriptions in three states: Montana, New Mexico, and North Carolina. They may practice with physicians in collaborative drug therapy management (CDTM) programs in 47 states—all except New York, Maine, Oklahoma, and Alabama. Pharmacists may prescribe controlled substances under physician supervision in California, Massachusetts, Montana, New Mexico, North Carolina, Ohio, and Washington.

New Mexico grants prescribing authority to medical psychologists with advanced training.

purchase these drugs, but they may be dispensed only on the order of a legally qualified prescriber. Thus, a **prescription** is actually three things: the **prescriber's order in the patient's chart**, the **written order to which the pharmacist refers** when dispensing, and the patient's **medication container with a label affixed**.

Whereas the US FDA controls the drugs and their labeling and distribution, the state legislatures control who may prescribe drugs through their licensing boards, eg, the Board of Medical Examiners. Prescribers must pass examinations, pay fees, and—in the case of some states and some professions—meet other requirements for

TABLE 65–2 Prescribing authority of certain allied health professionals in selected states.

State	Pharmacists	Nurse Practitioners	Physician's Assistants	Optometrists
California	Yes, under protocol ¹ ; must be trained in clinical practice	Yes ²	Yes, under protocol ¹	Yes; limited to certain drug classes
Florida	Yes, according to state formulary; protocol not required	Yes ²	Yes ²	Yes; limited to certain drug classes
Michigan	Yes, under protocol; must be specially qualified by education, training, or experience	Yes ²	Yes ²	Yes; limited to certain drug classes
Mississippi	Yes, under protocol in an institutional setting	Yes, ² under narrowly specified conditions	No	Yes; limited to certain drug classes
Nevada	Yes, under protocol, within a licensed medical facility	Yes ²	Yes ²	Yes; limited to certain drug classes
New Mexico	Yes, under protocol, must be "pharmacist clinician"	Yes; do not need physician supervision	Yes ²	Yes; limited to certain drug classes
North Dakota	Yes, under protocol in an institutional setting	Yes; do not need physician supervision	Yes ²	Yes; limited to certain drug classes
Oregon	Yes, under guidelines set by the state board	Yes; do not need physician supervision	Yes ²	Yes; limited to certain drug classes
Texas	Yes, under protocol set for a particular patient in an institutional setting	Yes; do not need physician supervision	Yes	Yes; limited to certain drug classes
Washington	Yes, under guidelines set by the state board	Yes; do not need physician supervision	Yes ²	Yes; limited to certain drug classes

¹Under protocol; see Box: Who May Prescribe?

²In collaboration with or under the supervision of a physician.

TABLE 65-3 Classification of controlled substances.
(See Inside Front Cover for examples.)

Schedule	Potential for Abuse	Other Comments
I	High	No accepted medical use; lack of accepted safety as drug.
II	High	Current accepted medical use. Abuse may lead to psychological or physical dependence.
III	Less than I or II	Current accepted medical use. Moderate or low potential for physical dependence and high potential for psychological dependence.
IV	Less than III	Current accepted medical use. Limited potential for dependence.
V	Less than IV	Current accepted medical use. Limited dependence possible.

relicensure such as continuing education. If these requirements are met, the prescriber is licensed to order dispensing of drugs.

The FDA Amendments Act of 2007 gave the FDA authority to require a **Risk Evaluation and Mitigation Strategy (REMS)** from manufacturers to ensure that the benefits of a drug or biological product outweigh its risks. The goal of this strategy is to inform physicians of the emphasized risks and benefits. Furthermore, some drugs have “boxed warnings” to elucidate their risks as part of FDA-mandated labeling.

The federal government and the states further impose special restrictions on drugs according to their perceived potential for abuse (Table 65-3). Such drugs include opioids, hallucinogens, stimulants, depressants, and anabolic steroids. Special requirements must be met when these drugs are to be prescribed. The Controlled Drug Act requires prescribers and dispensers to register with the Drug Enforcement Agency (DEA), pay a fee, receive a personal registration number, and keep records of all controlled drugs prescribed or dispensed. Every time a controlled drug is prescribed, a valid DEA number must appear on the prescription. In the USA, there is an opioid epidemic with an increase in overdoses. To combat this public health trend, prescriber education, tracking of prescribing patterns, limitations on amounts prescribed, and target education are being instituted.

Prescriptions for substances with a high potential for abuse (Schedule II drugs) cannot be refilled without a new prescription. However, multiple prescriptions for the same drug may be written with instructions not to dispense before a certain date and up to a total of 90 days. Prescriptions for Schedules III, IV, and V can be refilled if ordered, but there is a five-refill maximum, and in no case may the prescription be refilled after 6 months from the date of writing. Schedule II drug orders may not be transmitted over the telephone, and some states require a tamper-resistant security prescription blank to reduce the chances for drug diversion.

These restrictive prescribing laws are intended to limit the amount of drugs of abuse that are made available to the public.

Unfortunately, the inconvenience occasioned by these laws—and an unwarranted fear by medical professionals themselves

regarding the risk of patient tolerance and addiction—continues to hamper adequate treatment of patients with terminal conditions. This has been shown to be particularly true in children and elderly patients with cancer. *There is no excuse for inadequate treatment of pain in a terminal patient; not only is addiction irrelevant in such a patient, it is actually uncommon in patients who are being treated for pain* (see Chapter 31). Unfortunately, the initiative begun several years ago to manage pain more actively has led to the overuse of opioids in patients with chronic pain, a condition that does not respond well to these drugs. Chronic use of oxycodone, hydrocodone, and methadone has resulted in a marked increase in habituation, overdoses, and deaths. As a result, most professional authorities now advise limiting the use of any opioid to acute pain only and the use of NSAIDs and other nonaddicting therapies in chronic conditions.

Some states have recognized the underutilization of pain medications in the treatment of pain associated with chronic and terminal conditions. In California, upon receipt of a copy of the order from the prescriber, eg, by fax, a pharmacist may write a prescription for a Schedule II substance for a patient under hospice care or living in a skilled nursing facility or in cases in which the patient is expected to live less than 6 months, provided that the prescriber countersigns the order (by fax); the word “exemption” with regulatory code number is written on a typical prescription, thus providing easier access for the terminally ill.

Labeled & Off-Label Uses of Drugs

In the USA, the FDA approves a drug only for the specific uses proposed and documented by the manufacturer in its New Drug Application (see Chapter 1). These approved (*labeled*) uses or indications are set forth in the package insert that accompanies the drug. For a variety of reasons, these labeled indications may not include all the conditions in which the drug might be useful. Therefore, a clinician may wish to prescribe the agent for some other, unapproved (*off-label*), clinical condition, often on the basis of adequate or even compelling scientific evidence. Federal laws governing FDA regulations and drug use place no restrictions on such unapproved use.*

Even if the patient suffers injury from the drug, its use for an unlabeled purpose does not in itself constitute “malpractice.” However, the courts may consider the package insert labeling as a complete listing of the indications for which the drug is considered safe unless the clinician can show that other use is considered safe by competent expert testimony.

Drug Safety Surveillance

Governmental drug-regulating agencies have responsibility for monitoring drug safety. In the USA, the FDA-sponsored **Med Watch** program collects data on safety and adverse drug effects (ADEs)

*“Once a product has been approved for marketing, a physician may prescribe it for uses or in treatment regimens or patient populations that are not included in the approved labeling. Such ‘unapproved’ or, more precisely, ‘unlabeled’ uses may be appropriate and rational in certain circumstances, and may, in fact, reflect approaches to drug therapy that have been extensively reported in medical literature.”—FDA Drug Bull 1982;12:4.

through mandatory reporting by drug manufacturers and voluntary reporting by health care practitioners. Practitioners may submit reports on any suspected adverse drug (or medical device) effect using a simple form obtainable from <http://www.fda.gov/medwatch/index.html>. The FDA is expected to use these data to establish an adverse effect rate. It is not clear that the FDA has sufficient resources at present to carry out this mandate, but they are empowered to take further regulatory actions if deemed necessary. A similar vaccine-reporting program is in place to monitor vaccine safety (VAERS, vaccine adverse event reporting system). The FDA homepage can be found at <https://vaers.hhs.gov>.

The FDA has also increased requirements for labeling on drugs that carry special risks. Dispensers of medications are required to distribute “Med Guides” to patients when these medications are dispensed. These guides are generated by the manufacturers of the medications. In addition, pharmacists often provide patient educational materials that describe the drug, its use, adverse effects, storage requirements, methods of administration, what to do when a dose is missed, and the potential need for ongoing therapy.

SOCIOECONOMIC FACTORS

The Cost of Prescriptions

Multiple factors are involved in the pricing of pharmaceuticals. Research costs, marketing costs, production costs, shipping costs, regulatory costs, and profit all contribute to a drug's price. Insurance companies pay for the drug because an extensive formulary is mandated by regulations. Federal law and regulations require Medicare Part D pharmacy and therapeutics committees to make prescription drug coverage decisions based on scientific evidence and standards of practice, and also to prevent discrimination in a patient's drug therapy. Because these companies are publicly owned, the shareholders exert a strong influence to maximize profits. While the cost to make the drug may be 20% (or less) of the wholesale price, the aforementioned costs contribute to the cost of the drug to the pharmacist or physician. Greed and the excessive influence of shareholder funds (as opposed to the interests of consumers) add another component of cost and have sometimes resulted in startling increases in the price of long-established drugs (which have no current development costs) as well as newer ones. In the case of pyrimethamine, a simple and long-established drug used for toxoplasmosis, the US price increased from approximately \$13/tablet to \$750/tablet in 2015 when a new company acquired the rights to this drug. In 2016, the price of the formulation of epinephrine most commonly used for anaphylaxis (Epi-Pen) increased from \$50 to \$300 per single dose, even though no changes were made in the drug, the vehicle, or the injection unit.

A more complex situation applies to the pricing of new, complex molecules that, unlike the above examples, required massive research, development, and manufacturing investment, eg, the new agents used for hepatitis B and C. These agents are extremely expensive in the USA (\$75,000–\$120,000 for one course of treatment), but the manufacturers justify the cost as being less than the alternative (which is often a liver transplant). In fact, these

“specialty drugs” represent one third of the drug spending in the USA.

Because the US Congress currently prohibits price negotiations by the largest purchaser of drugs (Medicare), the public has no protection from excessive pricing by manufacturers. Currently, only the Veteran's Administration and the largest private pharmacy benefits manager (PBM) agencies are able to negotiate prices, and as a result, drug expenses constitute a large and growing burden to patients, Medicare, and private health insurers.

Generic Prescribing

Generic drug dispensing represents 10% of the total US drug expense but 90% of the drugs dispensed. Prescribing by generic name offers the pharmacist flexibility in selecting the particular drug product to fill the order and offers the patient a potential savings when there is price competition. For example, the brand name of a popular sedative is *Valium*. The generic (public non-proprietary) name of the same chemical substance adopted by United States Adopted Names (USAN) and approved by the FDA is *diazepam*. All diazepam drug products in the USA meet the pharmaceutical standards expressed in the *United States Pharmacopeia (USP)*. However, there are several manufacturers, and prices vary. For drugs in common use, the difference in cost between the trade-named product and generic products varies from less than twofold to more than 100-fold. For drugs with a limited market (eg, pyrimethamine, Epi-Pen), the incentive for generic manufacturing and marketing is very low, so only one or two generics (or none) may be available, and price competition is low or absent.

In most states and in most hospitals, pharmacists have the option of supplying a generically equivalent drug product even if a proprietary name has been specified in the order. If the prescriber wants a particular brand of drug product dispensed, handwritten instructions to “dispense as written” or words of similar meaning are required. Some government-subsidized health care programs and many third-party insurance payers *require* that pharmacists dispense the cheapest generically equivalent product in the inventory (generic substitution). However, the principles of drug product selection by private pharmacists do not permit substituting one therapeutic agent for another (therapeutic substitution); that is, dispensing trichlormethiazide for hydrochlorothiazide would not be permitted without the prescriber's permission even though these two diuretics may be considered pharmacodynamically equivalent. Pharmacists within managed care organizations may follow different policies; see below.

It cannot be assumed that every generic drug product is as satisfactory as the trade-named product, although examples of unsatisfactory generics are rare. Bioavailability—the effective absorption of the drug product—varies between manufacturers and sometimes between different lots of a drug produced by the same manufacturer. Despite the evidence, many practitioners avoid generic prescribing, thereby increasing medical costs. In the case of a very small number of drugs, which usually have a low therapeutic index, poor solubility, or a high ratio of inert ingredients to active drug content, a specific manufacturer's product may give more consistent results. In the case of life-threatening diseases,

the advantages of generic substitution may be outweighed by the clinical urgency so that the prescription should be filled as written.

In an effort to codify bioequivalence information, the FDA publishes *Approved Drug Products with Therapeutic Equivalence Evaluations*, with monthly supplements, commonly called “the Orange Book.” The book contains listings of multisource products in one of two categories: Products given a code beginning with the letter “A” are considered bioequivalent to a reference standard formulation of the same drug and to all other versions of that product with a similar “A” coding. Products not considered bioequivalent are coded “B.” Of the approximately 8000 products currently listed, 90% are coded “A.” Additional code letters and numerals are appended to the initial “A” or “B” and indicate the approved route of administration and other variables.

Mandatory drug product selection on the basis of price is common practice in the USA because third-party payers (insurance companies, health maintenance organizations, etc) enforce money-saving regulations. If outside a managed care organization, the prescriber can sometimes override these controls by writing “dispense as written” on a prescription that calls for a brand-named product. However, in such cases, the patient may have to pay the difference between the dispensed product and the cheaper one.

Within most managed care organizations, formulary controls have been put in place that force the selection of less expensive medications whenever they are available. In a managed care environment, the prescriber often selects the drug group rather than a specific agent, and the pharmacist dispenses the formulary drug

from that group. For example, if a prescriber in such an organization decides that a patient needs a thiazide diuretic, the pharmacist automatically dispenses the single thiazide diuretic carried on the organization’s formulary. As noted below, the choice of drugs for the organization’s formulary may change from time to time, depending on negotiation of prices and rebates with different manufacturers.

Other Cost Factors

The private pharmacy bases its charges on the cost of the drug plus a fee for providing a professional service. Each time a prescription is dispensed, there is a fee. The prescriber controls the frequency of filling prescriptions by authorizing refills and specifying the quantity to be dispensed. However, for medications used for chronic illnesses, the quantity covered by insurance may be limited to the amount used in 1 month or 30 days. Thus, the prescriber can save the patient money by prescribing standard sizes (so that drugs do not have to be repackaged) and, when chronic treatment is involved, by ordering the largest quantity consistent with safety, expense, and third-party plan. Optimal prescribing for cost savings often involves consultation between the prescriber and the pharmacist. Because of continuing increases in the wholesale prices of drugs in the USA, prescription costs have risen dramatically over the past three decades, and with the passage of the Affordable Care Act (ACA), prescription volume increased while hospital services decreased.

Important Drug Interactions & Their Mechanisms

John R. Horn, PharmD, FCCP

One of the factors that can alter the response to drugs is the concurrent administration of other drugs. There are several mechanisms by which drugs may interact, but most can be categorized as pharmacokinetic (absorption, distribution, metabolism, excretion), pharmacodynamic (additive, synergistic, or antagonistic effects), or combined interactions. The general principles of pharmacokinetics are discussed in Chapters 3 and 4; the general principles of pharmacodynamics are discussed in Chapter 2.

Botanical medications (“herbals”) may interact with each other or with conventional drugs. Unfortunately, botanicals are much less well studied than other drugs, so information about their interactions is scanty. Pharmacodynamic herbal interactions are described in Chapter 64. Pharmacokinetic interactions that have been documented (eg, St. John’s wort) are listed in Table 66–1.

Knowledge of the mechanism by which a given drug interaction occurs is often clinically useful, since the mechanism may influence both the time course and the methods of circumventing the interaction. Some important drug interactions occur as a result of two or more mechanisms.

■ PREDICTABILITY OF DRUG INTERACTIONS

The designations listed in Table 66–1 are used here to *estimate* the predictability of the drug interactions. These estimates are intended to indicate simply whether or not the interaction will occur, and they do not always mean that the interaction is likely to produce an adverse effect. Whether or not the interaction occurs (precipitant drug produces a measurable change in the object drug action) and produces an adverse effect depends on both patient- and drug-specific factors. Patient factors can include intrinsic drug clearance, genetics, gender, concurrent diseases, and diet.

Drug-specific factors include dose, route of administration, drug formulation, and the sequence of drug administration. The most important factor that can mitigate the risk of patient harm is recognition by the prescriber of a potential interaction followed by appropriate action.

PHARMACOKINETIC MECHANISMS

The gastrointestinal **absorption** of drugs may be affected by concurrent use of other agents that (1) have a large surface area upon which the drug can be adsorbed, (2) bind or chelate, (3) alter gastric pH, (4) alter gastrointestinal motility, or (5) affect transport proteins such as P-glycoprotein and organic anion transporters. One must distinguish between effects on absorption *rate* and effects on *extent* of absorption. A reduction in only the absorption *rate* of a drug is seldom clinically important, whereas a reduction in the *extent* of absorption is clinically important if it results in subtherapeutic serum concentrations. Similarly, an *increase* in the extent of absorption can lead to adverse patient outcomes.

The mechanisms by which drug interactions alter drug **distribution** include (1) competition for plasma protein binding, (2) displacement from tissue binding sites, and (3) alterations in local tissue barriers, eg, P-glycoprotein inhibition in the blood-brain barrier. Although competition for plasma protein binding can increase the free concentration (and thus the effect) of the displaced drug in plasma, the increase will be transient owing to a compensatory increase in drug disposition. The clinical importance of protein binding displacement has been overemphasized; current evidence suggests that such interactions are unlikely to result in adverse effects. Displacement from tissue binding sites would tend to transiently increase the blood concentration of the displaced drug. (Text continues on page 1171.)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Acid-reducing agents	Antacids may adsorb drugs in gastrointestinal tract, thus reducing absorption. Some antacids (eg, magnesium hydroxide with aluminum hydroxide) alkalize the urine somewhat, thus altering excretion of drugs sensitive to urinary pH. H ₂ -antagonists and proton-pump inhibitors can alter the absorption of drugs requiring gastric acidity for dissolution.	<p>Antivirals: [P] Decreased absorption of antivirals that require acid for dissolution including atazanavir, fosamprenavir, indinavir, nelfinavir, rilpivirine.</p> <p>Azole antifungals: [P] Reduced gastrointestinal absorption of itraconazole, ketoconazole, and posaconazole due to increased gastric pH.</p> <p>Digoxin: [NP] Decreased gastrointestinal absorption of digoxin.</p> <p>Iron: [P] Decreased gastrointestinal absorption of iron with calcium-containing antacids.</p> <p>Kinase inhibitors: [P] Reduced gastrointestinal absorption of bosutinib, dabrafenib, dasatinib, erlotinib, idelalisib, and lapatinib due to increased gastric pH.</p> <p>Quinolones: [HP] Decreased gastrointestinal absorption of ciprofloxacin, norfloxacin, and enoxacin (and probably other quinolones).</p> <p>Rosuvastatin: [P] Decreased absorption of rosuvastatin.</p> <p>Salicylates: [P] Increased renal clearance of salicylates due to increased urine pH; occurs only with large doses of salicylates.</p> <p>Tetracyclines: [HP] Decreased gastrointestinal absorption of tetracyclines.</p> <p>Thyroxine: [NP] Reduced gastrointestinal absorption of thyroxine.</p>
Alcohol	Chronic alcoholism results in enzyme induction. Acute alcoholic intoxication tends to inhibit drug metabolism (whether person is alcoholic or not). Severe alcohol-induced hepatic dysfunction may inhibit ability to metabolize drugs. Disulfiram-like reaction in the presence of certain drugs. Additive central nervous system depression with other central nervous system depressants.	<p>Acetaminophen: [NE] Increased formation of hepatotoxic acetaminophen metabolites (in chronic alcoholics).</p> <p>Acitretin: [P] Increased conversion of acitretin to etretinate (teratogenic).</p> <p>Anticoagulants, oral: [NE] Increased hypoprothrombinemic effect with acute alcohol intoxication.</p> <p>Central nervous system depressants: [HP] Additive or synergistic central nervous system depression.</p> <p>Insulin: [NE] Acute alcohol intake may increase hypoglycemic effect of insulin (especially in fasting patients).</p> <p>Drugs that may produce a disulfiram-like reaction:</p> <p>Cephalosporins: [NP] Disulfiram-like reactions are noted with cefamandole, cefoperazone, cefotetan, and moxalactam.</p> <p>Chloral hydrate: [NP] Mechanism not established.</p> <p>Disulfiram: [HP] Inhibited aldehyde dehydrogenase.</p> <p>Metronidazole: [NP] Mechanism not established.</p> <p>Sulfonylureas: [NE] Chlorpropamide is most likely to produce a disulfiram-like reaction; acute alcohol intake may increase hypoglycemic effect (especially in fasting patients).</p>
Allopurinol	Inhibits hepatic drug-metabolizing enzymes. Febuxostat will also inhibit the metabolism of azathioprine and mercaptopurine.	<p>Anticoagulants, oral: [NP] Increased hypoprothrombinemic effect.</p> <p>Azathioprine: [P] Decreased azathioprine detoxification resulting in increased azathioprine toxicity.</p> <p>Mercaptopurine: [P] Decreased mercaptopurine metabolism resulting in increased mercaptopurine toxicity.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

TABLE 66-1 Important drug interactions. (Continued)

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Anticoagulants, oral	Susceptible to induction and inhibition of CYP2C9 (warfarin), CYP3A4 (apixaban, rivaroxaban), and P-glycoprotein (apixaban, dabigatran, edoxaban, rivaroxaban). Warfarin highly bound to plasma proteins. Anticoagulation response altered by drugs that affect clotting factor synthesis or catabolism.	<p>Drugs that may increase anticoagulant effect:</p> <p>Acetaminophen: [NE] Impaired synthesis of clotting factors at higher doses.</p> <p>Amiodarone: [P] Inhibited anticoagulant elimination.</p> <p>Anabolic steroids: [P] Altered clotting factor disposition?</p> <p>Azole antifungals: [P] Ketoconazole, itraconazole, voriconazole, and posaconazole can decrease apixaban, dabigatran, edoxaban, rivaroxaban, and perhaps warfarin elimination.</p> <p>Cimetidine: [HP] Decreased warfarin metabolism.</p> <p>Clopidogrel: [NP] Decreased warfarin metabolism and inhibits platelet function.</p> <p>Disulfiram: [P] Decreased warfarin metabolism.</p> <p>Efavirenz: [NP] Decreased warfarin metabolism.</p> <p>Fluconazole: [P] Decreased warfarin metabolism.</p> <p>Fluoxetine: [P] Decreased warfarin metabolism.</p> <p>Gemfibrozil: [NE] Mechanism not established.</p> <p>Lovastatin: [NP] Decreased warfarin metabolism.</p> <p>Macrolide antibiotics: [NP] Clarithromycin and erythromycin inhibit the metabolism of oral anticoagulants.</p> <p>Metronidazole: [P] Decreased warfarin metabolism.</p> <p>Miconazole: [NE] Decreased warfarin metabolism.</p> <p>Nonsteroidal anti-inflammatory drugs (NSAIDs): [HP] Inhibition of platelet function, gastric erosions; some agents increase hypoprothrombinemic response (unlikely with diclofenac, ibuprofen, or naproxen).</p> <p>Propafenone: [NE] Probably decreases anticoagulant elimination.</p> <p>Quinidine: [NP] Additive hypoprothrombinemia, decreased apixaban, dabigatran, edoxaban, rivaroxaban elimination.</p> <p>Ritonavir: [P] Decreased apixaban, dabigatran, edoxaban, rivaroxaban elimination.</p> <p>Salicylates: [HP] Platelet inhibition with aspirin but not with other salicylates; [P] large doses have hypoprothrombinemic effect.</p> <p>Simvastatin: [NP] Decreased warfarin metabolism.</p> <p>Sulfinpyrazone: [NE] Inhibited warfarin metabolism.</p> <p>Sulfonamides: [NE] Inhibited warfarin metabolism.</p> <p>Trimethoprim-sulfamethoxazole: [P] Decreased warfarin metabolism.</p> <p>Verapamil: [P] Decreased apixaban, dabigatran, edoxaban, rivaroxaban elimination.</p> <p><i>See also</i> Alcohol; Allopurinol.</p> <p>Drugs that may decrease anticoagulant effect:</p> <p>Aminoglutethimide: [P] Increased metabolism of anticoagulant.</p> <p>Barbiturates: [P] Increased metabolism of anticoagulant.</p> <p>Bosentan: [P] Increased metabolism of anticoagulant.</p> <p>Carbamazepine: [P] Increased elimination of anticoagulant.</p> <p>Cholestyramine: [P] Reduced absorption of anticoagulant.</p> <p>Nafacillin: [NE] Increased metabolism of anticoagulant.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Anticoagulants, oral (cont.)		<p>Phenytoin: [NE] Increased metabolism of anticoagulant. Anticoagulant effect may increase transiently at start of phenytoin therapy due to protein-binding displacement of warfarin.</p> <p>Primidone: [P] Increased metabolism of anticoagulant.</p> <p>Rifabutin: [P] Increased elimination of anticoagulant.</p> <p>Rifampin: [P] Increased elimination of anticoagulant.</p> <p>St. John's wort: [NE] Increased elimination of anticoagulant.</p> <p>Tipranavir: [NP] Increased elimination of apixaban, dabigatran, edoxaban, rivaroxaban.</p>
Antidepressants, tricyclic and heterocyclic	Inhibition of transmitter uptake into 5-HT and NE neurons. Antimuscarinic effects may be additive with other antimuscarinic drugs. Susceptible to induction and inhibition of metabolism via CYP2D6, CYP3A4, and other CYP450 enzymes.	<p>Amiodarone: [P] Decreased antidepressant metabolism. Expect similar interactions with dronedarone.</p> <p>Barbiturates: [P] Increased antidepressant metabolism.</p> <p>Bupropion: [NE] Decreased antidepressant metabolism.</p> <p>Carbamazepine: [NP] Enhanced metabolism of antidepressants.</p> <p>Cimetidine: [P] Decreased antidepressant metabolism.</p> <p>Clonidine: [P] Decreased clonidine antihypertensive effect.</p> <p>Diphenhydramine: [P] Decreased metabolism of antidepressants metabolized by CYP2D6.</p> <p>Guanadrel: [P] Decreased uptake of guanadrel into sites of action.</p> <p>Haloperidol: [P] Decreased metabolism of antidepressants metabolized by CYP2D6.</p> <p>Monoamine oxidase inhibitors (MAOIs): [NP] Some cases of excitation, hyperpyrexia, mania, and convulsions, especially with serotonergic antidepressants such as clomipramine and imipramine, but many patients have received combination without ill effects.</p> <p>Quinidine: [NP] Decreased metabolism of antidepressants metabolized by CYP2D6.</p> <p>Rifampin: [P] Increased antidepressant metabolism.</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [P] Fluoxetine and paroxetine inhibit CYP2D6 and decrease metabolism of antidepressants metabolized by this enzyme (eg, desipramine). Citalopram, sertraline, and fluvoxamine are only weak inhibitors of CYP2D6, but fluvoxamine inhibits CYP1A2 and CYP3A4 and thus can inhibit the metabolism of antidepressants metabolized by these enzymes.</p> <p>Sympathomimetics: [P] Increased pressor response to norepinephrine, epinephrine, and phenylephrine.</p> <p>Terbinafine: [P] Decreased antidepressant metabolism.</p>
Azole antifungals	Inhibition of CYP3A4 (itraconazole = ketoconazole > posaconazole > voriconazole > fluconazole). Inhibition of CYP2C9 (fluconazole, voriconazole). Inhibition of P-glycoprotein (itraconazole, ketoconazole, posaconazole). Susceptible to enzyme inducers (itraconazole, ketoconazole, voriconazole).	<p>Antivirals: [P] Decreased metabolism of amprenavir, atazanavir, boceprevir, daclatasvir, darunavir, delavirdine, etravirine, fosamprenavir, indinavir, lopinavir, maraviroc, nelfinavir, rilpivirine, ritonavir, saquinavir, and tipranavir.</p> <p>Barbiturates: [P] Increased metabolism of itraconazole, ketoconazole, voriconazole.</p> <p>Benzodiazepines: [P] Decreased metabolism of alprazolam, midazolam, triazolam.</p> <p>Calcium channel blockers: [P] Decreased calcium channel blocker metabolism.</p> <p>Carbamazepine: [P] Decreased carbamazepine metabolism. Potential increased metabolism of itraconazole, ketoconazole, and voriconazole.</p> <p>Cisapride: [NP] Decreased metabolism of cisapride.</p> <p>Colchicine: [P] Decreased metabolism and transport of colchicine.</p> <p>Cyclosporine: [P] Decreased elimination of cyclosporine.</p> <p>Digoxin: [NE] Increased plasma concentrations of digoxin with itraconazole, posaconazole, and ketoconazole.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Azole antifungals (cont.)		<p>Eplerenone: [P] Decreased metabolism of eplerenone.</p> <p>Ergot alkaloids: [P] Decreased metabolism of ergot alkaloids.</p> <p>HMG-CoA reductase inhibitors: [HP] Decreased metabolism of lovastatin, simvastatin, and, to a lesser extent, atorvastatin.</p> <p>Opioid analgesics: [P] Decreased elimination of alfentanil, fentanyl, methadone, oxycodone, and sufentanil.</p> <p>Quinidine: [P] Decreased metabolism of quinidine.</p> <p>Phenytoin: [P] Decreased metabolism of phenytoin with fluconazole and probably voriconazole.</p> <p>Phosphodiesterase inhibitors: [P] Decreased metabolism of phosphodiesterase inhibitor.</p> <p>Pimozide: [NE] Decreased pimozide metabolism.</p> <p>Rifabutin: [P] Decreased rifabutin metabolism. Increased metabolism of itraconazole, ketoconazole, and voriconazole.</p> <p>Rifampin: [P] Increased metabolism of itraconazole, ketoconazole, and voriconazole.</p> <p>Sirolimus: [P] Decreased elimination of sirolimus.</p> <p>Tacrolimus: [P] Decreased elimination of tacrolimus.</p> <p><i>See also</i> Acid-Reducing Agents; Anticoagulants, oral.</p>
Barbiturates	Induction of hepatic microsomal drug metabolizing enzymes and P-glycoprotein. Additive central nervous system depression with other central nervous system depressants.	<p>Antivirals: Increased metabolism of antivirals amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir with barbiturates.</p> <p>Beta-adrenoceptor blockers: [P] Increased β-blocker metabolism.</p> <p>Calcium channel blockers: [P] Increased calcium channel blocker metabolism.</p> <p>Central nervous system depressants: [HP] Additive central nervous system depression.</p> <p>Corticosteroids: [P] Increased corticosteroid metabolism.</p> <p>Cyclosporine: [NE] Increased cyclosporine metabolism.</p> <p>Doxycycline: [P] Increased doxycycline metabolism.</p> <p>Estrogens: [P] Increased estrogen metabolism.</p> <p>Kinase inhibitors: [P] Increased metabolism of axitinib, bosutinib, ceritinib, cabozantinib, cobimetinib, crizotinib, dabrafenib, dasatinib, erlotinib, gefitinib, ibrutinib, idelalisib, imatinib, ixazomib, lapatinib, nilotinib, nintedanib, olaparib, osimertinib, palbociclib, pazopanib, ponatinib, regorafenib, ruxolitinib, sunitinib, tofacitinib, vandetanib, vemurafenib.</p> <p>Methadone: [NE] Increased methadone metabolism.</p> <p>Opioid analgesics: [P] Increased elimination of alfentanil, fentanyl, methadone, oxycodone, and sufentanil.</p> <p>Phenothiazine: [P] Increased phenothiazine metabolism.</p> <p>Phenytoin: [P] Increased phenytoin metabolism.</p> <p>Quinidine: [P] Increased quinidine metabolism.</p> <p>Sirolimus: [NE] Increased sirolimus metabolism.</p> <p>Tacrolimus: [NE] Increased tacrolimus metabolism.</p> <p>Theophylline: [NE] Increased theophylline metabolism.</p> <p>Valproic acid: [P] Decreased phenobarbital metabolism.</p> <p><i>See also</i> Anticoagulants, oral; Antidepressants, tricyclic.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Beta-adrenoceptor blockers	Beta blockade (especially with noncardioselective agents such as propranolol) alters response to sympathomimetics with β -agonist activity (eg, epinephrine, albuterol). Beta blockers that undergo extensive first-pass metabolism may be affected by drugs capable of altering this process.	<p>Drugs that may increase β-blocker effect:</p> <p>Amiodarone: [P] Decreased metabolism of β blockers metabolized by CYP2D6 (timolol, propranolol, nebivolol, metoprolol, carvedilol). Enhanced effects on myocardial conduction. Expect similar interactions with dronedarone.</p> <p>Cimetidine: [P] Decreased metabolism of β blockers that are cleared primarily by the liver, eg, propranolol. Less effect (if any) on those cleared by the kidneys, eg, atenolol, nadolol.</p> <p>Diphenhydramine: [P] Decreased metabolism of β blockers metabolized by CYP2D6 (timolol, propranolol, nebivolol, metoprolol, carvedilol).</p> <p>Haloperidol: [P] Decreased metabolism of β blockers metabolized by CYP2D6 (timolol, propranolol, nebivolol, metoprolol, carvedilol).</p> <p>Quinidine: [P] Decreased metabolism of β blockers metabolized by CYP2D6 (timolol, propranolol, nebivolol, metoprolol, carvedilol).</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [P] Fluoxetine and paroxetine inhibit CYP2D6 and increase concentrations of timolol, propranolol, metoprolol, carvedilol, and nebivolol.</p> <p>Terbinafine: [P] Decreased metabolism of β blockers metabolized by CYP2D6 (timolol, propranolol, nebivolol, metoprolol, carvedilol).</p> <p>Drugs that may decrease β-blocker effect:</p> <p>Nonsteroidal anti-inflammatory drugs (NSAIDs): [P] Indomethacin reduces antihypertensive response; other prostaglandin inhibitors probably also interact.</p> <p>Effects of β blockers on other drugs:</p> <p>Clonidine: [NE] Hypertensive reaction if clonidine is withdrawn; this is more likely to occur with non-cardioselective beta blockers.</p> <p>Insulin: [P] Inhibition of glucose recovery from hypoglycemia; inhibition of symptoms of hypoglycemia (except sweating); increased blood pressure during hypoglycemia.</p> <p>Prazosin: [P] Increased hypotensive response to first dose of prazosin.</p> <p>Sympathomimetics: [P] Increased pressor response to epinephrine (and possibly other sympathomimetics); this is more likely to occur with noncardioselective β blockers.</p> <p><i>See also</i> Barbiturates; Theophylline.</p>
Bile acid-binding resins	Resins may bind with orally administered drugs in gastrointestinal tract. Resins may bind in gastrointestinal tract with drugs that undergo enterohepatic circulation, even if the latter are given parenterally.	<p>Acetaminophen: [NE] Decreased gastrointestinal absorption of acetaminophen.</p> <p>Digitalis glycosides: [NE] Decreased gastrointestinal absorption of digitoxin (possibly also digoxin).</p> <p>Furosemide: [P] Decreased gastrointestinal absorption of furosemide.</p> <p>Methotrexate: [NE] Reduced gastrointestinal absorption of methotrexate.</p> <p>Mycophenolate: [P] Reduced gastrointestinal absorption of mycophenolate.</p> <p>Thiazide diuretics: [P] Reduced gastrointestinal absorption of thiazides.</p> <p>Thyroid hormones: [P] Reduced thyroid absorption.</p> <p><i>See also</i> Anticoagulants, oral.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Calcium channel blockers	Verapamil, diltiazem, and perhaps nicardipine inhibit hepatic drug-metabolizing enzymes (CYP3A4) and P-glycoprotein. Metabolism (via CYP3A4) of diltiazem, felodipine, nicardipine, nifedipine, verapamil, and other calcium channel blockers subject to induction and inhibition.	<p>Amiodarone: [P] Decreased metabolism of calcium channel blockers. Enhanced effects on myocardial conduction with bepridil, diltiazem, and verapamil. Expect similar interactions with dronedarone.</p> <p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the metabolism of calcium channel blockers.</p> <p>Boceprevir: [P] Decreased metabolism of calcium channel blockers.</p> <p>Carbamazepine: [P] Decreased carbamazepine metabolism with diltiazem and verapamil; possible increase in calcium channel blocker metabolism.</p> <p>Cimetidine: [NP] Decreased metabolism of calcium channel blockers.</p> <p>Colchicine: [P] Decreased colchicine elimination with diltiazem, nicardipine, and verapamil.</p> <p>Conivaptan: [P] Decreased metabolism of calcium channel blockers.</p> <p>Cyclosporine: [P] Decreased cyclosporine elimination with diltiazem, nicardipine, verapamil.</p> <p>Digitalis glycosides: [P] Decreased elimination of digitalis glycoside with bepridil, diltiazem and verapamil.</p> <p>Kinase inhibitors: [P] Decreased metabolism of calcium channel blockers with ceritinib, dasatinib, imatinib, idelalisib, and lapatinib. Decreased metabolism of kinase inhibitors by diltiazem, nicardipine, and verapamil.</p> <p>Macrolide antibiotics: [P] Clarithromycin and erythromycin inhibit the metabolism of calcium channel blockers.</p> <p>Phenytoin: [P] Increased metabolism of calcium channel blockers.</p> <p>Rifampin: [P] Increased metabolism of calcium channel blockers.</p> <p>Sirolimus: [P] Decreased sirolimus elimination with diltiazem, nicardipine, verapamil.</p> <p>Statins: [P] Decreased atorvastatin, lovastatin, and simvastatin elimination with diltiazem, nicardipine, verapamil.</p> <p>Tacrolimus: [P] Decreased tacrolimus elimination with diltiazem, nicardipine, verapamil.</p> <p>Theophylline: [P] Decreased theophylline metabolism with diltiazem, nicardipine, and verapamil.</p> <p><i>See also</i> Azole antifungals; Barbiturates.</p>
Carbamazepine	Induction of hepatic microsomal drug-metabolizing enzymes and P-glycoprotein. Susceptible to induction and inhibition of metabolism, primarily by CYP3A4.	<p>Amiodarone: [P] Decreased metabolism of carbamazepine; increased metabolism of amiodarone. Expect similar interactions with dronedarone.</p> <p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the metabolism of carbamazepine. Increased metabolism of antivirals by carbamazepine.</p> <p>Cimetidine: [P] Decreased carbamazepine metabolism.</p> <p>Corticosteroids: [P] Increased corticosteroid metabolism.</p> <p>Cyclosporine: [P] Increased cyclosporine metabolism and possible decreased carbamazepine metabolism.</p> <p>Danazol: [P] Decreased carbamazepine metabolism.</p> <p>Digitalis glycosides: [P] Increased digoxin elimination.</p> <p>Fluvoxamine: [NE] Decreased carbamazepine metabolism.</p> <p>Estrogens: [P] Increased estrogen metabolism.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66-1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Carbamazepine (cont.)		<p>Haloperidol: [P] Increased haloperidol metabolism.</p> <p>Isoniazid: [P] Decreased carbamazepine metabolism.</p> <p>Kinase inhibitors: [P] Decreased metabolism of carbamazepine with ceritinib, dasatinib, imatinib, idelalisib, and lapatinib. Increased metabolism of kinase inhibitors.</p> <p>Macrolide antibiotics: [P] Clarithromycin and erythromycin inhibit the metabolism of carbamazepine.</p> <p>Nefazodone: [NE] Decreased carbamazepine metabolism.</p> <p>Opioid analgesics: [P] Increased elimination of alfentanil, fentanyl, methadone, oxycodone, and sufentanil.</p> <p>Rifampin: [P] Increased carbamazepine metabolism.</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [NE] Fluoxetine and fluvoxamine decrease carbamazepine metabolism.</p> <p>Sirolimus: [P] Increased sirolimus metabolism.</p> <p>St. John's wort: [P] Increased carbamazepine metabolism.</p> <p>Tacrolimus: [P] Increased tacrolimus metabolism.</p> <p>Theophylline: [NE] Increased theophylline metabolism.</p> <p><i>See also</i> Anticoagulants, oral; Antidepressants, tricyclic; Azole antifungals; Calcium channel blockers.</p>
Cimetidine	Inhibits hepatic microsomal drug-metabolizing enzymes. (Ranitidine, famotidine, and nizatidine do not.) May inhibit the renal tubular secretion of weak bases.	<p>Antivirals: [P] Decreased metabolism of amprenavir, atazanavir, boceprevir, daclatasvir, darunavir, delavirdine, etravirine, fosamprenavir, indinavir, lopinavir, maraviroc, nelfinavir, rilpivirine, ritonavir, saquinavir, and tipranavir.</p> <p>Benzodiazepines: [P] Decreased metabolism of alprazolam, chlordiazepoxide, diazepam, halazepam, prazepam, and clorazepate but not oxazepam, lorazepam, or temazepam.</p> <p>Carmustine: [NE] Increased bone marrow suppression.</p> <p>Dofetilide: [NP] Decreased renal excretion of dofetilide.</p> <p>Lidocaine: [P] Decreased metabolism of lidocaine.</p> <p>Opioid analgesics: [P] Decreased elimination of alfentanil, fentanyl, methadone, oxycodone, and sufentanil.</p> <p>Phenytoin: [NE] Decreased phenytoin metabolism.</p> <p>Procainamide: [P] Decreased renal excretion of procainamide.</p> <p>Quinidine: [P] Decreased metabolism of quinidine.</p> <p>Theophylline: [P] Decreased theophylline metabolism.</p> <p><i>See also</i> Anticoagulants, oral; Antidepressants, tricyclic; Azole antifungals; β-Adrenoceptor blockers; Calcium channel blockers; Carbamazepine.</p>
Cisapride	Susceptible to induction and inhibition of metabolism by CYP3A4 inhibitors. High cisapride serum concentrations can result in ventricular arrhythmias.	<p>Amiodarone: [NP] Decreased cisapride metabolism. Expect similar interaction with dronedarone.</p> <p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the metabolism of cisapride.</p> <p>Cobicistat: [P] Decreased metabolism of cisapride.</p> <p>Conivaptan: [P] Decreased metabolism of cisapride.</p> <p>Cyclosporine: [NE] Decreased metabolism of cisapride.</p> <p>Kinase inhibitors: [P] Decreased metabolism of cisapride with ceritinib, dasatinib, imatinib, idelalisib, and lapatinib.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Cisapride (cont.)		<p>Macrolide antibiotics: [P] Clarithromycin and erythromycin inhibit the metabolism of cisapride.</p> <p>Nefazodone: [NP] Decreased metabolism of cisapride by CYP3A4.</p> <p>Ritonavir: [P] Decreased metabolism of cisapride.</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [NP] Fluvoxamine reduces cisapride metabolism.</p> <p><i>See also</i> Azole antifungals.</p>
Colchicine	Susceptible to changes in CYP3A4 metabolism and P-glycoprotein transport.	<p>Amiodarone: [NP] Decreased colchicine metabolism and transport. Expect similar interactions with dronedarone.</p> <p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the metabolism of colchicine.</p> <p>Carbamazepine: [P] Increased metabolism of colchicine.</p> <p>Cobicistat: [P] Decreased metabolism of colchicine.</p> <p>Conivaptan: [P] Decreased metabolism of colchicine.</p> <p>Cyclosporine: [P] Decreased colchicine elimination.</p> <p>Kinase inhibitors: [P] Decreased metabolism of colchicine with ceritinib, dasatinib, imatinib, idelalisib, and lapatinib.</p> <p>Macrolide antibiotics: [P] Clarithromycin and erythromycin inhibit the metabolism of colchicine.</p> <p>Nefazodone: [NE] Decreased colchicine metabolism.</p> <p>Rifampin: [P] Increased colchicine metabolism.</p> <p>St. John's wort: [NP] Increased colchicine metabolism.</p> <p><i>See also</i> Azole antifungals; Calcium channel blockers.</p>
Cyclosporine	Susceptible to induction and inhibition of elimination by CYP3A4 and P-glycoprotein. (Tacrolimus and sirolimus appear to have similar interactions.)	<p>Aminoglycosides: [NE] Possible additive nephrotoxicity.</p> <p>Amphotericin B: [NE] Possible additive nephrotoxicity.</p> <p>Cidofovir: [NE] Possible additive nephrotoxicity.</p> <p>Drugs that may increase cyclosporine effect:</p> <p>Amiodarone: [P] Decreased cyclosporine elimination. Expect similar interaction with dronedarone.</p> <p>Androgens: [NE] Increased serum cyclosporine concentration.</p> <p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the elimination of cyclosporine.</p> <p>Cobicistat: [P] Decreased cyclosporine elimination.</p> <p>Conivaptan: [P] Decreased cyclosporine elimination.</p> <p>Kinase inhibitors: [P] Decreased metabolism of cyclosporine with ceritinib, dasatinib, imatinib, idelalisib, and lapatinib. Cyclosporine reduces metabolism of kinase inhibitors.</p> <p>Macrolide antibiotics: [P] Clarithromycin and erythromycin inhibit the elimination of cyclosporine.</p> <p>Nefazodone: [P] Decreased cyclosporine metabolism.</p> <p>Quinupristin: [P] Decreased cyclosporine metabolism.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Cyclosporine (cont.)		<p>Statins: [NP] Decreased metabolism of atorvastatin, lovastatin, and simvastatin. Myopathy and rhabdomyolysis noted in patients taking statins and cyclosporine.</p> <p>Drugs that may decrease cyclosporine effect:</p> <p>Bosentan: [P] Increased cyclosporine elimination.</p> <p>Dexamethasone: [NP] Increased cyclosporine metabolism.</p> <p>Efavirenz: [P] Increased cyclosporine metabolism.</p> <p>Etravirine: [NP] Increased cyclosporine metabolism.</p> <p>Nevirapine: [NP] Increased cyclosporine metabolism.</p> <p>Phenytoin: [P] Increased cyclosporine metabolism.</p> <p>Rifabutin: [NP] Increased cyclosporine metabolism.</p> <p>Rifampin: [P] Increased cyclosporine elimination.</p> <p>St. John's wort: [NP] Increased cyclosporine elimination.</p> <p><i>See also</i> Azole antifungals; Barbiturates; Calcium channel blockers; Carbamazepine.</p>
Digitalis glycosides	Digoxin susceptible to alteration of gastrointestinal absorption. Renal and nonrenal excretion of digoxin susceptible to inhibition. Digitalis toxicity may be increased by drug-induced electrolyte imbalance (eg, hypokalemia).	<p>Drugs that may increase digitalis effect:</p> <p>Amiodarone: [P] Increased digoxin plasma concentrations. Expect similar interaction with dronedarone.</p> <p>Antivirals: [P] Daclatasvir, indinavir, nelfinavir, paritaprevir, ritonavir, saquinavir, and telaprevir reduce the elimination of digoxin.</p> <p>Conivaptan: [P] Increased digoxin plasma concentrations.</p> <p>Cyclosporine: [P] Increased digoxin plasma concentrations.</p> <p>Macrolide antibiotics: [P] Azithromycin, clarithromycin, and erythromycin inhibit the elimination of digoxin.</p> <p>Potassium-depleting drugs: [P] Increases likelihood of digitalis toxicity.</p> <p>Propafenone: [P] Increases digoxin plasma concentrations.</p> <p>Quinidine: [HP] Increased digoxin plasma concentrations; displaces digoxin from tissue binding sites.</p> <p>Spironolactone: [NE] Increased digoxin plasma concentrations.</p> <p>Tacrolimus: [P] Increased digoxin plasma concentrations.</p> <p>Ticagrelor: [P] Increased digoxin plasma concentrations.</p> <p><i>See also</i> Azole antifungals; Calcium channel blockers.</p> <p>Drugs that may decrease digitalis effect:</p> <p>Kaolin-pectin: [P] Decreased gastrointestinal digoxin absorption.</p> <p>Rifampin: [NE] Increased metabolism of digitoxin and elimination of digoxin.</p> <p>St. John's wort: [NP] Increased digoxin elimination.</p> <p>Sulfasalazine: [NE] Decreased gastrointestinal digoxin absorption.</p> <p><i>See also</i> Acid reducing agents; Bile acid-binding resins; Carbamazepine.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Disulfiram	Inhibits CYP2C9. Inhibits aldehyde dehydrogenase.	<p>Benzodiazepines: [P] Decreased metabolism of chlordiazepoxide and diazepam but not lorazepam and oxazepam.</p> <p>Metronidazole: [NE] Confusion and psychoses reported in patients receiving this combination; mechanisms unknown.</p> <p>Phenytoin: [P] Decreased phenytoin metabolism.</p> <p><i>See also</i> Alcohol; Anticoagulants, oral.</p>
Estrogens	Estrogen metabolism (CYP3A4) susceptible to induction and inhibition. Enterohepatic circulation of estrogen may be interrupted by alteration in bowel flora (eg, due to antibiotics).	<p>Ampicillin: [NP] Interruption of enterohepatic circulation of estrogen; possible reduction in oral contraceptive efficacy. Some other oral antibiotics may have a similar effect.</p> <p>Bexarotene: [P] Increased estrogen metabolism, possible reduction in oral contraceptive efficacy.</p> <p>Bosentan: [NP] Enzyme induction leading to reduced estrogen effect.</p> <p>Corticosteroids: [P] Decreased metabolism of corticosteroids leading to increased corticosteroid effect. Dexamethasone may increase estrogen metabolism.</p> <p>Efavirenz: [P] Increased estrogen metabolism, possible reduction in oral contraceptive efficacy.</p> <p>Griseofulvin: [NP] Increased estrogen metabolism, possible reduction in oral contraceptive efficacy.</p> <p>Nelfinavir: [P] Increased estrogen metabolism, possible reduction in oral contraceptive efficacy.</p> <p>Nevirapine: [NP] Increased estrogen metabolism, possible reduction in oral contraceptive efficacy.</p> <p>Phenytoin: [P] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p>Primidone: [P] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p>Rifabutin: [P] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p>Rifampin: [P] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p>St. John's wort: [P] Increased estrogen metabolism; possible reduction in oral contraceptive efficacy.</p> <p><i>See also</i> Barbiturates; Carbamazepine.</p>
HMG-CoA reductase inhibitors (statins)	Lovastatin, simvastatin, and, to a lesser extent, atorvastatin are susceptible to CYP3A4 inhibitors and inducers; additive risk with other drugs that can cause myopathy.	<p>Amiodarone: [NP] Decreased atorvastatin, lovastatin, and simvastatin metabolism. Expect similar interactions with dronedarone.</p> <p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the metabolism of atorvastatin, lovastatin, and simvastatin.</p> <p>Bosentan: [P] Increased atorvastatin, lovastatin, and simvastatin metabolism.</p> <p>Carbamazepine: [P] Increased atorvastatin, lovastatin, and simvastatin metabolism.</p> <p>Clofibrate: [NP] Increased risk of myopathy.</p> <p>Cobicistat: [P] Decreased metabolism of atorvastatin, lovastatin, and simvastatin.</p> <p>Conivaptan: [P] Decreased metabolism of atorvastatin, lovastatin, and simvastatin.</p> <p>Cyclosporine: [P] Decreased atorvastatin, lovastatin, rosuvastatin, pitavastatin, and simvastatin elimination.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
HMG-CoA reductase inhibitors (statins) (cont.)		<p>Gemfibrozil: [NP] Increased plasma lovastatin and simvastatin and increased risk of myopathy.</p> <p>Kinase inhibitors: [P] Decreased metabolism of atorvastatin, lovastatin, and simvastatin by ceritinib, dasatinib, imatinib, idelalisib, and lapatinib.</p> <p>Macrolide antibiotics: [P] Clarithromycin and erythromycin inhibit the elimination of statins.</p> <p>Nefazodone: [NP] Decreased atorvastatin, lovastatin, and simvastatin metabolism.</p> <p>Phenytoin: [P] Increased atorvastatin, lovastatin, and simvastatin metabolism.</p> <p>Rifampin: [P] Increased atorvastatin, lovastatin, and simvastatin metabolism.</p> <p>St. John's wort: [NP] Increased atorvastatin, lovastatin, and simvastatin metabolism.</p> <p><i>See also</i> Azole antifungals; Calcium channel blockers; Cyclosporine.</p>
Iron	Binds with drugs in gastrointestinal tract, reducing absorption.	<p>Methyldopa: [NE] Decreased methyldopa absorption.</p> <p>Mycophenolate: [P] Decreased mycophenolate absorption.</p> <p>Quinolones: [P] Decreased absorption of ciprofloxacin and other quinolones.</p> <p>Tetracyclines: [P] Decreased absorption of tetracyclines; decreased efficacy of iron.</p> <p>Thyroid hormones: [P] Decreased thyroxine absorption.</p> <p><i>See also</i> Antacids.</p>
Levodopa	Levodopa degraded in gut prior to reaching sites of absorption. Agents that alter gastrointestinal motility may alter degree of intraluminal degradation. Antiparkinsonism effect of levodopa susceptible to inhibition by other drugs.	<p>Clonidine: [NE] Inhibited antiparkinsonism effect.</p> <p>Haloperidol: [NP] Inhibited antiparkinsonism effect.</p> <p>Metoclopramide: [NP] Inhibited antiparkinsonism effect.</p> <p>Monoamine oxidase inhibitors (MAOIs): [P] Hypertensive reaction (carbidopa prevents the interaction).</p> <p>Papaverine: [NE] Inhibited antiparkinsonism effect.</p> <p>Phenothiazines: [P] Inhibited antiparkinsonism effect.</p> <p>Phenytoin: [NE] Inhibited antiparkinsonism effect.</p> <p>Pyridoxine: [P] Inhibited antiparkinsonism effect (carbidopa prevents the interaction).</p>
Lithium	Renal lithium excretion sensitive to changes in sodium balance. (Sodium depletion tends to cause lithium retention.) Susceptible to drugs enhancing central nervous system lithium toxicity.	<p>ACE inhibitors (ACEIs): [NE] Reduce renal clearance of lithium; increase lithium effect.</p> <p>Angiotensin II receptor blockers (ARBs): [NE] Reduce renal clearance of lithium; increase lithium effect.</p> <p>Diuretics (especially thiazides): [P] Decreased excretion of lithium; furosemide may be less likely to produce this effect than thiazide diuretics.</p> <p>Haloperidol: [NP] Occasional cases of neurotoxicity in manic patients, especially with large doses of one or both drugs.</p> <p>Methyldopa: [NE] Increased likelihood of central nervous system lithium toxicity.</p> <p>Nonsteroidal anti-inflammatory drugs (NSAIDs): [NE] Reduced renal lithium excretion (except sulindac and salicylates).</p> <p>Theophylline: [P] Increased renal excretion of lithium; reduced lithium effect.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Macrolides	The macrolides clarithromycin and erythromycin are known to inhibit CYP3A4 and P-glycoprotein. Azithromycin does not appear to inhibit CYP3A4 but is a modest inhibitor of P-glycoprotein.	<p>Benzodiazepines: [P] Decreased metabolism of alprazolam, midazolam, triazolam.</p> <p>Eplerenone: [P] Decreased metabolism of eplerenone.</p> <p>Ergot alkaloids: [P] Decreased elimination of ergot alkaloids.</p> <p>Kinase inhibitors: [P] Decreased metabolism of axitinib, bosutinib, ceritinib, cabozantinib, cobimetinib, crizotinib, dabrafenib, dasatinib, erlotinib, gefitinib, ibrutinib, idelalisib, imatinib, ixazomib, lapatinib, nilotinib, nintedanib, olaparib, osimertinib, palbociclib, pazopanib, ponatinib, regorafenib, ruxolitinib, sunitinib, tofacitinib, vandetanib, and vemurafenib by clarithromycin and erythromycin.</p> <p>Opioid analgesics: [P] Decreased elimination of alfentanil, fentanyl, methadone, oxycodone, and sufentanil.</p> <p>Phosphodiesterase inhibitors: [P] Decreased metabolism of phosphodiesterase inhibitor.</p> <p>Pimozide: [P] Increased pimozide concentrations.</p> <p>Quinidine: [P] Increased serum quinidine concentrations.</p> <p>Theophylline: [P] Decreased metabolism of theophylline.</p> <p><i>See also</i> Anticoagulants, oral; Calcium channel blockers; Carbamazepine; Cisapride; Colchicine; Cyclosporine; Digitalis glycosides; HMG-CoA reductase inhibitors.</p>
Monoamine oxidase inhibitors (MAOIs)	Increased norepinephrine stored in adrenergic neuron. Displacement of these stores by other drugs may produce acute hypertensive response. MAOIs have intrinsic hypoglycemic activity.	<p>Anorexiant: [P] Hypertensive episodes due to release of stored norepinephrine (benzphetamine, diethylpropion, mazindol, phendimetrazine, phentermine).</p> <p>Antidiabetic agents: [P] Additive hypoglycemic effect.</p> <p>Buspirone: [NE] Possible serotonin syndrome; <i>avoid</i> concurrent use.</p> <p>Dextromethorphan: [NP] Severe reactions (hyperpyrexia, coma, death) have been reported.</p> <p>Guanethidine: [P] Reversal of the hypotensive action of guanethidine.</p> <p>Mirtazapine: [NE] Possible serotonin syndrome; <i>avoid</i> concurrent use.</p> <p>Nefazodone: [NP] Possible serotonin syndrome; <i>avoid</i> concurrent use.</p> <p>Opioid analgesics: [NP] Some patients develop hypertension, rigidity, excitation; meperidine more likely to interact than morphine; <i>avoid</i> concurrent use.</p> <p>Phenylephrine: [P] Hypertensive episode, since phenylephrine is metabolized by monoamine oxidase.</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [P] Fatalities have occurred due to serotonin syndrome; contraindicated in patients taking MAOIs; <i>avoid</i> concurrent use.</p> <p>Sibutramine: [NE] Possible serotonin syndrome; <i>avoid</i> concurrent use.</p> <p>Sympathomimetics (indirect-acting): [HP] Hypertensive episode due to release of stored norepinephrine (amphetamines, ephedrine, isometheptene, phenylpropanolamine, pseudoephedrine).</p> <p>Tramadol: [NP] Possible serotonin syndrome; <i>avoid</i> concurrent use.</p> <p>Venlafaxine: [NP] Possible serotonin syndrome; <i>avoid</i> concurrent use.</p> <p><i>See also</i> Antidepressants, tricyclic and heterocyclic; Levodopa.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Prostaglandin inhibition may result in reduced renal sodium excretion, impaired resistance to hypertensive stimuli, and reduced renal lithium excretion. Most NSAIDs inhibit platelet function; may increase likelihood of bleeding due to other drugs that impair hemostasis.	<p>ACE inhibitors (ACEIs): [P] Decreased antihypertensive response.</p> <p>Angiotensin II receptor blockers (ARBs): [P] Decreased antihypertensive response.</p> <p>Furosemide: [P] Decreased diuretic, natriuretic, and antihypertensive response to furosemide.</p> <p>Hydralazine: [NE] Decreased antihypertensive response to hydralazine.</p> <p>Methotrexate: [NP] Possibly increased methotrexate toxicity (especially with anticancer doses of methotrexate).</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [P] Increased risk of bleeding due to platelet inhibition.</p> <p>Thiazide diuretics: [P] Decreased diuretic, natriuretic, and antihypertensive response.</p> <p>Triamterene: [NE] Decreased renal function noted with triamterene plus indomethacin in both healthy subjects and patients.</p> <p><i>See also</i> Anticoagulants, oral; β-Adrenoceptor blockers; Lithium.</p>
Opioid analgesics	Opioid analgesics that are substrates of CYP3A4 (alfentanil, fentanyl, oxycodone, sufentanil, and to a lesser extent methadone) are susceptible to inhibitors and inducers. Methadone is primarily metabolized by CYP2B6. Additive central nervous system depression with other central nervous system depressants.	<p>Amiodarone: [NP] Decreased CYP3A4-dependent opioid metabolism. Expect similar interactions with dronedarone.</p> <p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the metabolism of CYP3A4-dependent opioids.</p> <p>Boceprevir: [P] Decreased metabolism of CYP3A4-dependent opioids.</p> <p>Bosentan: [P] Increased CYP3A4-dependent opioid metabolism.</p> <p>Cobicistat: [P] Decreased metabolism of CYP3A4-dependent opioids.</p> <p>Conivaptan: [P] Decreased metabolism of CYP3A4-dependent opioids.</p> <p>Efavirenz: [P] Increased metabolism of CYP3A4-dependent opioids.</p> <p>Kinase inhibitors: [P] Decreased metabolism of CYP3A4-dependent opioid by ceritinib, dasatinib, imatinib, idelalisib, and lapatinib.</p> <p>Nefazodone: [NP] Decreased CYP3A4-dependent opioid metabolism.</p> <p>Nevirapine: [P] Increased metabolism of CYP3A4-dependent opioids.</p> <p>Phenytoin: [P] Increased CYP3A4-dependent opioid metabolism.</p> <p>Rifampin: [P] Increased CYP3A4-dependent opioid metabolism.</p> <p>St. John's wort: [NP] Increased CYP3A4-dependent opioid metabolism.</p> <p><i>See also</i> Azole antifungal agents; Barbiturates; Carbamazepine; Cimetidine; Macrolides; Monoamine oxidase inhibitors.</p>
Phenytoin	Induces hepatic microsomal drug metabolism. Susceptible to inhibition of metabolism by CYP2C9 and, to a lesser extent, CYP2C19.	<p>Drugs whose metabolism is stimulated by phenytoin:</p> <p>Corticosteroids: [P] Decreased serum corticosteroid levels.</p> <p>Doxycycline: [P] Decreased serum doxycycline levels.</p> <p>Mexiletine: [NE] Decreased serum mexiletine levels.</p> <p>Quinidine: [P] Decreased serum quinidine levels.</p> <p>Theophylline: [NP] Decreased serum theophylline levels.</p> <p><i>See also</i> Calcium channel blockers; Cyclosporine; Estrogens; Opioid analgesics.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Phenytoin (cont.)		<p>Drugs that inhibit phenytoin metabolism:</p> <p>Amiodarone: [P] Increased serum phenytoin concentration; possible reduction in serum amiodarone concentration.</p> <p>Capecitabine: [NE] Increased phenytoin plasma concentrations.</p> <p>Chloramphenicol: [P] Increased phenytoin plasma concentrations.</p> <p>Felbamate: [P] Increased phenytoin plasma concentrations.</p> <p>Fluorouracil: [NE] Increased phenytoin plasma concentrations.</p> <p>Fluvoxamine: [NP] Increased phenytoin plasma concentrations.</p> <p>Isoniazid: [NP] Increased serum phenytoin; problem primarily with slow acetylators of isoniazid.</p> <p>Metronidazole: [NP] Increased phenytoin plasma concentrations.</p> <p>Sulfamethoxazole: [P] Increased phenytoin plasma concentrations.</p> <p>Ticlopidine: [NP] Increased phenytoin plasma concentrations.</p> <p><i>See also</i> Azole antifungals; Cimetidine; Disulfiram.</p> <p>Drugs that enhance phenytoin metabolism:</p> <p>Bosentan: [P] Decreased phenytoin plasma concentrations.</p> <p>Carbamazepine: [P] Decreased phenytoin plasma concentrations.</p> <p>Rifampin: [P] Decreased phenytoin plasma concentrations.</p> <p>St. John's wort: [P] Decreased phenytoin plasma concentrations.</p> <p><i>See also</i> Barbiturates.</p>
Pimozide	Susceptible to CYP3A4 inhibitors; may exhibit additive effects with other agents that prolong QT _c interval.	<p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the metabolism of pimozide.</p> <p>Boceprevir: [P] Decreased metabolism of pimozide.</p> <p>Cobicistat: [P] Decreased metabolism of pimozide.</p> <p>Conivaptan: [P] Decreased metabolism of pimozide.</p> <p>Kinase inhibitors: [P] Decreased metabolism of pimozide with ceritinib, dasatinib, imatinib, idelalisib, and lapatinib.</p> <p>Nefazodone: [NP] Decreased pimozide metabolism.</p> <p><i>See also</i> Azole antifungals; Cyclosporine; Macrolides.</p>
Potassium-sparing diuretics (amiloride, eplerenone, spironolactone, triamterene)	Additive effects with other agents increasing serum potassium concentration. Eplerenone is a substrate for CYP3A4 and is susceptible to inhibition and induction. May alter renal excretion of substances other than potassium (eg, digoxin, hydrogen ions).	<p>ACE inhibitors (ACEIs): [NP] Additive hyperkalemic effect.</p> <p>Angiotensin II receptor blockers (ARBs): [NP] Additive hyperkalemic effect.</p> <p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the metabolism of eplerenone.</p> <p>Boceprevir: [P] Decreased metabolism of eplerenone.</p> <p>Cobicistat: [P] Decreased metabolism of eplerenone.</p> <p>Conivaptan: [P] Decreased metabolism of eplerenone.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66-1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Potassium-sparing diuretics (amiloride, eplerenone, spironolactone, triamterene) (cont.)		<p>Kinase inhibitors: [P] Decreased metabolism of eplerenone with ceritinib, dasatinib, imatinib, idelalisib, and lapatinib.</p> <p>Potassium-sparing diuretics: [P] Additive hyperkalemic effect.</p> <p>Potassium supplements: [P] Additive hyperkalemic effect; especially a problem in presence of renal impairment.</p> <p><i>See also</i> Azole antifungals; Digitalis glycosides; Macrolides; Nonsteroidal anti-inflammatory drugs.</p>
Probenecid	Interference with renal excretion of drugs that undergo active tubular secretion, especially weak acids. Inhibition of glucuronide conjugation of other drugs.	<p>Clofibrate: [P] Reduced glucuronide conjugation of clofibric acid.</p> <p>Methotrexate: [P] Decreased renal methotrexate excretion; possible methotrexate toxicity.</p> <p>Pralatrexate: [P] Decreased renal pralatrexate excretion; possible pralatrexate toxicity.</p> <p>Penicillin: [P] Decreased renal penicillin excretion.</p> <p>Salicylates: [P] Decreased uricosuric effect of probenecid (interaction unlikely with less than 1.5 g of salicylate daily).</p>
Quinidine	Substrate of CYP3A4. Inhibits CYP2D6. Renal excretion susceptible to changes in urine pH. Additive effects with other agents that prolong the QT _c interval.	<p>Acetazolamide: [P] Decreased renal quinidine excretion due to increased urinary pH; elevated serum quinidine.</p> <p>Amiodarone: [NP] Increased serum quinidine levels; additive prolongation of QT_c interval.</p> <p>Antivirals: [P] Amprenavir, atazanavir, boceprevir, darunavir, delavirdine, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, simeprevir, and telaprevir inhibit the metabolism of quinidine.</p> <p>Boceprevir: [P] Decreased metabolism of quinidine.</p> <p>Cobicistat: [P] Decreased metabolism of quinidine.</p> <p>Conivaptan: [P] Decreased metabolism of quinidine.</p> <p>Kaolin-pectin: [NE] Decreased gastrointestinal absorption of quinidine.</p> <p>Kinase inhibitors: [P] Decreased metabolism of quinidine with ceritinib, dasatinib, imatinib, idelalisib, and lapatinib.</p> <p>Rifampin: [P] Increased quinidine metabolism.</p> <p>Thioridazine: [NE] Decreased thioridazine metabolism; additive prolongation of QT_c interval.</p> <p><i>See also</i> Anticoagulants, oral; Antidepressants, tricyclic; Azole antifungals; Barbiturates; Cimetidine; Digitalis glycosides; Macrolides; Phenytoin.</p>
Quinolone antibiotics	Susceptible to inhibition of gastrointestinal absorption. Some quinolones (ciprofloxacin, enoxacin) inhibit CYP1A2, while ciprofloxacin also inhibits CYP3A4.	<p>Caffeine: [P] Ciprofloxacin, enoxacin, and, to a lesser extent, norfloxacin inhibit caffeine metabolism.</p> <p>Frovatriptan: [P] Ciprofloxacin, enoxacin, and, to a lesser extent, norfloxacin inhibit frovatriptan metabolism.</p> <p>Ropinirole: [P] Ciprofloxacin, enoxacin, and, to a lesser extent, norfloxacin inhibit ropinirole metabolism.</p> <p>Sucralfate: [HP] Reduced gastrointestinal absorption of ciprofloxacin, norfloxacin, and probably other quinolones.</p> <p>Theophylline: [P] Ciprofloxacin, enoxacin, and, to a lesser extent, norfloxacin inhibit theophylline metabolism.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

(continued)

TABLE 66–1 Important drug interactions.

Drug or Drug Group	Properties Promoting Drug Interaction	Clinically Documented Interactions
Quinolone antibiotics (cont.)		<p>Tizanidine: [P] Ciprofloxacin, enoxacin, and, to a lesser extent, norfloxacin inhibit tizanidine metabolism.</p> <p>Zolmitriptan: [P] Ciprofloxacin, enoxacin, and, to a lesser extent, norfloxacin inhibit zolmitriptan metabolism.</p> <p><i>See also</i> Acid-reducing agents; Anticoagulants, oral; Iron.</p>
Rifampin	Inducer (strong) of hepatic microsomal drug-metabolizing enzymes and P-glycoprotein.	<p>Corticosteroids: [P] Increased corticosteroid hepatic metabolism; reduced corticosteroid effect.</p> <p>Mexiletine: [NE] Increased mexiletine metabolism; reduced mexiletine effect.</p> <p>Sulfonylurea hypoglycemics: [P] Increased hepatic metabolism of tolbutamide and probably other sulfonylureas metabolized by the liver (including chlorpropamide).</p> <p>Theophylline: [P] Increased theophylline metabolism.</p> <p><i>See also</i> Anticoagulants, oral; Antidepressants, tricyclic and heterocyclic; Azole antifungals; Beta-adrenoceptor blockers; Calcium channel blockers; Cyclosporine; Digitalis glycosides; Estrogens; HMG-CoA reductase inhibitors; Opioid analgesics; Phenytoin; Quinidine.</p>
Salicylates	Interference with renal excretion of drugs that undergo active tubular secretion. Salicylate renal excretion dependent on urinary pH when large doses of salicylate used. Aspirin (but not other salicylates) interferes with platelet function. Large doses of salicylates have intrinsic hypoglycemic activity.	<p>Carbonic anhydrase inhibitors: [NE] Increased acetazolamide serum concentrations; increase salicylate toxicity due to decreased blood pH.</p> <p>Corticosteroids: [P] Increased salicylate elimination; possible additive toxic effect on gastric mucosa.</p> <p>Heparin: [NP] Increased bleeding tendency with aspirin, but probably not with other salicylates.</p> <p>Methotrexate: [P] Decreased renal methotrexate clearance; increases methotrexate toxicity (primarily at anticancer doses).</p> <p>Selective serotonin reuptake inhibitors (SSRIs): [P] Increased risk of bleeding due to platelet inhibition.</p> <p>Sulfinpyrazone: [HP] Decreased uricosuric effect of sulfinpyrazone (interaction unlikely with less than 1.5 g of salicylate daily).</p> <p><i>See also</i> Acid-reducing agents; Anticoagulants, oral; Probenecid.</p>
Selective serotonin reuptake inhibitors (SSRIs)	SSRIs can lead to excessive serotonin response when administered with other serotonergic drugs (eg, MAOIs). Some SSRIs inhibit various cytochrome P450s including CYP2D6, CYP1A2, CYP3A4, and CYP2C19.	<p>Codeine: [HP] Reduced analgesic effect due to inhibition of codeine metabolism to morphine by fluoxetine and paroxetine.</p> <p>Theophylline: [P] Decreased metabolism of theophylline by fluvoxamine-induced inhibition of CYP1A2.</p> <p><i>See also</i> Anticoagulants, oral; Antidepressants, tricyclic and heterocyclic; β-Adrenoceptor blockers; Carbamazepine; Cisapride; Colchicine; Cyclosporine; HMG-CoA reductase inhibitors; Monoamine oxidase inhibitors; Nonsteroidal anti-inflammatory drugs; Phenytoin; Pimozide; Salicylates.</p>
Theophylline	Susceptible to induction and inhibition of hepatic metabolism by CYP1A2 and CYP3A4.	<p>Beta-adrenoceptor blockers: [NP] Decreased theophylline bronchodilation especially with noncardioselective β blockers.</p> <p>Smoking: [HP] Increased theophylline metabolism.</p> <p>Tacrine: [NP] Decreased theophylline metabolism.</p> <p>Ticlopidine: [NP] Decreased theophylline metabolism.</p> <p>Zileuton: [NP] Decreased theophylline metabolism.</p> <p><i>See also</i> Barbiturates; Calcium channel blockers; Carbamazepine; Cimetidine; Lithium; Macrolides; Phenytoin; Quinolones; Rifampin; Selective serotonin reuptake inhibitors.</p>

E, Expected; HP, Highly predictable. Interaction occurs in almost all patients receiving the interacting combination; P, Predictable. Interaction occurs in most patients receiving the combination; NP, Not predictable. Interaction occurs only in some patients receiving the combination; NE, Not established. Insufficient data available on which to base estimate of predictability.

The **metabolism** of drugs can be induced or inhibited by concurrent therapy, and the importance of the effect varies from negligible to dramatic. Drug metabolism primarily occurs in the liver and the wall of the small intestine, but other sites include plasma, lung, and kidney. Induction of cytochrome P450 isozymes in the liver and small intestine can be caused by drugs such as barbiturates, bosentan, carbamazepine, efavirenz, nevirapine, phenytoin, primidone, rifampin, rifabutin, and St. John's wort. Enzyme inducers can also increase the activity of phase II metabolism such as glucuronidation. Enzyme induction does not take place quickly; maximal effects usually occur after 7–14 days and require an equal or longer time to dissipate after the enzyme inducer is stopped. Inhibition of metabolism generally takes place more quickly than enzyme induction and may begin as soon as the tissue concentration of the inhibitor is sufficient to cause reduced enzyme activity. However, if the half-life of the affected (object) drug is long, it may take a week or more (3–4 half-lives) to reach a new steady-state serum concentration. Drugs that may inhibit the cytochrome P450 metabolism of other drugs include amiodarone, androgens, atazanavir, chloramphenicol, cimetidine, ciprofloxacin, clarithromycin, cyclosporine, delavirdine, diltiazem, diphenhydramine, disulfiram, enoxacin, erythromycin, fluconazole, fluoxetine, fluvoxamine, furanocoumarins (substances in grapefruit juice), indinavir, isoniazid, itraconazole, ketoconazole, metronidazole, mexiletine, miconazole, omeprazole, paroxetine, quinidine, ritonavir, sulfamethizole, sulfamethoxazole, verapamil, voriconazole, zafirlukast, and zileuton.

The **renal excretion** of active drug can also be affected by concurrent drug therapy. The renal excretion of drugs that are weak acids or weak bases may be influenced by other drugs that affect urinary pH. This is due to changes in ionization of the object drug, as described in Chapter 1 under Ionization of Weak Acids and Weak Bases; the Henderson-Hasselbalch Equation. For some drugs, active secretion into the renal tubules is an important elimination pathway. P-glycoprotein, organic anion transporters, and organic cation transporters are involved in active tubular secretion of some drugs, and inhibition of these transporters can inhibit renal elimination with attendant increase in serum drug concentrations. Many drugs are partially eliminated by P-glycoprotein, including digoxin, cyclosporine, dabigatran, colchicine, daunorubicin, and tacrolimus. The plasma concentration of these drugs can be increased by inhibitors of P-glycoprotein including amiodarone, clarithromycin, erythromycin, ketoconazole, ritonavir, and quinidine. To access over 200 brief reviews of specific drug interactions visit <http://www.hanstenandhorn.com/news.htm>.

PHARMACODYNAMIC MECHANISMS

When drugs with similar pharmacologic effects are administered concurrently, an additive or synergistic response is usually seen. The two drugs may or may not act on the same receptor to

produce such effects. In theory, drugs acting on the same receptor or process are usually additive, eg, benzodiazepines plus barbiturates, until the receptor is saturated or the effect is maximal. However, two drugs competing for the same binding site may result in less than an additive effect. Drugs acting on different receptors or sequential processes may be synergistic, eg, nitrates plus sildenafil or sulfonamides plus trimethoprim. Conversely, drugs with opposing pharmacologic effects may reduce the response to one or both drugs. Pharmacodynamic drug interactions are relatively common in clinical practice, but adverse effects can usually be minimized if one understands the pharmacology of the drugs involved. In this way, the interactions can be anticipated and appropriate counter-measures taken.

COMBINED TOXICITY

The combined use of two or more drugs, each of which has toxic effects on the same organ, can greatly increase the likelihood of organ damage. For example, concurrent administration of two nephrotoxic drugs can produce kidney damage, even though the dose of either drug alone may be insufficient to produce toxicity. Furthermore, some drugs can enhance the organ toxicity of another drug, even though the enhancing drug has no intrinsic toxic effect on that organ.

Appendix: Vaccines, Immune Globulins, & Other Complex Biologic Products

Harry W. Lampiris, MD & Daniel S. Maddix, PharmD

Vaccines and related biologic products constitute an important group of agents that bridge the disciplines of microbiology, infectious diseases, immunology, and immunopharmacology. A list of the most important preparations is provided here. The reader who requires more complete information is referred to the sources listed at the end of this appendix.

ACTIVE IMMUNIZATION

Active immunization consists of the administration of antigen to the host to induce formation of antibodies and cell-mediated immunity. Immunization is practiced to induce protection against many infectious agents and may utilize either inactivated (killed) materials or live attenuated agents (Table A-1). Desirable features of the ideal immunogen include complete prevention of disease, prevention of the carrier state, production of prolonged immunity with a minimum of immunizations, absence of toxicity, and suitability for mass immunization (eg, cheap and easy to administer). Active immunization is generally preferable to passive immunization—in most cases because higher antibody levels are sustained for longer periods of time, requiring less frequent immunization, and in some cases because of the development of concurrent cell-mediated immunity. However, active immunization requires time to develop and is therefore generally inactive at the time of a specific exposure (eg, for parenteral exposure to hepatitis B, concurrent hepatitis B IgG [passive antibodies] and active immunization are given to prevent illness).

Current recommendations for routine active immunization of children are given in Table A-2.

PASSIVE IMMUNIZATION

Passive immunization consists of transfer of immunity to a host using preformed immunologic products. From a practical standpoint, only immunoglobulins have been used for passive immunization, because passive administration of cellular components of the immune system has been technically difficult and associated with graft-versus-host reactions. Products of the cellular immune system (eg, interferons) have also been used in the therapy of a wide variety of hematologic and infectious diseases (see Chapter 55).

Passive immunization with antibodies may be accomplished with either animal or human immunoglobulins in varying degrees of purity. These may contain relatively high titers of antibodies directed against a specific antigen or, as is true for pooled immune globulin, may simply contain antibodies found in most of the population. Passive immunization is useful for (1) individuals unable to form antibodies (eg, congenital agammaglobulinemia); (2) prevention of disease when time does not permit active immunization (eg, postexposure); (3) for treatment of certain diseases normally prevented by immunization (eg, tetanus); and (4) for treatment of conditions for which active immunization is unavailable or impractical (eg, snakebite).

Complications from administration of *human* immunoglobulins are rare. The injections may be moderately painful, and rarely a sterile abscess may occur at the injection site. Transient hypotension and pruritus occasionally occur with the administration of intravenous immune globulin (IVIG) products, but generally are mild. Individuals with certain immunoglobulin deficiency states (IgA deficiency, etc) may occasionally develop (text continues on page 1177)

TABLE A-1 Materials commonly used for active immunization in the United States.¹

Vaccine	Type of Agent	Route of Administration	Primary Immunization	Booster ²	Indications
Diphtheria tetanus acellular pertussis (DTaP)	Toxoids and inactivated bacterial components	Intramuscular	See Table A-2	None	For all children
<i>Haemophilus influenzae</i> type b conjugate (Hib) ³	Bacterial polysaccharide conjugated to protein	Intramuscular	One dose (see Table A-2 for childhood schedule)	Not recommended	1. For all children 2. Asplenia and other at-risk conditions
Hepatitis A	Inactivated virus	Intramuscular	One dose (see Table A-2 for childhood schedule) (administer at least 2-4 weeks before travel to endemic areas)	At 6-12 months for long-term immunity	1. Travelers to hepatitis A endemic areas 2. Men who have sex with men (MSM) 3. Injection or noninjection illicit drug users 4. Chronic liver disease or clotting factor disorders 5. Persons with occupational risk for infection 6. Persons living in, or relocating to, endemic areas 7. Household and sexual contacts of individuals with acute hepatitis A (with additional gamma globulin in select patients) 8. For all children 9. Unvaccinated persons who anticipate close personal contact with an international adoptee during the first 60 days after arrival in the USA from a country with high or intermediate endemicity
Hepatitis B	Inactive viral antigen, recombinant	Intramuscular (subcutaneous injection is acceptable in individuals with bleeding disorders)	Three doses at 0, 1, and 6 months (see Table A-2 for childhood schedule)	Not routinely recommended	1. For all infants 2. Preadolescents, adolescents, and young adults 3. Persons with occupational, lifestyle, or environmental risk 4. Diabetic adults <60 years of age 5. Persons with end-stage renal disease, HIV, or chronic liver disease 6. Postexposure prophylaxis 7. Household and sexual contacts of individuals with acute and chronic hepatitis B
Human papillomavirus (HPV) ⁴	Virus-like particles of the major capsid protein	Intramuscular	Three doses at 0, 4-8, and 24 weeks	None	1. HPV2, HPV4, or HPV9 for females between 9 and 26 years of age; HPV4 or HPV9 for males aged 9-21 years 2. MSM through age 26 years 3. Immunocompromised persons through age 26 years
Influenza, inactivated	Inactivated virus or viral components	Intramuscular; an intradermal vaccine is available for adults aged 18-64 years; a high-dose formulation is an option for adults ≥65 years	One dose (Children <9 years who are receiving influenza vaccine for the first time should receive two doses administered at least 4 weeks apart.)	Yearly with current vaccine	1. All adults >18 years 2. All children aged 6 months to 18 years

Influenza, live attenuated	Live virus	Intranasal	Split dose in each nostril. Children age 5–8 who are receiving influenza vaccine for the first time should receive two doses administered 6–10 weeks apart	Yearly with current vaccine	Healthy persons aged 19–49 years who desire protection against influenza. May be substituted for inactivated vaccine in healthy children 2–18 years except (1) asthmatics, and (2) those aged 2–4 years with wheezing in the past year
Measles-mumps-rubella (MMR)	Live virus	Subcutaneous	See Table A-2	None	1. For all children 2. Adults born after 1956
Meningococcal conjugate vaccine	Bacterial polysaccharides conjugated to diphtheria toxoid	Intramuscular	One dose	Every 5 years if there is continuing high risk of exposure	1. All adolescents 2. Preferred over polysaccharide vaccine in persons aged 11–55 years 3. College freshman aged <22 years who live in dormitories 4. Military recruits 5. Individuals with asplenia or complement deficiency (two-dose series) 6. Microbiologists who are routinely exposed to isolates of <i>Neisseria meningitidis</i> 7. HIV-positive men who have sex with men
Meningococcal polysaccharide vaccine	Bacterial polysaccharides of serotypes A/C/Y/W-135	Subcutaneous	One dose	Every 5 years if there is continuing high risk of exposure	1. Adult travelers >55 years to areas with hyperendemic or epidemic meningococcal disease
Pneumococcal conjugate vaccine	Bacterial polysaccharides conjugated to protein	Intramuscular or subcutaneous	See Table A-2	None	1. For all children 2. Adults with immunocompromising conditions, asplenia, cerebrospinal fluid leaks, or cochlear implants 3. Adults ≥65 years who have not been vaccinated previously
Pneumococcal polysaccharide vaccine	Bacterial polysaccharides of 23 serotypes	Intramuscular or subcutaneous	One dose	Repeat after 5 years in patients at high risk	1. Adults ≥65 years 2. Persons at increased risk for pneumococcal disease or its complications
Poliovirus vaccine, inactivated (IPV)	Inactivated viruses of all three serotypes	Subcutaneous	See Table A-2 for childhood schedule. Adults: Two doses 4–8 weeks apart, and a third dose 6–12 months after the second	One-time booster dose for adults at increased risk of exposure	1. For all children 2. Previously unvaccinated adults at increased risk for occupational or travel exposure to polioviruses
Rabies	Inactivated virus	Intramuscular	Preexposure: Three doses at days 0, 7, and 21 or 28 Postexposure: Four doses at days 0, 3, 7, and 14; immunosuppressed patients should receive a 5th dose at day 28	Serologic testing every 6 months to 2 years in persons at high risk	1. Preexposure prophylaxis in persons at risk for contact with rabies virus 2. Postexposure prophylaxis (administer with rabies immune globulin in previously unvaccinated individuals)
Rotavirus	Live virus	Oral	See Table A-2	None	For all infants
Tetanus-diphtheria (Td or DT) ⁵	Toxoids	Intramuscular	Two doses 4–8 weeks apart, and a third dose 6–12 months after the second	Every 10 years	1. All adults 2. Postexposure prophylaxis if >5 years has passed since last dose

(continued)

TABLE A-1 Materials commonly used for active immunization in the United States.¹ (Continued)

Vaccine	Type of Agent	Route of Administration	Primary Immunization	Booster ²	Indications
Tetanus, diphtheria, pertussis (Tdap)	Toxoids and inactivated bacterial components	Intramuscular	Substitute one dose of Tdap for Td in all adults	None	All adults; pregnant women should receive a dose with each pregnancy (preferred during 27–36 weeks of gestation)
Typhoid, Ty21a oral	Live bacteria	Oral	Four doses administered every other day	Four doses every 5 years	Risk of exposure to typhoid fever
Typhoid, Vi capsular polysaccharide	Bacterial polysaccharide	Intramuscular	One dose	Every 2 years	Risk of exposure to typhoid fever
Varicella	Live virus	Subcutaneous	Two doses 4–8 weeks apart in persons past their 13th birthday (see Table A-2 for childhood schedule)	Unknown	1. For all children 2. Persons past their 13th birthday without a history of varicella infection or immunization 3. Postexposure prophylaxis in susceptible persons
Yellow fever	Live virus	Subcutaneous	One dose 10 years to 10 days before travel	Every 10 years	1. Laboratory personnel who may be exposed to yellow fever virus 2. Travelers to areas where yellow fever occurs
Zoster	Live virus	Subcutaneous	One dose	None	All adults ≥60 years of age

¹Dosages for the specific product, including variations for age, are best obtained from the manufacturer's package insert.

²One dose unless otherwise indicated.

³Three Hib conjugate vaccines are available for use: (1) oligosaccharide conjugate Hib vaccine (HbOC), (2) polyribosylribitol phosphate-tetanus toxoid conjugate (PRP-T), and (3) *Haemophilus influenzae* type b conjugate vaccine (meningococcal protein conjugate) (PRP-OMP).

⁴Three HPV vaccines are available for use: (1) quadrivalent vaccine (HPV4) and (2) 9-valent vaccine (HPV9) for the prevention of cervical, vaginal, and vulvar cancers (in females), and genital warts (in males and females), and (3) bivalent vaccine (HPV2) for the prevention of cervical cancers in females.

⁵Td is tetanus and diphtheria toxoids for use in persons ≥7 years of age (contains less diphtheria toxoid than DPT and DT). DT is tetanus and diphtheria toxoids for use in persons <7 years of age (contains the same amount of diphtheria toxoid as DPT).

TABLE A-2 Recommended routine childhood immunization schedule.

Age	Immunization	Comments
Birth to 2 months	Hepatitis B vaccine (HBV)	Infants born to seronegative mothers: Administration should begin prior to hospital discharge, with the second dose administered at least 4 weeks after the first dose. Infants born to seropositive mothers: Should receive the first dose within 12 hours of birth (with hepatitis B immune globulin), the second dose at 1–2 months of age, and the third dose at 6–18 months of age.
2 months	Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP), inactivated poliovirus vaccine (IPV), <i>Haemophilus influenzae</i> type b conjugate vaccine (Hib), ¹ pneumococcal conjugate vaccine (PCV), rotavirus vaccine (RV) ²	
1–2 months	HBV	The second dose should be given at least 4 weeks after the first dose.
4 months	DTaP, Hib, ¹ IPV, PCV, RV ²	
6 months	DTaP, Hib, ¹ PCV, RV ²	The third dose of RV is only necessary if RV-5 is used for one or two of the first two doses.
6–18 months	HBV, IPV, influenza	The third dose of HBV should be given at least 16 weeks after the first dose and at least 8 weeks after the second dose, but not before age 24 weeks. Influenza vaccine should be administered annually to children aged 6 months to 18 years. Live attenuated influenza vaccine cannot be administered until age 2 years.
12–15 months	Measles-mumps-rubella vaccine (MMR), Hib, ¹ PCV, varicella vaccine	The first dose of MMR may be administered at 6–11 months before departure from the USA for international travel. These infants should receive two additional doses at the usual interval. Children ≥12 months of age should receive a second dose at least 4 weeks after the first dose before departure from the USA for international travel.
15–18 months	DTaP	DTaP may be given as early as age 12 months if there has been at least 6 months since the third dose.
12–23 months	Hepatitis A vaccine	Two doses ≥6 months apart.
4–6 years	DTaP IPV, MMR, varicella vaccine	The second dose of MMR should be routinely administered at age 4–6 years but may be given during any visit if at least 4 weeks have elapsed since administration of the first dose.
11–12 years	Tetanus, diphtheria, pertussis (Tdap) vaccine, human papillomavirus vaccine (HPV), ³ meningococcal conjugate vaccine (MCV)	Three doses of HPV should be administered to females at 0, 1–2, and 6 months (may be started as early as age 9 years). HPV4 or HPV9 may be administered to males aged 9–18 years to reduce the likelihood of developing genital warts. Administer one dose of Tdap to pregnant adolescents during each pregnancy at 27–36 weeks of gestation. A booster dose of MCV should be given at age 16 years.

¹Three Hib conjugate vaccines are available for use: (1) oligosaccharide conjugate Hib vaccine (HbOC), (2) polyribosylribitol phosphate-tetanus toxoid conjugate (PRP-T), and (3) *Haemophilus influenzae* type b conjugate vaccine (meningococcal protein conjugate) (PRP-OMP). Children immunized with PRP-OMP at 2 and 4 months of age do not require a dose at 6 months of age. PRP-T should only be used for the booster dose in children aged 12–15 months.

²Two RV vaccines are available for use: (1) RV-1 (Rotarix) monovalent live, oral, human attenuated rotavirus vaccine is approved for a two-dose series, and (2) RV-5 (RotaTeq) pentavalent live, oral, human-bovine reassortant rotavirus vaccine is approved for a three-dose series.

³Three HPV vaccines are available for use: (1) quadrivalent vaccine (HPV4) and (2) 9-valent vaccine (HPV9) for the prevention of cervical, vaginal, and vulvar cancers (in females) and genital warts (in males and females), and (3) bivalent vaccine (HPV2) for the prevention of cervical cancers in females.

Adapted from MMWR Morb Mortal Wkly Rep 2013;62(Suppl 1).

hypersensitivity reactions to immune globulin that may limit therapy. Conventional immune globulin contains aggregates of IgG; it will cause severe reactions if given intravenously. However, if the passively administered antibodies are derived from *animal* sera, hypersensitivity reactions ranging from anaphylaxis to serum sickness may occur. Highly purified immunoglobulins, especially from rodents or lagomorphs, are the least likely to cause reactions. To avoid anaphylactic reactions, tests for hypersensitivity to the animal serum must be performed. If an alternative preparation

is not available and administration of the specific antibody is deemed essential, desensitization can be carried out.

Antibodies derived from human serum not only avoid the risk of hypersensitivity reactions but also have a much longer half-life in humans (about 23 days for IgG antibodies) than those from animal sources (5–7 days or less). Consequently, much smaller doses of human antibody can be administered to provide therapeutic concentrations for several weeks. These advantages point to the desirability of using human antibodies for passive protection

TABLE A-3 Materials available for passive immunization.¹

Indication	Product	Dosage	Comments
Black widow spider bite	Antivenin (<i>Latrodectus mactans</i>), equine	One vial (6000 units) IV or IM. Some patients may require a repeat dose.	For persons with hypertensive cardiovascular disease or aged <16 or >60 years.
Bone marrow transplantation	Immune globulin (intravenous [IV]) ²	500 mg/kg IV on days 7 and 2 prior to transplantation and then once weekly through day 90 after transplantation.	Prophylaxis to decrease the risk of infection, interstitial pneumonia, and acute graft-versus-host disease in adults undergoing bone marrow transplantation.
Botulism	Botulism antitoxin heptavalent equine, Types A–G	Consult the CDC. ³	Treatment of symptomatic botulism. Available from the CDC. ³ Incidence of serum reactions is <1%.
	Botulism immune globulin (IV)	75 mg/kg IV.	For the treatment of patients <1 year of age with infant botulism caused by toxin type A or B.
Chronic lymphocytic leukemia (CLL)	Immune globulin (IV) ²	400 mg/kg IV every 3–4 weeks. Dosage should be adjusted upward if bacterial infections occur.	CLL patients with hypogammaglobulinemia and a history of at least one serious bacterial infection.
Cytomegalovirus (CMV)	Cytomegalovirus immune globulin (IV)	Consult the manufacturer's dosing recommendations.	Prophylaxis of CMV infection in bone marrow, kidney, liver, lung, pancreas, and heart transplant recipients.
Diphtheria	Diphtheria antitoxin, equine	20,000–100,000 units IV or IM depending on the severity and duration of illness.	Early treatment of respiratory diphtheria. Available from the CDC. ³ Anaphylactic reactions in ≥7% of adults and serum reactions in ≥5–10% of adults.
Hepatitis A	Immune globulin (intramuscular [IM])	Preexposure prophylaxis: 0.02 mL/kg IM for anticipated risk of ≥3 months, 0.06 mL/kg for anticipated risk of >3 months, repeated every 4–6 months for continued exposure. Postexposure: 0.02 mL/kg IM as soon as possible after exposure up to 2 weeks.	Preexposure and postexposure hepatitis A prophylaxis. The availability of hepatitis A vaccine has greatly reduced the need for preexposure prophylaxis. Patients >40 years should receive hepatitis A vaccine in addition to immune globulin for postexposure prophylaxis
Hepatitis B	Hepatitis B immune globulin (HBIG)	0.06 mL/kg IM as soon as possible after exposure up to 1 week for percutaneous exposure or 2 weeks for sexual exposure. 0.5 mL IM within 12 hours after birth for perinatal exposure.	Postexposure prophylaxis in nonimmune persons following percutaneous, mucosal, sexual, or perinatal exposure. Hepatitis B vaccine should also be administered.
HIV-infected children	Immune globulin (IV) ²	400 mg/kg IV every 28 days.	HIV-infected children with recurrent serious bacterial infections or hypogammaglobulinemia.
Idiopathic thrombocytopenic purpura (ITP)	Immune globulin (IV) ²	Consult the manufacturer's dosing recommendations for the specific product being used.	Response in children with ITP is greater than in adults. Corticosteroids are the treatment of choice in adults, except for severe pregnancy-associated ITP.
Kawasaki disease	Immune globulin (IV) ²	400 mg/kg IV daily for 4 consecutive days within 4 days after the onset of illness. A single dose of 2 g/kg IV over 10 hours is also effective.	Effective in the prevention of coronary aneurysms. For use in patients who meet strict criteria for Kawasaki disease.
Measles	Immune globulin (IM)	Normal hosts: 0.25 mL/kg IM. Immunocompromised hosts: 0.5 mL/kg IM (maximum 15 mL for all patients).	Postexposure prophylaxis (within 6 days after exposure) in nonimmune contacts of acute cases.
Primary immunodeficiency disorders	Immune globulin (IV) ²	Consult the manufacturer's dosing recommendations for the specific product being used.	Primary immunodeficiency disorders include specific antibody deficiencies (eg, X-linked agammaglobulinemia) and combined deficiencies (eg, severe combined immunodeficiencies).
Rabies	Rabies immune globulin	20 IU/kg. The full dose should be infiltrated around the wound and any remaining volume should be given IM at an anatomic site distant from vaccine administration.	Postexposure rabies prophylaxis in persons not previously immunized with rabies vaccine. Must be combined with rabies vaccine.

(continued)

TABLE A-3 Materials available for passive immunization.¹

Indication	Product	Dosage		Comments
Respiratory syncytial virus (RSV)	Palivizumab	15 mg/kg IM once prior to the beginning of the RSV season and once monthly until the end of the season.		For use in infants and children <24 months with chronic lung disease, hemodynamically significant congenital heart disease, or a history of premature birth (≥35 weeks of gestation).
Rubella	Immune globulin (IM)	0.55 mL/kg IM.		Nonimmune pregnant women exposed to rubella who will not consider therapeutic abortion. Administration does not prevent rubella in the fetus of an exposed mother.
Scorpion sting (Centruroides)	Scorpion Immune F(ab) ₂	3 vials IV over 10 minutes		Use as soon as possible after scorpion sting
Snake bite (coral snake)	Antivenin (<i>Micrurus fulvius</i>), equine	At least 3–5 vials (30–50 mL) IV initially within 4 hours after the bite. Additional doses may be required.		Neutralizes venom of eastern coral snake and Texas coral snake. Serum sickness occurs in almost all patients who receive >7 vials.
Snake bite (pit vipers)	Antivenin (Crotalidae) polyvalent immune Fab, ovine	An initial dose of 4–6 vials should be infused intravenously over 1 hour. The dose should be repeated if initial control is not achieved. After initial control, 2 vials should be given every 6 hours for up to three doses.		For the management of minimal to moderate North American crotalid envenomation.
Tetanus	Tetanus immune globulin	Postexposure prophylaxis: 250 units IM. For severe wounds or when there has been a delay in administration, 500 units is recommended. Treatment: 3000–6000 units IM.		Treatment of tetanus and postexposure prophylaxis of nonclean, nonminor wounds in inadequately immunized persons (less than two doses of tetanus toxoid or less than three doses if wound is >24 hours old).
Vaccinia	Vaccinia immune globulin	Consult the CDC. ³		Treatment of severe reactions to vaccinia vaccination, including eczema vaccinatum, vaccinia necrosum, and ocular vaccinia. Available from the CDC. ³
Varicella	Varicella-zoster immune globulin	Weight (kg)	Dose (units)	Postexposure prophylaxis (preferably within 48 hours but no later than within 96 hours after exposure) in susceptible immunocompromised hosts, selected pregnant women, and perinatally exposed newborns.
		≥2	62.5 IM	
		2.1–10	125 IM	
		10.1–20	250 IM	
		20.1–30	375 IM	
		30.1–40	500 IM	
		≥40	625 IM	

¹Passive immunotherapy or immunoprophylaxis should always be administered as soon as possible after exposure. Prior to the administration of animal sera, patients should be questioned and tested for hypersensitivity.

²See the following references for an analysis of additional uses of intravenously administered immune globulin: Ratko TA et al: Recommendations for off-label use of intravenously administered immunoglobulin preparations. JAMA 1995;273:1865; and Feasby T et al: Guidelines on the use of intravenous immune globulin for neurologic conditions. Transfus Med Rev 2007;21(2 Suppl 1):S57.

³Centers for Disease Control and Prevention, 404-639-3670 during weekday business hours; 770-488-7100 during nights, weekends, and holidays (emergency requests only); <http://www.cdc.gov/laboratory/drugservice/formulary.html>. Clinicians who suspect a diagnosis of botulism should immediately call their state health department's 24-hour emergency number.

whenever possible. Materials available for passive immunization are summarized in Table A-3.

LEGAL LIABILITY FOR UNTOWARD REACTIONS

It is the physician's responsibility to inform the patient of the risk of immunization and to use vaccines and antisera in an appropriate manner. This may require skin testing to assess

the risk of an untoward reaction. Some of the risks previously described are, however, currently unavoidable; on balance, the patient and society are clearly better off accepting the risks for routinely administered immunogens (eg, influenza and tetanus vaccines).

Manufacturers should be held legally accountable for failure to adhere to existing standards for production of biologicals. However, in the present litigious atmosphere of the USA, the filing of large liability claims by the statistically inevitable victims of good public health practice has caused many manufacturers to abandon

efforts to develop and produce low-profit but medically valuable therapeutic agents such as vaccines. Since the use and sale of these products are subject to careful review and approval by government bodies such as the Surgeon General's Advisory Committee on Immunization Practices and the US Food and Drug Administration, "strict product liability" (liability without fault) may be an inappropriate legal standard to apply when rare reactions to biologicals, produced and administered according to government guidelines, are involved.

RECOMMENDED IMMUNIZATION OF ADULTS FOR TRAVEL

Every adult, whether traveling or not, should be immunized with tetanus toxoid and should also be fully immunized against poliomyelitis, measles (for those born after 1956), and diphtheria. In addition, every traveler must fulfill the immunization requirements of the health authorities of the countries to be visited. These are listed in *Health Information for International Travel*, available from the Superintendent of Documents, US Government Printing Office, Washington, DC 20402. A useful website is <http://wwwnc.cdc.gov/travel/>. *The Medical Letter on Drugs and Therapeutics* also offers periodically updated recommendations for international travelers (see *Treatment Guidelines from The Medical Letter*, 2012;10:45). Immunizations received in preparation for travel should be recorded on the International Certificate of Immunization. *Note:* Smallpox vaccination is not recommended or required for travel in any country.

 α-glucosidase inhibitors, 761, 768*t*
 bromocriptine, 764, 769*t*
 colesevelam hydrochloride, 764, 769*t*
 drugs lowering glucose by tissue actions, 759–761
 biguanides, 759–760, 768*t*
 thiazolidinediones, 760–761, 768*t*
 glucose absorption agents, 761
 incretin mimics and action prolongers
 dipeptidyl peptidase-4 inhibitors, 762–763, 769*t*
 glucagon-like peptide-1 and, 762
 glucagon-like peptide-1 receptor agonists, 762, 769*t*
 pramlintide, 764, 769*t*
 sodium-glucose co-transporter 2 (SGLT2) inhibitors, 763–764, 769*t*
 sulfonylurea receptor binders, 757–759
 D-phenylalanine derivatives, 759, 768*t*
 meglitinide analogs, 759, 768*t*
 sulfonylureas, 757–759, 758*t*, 768*t*
- Antidiarrheal agents
 bile salt-binding resins, 1100
 colloidal bismuth compounds, 1100
 octreotide, 1101
 opioid agonists, 1100
 opioids for, 563
 OTC, 1123*t*–1124*t*
 use of, 1101, 1115*t*
- Antidiuretic hormone (ADH), 268. *See* Vasopressin
- Antidotes, 1040, 1041*t*
- Antiemetic agents, 1103–1106, 1116*t*
 benzodiazepines, 1106
 cannabinoids, 1106, 1116*t*

 H₁ antihistamines and anticholinergic drugs, 1106
 mechanisms of action of, 1103, 1104*f*
 neurokinin receptor antagonists, 1105
 phenothiazines and butyrophenones, 1105–1106
 serotonin 5-HT₃-antagonists, 1103–1105, 1116*t*, 1117*t*
 substituted benzamides, 1106
- Antiepileptics, 409–439. *See also Antiseizure drugs*
- Antifolate drugs, 834–837. *See also specific drugs*
 DNA gyrase inhibitors, 837–840, 840*t*
 methotrexate, 957, 958*t*
 pemetrexed, 957–958, 958*t*
 pralatrexate, 958–959
 preparations available, 840*t*
 sulfonamides, 834–836, 840*t*
 trimethoprim and trimethoprim-sulfamethoxazole mixtures, 836–837, 840*t*
- Antifungal agents, 853–861, 861*t*, 862*t*. *See also specific types*
- Antifungal agents, dermatologic
 oral
 azole derivatives, 1073
 griseofulvin, 1074
 terbinafine, 1074
 topical
 allylamines, 1073
 azole derivatives, 1073
 butenafine, 1073
 ciclopirox olamine, 1072
 nystatin and amphotericin B, 1073
 tolnaftate, 1073
- Antifungal agents, OTC preparations
 topical, 1124*t*
 vaginal, 1124*t*

- Antifungal agents, systemic, 853–860
 allylamine, 861, 861*t*
 amphotericin B, 853–854, 861*t*
 azoles
 description of, 856–859, 861*t*
 drug interactions of, 1159*t*–1160*t*
 echinocandins, 859–860, 861*t*
 flucytosine, 855*f*, 856, 861*t*
 oral, for mucocutaneous infections
 griseofulvin, 860
 terbinafine, 860, 861*t*
- Antifungal agents, topical
 allylamines, 860–861, 861*t*
 azoles, 860–861
 nystatin, 860
- Antigen-presenting cells (APCs), 979, 979*f*
- Anthelmintics
 albendazole, 938–940, 939*t*
 bithionol, 939*t*, 940
 diethylcarbazine citrate, 939*t*, 940–941
 ivermectin, 939*t*, 941–942
 mebendazole, 939*t*, 942
 metrifonate, 939*t*, 943
 niclosamide, 939*t*, 943
 oxamniquine, 939*t*, 943–944
 piperazine, 939*t*, 944
 praziquantel, 939*t*
 preparations available, 939*t*, 946
 pyrantel pamoate, 939*t*
 thiabendazole, 939*t*, 946
- Antihepatitis agents, 884–891
 hepatitis B
 adefovir dipivoxil, 886
 entecavir, 886
 fundamentals of, 884
 lamivudine, 886–887
 telbivudine, 887
 tenofovir, 887
 hepatitis C, 887–891
 fundamentals of, 887
 polymerase inhibitors, 889
 protease inhibitors, 889, 890*f*
 simeprevir, 890–891
 sofosbuvir, 889
 ribavirin, 891
 interferon alfa, 884*t*, 884–885, 893*t*–894*t*
- Antihistamines, 281–285, 1129*t*
- Antihypertensive agents, 173–193, 191*t*–192*t*. *See also specific types*
 angiotensin inhibitors, 176, 187–189
 angiotensin-converting enzyme inhibitors, 179*t*, 187–189, 192*t*, 193*t*
 angiotensin receptor blockers, 179*t*, 189, 192*t*, 193*t*
 mechanisms and sites of action of, 187, 188*f*
 case study of, 1058, 1067
 categories of, 175–176, 176*f*
 clinical pharmacology of, 189
 chronic hypertension, alpha-receptor antagonists, 161
 hypertensive emergencies, 190–191
 outpatient therapy, 189–190
 diuretics, 175, 176–178, 191*t*
 mechanisms of action and hemodynamic effects of, 177
 toxicity of, 178
 use of, 177–178, 179*t*
 in elderly, 1063
 ganglion-blocking agents, 181
 hypertension and blood pressure
 regulation by, 173–175, 174*f*, 175*f*. *See also Hypertension*
 preparations available, 193*t*
 sites of action of, 175, 176*f*
 sympathoplegics, 176, 176*f*, 178–182
 adrenergic neuron-blocking agents
 guanethidine, 181–182, 191*t*
 reserpine, 179*t*, 182, 191*t*
 alpha-adrenoceptor blockers, other, 184
 beta-adrenoceptor blocking agents, 179*t*, 182–183. *See also*
 β-receptor antagonist drugs
 esmolol, 183
 centrally acting, 179*t*, 179–180, 191*t*
 clonidine, 179*t*, 179–181
 guanabenz and guanfacine, 180
 methyldopa, 179, 179*t*
 preparations of, 193*t*
 vasodilators, 178*f*, 179*t*, 184–187, 192*t*
 calcium channel blockers, 179*t*, 186–187, 193*t*
 diazoxide, 186, 192*t*
 direct, 176
 fenoldopam, 186, 192*t*
 hydralazine, 179*t*, 184–185

preparations available, 753t–754t,
753–756
rapid-acting, 754
regimens for, 766
regulation of release of, 758t
secretion of, 748, 749f
short-acting, 753–754
types of, 754
tyrosine kinase receptors for, 28
- Insulin-like growth factor-I (IGF-I),
669
- Insulin pumps, 756–757
- Insulin receptor, 748–749, 749f, 750t
- Insulin receptor substrates, 749
- Insulin resistance, 757, 771
- Insulin secretagogues
meglitinide analogs, 759, 769t
sulfonylureas, 757–759, 769t. *See also*
Sulfonylureas
- Integrase strand transfer inhibitors (INSTIs),
883–884
dolutegravir, 871t, 883
elvitegravir, 871t, 883
fundamentals of, 883
raltegravir, 872t, 884
- Integrins, 1112
- Intensity of exposure, 1005
- Intention tremor, 504
- Intercalated cells, 258, 258f
- Interferon- α
description of, 996, 997t
hepatitis treated with, 884t, 884–885,
893t–894t
- Interferon, pegylated
preparations available, 893t–894t
with ribavirin, 80t, 85
- Interferons, 996, 997t
condylomata acuminata treated with,
892
preparations available, 893t–894t,
893–894
- Interleukin-1 inhibitors
adverse effects of, 658
anakinra, 657
canakinumab, 657
gout treated with, 663
mechanism of action of, 657
rheumatoid arthritis treated with,
657–658
rilonacept, 657–658
- Interleukin-1 α , 657
- Interleukin-11 (IL-11), 604–605, 606t
- Interleukins, 997t
- Intermediate-density lipoproteins (IDLs),
626
- Intermittent claudication, 209, 211t
- International normalized ratio (INR), 615
- Interval reduction, in cancer chemotherapy,
952
- Intestinal flukes, 943
- Intestinal metabolism, in first-pass effect, 58
- Intestinal osteodystrophy, 786
- Intestinal sterol absorption inhibitors, 637,
640t
- Intracellular receptors, for lipid-soluble
agents, 27, 27f
- Intraocular pressure, 165b, 267
- Intraoperative floppy iris syndrome (IFIS),
160
- Intravenous immunoglobulins (IGIV),
990–991
- Intravenous lipid emulsion, 469b
- Intrinsic efficacy, 5
- Intrinsic factor, 596
- Intubation, endotracheal, 484–485
- Inverse agonists
 β -receptor antagonist drugs as, 162
description of, 5–6, 7f, 23, 387
- Investigational New Drug (IND), 12f,
15–17
- Iodide
metabolism of, 687
organification of, 688, 688f
- Iodides, 695, 701t
- Iodine
bactericidal, 899
radioactive (¹³¹I, RAI), 695–696, 701t
- Iodism, 695
- Iodophors, 899
- Iodoquinol, 929t, 930, 930f
- Ion channels, 229. *See also specific types*
in addiction, 576, 577f, 577t
in central nervous system, 369f,
369–370, 370b, 370t
ligand-gated, 29f, 29–30, 35
novel analgesic targets and, 560b
voltage-gated, 30
- Ionization, of weak acids and bases, 9
- Ionization constants, 10t
- Ionotropic receptors
in addiction, 576, 577f, 577t
drugs mediating effects via, 583–585.
See also specific drugs
alcohol, 585
benzodiazepines, 584
inhalants, 585
ketamine and phencyclidine, 584
nicotine, 583–584
- Ions, 229–230, 230f. *See also specific ions*
- Ipecac syrup, 1040
- Ipilimumab, 974, 992
- Ipragliflozin, 261
- Ipratropium (bromide). *See also* Muscarinic
receptor blockers (antagonists)
asthma treated with, 353–354
characteristics of, 135t
chronic obstructive pulmonary disease
treated with, 130

- Irbesartan
hypertension treated with, 189
on vasoactive peptides, 317*t*
- Irinotecan
description of, 962*t*
UGT1A1 on metabolism of, 79*t*, 81
- Iron, 592–596, 593*f*, 594*t*
clinical pharmacology of, 593*f*, 594–596
indications in, 594*t*, 594–595
oral iron therapy, 595, 595*t*
parental iron therapy, 595–596
toxicity of, 596
drug interactions of, 1167*t*
female hormonal contraceptives effect on, 733
in hematopoiesis, 592
pharmacokinetics of, 592–594, 593*f*, 594*t*
pharmacology of, 592
poisoning management for, 1045
preparations available, 607*t*
toxicity of, clinical, 596, 606*t*
- Iron-deficiency anemia, 592–596, 593*f*, 594*t*
- Iron dextran, 595, 605*t*
- Iron overload, 596, 605*t*
- Iron sucrose complex, 595, 605*t*
- Irreversible antagonists, 23*f*, 24
- Irreversible cholinesterase inhibitors, 117
- Irrigation, whole bowel, 596
- Irritable bowel syndrome
description of, 1101–1102
drugs for, 1101–1103, 1115*t*
antispasmodics, 1101–1102
chloride channel activators, 1103
serotonin 5-HT₃-receptor antagonists, 1102, 1102*f*, 1116*t*, 1117*t*
- Isavuconazole, 859, 861*t*
- Isavuconazonium sulfate, 859
- Ischemic heart disease, 167*f*, 167–168, 168*f*
- Islet amyloid, 769*t*
- Islet amyloid polypeptide (IAPP) analogs, 747, 764, 769*t*
- Isocarboxazid, 546*t*
- Isoeicosanoids, 326
- Isoflurane, 441–449. *See also* Anesthetics, inhaled
properties of, 443*t*
structure of, 443*f*
- Isolated systolic hypertension, 174
- Isoniazid
phase II activation of, 57, 57*f*
tuberculosis treated with, 842–845, 843*t*, 851*t*
- Isopropyl alcohol (isopropanol)
antiseptic and disinfection uses of, 898, 898*t*
ingestion of, 405
- Isoprostanes, 326
- Isoproterenol, 146*f*, 146*t*, 149. *See also* Sympathomimetics, direct-acting
asthma treated with, 351, 362*t*
cardiovascular responses to, 146*t*
structure of, 144*f*, 350*f*
- Isosorbide dinitrate
angina pectoris treated with, 198, 202*t*, 209*t*
heart failure treated with, 225*t*
- Isosorbide dinitrate/hydralazine (BiDil), 222
- Isosorbide mononitrate, 198, 202*t*, 209*t*. *See also* Nitrates and nitrites
- Isotretinoin, 1077–1078
- Isoxazolyl penicillins, 801
- Isradipine
angina pectoris treated with, 203*t*
hypertension treated with, 187
- Istaroxime, for heart failure, 219
- Itraconazole, 857*f*, 858, 858*t*, 861*t*
dermatologic, 1073
- Ivabradine
angina pectoris treated with, 207, 210*t*
arrhythmia treated with, 247
chronic heart failure treated with, 222
- Ivacaftor, 24, 248*b*, 252*t*
- Ivermectin
ectoparasiticide action of, 1075
helminths treated with, 939*t*, 941–942
- Ixabepilone, 963
- Ixekizumab, 994
- ## J
- JAK/STAT receptors, 667
- Janus-kinase (JAK) family, 28–29, 29*f*
- Jaw, osteonecrosis of, 780
- Jet lag, 1143–1144
- Jimson-weed, 125. *See also* Atropine; Muscarinic receptor blockers
