allele, which results in reduced serum levels of C1q compared to the C1qG276 allele, had prolonged remission following rituximab monotherapy compared to patients with the G allele.[24] Efforts to optimize CDC led to the development of ofatumumab, which also binds to CD20 but at a distinct epitope from rituximab.[25] Ofatumumab has been demonstrated to induce more CDC in vitro compared to rituximab, even in the setting of low CD20 expression where rituximab is not efficacious.[26] Unlike rituximab, ofatumumab does not directly induce apoptosis in B-cell lines, suggesting that ADCC and CDC are the primary mechanisms of action of ofatumumab.[25] However, preliminary clinical data show that ofatumumab has limited efficacy in the setting of rituximab-resistant follicular lymphoma[27] and comparable efficacy in the setting of non-Hodgkin lymphoma (NHL), although data from trials directly comparing ofatumumab to rituximab are lacking.[25] In the setting of refractory chronic lymphocytic leukemia (CLL), patients demonstrated a 47% to 58% response rate to ofatumumab, leading to its approval by the U.S. Food and Drug Administration (FDA) in 2009 for the treatment of refractory CLL.[28]

Induction of Adaptive Immunity

There is growing evidence to suggest that tumor-targeted antibodies are capable of inducing a therapeutically relevant, tumor-targeted adaptive immune response. ADCC, CDC, and tumor cell signaling perturbation result in target cell apoptosis, which creates tumor cell fragments that can be phagocytosed by antigen-presenting cells (APCs), such as macrophages and dendritic cells. Antibodies can also serve as opsonins by coating tumor cells and engaging Fc receptors on APCs to induce phagocytosis. These engulfed antigens can be processed through the endocytic pathway and presented on MHCII molecules to prime tumor-specific $CD4^+$ T-cell responses. Alternatively, tumor antigens can be loaded on to MHCI molecules to prime $CD8^+$ cytotoxic T cell (CTL) responses, in a process called *cross presentation*[29] (see Figure 50-3). Activated CTLs are capable of directly killing tumor cells that express cognate antigen on MHCI and have powerful prognostic significance in a wide range of human cancers.[30] In vitro, myeloma cells coated with an anti-syndecan1 antibody are capable of activating dendritic cells and inducing the cross presentation of cancer-testis antigen NY-Eso-1, generating NY-Eso-1–specific CTLs capable of lysing myeloma targets.[31] Similarly, antibody-coated melanoma and ovarian cancer cells were capable of inducing cross presentation of various tumor cell antigens, resulting in the generation of melanoma- and ovarian cancer–specific CTLs capable of lysing tumor cell targets.[32] Blockade of inhibitory FcγRIIB enhances dendritic cell activation and cross presentation, suggesting a potential therapeutic approach to boost antibody-initiated adaptive immunity.[33] Recent work in the setting of colorectal cancer shows that cetuximab in combination with chemotherapy induces a potent CTL

Table 50-1 FDA-Approved Antibodies Used in Oncology

Generic Name (Trade Name)	Target	Antibody Isotype	Cancer Indication
Rituximab (Rituxan)	CD20	Chimeric IgG1	Chronic lymphocytic leukemia B-cell non-Hodgkin lymphoma
Trastuzumab (Herceptin)	HER2/neu	Humanized IgG1	Breast cancer, gastric/gastroesophageal junction adenocarcinomas
Alemtuzumab (Campath-1H)	CD52	Humanized IgG1	Chronic lymphocytic leukemia
Cetuximab (Erbitux)	EGF receptor	Chimeric IgG1	Colorectal cancer, squamous carcinoma of the head and neck
Bevacizumab (Avastin)	VEGF	Humanized IgG1	Colorectal cancer, non–small-cell lung cancer, renal cancer, glioblastoma
Panitumumab (Vectibix)	EGF receptor	Human IgG2	Colorectal cancer
Ofatumumab (Arzerra)	CD20	Human IgG1	Chronic lymphocytic leukemia
Pertuzumab (Perjeta)	HER2/neu	Humanized IgG1	Breast cancer
Ipilimumab (Yervoy)	CTLA-4	Human IgG1	Melanoma
Immunoconjugates			
Ibritumomab tiuxetan (Zevalin)	CD20	Murine IgG1	B-cell non-Hodgkin lymphoma
^{131}I-tositumomab/tositumomab (Bexxar)	CD20	Murine IgG2a	B-cell non-Hodgkin lymphoma
Brentuximab vedotin (Adcetris)	CD30	Chimeric IgG1	Anaplastic large-cell lymphoma, Hodgkin's lymphoma

response and thus may contribute to the in vivo activity of cetuximab.[34] Animal models demonstrate that the therapeutic efficacy of HER2/neu-directed antibodies is due in part to induction of an adaptive immune response, as depletion of T cells abrogates antitumor activity.[35,36] Although the preclinical data implicating the induction of adaptive immunity as an important effector mechanism of tumor-targeted antibodies are provocative, more clinical evidence is needed to determine the clinical relevance of this mechanism of action.

Antibodies Targeting Solid Tumors

As mentioned earlier, EGFR family members are overexpressed in a multitude of solid tumors, including colorectal, lung, head and neck, ovarian, and malignant gliomas. The most extensively studied anti-EGFR1 antibody (Table 50-1) is cetuximab, which binds to EGFR1 and blocks ligand binding, receptor dimerization and induces EGFR internalization and degradation, culminating in inhibition of receptor-mediated phosphorylation.[37,38] Preclinical data suggest that ADCC and CDC may be important to the efficacy of cetuximab; however, more clinical data are needed to validate these claims. Cetuximab monotherapy has limited clinical activity but significantly improves outcomes when combined with chemotherapy.[39] First-line therapy with cetuximab added to a regimen of FOLFIRI (leucovorin, fluorouracil, and irinotecan) chemotherapy significantly improves overall survival compared to FOLFIRI alone in the setting of metastatic colorectal cancer.[40] It is important to note that the mutational status of KRAS, which is downstream of EGFR, is critical in predicting response to cetuximab: patients harboring activating KRAS mutations generally do not benefit from cetuximab therapy.[39]

Panitumumab is another antibody targeting EGFR, but unlike cetuximab, panitumumab possesses an IgG2 isotype and thus is unable to induce high levels of ADCC or CDC. Panitumumab significantly improves progression-free survival (PFS) and overall response rates in patients with refractory metastatic colon cancer compared to best supportive care (BSC).[12] Like cetuximab, use of panitumumab is relegated to patients with wild-type KRAS.[41]

Three new anti-EGFR antibodies are currently being evaluated in Phase I and Phase II clinical trials: necitumumab, zalutumumab, and nimotuzumab. Necitumumab is a fully human IgG1 that binds to a similar epitope of EGFR compared to cetuximab and has antitumor activity that is comparable or superior to cetuximab in preclinical models.[42,43] No hypersensitivity reactions have been reported so far, whereas for cetuximab, approximately 3% of patients develop hypersensitivity reactions requiring treatment, mostly during the first infusion of antibody. Phase III studies are ongoing in the setting of non–small-cell lung cancer (NSCLC) (NCT00982111).

Zalutumumab is capable of inducing ADCC in addition to inhibiting receptor phosphorylation. Results from a Phase III trial showed modest improvement in PFS compared to BSC in patients with squamous carcinoma of the head and neck, although no improvement in overall survival was demonstrated.[44]

Nimotuzumab has been shown to sensitize NSCLC cell lines with high EGFR expression to radiation therapy while having no effect on EGFR low-expressing lines.[45] Nimotuzumab has a highly favorable toxicity profile with virtually no grade 3 or 4 skin toxicities observed, often a dose-limiting toxicity seen with other anti-EGFR antibodies. Unlike cetuximab and panitumumab, nimotuzumab has a 10-fold lower affinity for EGFR and binds to EGFR in a manner that still allows the receptor to adopt an active confirmation and mediate ligand independent signaling.[46] This basal level of signaling may be enough to sustain growth of normal cells and explain nimotuzumab's favorable toxicity profile. An alternate hypothesis is that nimotuzumab requires bivalent binding for stable attachment to EGFR, and that normal cells do not have sufficient EGFR expression to mediate enough bivalent binding to be adversely affected.[47] Based on favorable Phase II studies, nimotuzumab is approved for use in more than 20 countries in patients with head and neck cancer and/or gliomas.[48]

HER2/neu is overexpressed and gene amplified in 25% to 30% of breast cancer, and these properties confer a negative prognosis in patients. It is also overexpressed in some adenocarcinomas of the lung, ovary, and gastrointestinal tract.[49] Trastuzumab monotherapy showed a 26% response rate in patients with untreated metastatic breast cancer[50] and significantly improved PFS and OS when combined with chemotherapy, although some patients developed serious cardiotoxicity.[51] The exact mechanism of action of trastuzumab is still unclear but is thought to involve inhibition of receptor dimerization, inhibition of receptor shedding, and activation of immune effector mechanisms such as ADCC.[14]

Trastuzumab emtansine, commonly referred to as trastuzumab-DM1 (T-DM1), is an immunoconjugate in which the cytotoxic agent DM1 is covalently attached to trastuzumab. DM1, a derivative of maytansine, is a highly potent antimitotic but has limited clinical utility due to a poor therapeutic window. Phase I and II studies have demonstrated that targeted delivery of DM1 with T-DM1 significantly improves toxicity and has antitumor activity in patients with metastatic breast cancer previously treated with HER2 targeted agents.[52,53] In addition to the cytotoxic effects of DM1, T-DM1 maintains trastuzumab's mechanisms of action, including signaling perturbation and induction of ADCC.[54] Results from a pivotal Phase III trial demonstrate that T-DM1 improved PFS without significant cardiotoxicity in breast cancer patients whose disease had progressed following trastuzumab therapy.[55]

Pertuzumab is another approved HER2-directed antibody that binds to a distinct epitope from trastuzumab, but has complementary mechanisms of action including inhibition of receptor dimerization and induction of ADCC.[56,57] Results from the CLEOPATRA trial demonstrated that adding pertuzumab to a combination of trastuzumab plus chemotherapy significantly increased PFS in patients with metastatic breast cancer compared to trastuzumab plus chemotherapy alone.[58] Notably, no enhanced cardiotoxicity was seen in patients receiving pertuzumab and trastuzumab combination therapy.[58] These results formed the basis for the FDA approval of pertuzumab in 2012.

Antibodies Targeting Hematological Malignancies

Rituximab is a chimeric antibody that targets CD20 and is used clinically for the treatment of a wide range of B-cell malignancies. A pivotal study leading to FDA approval showed a 48% response rate to rituximab in patients with relapsed low-grade or follicular lymphoma.[59] Combination therapy with rituximab and cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) chemotherapy improved OS in elderly patients with large B-cell lymphoma.[60] In the setting of CLL, rituximab seems to be more effective in patients who have not received prior chemotherapy.[61] This antibody continues to be an indispensable backbone for the therapy of patients with B-cell malignancies.

Alemtuzumab is approved for the treatment of fludarabine-refractory CLL and binds to CD52, which is highly expressed on various B- and T-cell malignancies. CD52 is a GPI-linked protein with unknown function that is normally expressed in parts of the male reproductive tract and on a wide range of leukocytes, including lymphocytes and monocytes. The exact mechanism of action of alemtuzumab is unclear but is thought to involve CDC, ADCC, and induction of apoptosis. In addition to chemoresistant CLL, alemtuzumab has activity in the setting of prolymphocytic leukemia (PLL) and low-grade NHL.[62-64] Significant toxicities attributed to alemtuzumab therapy include myelosuppression and opportunistic infections, sometimes leading to death. These toxicities are presumably a result of CD52 expression on normal leukocytes.

CD30 is a member of the TNF superfamily and is expressed by the malignant Reed-Sternberg cells characteristic of Hodgkin's lymphoma. Brentuximab vedotin is an antibody-drug conjugate composed of the anti-CD30 antibody brentuximab linked to the anti-microtubule agent

monomethyl auristatin E (MMAE). On binding to CD30, the antibody-CD30 complex is internalized and trafficked to the lysosome, where MMAE is released by proteolysis. MMAE binds to tubulin, resulting in cell cycle arrest and apoptosis. Brentuximab vedotin is generally well tolerated, with neutropenia and peripheral neuropathy being the most common serious adverse events. Results of Phase II studies show a 75% overall response rate in patients with relapsed or refractory Hodgkin's lymphoma after stem cell transplant and an 86% response rate in patients with anaplastic large-cell lymphoma.[65,66]

CD74 is another interesting target for non–CD20-expressing malignancies such as multiple myeloma. CD74 was originally described as the invariant chain of MHC Class II and was shown to be critical for proper loading of peptide and trafficking of MHCII molecules to the cell surface. More recently, non-MHC Class II–related functions of CD74 have been described, including its role in cell survival and proliferation. The ligand for CD74 is macrophage inhibitory factor (MIF), and because CD74 is not capable of initiating signaling on its own, CD44 is required as a co-receptor. CD74 is expressed on 85% of NHL, CLL, and various multiple myeloma cell lines and has limited cell surface expression on normal cells.[67] Milatuzumab is a chimeric antibody that targets CD74 and has shown efficacy in preclinical studies of multiple myeloma and NHL.[68,69] Milatuzumab does not induce ADCC or CDC and is rapidly internalized on binding to CD74. This rapid internalization of antibody-CD74 complexes makes milatuzumab a prime candidate for the development of an antibody drug conjugate. Preclinical studies on a milatuzumab-doxorubicin conjugate are encouraging.[70] Currently, milatuzumab is in multiple Phase I and II studies for multiple myeloma (NCT00421525), CLL (NCT00603668), and NHL (NCT00989586).

Antibodies Targeting Immune Cells

Ipilimumab, an antibody that targets cytotoxic T-lymphocyte–associated antigen (CTLA-4), is the first anti-cancer antibody to gain FDA approval that specifically targets non-malignant immune cells. CTLA-4 is expressed on T-cells and is a negative regulator of T-cell activation (Figure 50-4). T-cell activation is initiated by engagement of the T-cell receptor (TCR) with peptide-loaded MHC; however, co-stimulatory signals are needed to ensure proper activation. The most important of these signals is the interaction of CD28 on T cells with the B7 family members CD80 and CD86 on APCs. CTLA-4 binds to CD80 and CD86 with higher affinity than CD28 and serves to inhibit activation by outcompeting CD28 and transducing inhibitory signals. CTLA-4 suppresses antitumor immunity by downregulating $CD4^+$ T-cell responses and enhancing the immunosuppressive effect of T-regulatory cells (Treg).[71] Targeting CTLA-4 with a monoclonal antibody demonstrated remarkable antitumor activity in preclinical models,[72] and ipilimumab showed promise in early clinical studies that demonstrated antitumor activity and activation of antitumor immune responses.[73] Notable adverse events included immune-related diarrhea and vitiligo, consistent with ipilimumab's mechanism of action. A pivotal Phase III trial showed that ipilimumab therapy improved median survival by 3.6 months in patients with metastatic melanoma, making ipilimumab the only therapeutic demonstrated to improve survival in patients with metastatic melanoma.[74]

Another emerging target for antibody therapy is programmed cell death protein 1 (PD-1). PD-1 is upregulated on activated T cells and serves to dampen effector T-cell responses in peripheral tissues, including the tumor microenvironment. PD-1 is also expressed on Treg cells and has been demonstrated to promote the development and activity of peripherally induced Treg cells.[75] PD-1 ligands, most notably PD-L1, are expressed on tumor cells and myeloid cells in the tumor microenvironment, providing further rationale for therapeutic targeting of this pathway.[76] Data from two large Phase I trials of the anti-PD-1 antibody BMS-936558, a fully human IgG4, demonstrated safety and antitumor efficacy in the setting of metastatic melanoma, renal cancer, and NSCLC.[77,78] Remarkably, monotherapy with BMS-936558 resulted in durable antitumor responses, even in the setting of NSCLC, which in contrast to melanoma and renal cancer had not been considered to be an immunotherapy-responsive tumor. In addition to multiple Phase I and II trials, BMS-936558 is also being evaluated in combination with ipilimumab for the treatment of metastatic melanoma (NCT01024231).

Whereas ipilimumab and BMS-936558 block signaling through inhibitory receptors, another approach to re-activate anti-tumor immunity is to activate stimulatory receptors. CD40 is a stimulatory receptor expressed by many different cell types including B cells, dendritic cells, monocytes, endothelial cells, and fibroblasts. The ligand for CD40, CD40L, is primarily expressed on activated T cells and platelets. Engagement of CD40 leads to B-cell proliferation and maturation of dendritic cells, resulting in enhancement of T-cell activation. Interestingly, CD40 is expressed on a wide range of malignancies, including nearly all B-cell malignancies and many solid tumors, and engagement of CD40 on some malignant cells leads to apoptosis.[79] Three antibodies targeting CD40 are currently being evaluated for safety and efficacy. Dacetuzumab (SGN-40) is a humanized IgG1 with weak agonist activity that is capable of inducing ADCC in vitro and has antitumor activity against B-cell

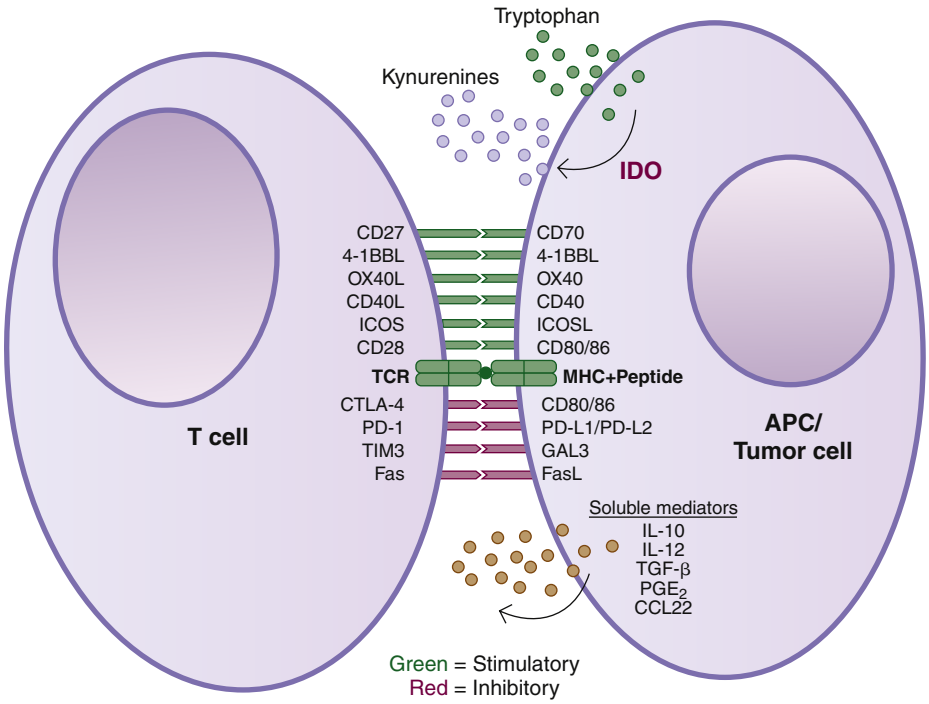

Figure 50-4 Potential targets to enhance T-cell activation. *APC*, Antigen-presenting cell; *IDO*, indoleamine 2,3-dioxygenase; *MHC*, major histocompatibility complex; *TCR*, T-cell receptor.

lymphoma xenografts in vivo.[80] A Phase I study of dacetuzumab showed encouraging antitumor activity in NHL patients, with the most common adverse events being related to cytokine release syndrome, including fever, headache, and fatigue.[81]

Lucatumumab (HCD122) is an IgG1 that is a pure antagonist of CD40 capable of inducing ADCC and has shown activity against B-cell CLL in preclinical models.[82] A recent Phase I study showed that lucatumumab is reasonably well tolerated; however, it shows minimal activity as a single agent in the setting of relapsed CLL.[83]

CP-870,813 is a fully human IgG2 that functions as a CD40 agonist and has antitumor and immunostimulatory activity in patients with melanoma.[84] Remarkably, CP-870,813 in combination with gemcitabine has also demonstrated activity in a small cohort of patients with pancreatic cancer.[85] In the same study, the authors used a mouse model of spontaneous pancreatic cancer to identify a potential mechanism of action of CP-870,813. Unexpectedly, the antitumor activity of CP-870,813 was independent of T cells and dependent on its capacity to alter the phenotype of tumor-associated macrophages to a more tumoricidal phenotype.[85]

Antibodies Targeting Angiogenesis

The tumor stroma is enriched with pro-angiogenic factors that facilitate recruitment and remodeling of blood vessels essential for tumor growth. A critical driver of vascular endothelial cell migration and proliferation is the vascular endothelial growth factor (VEGF) family, comprising six members (VEGF-A through -E and placental growth factor [PlGF]). VEGF has three known receptors, VEGFR1 through -3, with VEGFR-1 and -2 being most relevant to tumor biology. VEGF levels are increased in a wide range of malignancies and are often associated with a poor prognosis.[86] Bevacizumab is an antibody targeting VEGF-A and has been shown to improve survival when combined with chemotherapy in patients with metastatic colon cancer.[87] The most frequent adverse event was hypertension, with no increased incidence of hemorrhage, frequently observed in other trials of bevacizumab.[87] The addition of bevacizumab to a regimen of carboplatin and paclitaxel improved response rates and survival in patients with NSCLC, although a significant increase in bleeding, specifically lethal pulmonary hemorrhage, was observed.[88] Single-agent bevacizumab received accelerated approval for the treatment of glioblastoma multiforme (GBM) based on demonstrated durable response rates and manageable adverse events when administered as monotherapy.[89,90] Larger clinical trials are needed to evaluate bevacizumab's impact on the clinical course of GBM. The role of bevacizumab in the setting of HER2/neu–negative metastatic breast cancer is a subject of debate. In 2008, bevacizumab received accelerated approval for the treatment of HER2/neu–negative metastatic breast cancer based largely on results from the E2100 trial, which demonstrated that combination therapy with bevacizumab and paclitaxel improved PFS compared to paclitaxel alone,

with no significant difference in OS between the two treatment arms.[91] However, subsequent trials showed that the addition of bevacizumab to chemotherapy resulted in only modest improvements in PFS, with no impact on overall survival.[92-94] Based on the results of these trials, the FDA revoked approval of bevacizumab for the treatment of metastatic breast cancer in 2011, citing an unfavorable risk/benefit profile. Debate continues on the utility of using PFS or pathological complete response (pCR) versus overall survival to evaluate the clinical efficacy of new drugs and treatment regimens.

VEGFR-2 is upregulated in the tumor vasculature. Signaling through VEGFR-2, as opposed to VEGF-1, is sufficient to mediate the pro-angiogenic functions of VEGF.[95] The VEGF/VEGFR-2 axis is also detrimental to the antitumor immune response, whereas signaling through VEGF-1 may promote lymphoid development.[96] Ramucirumab is a fully human IgG1 that specifically targets VEGFR-2 and inhibits VEGF binding. A Phase I study demonstrated antitumor efficacy. However, significant toxicities were observed including hypertension, abdominal pain, vomiting, and deep-vein thromboses.[97] Several Phase II and III studies in the setting of renal, breast, colon, and NSCLC are ongoing.[95]

Recent work suggests that cancer-associated fibroblasts (CAFs) are an important source of pro-angiogenic stimuli, such as VEGF and fibroblast growth factor (FGF). CAFs from tumors resistant to anti-VEGF therapy upregulate expression of other pro-angiogenic factors and may contribute to resistance of VEGF targeted therapy.[98] A potential therapeutic target for CAFs is fibroblast activated protein-alpha (FAP), which is highly expressed on CAFs compared to normal fibroblasts.[99] Depletion of FAP$^+$ stromal cells results in inhibition of tumor growth and activation of antitumor immune responses.[100] However, clinical efforts to target FAP using the anti-FAP antibody sibrotuzumab have been disappointing.[101] One possible explanation for this lack of efficacy is that sibrotuzumab does not inhibit the enzymatic activity of FAP.[102] Conjugation of sibrituzumab to the antimitotic DM1 has shown promise in a preclinical study. However, further studies are needed to determine the clinical utility of this antibody-drug conjugate.[103]

Antibody Engineering

Advancements in protein engineering have allowed for the modification of antibody structure in an attempt to improve targeting and enhance antitumor activity. Bispecific antibodies represent an important class of engineered antibodies that are capable of recognizing two distinct antigens. The most common bispecific antibodies target a tumor antigen and CD3, which is a component of the T-cell receptor. Bispecific T-cell engagers (BiTEs) are a class of bispecific antibodies that link the variable domains of an antitumor antibody with the variable region of an anti-CD3 antibody. BiTEs induce robust polyclonal T-cell activation, resulting in targeted release of perforin and granzyme and tumor cell apoptosis. Importantly, BiTES are capable of stimulating T-cells and inducing tumor cell lysis in the absence of co-stimulatory signals and MHC expression. Blinatumomab is a BiTE that binds to CD19 and CD3 that has clinical activity in patients with minimal residual disease (MRD) positive, B-cell acute lymphoblastic leukemia (ALL).[104] Of the 20 patients treated, 16 became MRD negative, and 12 of the 16 responders had never turned MRD negative with any previous treatment.[104]

Bispecific antibodies that have an intact Fc domain are termed *trifunctional antibodies*, because of their capacity to bind and activate FcγR$^+$ immune effectors. Trifunctional antibodies targeting a tumor antigen and CD3 are capable of inducing T-cell–mediated lysis in addition to ADCC and phagocytosis. Catumaxomab is an example of a trifunctional antibody that has dual specificity for CD3 and epithelial cell adhesion molecule (EpCAM), which is ubiquitously expressed on tumors of epithelial origin.[105] Catumaxomab contains one light chain and one heavy chain from an anti-EpCAM mouse IgG2, and one light chain and one heavy chain from an anti-CD3 rat IgG2b. The Fc domain generated from mouse and rat constant regions binds preferentially to activating FcγRs, with low binding to FcγRIIB, resulting in potent ADCC and phagocytosis of EpCAM$^+$ tumor cells.[105] Interestingly, preclinical studies demonstrated that the related antibody, BiLU (anti-human EpCAM × anti-mouse CD3), was capable of eliciting a protective adaptive immune response against syngeneic tumors.[106] A small clinical study showed that catumaxomab was capable of eliciting tumor-specific T cells, suggesting that induction of adaptive immunity may contribute to catumaxomab's mechanisms of action.[107] Catumaxomab is approved in the European Union for the treatment of malignant ascites and been shown to improve quality of life and increase time to next paracentesis.[108] The main adverse events associated with catumaxomab are related to severe cytokine release syndrome, necessitating careful dosing and patient monitoring.

Modifications to the Fc domain are capable of enhancing effector functions and improving the pharmacokinetic profile of monoclonal antibodies. Fc mutational analyses have identified optimal amino acid sequences that result in greater binding to activating FcγRs and C1q to enhance ADCC and CDC. An anti-CD19 antibody engineered to have greater FcγR binding demonstrated more potent ADCC, phagocytosis, and antitumor activity compared to its parent antibody.[109] Improving interactions with neonatal

FcRs can extend serum-half life and potentially reduce the cost of treatment.[110] However, modulation of oligosaccharide residues within the CH2 domain is the modification that has been most widely used to date.

Human IgG molecules contain two N-linked, complex-type oligosaccharides within the CH2 domain. These oligosaccharides contain a fucose residue, and removal of this residue dramatically enhances the capacity of antibodies to mediate ADCC, even at low antigen densities.[111] Obinutuzumab is a defucosylated anti-CD20 antibody that displays greater ADCC in vitro and anti-lymphoma activity in vivo compared to rituximab.[112] Two Phase I studies of obinutuzumab demonstrated activity in the setting of relapsed NHL with manageable adverse events, mostly associated with infusion-related toxicity.[113,114] Interestingly, both studies showed activity (13% to 22% response rate) in a subset of patients refractory to rituximab.[113,114]

Summary and Future Directions

Monoclonal antibodies have revolutionized the treatment of cancer and will continue to serve as mainstays of cancer therapy for the foreseeable future. Antibodies offer the unique capability to specifically engage a tumor cell and stimulate a multifaceted program of cell death involving perturbation of homeostatic signaling and activation of the host immune system, without overt toxicity. Advances in antibody therapy are contingent on the identification and validation of new tumor antigens, manipulation of the tumor microenvironment, and optimization of antibody structure to improve effector functions and cytotoxic drug delivery.

Cancer and the Cellular Immune Response

Introduction

Key features of the immune system are its abilities to distinguish self from nonself, to recognize and respond to a myriad of foreign molecules (antigens) with exquisite specificity, to remember previously encountered antigens and quickly mobilize an expanded response, and to scan the entire body continuously for antigens. These properties make the immune system ideal for defending the host against developing and recurrent cancers and nascent metastatic tumor deposits, at least in theory. In spite of its promise, however, the application of immunological approaches to the cancer problem has only recently started to yield the dramatic results long anticipated by immunologists.[1-4] The major obstacle to using the immune system and its various components to prevent or treat human cancer has been a lack of understanding of the fundamental mechanisms that govern the immune response. These include the mechanisms by which cells of the immune system recognize antigens, expand and differentiate, find and destroy aberrant cells and pathogens, and die or become quiescent when no longer needed. The inability to direct these processes toward the destruction of cancer cells in the body in a consistent and effective way has thwarted many attempts at cancer immunotherapy to date. However, there are now a number of clear instances in which immunological approaches have brought significant benefit to cancer patients. This progress sustains the belief that the immune system has much to offer in controlling cancer, if only we could better control and direct its destructive powers.

Very recently, major advances have been made in understanding how cells of the immune system become activated on encountering an antigen and how they communicate with their external environment and with each other. Some of these advances are a direct result of the Human Genome Project, which has enabled the discovery of previously unknown genes coding for families of cytokines and receptors involved in regulating inflammatory and immune responses.[5] Others are derived from insights gleaned from studies of how the immune system defends the host against microbial pathogens. The normal host has various mechanisms that help rid it of invading pathogens.[6] Collectively, these mechanisms are called *innate* or *natural immunity*, and they require no previous contact with the pathogen to become active. *Acquired immunity*, on the other hand, is an immune response triggered by an encounter with a foreign cell or molecule and involves an amplification process that increases the number of lymphocytes able to recognize and respond to an invader. Until recently, the means by which innate immune mechanisms distinguish pathogens from self were unknown. A number of studies have demonstrated that the innate immune system recognizes many lethal microbial pathogens by means of pattern recognition receptors (Toll-like receptors, TLRs) on antigen-presenting cells (APCs).[7-10] These receptors recognize common molecular patterns shared among bacteria or viruses but not present on normal or cancerous host cells, such as lipoprotein, peptidoglycan, lipopolysaccharide, lipoteichoic acid, bacterial DNA, and viral double-stranded RNA. The triggering of pattern recognition receptors by such molecules has three important effects on the APCs of the immune system: (1) expression of stable and high levels of pathogen-derived peptide-MHC complexes on the cell surface, which will trigger T-cell responses; (2) expression of high levels of co-stimulatory molecules such as CD80 and CD86 that prime and activate antigen-specific T cells; and (3) secretion of a large number of proinflammatory cytokines, such as interleukin 1 (IL-1), IL-6, IL-12, TNF-α, GM-CSF, and type 1 interferon.[7-10] The proinflammatory cytokines further activate APCs, directly activate the innate killer cells of the immune system (NK cells and macrophages), and promote T-cell differentiation into antigen-specific helper T cells or cytotoxic T cells that mediate acquired immunity. These new findings explain the mechanism of action of bacterial adjuvants, which have long been used in animal models to enhance immunization toward protein and peptide antigens. They also suggest that the relative inefficiency of immunization with tumor antigens may be due, in part, to failure of the vaccines to stimulate the innate arm of the immune system, which is required for maximal amplification of antigen-specific, T-cell–mediated (acquired) immune responses. Thus, developing approaches to trigger

innate immunity in concert with more traditional approaches to stimulate acquired immunity represents a promising new strategy for cancer immunotherapy.

Other important advances concern the biology and activities of dendritic cells (DCs).[11-13] These are a heterogeneous group of cells involved in antigen detection, capture, processing, and presentation to T cells. DCs are the major cell type expressing germline-encoded immunoreceptors (TLRs, C-type lectin-like receptors, Ig-like molecules), and they are at the forefront of host defense mechanisms against microbial pathogens and altered self-molecules, such as those as encountered in virus-infected cells and autoimmune and antitumor responses.

Innate Recognition of Microbial Pathogens by Toll-Like Receptors

Recognition of Pathogen-Associated Molecular Patterns

An essential role of our immune system is to sense and protect us from infection by pathogenic microorganisms and establish tolerance to self-antigens. One of the most important mechanisms that the immune system distinguishes "infectious non-self" from "self" is the development of recognition of *pathogen-associated molecular patterns* (PAMPs).[6] This PAMPs recognition system was first identified in *Drosophila* as Toll, an essential molecule for embryonic patterning, as well as for antifungal immunity.[14] The first mammalian homologue of Toll was identified as Toll-like receptor 4 (TLR-4), which was shown to recognize lipopolysaccharides (LPS) from gram-negative bacteria. Signaling TLR-4 triggers APCs to upregulate MHC class I/class II molecules and co-stimulatory molecules, as well as secrete proinflammatory cytokines, and therefore enable DCs to activate T-cell–mediated adaptive immune responses.[15,16] To date, 10 TLR family members have been found in humans and 12 TLR family members in mice, which recognize the pathogen-associated molecular patterns, including proteins, lipids, and nucleic acids.

TLR Structure

TLRs are type 1 transmembrane proteins. The extracellular portion of TLRs contains the leucine-rich repeats, which are essential for ligand binding. The intracellular portion shares a common structure with IL-1 receptor, called the Toll/IL-1 receptor homologous (TIR) domain, which is critical for signal transduction. The TLR genes are dispersed throughout the genome, with TLR1 and TLR6 genes on chromosome 4p14, TLR2 and TLR3 on 4q3.3-q35, TLR4 on 9q32-q33, TLR5 on 1q33.3-q42, TLR7 and TLR8 on Xq22, and TLR9 on 3q21.3.[7-9]

TLR Subdivision and Ligands

Phylogenetic analyses of the amino acid sequence and structure of TLRs, in combination with analyses of TLR ligand binding, suggest that TLRs evolved along three major pathways (Figure 51-1):

1. Recognition of nucleic acid: TLR7 and TLR8 recognize single-stranded viral RNA; TLR9 recognizes

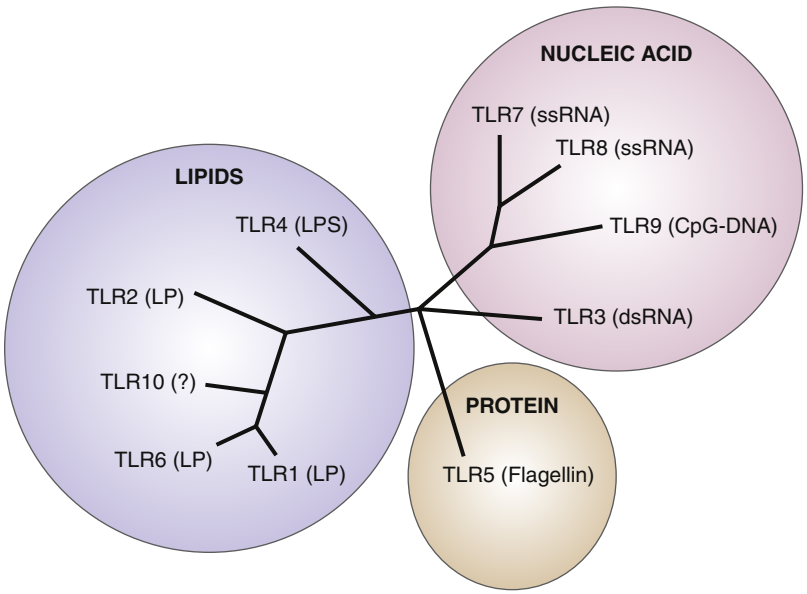

Figure 51-1 Toll-like receptor (TLR) family subdivision Phylogenetic analyses of the amino acid sequence and structure of TLRs suggest that they are evolved to recognize a variety of pathogen-derived signals such as microbial nucleic acids, lipids, and proteins.

double-stranded bacterial and viral DNA. TLR3 recognizes double-stranded viral RNA.

2. Recognition of lipid and lipoprotein: TLR4 recognizes LPS; TLR1, TLR2, and TLR6 recognize bacterial lipoprotein.
3. Recognition of protein: TLR5 recognizes bacterial flagellin.

Dendritic Cells Link Innate and Adaptive Immunity

Dendritic cells are specialized antigen-presenting cells, which display an extraordinary capacity to stimulate naïve T cells and initiate primary immune responses.[11,12] This established function of DCs has now offered the hope to apply DC-based immunotherapy for cancers. Recent studies suggest that DCs also play critical roles in the induction of peripheral immunological tolerance, regulate the types of T-cell immune responses, and function as effector cells in innate immunity against microbes. In both humans and mice, DCs can be grouped into two major subsets: the myeloid conventional DCs (mDC) and the plasmacytoid DCs (pDCs). Both display functional plasticity depending on the types of activation signals and also their resident microenvironments. However, mDCs and pDCs display different sets of TLRs and appear to regulate innate and adaptive immunity in different ways (Figure 51-2).

Myeloid DCs and Plasmacytoid DCs Express Different Sets of TLRs

In humans, mDCs can be identified by CD4+CD11c+lineage and pDCs can be identified by CD4+CD11c-lineage-BDCA-2+ILT7+. Strikingly, whereas mDCs express TLR2, 3, 4, 5, 6 and 8, pDCs express only TLR7 and TLR9. In response to the microbial ligands for TLR2, 3, 4, 5, 6 and 8, mDCs produce the TH1 polarizing cytokine IL-12 and cytokines IL-1, IL-6, IL-10, and TNF-α and undergo maturation by upregulation of MHC class I/class II and co-stimulatory cytokines CD80, CD83, and CD86.[10-12] In response to microbial ligands for the TLR7 and TLR9 and viral infection, pDCs rapidly produce massive amounts of type 1 IFNs, including IFN-α, IFN-β, and IFN-ω. Therefore, pDCs are also known as specialized type 1 IFN-producing cells (IPC), which represent the key cell type in antiviral innate immunity. pDCs also have the ability to produce IL-6 and TNF-α on activation through TLR7 and TLR9 and undergo differentiation into mature DCs that express high MHC class I/class II and co-stimulatory molecules CD80/CD86 and acquire the ability to prime naïve T-cell activation.[10-12]

Functional Plasticity of DCs

In humans, DCs were found to display different effector functions in directing T-cell responses that are regulated by

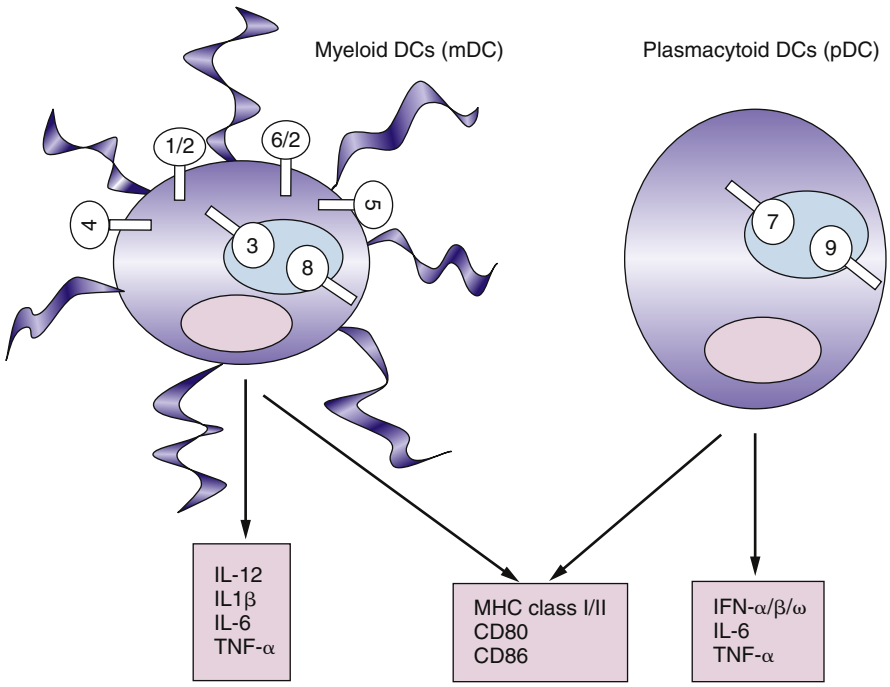

Figure 51-2 Toll-like receptor (TLR) expression in human dendritic cell subsets Myeloid DCs (mDC) and plasmacytoid DCs (pDC) express different sets of TLRs. Whereas mDCs preferentially express TLRs 1, 2, 3, 4, 5, 6, and 8, pDCs preferentially express TLRs 7 and 9. TLR stimulation of both DC subsets leads to the upregulation of MHC class I and class II molecules and T-cell co-stimulatory molecules CD80 and CD86. However, the two DC subsets express distinct cytokine profiles in response to TLR recognition, with mDCs producing IL-12 and pDCs producing primarily type I interferons.

the maturation stage of DCs and the maturation signals.[11,12] Whereas mDCs at the mature stage induce T_H1 differentiation and strong cytotoxic T lymphocyte (CTL) responses, mDCs at the immature stage induce IL-10–producing $CD4^+$ and $CD8^+$ regulatory T cells. Two groups of signals were shown to stimulate immature mDCs to induce T_H1 differentiation: (1) LPS derived from gram-negative bacteria (TLR4-L), gram-positive bacteria *Staphylococcus aureus* (SAC) (may trigger multiple TLRs), and double-stranded viral RNA (TLR3-L); and (2) T-cell signals such as CD40L and IFN-γ. Several signals were shown to stimulate immature mDC to induce T_H2 differentiation, including epithelial cell–derived cytokine TSLP and helminth *Schistosoma mansoni* egg antigen.[17,18] pDC-derived mature DCs also display different effector functions depending on the types of differentiation factors. Whereas pDCs activated by IL-3 and CD40L preferentially promote T_H2 differentiation, pDCs activated through TLR7 or TLR9 prime naïve T cells to produce IFN-γ and IL-10.[12]

Targeting TLRs on DCs to Induce Effective Antitumor Immunity

A major class of adjuvants for vaccines used in humans or in experimental animal models are killed microbials or microbial-derived products that trigger different TLRs.[19] The current understanding of TLR biology and DC biology reveals that the immune system has been evolved to fight against microbial pathogens, but does not have an optimal system for sensing and effectively responding to cancer. Therefore, a basic principle of developing a cancer vaccine is to instruct DCs to recognize tumor antigens as foreign by introducing microbial-derived adjuvants together with tumor antigens (Figure 51-3). In animal models, stimulation of TLR9 mainly expressed on plasmacytoid DCs with CpGs has been shown to increase the immunogenicity of different forms of cancer vaccines, including peptide vaccines, DNA vaccines, tumor cell–based vaccines, and DC-based vaccines.[19] Stimulation of TLR4 (mainly expressed

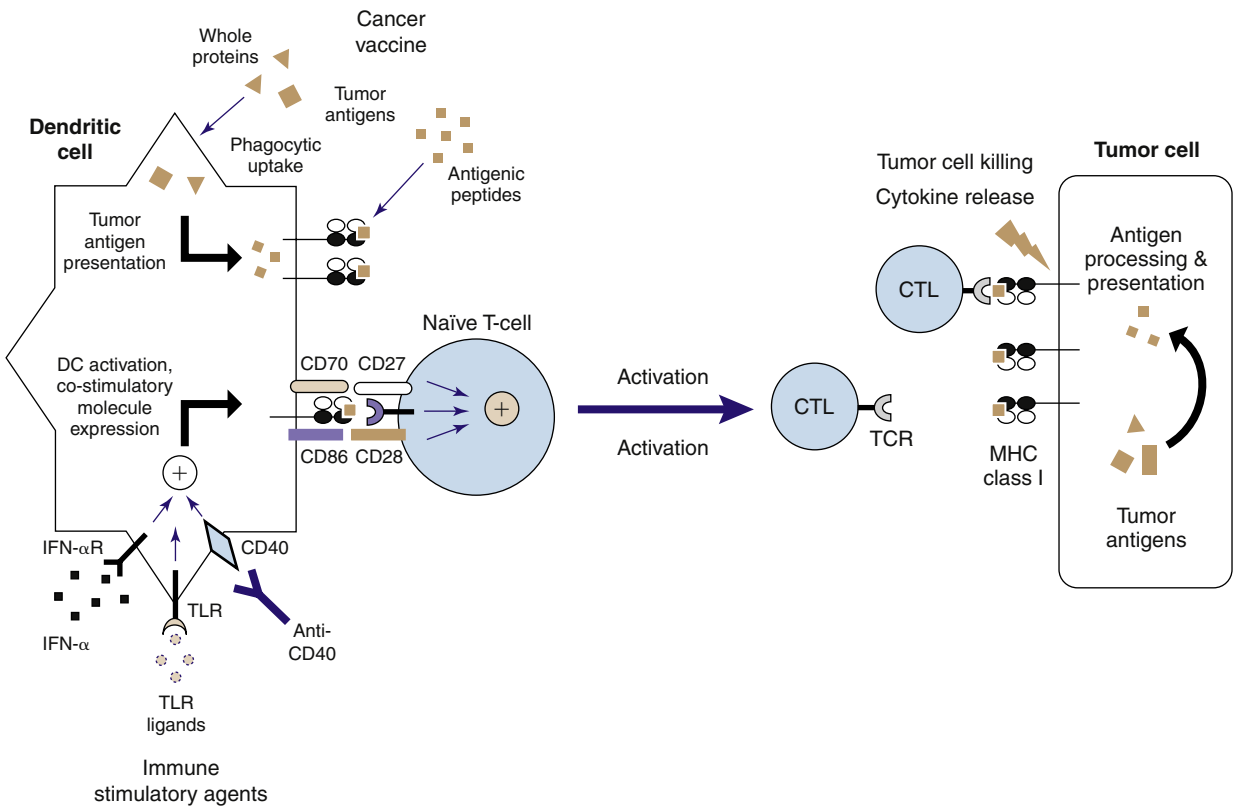

Figure 51-3 Generation of antitumor immune responses through dendritic cell–mediated T-cell priming Tumor-associated peptide antigens (TAA, *red*) expressed in the context of surface MHC class I (HLA) molecules on the surface of tumor cells can activate TAA-specific T cells to perform cytolytic functions and/or release inflammatory cytokines to further amplify the adaptive immune response. Generation of such tumor-reactive T cells requires stimulation of naïve T cells by activated dendritic cells (DCs) expressing both the appropriate TAA and co-stimulatory molecules such as CD86 and CD70. These signals together lead to the activation, proliferation, and trafficking of TAA-specific T cells to the tumor site, where they can induce tumor regressions. Cancer vaccines can introduce TAAs into DCs in several ways, including nucleic acids coding for TAAs, tumor cell lysates, whole TAA proteins, or TAA-derived peptides. DCs can then process and present these TAAs to naïve T cells in the context of MHC class I molecules. However, optimal T-cell activation requires the expression by DCs of co-stimulatory ligands for CD27 and CD28, which are known to be upregulated by the combination of TLR stimulation or interferon-α, along with ligation of the CD40 receptor. Thus, the generation of an optimal antitumor T-cell response requires a combination of TAA-specific vaccination with DC activation signals provided by TLR ligands and CD40-specific antibody.

by mDCs) by MPL, BCG, or murine β-defensin can also promote the immunogenicity of cancer vaccines. Several studies suggest that the ability of mDCs to present antigens and activate antigen-specific T cells can be greatly enhanced by activated pDCs through a type-1 IFN-dependent mechanism in both antiviral immune responses and autoimmune responses.[20] We have shown that pDCs activated by CpG promote the ability of mDCs to present melanoma antigens to T cells and induce strong tumor-specific CTL responses in vitro and in vivo. In addition, pDCs activated by CpG also strongly activate NK cells, which kill tumor cells and further enhance the ability of mDCs to take up dead tumor cells and cross-present tumor antigens to $CD8^+$ T cells.[21]

The Nature of Antitumor Immunity

T Cells Can Recognize Self-Antigens Expressed by Tumors

Over the past 10 years, numerous tumor antigens have been described that can be recognized by T cells.[22] These have been identified by two major methods: (1) molecular cloning using tumor antigen–specific T cells derived from cancer patients, and (2) analysis of candidate antigens based on gene expression and molecular profiling of tumors. Many of these antigens are expressed on normal tissues and are therefore considered to be "self" antigens. Examples of this class of antigen include melanocyte differentiation antigens that are expressed on melanoma cells as well as normal melanocytes. These include tyrosinase, MART-1, gp100, and TRP-1.[22] Differentiation antigens, expressed on tumor as well as the normal tissue of origin, can be targeted in immunotherapeutic strategies, as long as the normal tissue is nonessential. Mutated antigens, endogenous retroviral antigens, and antigens expressed in tumor and testis have also been described to be expressed in the context of MHC class I and class II molecules, capable of being recognized by $CD8^+$ and $CD4^+$ T cells, respectively. Although mutated antigens may be more easily recognized than "self" antigens, it is also possible that peripheral tolerance develops against the mutations, because co-stimulation may be absent in tumors, which are often present for many years before clinical diagnosis.

Autoimmune Vitiligo and Response to Immunotherapy

Because many tumor antigens are also expressed by normal host tissues, such as normal melanocytes in the case of melanoma antigens, obtaining an effective antitumor immune response requires overcoming self-tolerance. Indeed, in some settings, effective immunotherapy has been correlated with autoimmune responses against host tissues. IL-2, a cytokine that can stimulate the proliferation of T cells, can result in significant long-lasting regression of disease in some patients with metastatic melanoma and renal cell cancer (see later discussion). Interestingly, Rosenberg found that whereas 0 of 104 renal cancer patients treated with high-dose IL-2 developed vitiligo, the immune destruction of normal melanocytes, 11 of 74 melanoma patients treated with high-dose IL-2 developed vitiligo.[23] Furthermore, vitiligo was seen in 26% of melanoma patients who demonstrated objective tumor response to IL-2, whereas no vitiligo was observed in patients who did not respond to the IL-2. This suggests that tolerance to self-antigens can be overcome in the induction of an effective antitumor immune response.

Cancer Vaccines, Cytokines, and Immunotherapy

Cytokine Therapy of Cancer

Perhaps the strongest evidence that immune responses can result in a significant antitumor effect in patients is the fact that a subset of patients with metastatic melanoma can have complete tumor regressions and long-term survival following the administration of the T-cell growth factor IL-2. Of 270 patients with metastatic melanoma treated with high-dose IL-2, 43 (16%) had an objective response (complete or partial response).[24] More importantly, 60% of those patients who achieved a complete response had prolonged disease-free intervals and long-term survival (more than 10 years). This demonstrates that it is possible, by activation of the immune system, to induce clinically meaningful responses in patients. Future studies are needed to focus on understanding more fully the mechanism of response in patients so that improved strategies can be designed that will result in higher response rates and improved survival.

Another cytokine with significant clinical activity is interferon alpha, a type I interferon that is normally produced by plasmacytoid dendritic cells following viral infections. In randomized trials, high-dose interferon therapy has been shown to decrease tumor recurrence and increase survival in stage III melanoma patients (following surgical resection of tumor-positive lymph nodes).[25] Another study investigated prognostic markers in melanoma patients receiving interferon alpha in the adjuvant setting. Patients who developed autoantibodies during interferon therapy, including antithyroid, antinuclear, or anticardiolipin antibodies, had significantly enhanced survival compared to patients who did not develop signs of autoimmunity.[26] This again highlights the link between immunotherapy and autoimmunity as discussed earlier. In addition, it suggests that although interferon has

pleiotropic effects on tumor and host tissues, such as effects on tumor vasculature and direct inhibitory effects on tumor proliferation, the mechanism of action in melanoma patients is by stimulating antitumor immunity by breaking tolerance to self-antigens. This may be due to the effects of type I interferons on antigen-presenting cells or T cells. In addition, interferon alpha can upregulate MHC molecules on tumor cells, thereby rendering them better targets for T cells.

Current Status of Cancer Vaccines

With clear evidence that the immune system can play an important role in mediating clinical responses in cancer patients, current efforts are focused on developing cancer vaccines in order to enhance efficacy as well as specificity, because nonspecific immune stimulation can result in autoimmunity, as discussed. Two major approaches have been pursued in cancer vaccine strategies: the use of whole tumor cells or the use of specific tumor antigens (Table 51-1).

Whole-Cell Cancer Vaccine Strategies

Cancer vaccine strategies have been performed using derivatives of both autologous and allogeneic tumor cells. Although the use of autologous tumor cells is more labor intensive, in that vaccines need to be prepared individually for each patient, autologous tumor has the advantage of containing specific mutations for that patient, which may be seen as more foreign compared to shared self antigens. Cell lysates fed to autologous dendritic cells, isolation of heat shock proteins bound to autologous antigens, and gene modification of autologous tumor with immune-enhancing cytokines have been evaluated in clinical trials. In murine models, transduction of tumor cells to express GM-CSF results in enhanced antitumor immune responses against parental non-transduced tumor cells.[27] Antitumor activity of GM-CSF–expressing tumors was found to be dependent on host bone-marrow–derived antigen-presenting cells, CD1d-restricted NK T cells, $CD4^+$ and $CD8^+$ T cells, and antibodies.[28,29]

Antigen-Specific Vaccine Approaches

As discussed earlier, numerous tumor antigens have now been identified that can be recognized by T cells in the context of MHC class I and class II molecules. Many of these antigens are shared among specific types of tumors, and represent a feasible target for vaccine development. Antigen-specific vaccine approaches have included the use of specific peptide epitopes, whole proteins, and recombinant DNA and viral vaccines. The advantage of whole protein and recombinant approaches

Table 51-1 Advantages and Disadvantages of Various Cancer Vaccine Approaches

	Whole-Tumor Vaccines		Antigen-Specific Vaccines			
	Autologous	**Allogeneic**	**Peptide**	**Whole Protein**	**DNA**	**Recombinant Viral**
Advantages						
Easily produced		X	X		X	
Contains shared antigens, so can be used on multiple patients		X	X	X	X	X
Contains multiple antigens, including unknown antigens	X	X				
Contains multiple epitopes from the same antigen	X	X		X	X	X
Contains individual mutated antigens	X					
Disadvantages						
Costly	X			X		X
Needs to be produced for individual patients	X					
Stimulates a neutralizing antibody						X
Low levels of antigen expression	X	X			X	
Potentially stimulates competing antiviral immune responses						X

using the entire antigen gene is that multiple class I and class II epitopes may be presented.[30] However, whole proteins have been expensive and challenging to produce clinically, and viral vaccines can induce neutralizing antibodies that prevent the efficacy of serial doses of vaccine. Peptide vaccines, in combination with specific adjuvants, have demonstrated potential clinical efficacy in the case of chronic myelogenous leukemia and have been the most consistent method of inducing high levels of circulating antigen-specific T cells.[31,32] However, in the case of patients with metastatic melanoma, high levels of tumor-specific T cells in the blood do not always result in tumor regression.[33] Therefore, future efforts are focused on stimulating stronger and more effective T-cell priming through the use of specific adjuvants such as TLR agonists, using concepts learned from basic studies of antiviral immunity as described earlier. This may result in T cells with increased affinity and specificity as well as enhanced memory and effector function. One method to more carefully manipulate the specific phenotype of tumor-reactive immune cells is to generate and select specific T cells in the laboratory followed by reinfusion into patients. This is termed *adoptive immunotherapy*.

Adoptive Immunotherapy of Cancer

One of the most significant recent advances in clinic immunotherapy has been the adoptive transfer of tumor-reactive lymphocytes. A number of lines of evidence have demonstrated the clinical effectiveness of this approach, including donor-lymphocyte infusion following allogeneic bone marrow transplantation, treatment of metastatic EBV-driven lymphoproliferative tumors, and therapy of metastatic melanoma.[34,35]

Tumor-Infiltrating Lymphocytes

In the setting of metastatic melanoma, T cells can be found at the tumor site (tumor-infiltrating lymphocytes, or TILs) that are specific for melanoma antigens, such as MART-1 and gp100 (Figure 51-4). Because the tumor is growing, either these T cells are nonfunctional or the tumor is resistant to recognition or lysis. However, when TILs are expanded ex vivo and reinfused, clinical regressions are seen in patients with metastatic disease. A number of reasons may explain the effectiveness of ex vivo expanded lymphocytes compared to endogenous T cells. First, large numbers can be generated in the laboratory that may be difficult to achieve in vivo. Second, expanding the lymphocytes ex vivo takes them out of the suppressive tumor microenvironment. Finally, growth ex vivo may allow reactivation of lymphocytes rendered anergic or nonfunctional by in vivo toleragenic mechanisms. Initially, transfer of tumor-reactive T cells alone resulted in response rates of greater than 20%, but clinical regressions were often transient, and it was clear from gene marking studies that the T cells did not survive long in vivo.[36,37]

More recently it was found that transient lymphodepletion using cytoxan and fludarabine before T-cell infusion resulted in improved response rates and T-cell survival. Eighteen of 35 patients (51%) with metastatic melanoma exhibited objective responses following lymphodepletion and adoptive T-cell transfer.[38,39] Substantial numbers of infused lymphocytes were found in the circulation in some patients more than 2 years after infusion. This dramatic improvement following lymphodepletion may be due to a number of potential mechanisms including elimination of regulatory T cells and enhancement of lymphocyte homeostatic proliferation.

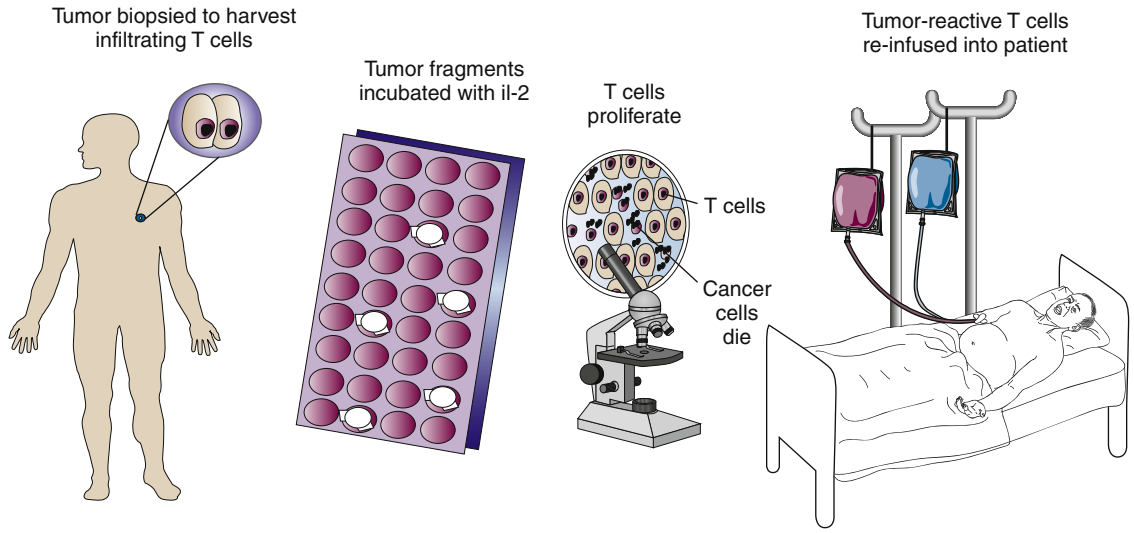

Figure 51-4 Expansion of tumor-infiltrating lymphocytes (TILs) from melanoma tumors T cells capable of specifically recognizing tumors can be found in some metastatic melanomas. When tumor fragments are cultured in the T-cell growth factor interleukin-2 (IL-2), the T cells expand and destroy the tumor cells in vitro. The expanded TIL can then be reinfused into metastatic melanoma patients in combination with interleukin-2.

Current studies of adoptive immunotherapy are focused on optimizing the generation of T cells ex vivo and their proliferation in vivo. For example, murine models suggest that proliferation of adoptively transferred T cells can be greatly enhanced in vivo by the addition of active immunization, such as dendritic cell vaccines.[40] In addition, significant efforts are focused on the introduction of novel genes into T cells in order to enhance their ability to recognize, migrate to, and eliminate tumor cells. In a recent study, nonspecific peripheral blood T cells were gene modified with a melanoma-specific T-cell receptor and then reinfused into melanoma patients. Two patients (of 17) demonstrated objective clinical responses, demonstrating that gene modification of lymphocytes is a feasible and potentially efficacious maneuver, although future studies are focused on enhancing the overall response rate.[41]

Gene-Modified T Lymphocytes

Because tumor-reactive lymphocytes are naturally found in melanomas, much of the work in adoptive therapy has focused on this disease. Although tumor-reactive lymphocytes are rarely found in other common cancers, antibodies that recognize these tumors in a relatively specific fashion have been described. Therefore, chimeric receptors have been designed using antibody variable regions extracellularly fused to T-cell signaling chains intracellularly (Figure 51-5). The initial studies demonstrated the ability to redirect T-cell specificity in vitro against ovarian cancer.[42] Lysis of ovarian cancer cells by human lymphocytes redirected with a chimeric gene composed of an antibody variable region and the Fc receptor gamma chain, but subsequent receptors have been designed that recognize human immunodeficiency virus (HIV) as well as a number of other tumor types.[43-45]

Besides redirecting T-cell recognition, the introduction of novel genes into effector lymphocytes may be used to enhance other functional properties, such as T-cell migration to the site of tumor and activation status. For example, Kershaw and colleagues introduced the chemokine receptor gene CXCR2 into T cells and demonstrated the ability of these modified cells to migrate toward chemokines produced by tumor cells.[46] In addition, receptor genes have been introduced with signaling chains containing co-stimulatory sequences in order to enhance T-cell activation.[47]

In summary, the infusion of tumor-reactive, ex vivo expanded T cells has clearly demonstrated the effectiveness of T-cell–mediated immunity in the treatment of patients with metastatic cancer. Future studies will focus on enhancing response rates through generation of T cells with greater activity and ability to migrate to tumor, durability of response by improved maintenance of T cells in vivo, and the use of T cells in nonmelanoma tumors by redirecting cells with native T-cell receptor or novel chimeric receptor genes.

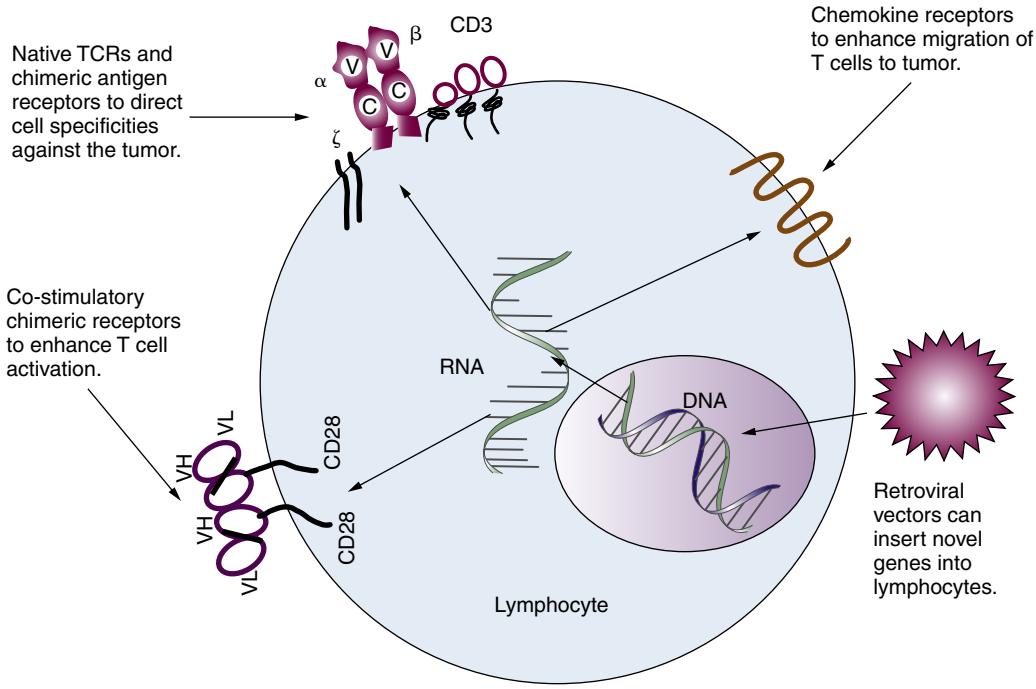

Figure 51-5 Insertion of genes into lymphocytes to enhance antitumor properties Genes can be inserted into T cells using retroviral vectors. These genes can endow the T cells with novel properties. Using genes encoding tumor antigen-specific T-cell receptors (TCRs) or chimeric antibody/T-cell receptor genes, T cells can gain the ability to recognize new targets. Using co-stimulatory receptor genes, T-cell activation can be further enhanced. Finally, introducing chemokine receptor genes into T cells can enhance T-cell migration to tumor sites.

Immune Regulatory Cells and Molecules in Human Cancer

Immunoregulatory cells and molecules are natural mechanisms that the immune system uses to prevent autoimmune destruction. Tumors often exploit these mechanisms to evade antitumor immunity, and several have been reported to be upregulated in human malignancy, including gastric cancer, ovarian cancer, melanoma, Hodgkin's disease, and kidney cancer (Table 51-2).

Regulatory T Lymphocytes in Human Cancer

$CD4^+D25^+$, naturally occurring regulatory T cells (Treg), constitute 5% to 10% of peripheral $CD4^+$ T cells, which play an essential role in the active suppression of autoimmunity in both humans and rodents. Treg appear to differentiate as a unique T-cell lineage in the thymus from immature T cells expressing T-cell receptor (TCR) with medium to high affinity for self-antigens, which depends on IL-2 and co-stimulatory molecules provided by activated APCs.[48-52] Foxp3, a member of the forkhead transcriptional factor family, has been demonstrated to be the master regulator of Treg development in the thymus, as well as Treg suppressive function. Increasing evidence suggests that tumor-specific Treg exist and play an essential role in immune tolerance to tumors and thus represent a major hurdle for antitumor immunotherapy. In addition, the tumor microenvironment appears to be the site where tumor-specific infiltrating T cells are actively converted into tumor-specific Treg.[53]

Table 51-2 Potentially Targetable Immunoregulatory Molecules

Molecule	Cellular Expression	Mechanism of Action
CTLA-4	Helper T Cytotoxic T	Provides co-inhibitory signaling during naive T-cell priming
	Treg	Induces local tryptophan metabolism by DCs, directly inhibits T cells
Membrane Bound		
PD-1	Helper T Cytotoxic T	Inhibits T-cell proliferation, cytokine production, and cytotoxicity
IL-10	Tumor Tri	Regulates growth and differentiation of a wide variety of immune cells
IL-13	iNKT	Induces immature myeloid cells to produce TGF-β
TGF-β	Tumor Tr1, Treg	Directly suppresses proliferation of antigen-activated T cells
	Immature myeloid	
Soluble		
VEGF	Tumor	Blocks DC differentiation and maturation, leading to accumulation of iDC and iMC
IDO	Tumor Dendritic	Depletes local tryptophan, inhibiting T-cell proliferation
ARG1	Tumor Immature myeloid	Depletes local arginine, inhibiting CD3f expression and T-cell activation
iNOS	Tumor Immature myeloid	Generates nitric oxide, inhibiting T-cell priming, proliferation, and cytotoxicity

Melanoma is perhaps the most immunogenic of solid tumors, as melanoma-specific $CD4^+$ and $CD8^+$ T cells can be isolated directly from tumor deposits. Yet the tumor metastases grow unabated, thereby implying that immune regulatory mechanisms may be preventing full activation and effector function by tumor-infiltrating T cells. Although it is not clear why melanoma-specific T cells found in tumor deposits are not functioning to eliminate the tumor in vivo, a number of studies have been performed in melanoma patients to help provide some insight into potential regulatory pathways that are active.

Indeed, $CD4^+CD25^+$ Treg have been isolated from melanoma deposits, and in fact some Treg lines have been found to be specific for LAGE-1 and ARCT1, expressed by melanoma cells.[54,55] In a DC melanoma vaccine study, Chakraborty and colleagues found that vaccine-induced specific CTL responses declined by day 28, and this was associated with expansion of $CD4^+CD25^+IL\text{-}10^+$ T cells.[56] $CD4^+CD25^+$ FoxP3 expressing cells were also found to be overrepresented in melanoma lymph-node metastases.[57] This may represent a mechanism by which tumors escape the immune system by first generating immunosuppression at the local lymph-node site.

Besides $CD4^+CD25^+$ Treg, melanoma cells themselves may produce factors or express receptors that can either induce regulatory immune cells or suppress effector T cells directly. For example, melanoma cells have been found to express IL-10, which is capable of inducing Tr-1 cells, another $CD4^+$ regulatory cell type that can induce T-cell anergy and suppression of immune responses, primarily via the production of high levels of IL-10 and TGF-β.[58,59]

A significant body of work has been performed in evaluating the cellular infiltrate of ovarian cancer. Zhang and co-workers performed immunohistochemical analysis of 186 advanced-stage ovarian cancer patients and found that the 5-year survival was 38% for patients whose tumors were infiltrated by $CD3^+$ T cells versus 4.5% for patients with

an absence of intratumoral T cells.[60] T-cell infiltration was associated with increased interferon-γ, interleukin-2, and specific chemokines within the tumor. However, another group found that not all $CD3^+$ T-cell subpopulations were favorably correlated with outcome in ovarian cancer patients. Accumulation of $CD4^+CD25^+$ Treg cells in ovarian cancer was found to predict decreased survival for both stage III and stage IV patients.[61] Wolf and associates confirmed and extended these findings by demonstrating that quantitative FoxP3 levels of ovarian biopsies by real-time PCR could identify a patient subgroup with decreased overall survival.[62] Finally, Sato and colleagues found that ovarian cancer patients with a higher $CD8^+$/Treg ratio in tumor tissue had an increased survival.[63] Together, these studies suggest that effector T cells play an important role in mediating an antitumor immune response in ovarian cancer patients, whereas Treg negatively influences this response. This implies that strategies to enhance tumor-specific $CD8^+$ T cells while decreasing Treg may be effective in improving the outcome for ovarian cancer patients.

Myeloid-Derived Suppressor Cells in Human Cancer

There is accumulating evidence that progressive tumor growth is correlated with an increased frequency of immature myeloid cells (iMC) and immature DCs (iDC) in the tumor microenvironment, which can inhibit the function of tumor-specific T lymphocytes.[64-66] These immature myeloid cells can be induced by tumor-derived factors such as vascular endothelial growth factor (VEGF), macrophage colony-stimulating factor, IL-6, granulocyte-macrophage colony-stimulating factor, IL-10, and gangliosides. The proangiogenic cytokine VEGF is a major contributor to immune suppression, and tumors often produce large quantities of VEGF that can be detected in the serum of cancer patients.[67,68] In vitro studies have shown that VEGF can block DC maturation, leading to the production of iMCs; conversely, blocking VEGF promotes normal DC differentiation and enhances antitumor function.[69]

Tumors from patients with cancer often contain iDCs with reduced T-cell stimulatory capacity, often expressing low levels of the co-stimulatory molecules CD80 and CD86; further, they fail to upregulate them even in the presence of DC maturation factors.[70,71] Increased levels of circulating immature myeloid cells have also been observed in the peripheral blood of patients with lung, breast, head and neck, and esophageal cancer.[65,72] Importantly, patients with cancer often show a significant reduction in normal circulating levels of mature DCs that can be reversed on surgical removal of tumors.[73,74] Thus, abnormal differentiation and maturation of DCs in vivo, mediated by tumor-derived soluble factors, likely play a substantial role in preventing the effective priming of a productive, T-cell–mediated antitumor immune response. Circulating levels of iMCs have been well correlated with stage of disease and poorer prognosis, and surgical resection of tumors has been shown to decrease the number of peripheral blood iMCs in both human and animal models.[75-77]

Immature MCs mediate their immunosuppressive activity through the inhibition of IFN-γ production by $CD8^+$ T cells in response to MHC class I–associated peptide epitopes presented on the iMC surface.[78] This effect requires direct cell-to-cell contact and is mediated by reactive oxygen and nitrogen species, such as hydrogen peroxide (H_2O_2) and nitric oxide (NO), secreted by the iMCs in close proximity to the T cell.[79,80] Although the precise mechanism of action on T cells has yet to be fully elucidated, there is some indication that iMCs act, in part, through downregulation of the CD3ζ chain on responding $CD8^+$ T cells.[81,82] A population of iMCs has been described in the peripheral blood of cancer patients having high arginase-1 activity capable of depleting local arginine levels and down-modulating CD3ζ levels on T cells. Depletion of this iMC subset in vitro restored CD3 expression and normal T-cell responses.[83,84]

In summary, there is evidence to suggest that the balance of immature and mature myeloid cells can have a significant effect on both naturally occurring and vaccine-induced antitumor T-cell responses. It is becoming increasingly apparent that effective cancer immunotherapy may require the correction of aberrant myeloid cell differentiation frequently observed in tumor-bearing hosts.

Immune Checkpoint Blockade

The development of a new class of effective cancer immunotherapy agents has recently become possible because of advances in our understanding of T-cell activation and regulation. T-cell activation is initiated by interaction of the TCR with MHC-bound peptide antigens on APCs (see Figure 51-3). However, effective priming of naïve T cells also requires a second, co-stimulatory signal mediated by the binding of CD28 on the T-cell surface to CD80 or CD86 (Figure 51-6). These two signals together allow T cells to proliferate, acquire antitumor effector functions, and eventually migrate to disease sites for tumor-cell killing.[85] T-cell activation is tightly regulated by a number of inhibitory signals in order to avoid prolonged immune responses that can potentially damage normal tissues. Inhibitory signals that are intrinsic to T cells are known as *immune checkpoint molecules*, with

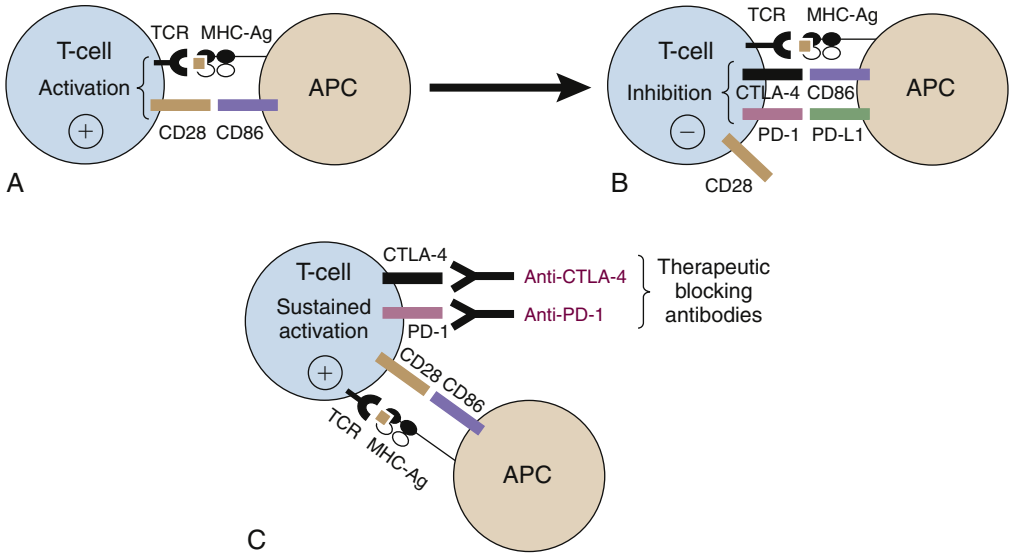

Figure 51-6 Immune checkpoint blockade therapies **(A)** T-cell activation is initiated by the interaction of the T-cell receptor (TCR) with major histocompatibility complex (MHC) molecules presenting antigen on an antigen-presenting cell (APC). Optimal activation of the T cell requires additional signals that are provided by the interaction between CD28 and CD86. **(B)** T-cell activation is naturally attenuated by upregulation of cytotoxic T lymphocyte–associated protein 4 (CTLA-4) on the surface of activated T cells, where it outcompetes CD28 for binding to CD86 on APCs. Additional regulation of T-cell activity is also provided by later inhibitory signals through programmed cell death 1 (PD-1), which binds to PD1 ligand 1 (PD-L1). **(C)** Strategies to sustain activated tumor-specific T cells include the use of blocking monoclonal antibodies targeting CTLA-4, PD-1, or PD-L1 to neutralize co-inhibitory receptors. Therapeutic antibodies that block intrinsic inhibitory immune checkpoints can allow for sustained T-cell effector responses, including increased production of cytokines and cytotoxic function.

the most well studied being cytotoxic T lymphocyte–associated protein 4 (CTLA-4) or programmed cell death 1 (PD-1).[85,86]

CTLA-4 Blockade

CTLA-4 is expressed by activated CD4 and CD8 T cells. It is a homologue of T-cell co-stimulator CD28 but has a higher binding affinity for its ligands. On T-cell activation, signaling pathways lead to the expression of CTLA-4, which is then mobilized from intracellular vesicles to the cell surface, where it outcompetes co-stimulator CD28 for binding to its ligands. Binding of CTLA-4 to CD86 proteins interrupts CD28 co-stimulatory signals and, as a result, limits T-cell responses (see Figure 51-6). In addition to the intrinsic restriction of effector T-cell responses due to expression of CTLA-4 on effector cells, there can also be extrinsic restriction of effector T-cell responses due to the expression of CTLA-4 on regulatory T cells as well.[87-89]

Because of the negative regulatory effects of CTLA-4 on T-cell responses, it was hypothesized that blockade of CTLA-4 signaling would potentiate antitumor immune responses. Indeed, anti-CTLA-4 antibodies were able to cause rejection of syngeneic transplanted tumors in mice.[90] These preclinical studies led to the development of an antibody to block human CTLA-4 (ipilimumab), which was shown in Phase III clinical trials to improve overall survival of patients with advanced melanoma.[91] Initial Phase I and Phase II clinical trials in other cancer patients demonstrated that ipilimumab treatment could also induce significant antitumor activity.[92,93] Subsequently, a Phase III randomized trial showed that ipilimumab improved the median overall survival of advanced metastatic melanoma patients by 3.7 months (10.1 vs. 6.4 months; $P = .003$).[91] However, the most striking feature of this study was the fact that nearly a quarter of the patients survived longer than 4 years. This trial led to the approval of ipilimumab by the U.S. Food and Drug Administration (FDA) in March 2011 for the treatment of patients with metastatic melanoma. Most recently, a second randomized, Phase III clinical trial showed that the addition of ipilimumab to standard dacarbazine chemotherapy significantly improved overall survival by 2.1 months in melanoma patients.[94] More importantly, anti-CTLA-4 therapy has demonstrated the long-awaited promise of immunotherapeutic agents to elicit durable responses in patients with many different types of cancers.

PD-1/PD-L1 Blockade

Another important T-cell checkpoint that can be targeted clinically is the interaction of PD-1 and its ligands (see Figure 51-6). PD-1 is mainly expressed by activated CD4 and CD8 T cells, and it has two ligands, PD-L1 and PD-L2, with distinct expression profiles.[95] PD-L1 is expressed not only on APCs, but also on T cells, B cells, and nonhematopoietic

cells, including tumor cells. Expression of PD-L2 is largely restricted to APCs, including macrophages and myeloid DCs. The role of PD-1 as a negative regulator of T and B cells was best demonstrated by the findings that PD-1–deficient mice developed significant autoimmunity.[96,97] Subsequently, blocking antibodies against PD-1 were shown to induce a reduction of tumor growth and metastasis in a number of experimental mouse models.[98,99] Consistent with the immune inhibitory role of PD-1/PD-L1/2 signaling, enforced expression of PD-L1 on tumor cells caused enhanced tumor growth in vivo, which could otherwise be kept in check by T cells. Again, this augmentation of tumor growth could be reversed with the use of blocking antibodies against PD-L1.[100]

Consistent with these preclinical studies, a recent Phase I clinical trial using an anti-PD-1 antibody (BMS-936558) showed an 18% to 28% objective response rate in patients with advanced non–small-cell lung cancer (NSCLC), renal call carcinoma (RCC), and melanoma.[101] In addition, another concurrent Phase I trial with anti-PD-L1 antibody demonstrated an objective response rate of 6% to 17% in patients with advanced NSCLC, melanoma, and RCC.[102] These early-phase clinical studies show a very promising potential for employing blocking antibodies against the inhibitory PD-1/PDL-1/2 signaling pathway in anticancer immunotherapy.

Checkpoint Blockade and the Induction of Autoimmunity

As with most experimental cancer therapies, treatment with immune checkpoint blockade agents is sometimes associated with a distinct set of on-target toxicities due to immune-related adverse events. For example, among melanoma patients treated with ipilimumab, up to 60% of patients manifested autoimmune reactions including dermatitis, colitis, hepatitis, and hypopituitarism.[91] Early recognition, diagnosis, and treatment of such drug-induced inflammatory conditions with steroids are critical for minimizing the adverse effects while maximizing the therapeutic benefits of this promising anticancer agent. By contrast, the early Phase I results targeting the PD-1 pathway have shown less overall toxicity in cancer patients, although future studies are required to confirm this. Regardless, investigations into biomarkers/pathways that are associated with or predict clinical benefit or toxicities will be important as the field of cancer immunotherapy moves forward, and recent studies in these areas have been promising.[103,104] Perhaps future strategies combining checkpoint blockade strategies with an effective cancer vaccine may skew the immune response toward tumor-specific antigens and away from normal tissue-associated self-antigens.

In summary, the recent clinical successes with immune checkpoint blockade agents have provided clear data to indicate that the immune system can be harnessed successfully to treat cancer and that the exquisite ability of the immune response to target tumor-specific antigens, as well as generate memory cells to thwart recurrences, can lead to durable clinical benefit in patients. These exciting study results and clinical benefits with anti-CTLA-4 and anti-PD-1 have provided a strong foundation on which to build for even greater success as we determine how to best select patients for treatment and how to combine immunotherapy with other agents to increase the number of patients who benefit.

Future Cancer Immunotherapies Will Use Basic Principles of Cellular Immunity

Although the adoptive transfer of carefully selected T-cell populations or the use of optimized vaccine strategies may allow for the presence of more potent T cells in vivo, this must be coupled with enhanced conditioning of the immunosuppressive tumor microenvironment to allow for both migration and function of specific T cells. In successful immune responses against viruses, a proinflammatory state exists in the infected site by TLR activation through specific viral components, as discussed earlier. This inflammation induces the upregulation of specific adhesion molecules on endothelial cells that will in turn mediate trafficking of primed T cells into the infected site. In addition, the proinflammatory state may enhance effector T-cell function while limiting the effects of immune regulation. Successful immunotherapy will require a better understanding of the interplay between immune-cell subpopulations that results in optimal T-cell induction as well as tumor site conditioning that will allow for enhanced efficacy of the T cells within the tumor microenvironment. Thus, the most effective strategies will likely involve combination approaches that aim to boost antitumor T-cell responses while simultaneously blocking immune inhibitory pathways. A number of immunosuppressive mechanisms are now targetable, including immune checkpoint blockade, depletion of regulatory immune cell subsets, and inhibition of oncogenic signaling.[105] This multidimensional approach will require exploring combinations of new and existing clinical agents to determine which are the most effective.

Finally, although many of the initial principles have been developed using more immunogenic tumors such as melanoma, future goals include the application of these same principles to develop successful immunotherapeutic approaches against other common cancers such as breast, lung, colon, and prostate cancer.

Cancer Immunotherapy with Vaccines and Checkpoint Blockade

Therapeutic vaccination for cancer continues to be a major approach to the overall immunotherapy of cancer. Historically, interest in cancer immunology stemmed from the perceived potential activity of the immune system as a weapon against cancer cells. In fact, the term *magic bullet*, commonly used to describe many visions of cancer therapy, was coined by Paul Ehrlich in the late 1800s in reference to antibodies targeting both microbes and tumors. Central to the concept of successful cancer immunotherapy are the dual tenets that tumor cells express an antigenic profile distinct from their normal cellular counterparts and that the immune system is capable of recognizing these antigenic differences. Support for this notion originally came from animal models of carcinogen-induced cancer in which it was demonstrated that a significant number of experimentally induced tumors could be rejected on transplantation into syngeneic immunocompetent animals.[1-4] Extensive studies by Prehn on the phenomenon of tumor rejection suggested that the most potent tumor rejection antigens were unique to the individual tumor.[5]

Since the original reports of Jenner over two centuries ago, prophylactic vaccination against infectious diseases has been one of the most influential medical interventions. Cancer vaccination, an immunotherapy approach applied to patients with established cancer, has tremendous potential based on the ability of both T cells and antibodies to specifically recognize cancer antigens and kill cancer cells expressing these antigens. However, at the time of this writing, only one human cancer vaccine has received U.S. Food and Drug Administration (FDA) approval, despite multiple Phase III clinical trials over the past two decades. Despite the clinical failures of cancer vaccines to date, continuing molecular definition of tumor-specific and tumor-selective antigens, new vaccine platforms that selectively target and activate dendritic cells, and preclinical results with combinations of vaccination together with other immune modulators have generated renewed optimism that cancer vaccination will ultimately take its place among the pantheon of cancer therapies.

As cancer genetics and genomics have exploded over the past decade, it is now quite clear that altered genetic and epigenetic features of tumor cells indeed result in a distinct tumor antigen profile. Overexpression of "oncogenic" growth factor receptor tyrosine kinases such as HER2/Neu and epidermal growth factor receptor (EGFR) via epigenetic mechanisms has provided clinically relevant targets for one arm of the immune system—antibodies.[6,7] Indeed, monoclonal antibodies are the fastest growing single class of cancer therapeutics based on successful new FDA approvals. In striking contrast, cellular immunotherapy of cancer has been quite disappointing in establishing therapeutic success in clinical trials to date. Emerging insights about the nature of the interaction between the cancer and the immune system have led us to understand why cell-based cancer immunotherapy approaches such as therapeutic vaccines have been less potent against established cancer than originally imagined. In general, we have learned that tumors employ mechanisms of tolerance induction to turn off T cells specific for tumor-associated antigens. Oncogenic pathways in tumors result in the elaboration of factors that organize the tumor microenvironment in ways that are quite hostile to antitumor immune responses.

Not only is the cancer capable of inducing potent tolerance among tumor-specific T cells, we now know that there are distinct forms of inflammatory and immune responses that are procarcinogenic. Thus, two frontiers in cancer immunology are the elucidation of how the tumor organizes its immune microenvironment and the nature of immune responses that are anticarcinogenic versus procarcinogenic. As the receptors, ligands, and signaling pathways that mediate immune tolerance and immune-induced procarcinogenic events are elucidated, these factors and pathways can be selectively inhibited by both antibodies and drugs in a way to shift the balance to antitumor immune responses. This chapter outlines the

major features of tumor–immune system interactions and set the stage for molecularly based approaches to manipulate immune responses for successful cancer therapy. The clinical results over the past few years, particularly with checkpoint blockade, validate clinically the tremendous potential of the immune system to destroy cancer cells (Figure 52-1).

Indeed, adoptive T-cell transfer trials using ex vivo expanded tumor-specific T cells have demonstrated clear proof of the principle that activated tumor-specific T cells can induce tumor regressions, even in patients with bulky metastatic cancer. Because adoptive T-cell transfer is expensive, labor intensive, and extremely difficult to standardize, it is an immunotherapy approach that is difficult to broadly export. Most cancer immunotherapy efforts, including those that involve vaccination, seek to activate and expand tumor-specific T cells in vivo via various manipulations involving standardized reagents. The major barriers to be overcome are induction of tolerance among tumor-specific T cells and a tumor microenvironment that has developed to resist infiltration and attack by activated tumor-specific T cells. Although these two barriers represent significant hurdles to successful cancer immunotherapy, the elucidation of specific molecular mechanisms for tolerance induction as well as immune inhibition within the tumor microenvironment have led to the generation of specific combinatorial approaches to cancer therapy.

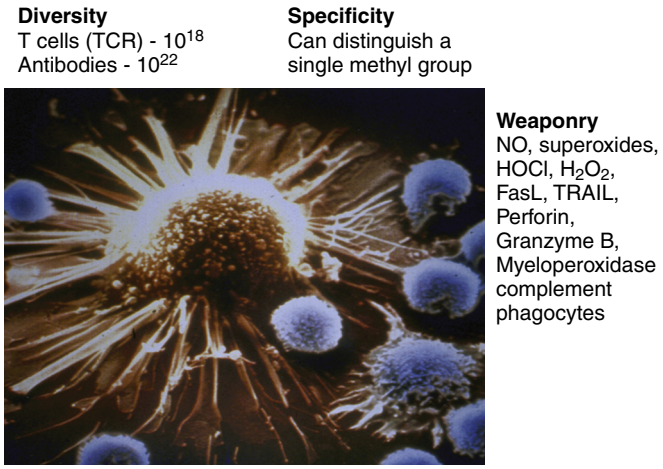

Figure 52-1 The immune system as the perfect anti-cancer weapon Shown in the figure is a single cytotoxic T lymphocyte specific for a tumor antigen expressed by the tumor cell it is about to kill. Although other lymphocytes contact the tumor cell, if they do not express a T-cell receptor specific for a peptide derived from a protein in the tumor cell and presented on MHC class I, they will ignore the tumor cell. Fundamentally, the immune system is endowed with all of the assets desired to specifically eliminate cancer cells while having a minimal effect on normal cells. The tremendous diversity of T-cell receptors and antibodies affords the adaptive immune system both specificity and adaptability. The MHC transport system that carries peptides from degraded proteins to the cell surface allows T cells to recognize protein antigens expressed anywhere in the cell. In addition, the immune system can produce more than 20 cytocidal molecules with diverse mechanisms of killing once activated.

Cancer Antigens—the Difference between Tumor and Self

Tumors reflect the biologic and antigenic characteristics of their tissue of origin but also differ fundamentally from their normal-cell counterparts in both antigenic composition and biologic behavior. Both these elements of cancer provide potential tumor-selective or tumor-specific antigens as potential targets for cancer vaccination specifically and antitumor immune responses in general. Genetic instability, a basic hallmark of cancer, is a primary generator of tumor-specific antigens. The most common genetic alteration in cancer is mutation arising from defects in DNA damage repair systems of the tumor cell.[8-15] Recent estimates from genome-wide sequencing efforts suggest that every tumor contains a few hundred mutations in coding regions.[16] In addition, deletions, amplifications, and chromosomal rearrangements can result in new genetic sequences resulting from the juxtaposition of coding sequences that are not normally contiguous in untransformed cells. The vast majority of these mutations occur in intracellular proteins, and thus the "neoantigens" they encode would not be readily targeted by antibodies. However, the major histocompatibility complex (MHC) presentation system for T-cell recognition makes peptides derived from all cellular proteins available on the cell surface as peptide MHC complexes capable of being recognized by T cells. Based on analysis of sequence motifs, it is estimated that roughly one third of the mutations identified from genome sequencing of 22 breast and colon cancers[16] were capable of binding to common human leukocyte antigen (HLA) alleles based on analysis of sequence motifs.

In accordance with the original findings of Prehn,[5] the vast majority of tumor-specific antigens derived from mutation as a consequence of genetic instability are unique to individual tumors. The consequence of this fact is that antigen-specific immunotherapies targeted at most truly tumor-specific antigens would by necessity be patient specific. However, there are a growing number of examples of tumor-specific mutations that are shared. The three best studied examples are the Kras codon 12 G→A (found in roughly 40% of colon cancers and more than 75% of pancreas cancers), the BrafV599E (found in roughly 70% of melanomas), and the P53 codon 249 G→T mutation (found in about 50% of hepatocellular carcinomas).[17-20] As with nonshared mutations, these common tumor-specific mutations all occur in intracellular proteins and therefore require T-cell recognition of MHC-presented peptides for immune recognition. Indeed, both the Kras codon 12 G→A and the BrafV599E mutations result in "neopeptides" capable of being recognized by HLA class 1– and class II–restricted T cells.[21-24]

The other major difference between tumor cells and their normal counterparts derives from epigenetics.[25] Global alterations in DNA methylation as well as chromatin structure in tumor cells result in dramatic shifts in gene expression. All tumors overexpress hundreds of genes relative to their normal counterparts and, in many cases, turn on genes that are normally completely silent in their normal cellular counterparts. Overexpressed genes in tumor cells represent the most commonly targeted tumor antigens by both antibodies and cellular immunotherapies. This is because, in contrast to most antigens derived from mutation, overexpressed genes are shared among many tumors of a given tissue origin or sometimes multiple tumor types. For example, mesothelin, which is targeted by T cells from vaccinated pancreatic cancer patients,[26] is highly expressed in virtually all pancreatic cancers, mesotheliomas, and most ovarian cancers.[27,28] Although mesothelin is expressed at low to moderate levels in the pleural mesothelium, it is not expressed at all in normal pancreatic or ovarian ductal epithelial cells.

The most dramatic examples of tumor-selective expression of epigenetically altered genes are the so-called cancer-testis antigens.[29] These genes appear to be highly restricted in their expression in the adult. Many are expressed selectively in the testes of males and are not expressed at all in females. Expression in the testis appears to be restricted to germ cells, and in fact some of these genes appear to encode proteins associated with meiosis.[30-32] Cancer-testis antigens therefore represent examples of widely shared tumor-selective antigens whose expression is highly restricted to tumors. Many cancer-testis antigens have been shown to be recognized by T cells from nonvaccinated and vaccinated cancer patients.[29] From the standpoint of immunotherapeutic targeting, a major drawback of the cancer-testis antigens is that none appears to be necessary for the tumors' growth or survival. Therefore, their expression appears to be purely the consequence of epigenetic instability rather than selection, and antigen-negative variants are easily selected out in the face of immunotherapeutic targeting.

A final category of tumor antigen that has received much attention encompasses tissue-specific antigens shared by tumors of similar histologic origin. Interest in this class of antigen as a tumor-selective antigen arose when melanoma-reactive T cells derived from melanoma patients were found to recognize tyrosinase, a melanocyte-specific protein required for melanin synthesis.[33,34] In fact, the most commonly generated melanoma-reactive T cells from melanoma patients recognize melanocyte antigens.[35,36] Although one cannot formally call tissue-specific antigens tumor-specific, they are nonetheless potentially viable targets for therapeutic T-cell responses when the tissue is dispensable (i.e., prostate cancer or melanoma).

From the standpoint of T-cell targeting, tumor antigens upregulated as a consequence of epigenetic alterations represent "self-antigens" and are therefore likely to induce some level of immune tolerance. However, it is now clear that the stringencies of immune tolerance against different self-antigens differ according to tissue distribution and normal expression level within normal cells. The mesothelin antigen described earlier is an example. In a recent set of clinical pancreatic cancer vaccine studies, mesothelin-specific T-cell responses were induced by vaccination with genetically modified pancreatic tumor cell vaccines, and induction of mesothelin-specific T cells correlated with ultimate disease outcome.[37] Given that the immune system is capable of differential responsiveness determined by antigen levels, it is quite possible to imagine generating tumor-selective immune responses against antigens whose expression level in the tumor is significantly greater within normal cells in the tumor-bearing host. In addition, upregulated antigens that provide physiologically relevant growth or survival advantages to the tumor are preferred targets for any form of therapy because they are not so readily selected out.

Beyond the antigenic differences between tumor cells and normal cells, there are important immunologic consequences to the distinct biological behavior of tumor cells relative to their normal counterparts. Whereas uncontrolled growth is certainly a common biological feature of all tumors, the major pathophysiologic characteristics of malignant cancer responsible for morbidity and mortality are their ability to invade through natural tissue barriers and ultimately to metastasize. Both of these characteristics, never observed in nontransformed cells, are associated with dramatic disruption and remodeling of tissue architecture. Indeed, the tumor microenvironment is quite distinct from the microenvironment of normal tissue counterparts. One of the important consequences of tissue disruption, even when caused by noninfectious mechanisms, is the elaboration of pro-inflammatory signals. These signals, generally in the form of cytokines and chemokines, are potentially capable of naturally initiating innate and adaptive immune responses. Indeed, the level of leukocyte infiltration into the microenvironment of tumors tends to be significantly greater than the leukocyte component of their normal-tissue counterparts. Cancers are therefore constantly confronted with inflammatory responses as they invade tissues and metastasize. In some circumstances these inflammatory and immune responses can potentially eliminate a tumor—so-called immune surveillance. However, as discussed later, oncogenic pathways in the tumor appear to organize the immunologic component of the microenvironment in a fashion that not only protects the tumor from antitumor immune responses but can qualitatively shift immune responses to those that actually support and promote tumor growth. It is these elements of

the cancer–immune system interaction that will be the central targets of future immunotherapeutic strategies.

Evidence Pro and Con for Immune Surveillance of Cancer

The fundamental tenet of the immune surveillance hypothesis, first conceived nearly a half century ago,[38,39] is that a fundamental role of the immune system is to survey the body for tumors as it does for infection with pathogens, recognizing and eliminating them based on their expression of tumor-associated antigens. In animal models, carcinogen-induced tumors can be divided into those that grow progressively (termed *progressor tumors*) and those that are rejected after an initial period of growth (termed *regressor tumors*).[1,2] The phenomenon of regressor tumors was thought to represent an example of the ongoing process of immune surveillance of cancer. A corollary to the original immune surveillance hypothesis is that progressor tumors in animals (presumed to represent clinically progressing cancers in humans) fail to be eliminated because they develop active mechanisms of either immune escape or resistance.

A fundamental prediction of the immune surveillance hypothesis is that immunodeficient individuals would display a dramatic increase in tumor incidence. After an extensive analysis of spontaneous tumor formation in immunodeficient nude mice, which have atrophic thymi and therefore significantly reduced numbers of T cells and T-cell–dependent immune responses, no increased incidence of tumors was observed.[40-44] These studies were taken as a major blow to the immune surveillance hypothesis. However, a caveat to the interpretation of these results is that nude mice still produce diminished numbers of T cells via thymus-independent pathways and therefore can mediate some degree of T-cell–dependent immunity. In addition, nude mice frequently display compensatory increases in innate immunity that, as discussed later, may represent a potent form of antitumor immunity and could contribute to immune surveillance of cancer.

Epidemiologic studies of patients with heritable immunodeficiencies revealed a significantly increased risk of certain cancers that are distinct from the epithelial cancers commonly observed in normal immunocompetent adults.[45-47] Many of these cancers are also observed in transplant patients on chronic pharmacologic immune suppression as well as in patients with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) whose immune system is depressed. The most common cancers in these individuals include lymphoblastic lymphomas as well as Kaposi's sarcoma; however, certain epithelial cancers, such as stomach cancer, were also observed at increased frequency. A unifying theme for the majority of cancers observed in immunodeficient individuals is their microbial origin. The majority of lymphoblastic lymphomas are associated with Epstein-Barr virus (EBV),[48] and Kaposi's sarcoma is a result of infection with the herpesvirus KSHV (Kaposi's sarcoma–associated herpesvirus).[49] Other virus-associated cancers such as cervical cancer (from human papillomavirus)[50,51] are also observed at increased frequency. It is now appreciated that stomach cancer is associated with ulcer disease related to infection with the bacterium *Helicobacter pylori*.[52] From these studies, the notion emerged that immune surveillance indeed protects individuals against certain pathogen-associated cancers by either preventing infection or altering chronic infection by viruses and other microbes that can eventually induce cancer. These studies were taken to represent evidence that the common non–pathogen-associated cancers most commonly seen in adults in developed countries (i.e., prostate cancer, colon cancer, lung cancer, etc.) are not subject to immune surveillance.

Two caveats to this interpretation must, however, be noted. First, detailed epidemiologic analyses of immunodeficient individuals were performed at a time when these patients rarely lived beyond their 20s and 30s, when cancer incidence normally increases most significantly. It is therefore possible that a subtler cumulative increased incidence of common non–pathogen-associated cancers would have been observed had these individuals lived further into adulthood. Indeed, more recent analyses definitively demonstrate an increased incidence of some non–pathogen-associated cancers, particularly melanoma, in immunodeficient individuals.[53] In addition to epidemiologic data, dramatic antidotal examples are difficult to ignore. There have been reports that patients receiving kidneys from a cadaver donor who had been in complete remission from a melanoma before organ donation each rapidly developed metastatic melanoma of donor origin after the transplant.[54-56] These results indicate that at least for some non–pathogen-associated tumors, the immune system can play a significant role in maintaining the micrometastatic disease in a dormant state. Whether this principle applies to non–pathogen-associated human tumors besides melanoma remains to be demonstrated.

A number of recent studies reevaluating tumor immune surveillance in genetically manipulated mice has revealed clear-cut evidence that various components of the immune system can at least modify, if not eliminate, both carcinogen-induced and spontaneously arising cancers. A series of studies by Schreiber and colleagues reexamined cancer incidence in mice rendered immunodeficient via genetic knockout of the *RAG2* gene (deficient in both B and T cells), the *γ-interferon receptor* gene, the *STAT 1* gene, or the *type 1 interferon receptor* gene.[57-59] When these knockout mice were either treated with carcinogens or crossed onto

a cancer-prone *P53* knockout background, the incidence of cancers was modestly but significantly increased relative to nonimmunodeficient counterparts when observed over an extended period (longer than 1 year). Transplantation studies demonstrated that direct γ-interferon insensitivity by the developing tumors played a significant role in the defect in immune surveillance. Interestingly, in contrast to *γ-interferon receptor* knockout mice, the mechanism for increased tumor incidence in tumors in *type 1 interferon receptor* knockout mice did not involve sensitivity by the tumor to type 1 interferons but rather reflected role of the type 1 interferons in the induction of innate and adaptive immunity. Even animals not crossed onto a cancer-prone genetic background or treated with carcinogens developed an increased incidence of invasive adenocarcinomas when observed over their entire life span. Furthermore, *γ-interferon, RAG2* double knockout mice developed a broader spectrum of tumors than *RAG2* knockout mice. All of the tumors that arise in these genetically manipulated immunodeficient animals behave as regressor tumors when transplanted into immunocompetent animals. These findings indeed suggest that tumors that arise in immunodeficient animals would have been eliminated had they arisen in immunocompetent animals. The relatively subtle effects on tumorigenesis, requiring observation over the life span of the animal, suggests that the original concept of immune surveillance of tumors arising on a daily basis is in fact not correct. Instead, it is clear that the presence of a competent immune system "sculpts" the tumor through processes that have been termed *immunoediting*.

The immunoediting hypothesis has been somewhat controversial, with differing outcomes in different animal models. One of the caveats in the interpretation of these studies comes from the work of Dranoff and colleagues, who studied mechanisms of increased tumor genesis in GM-CSF × γ-IFN double knockout mice.[60] Although they observed an increase in gastrointestinal and pulmonary tumors, they noted that such animals harbored infection with a particular bacterium not normally observed in immunocompetent animals. Maintenance of these double knockout mice on antibiotics essentially eliminated the increased rate of tumor formation. Thus, it is possible that some of the increased tumor rates in genetically immunodeficient animals could be related to unappreciated chronic infections that develop in these animals, which are not housed under germ-free conditions. Nonetheless, although the classic concepts of immune surveillance of cancer remain unsupported by experimental evidence, studies on tumorigenesis in genetically manipulated immunodeficient mice indeed suggest that developing tumors must actively adapt themselves to their immune microenvironment in order to exist within the context of a competent immune system.

One of the approaches to test the immune surveillance and immunoediting of endogenously arising tumors has been to combine genetically engineered autochthonous tumor models with T-cell receptor transgenic models expressing defined marked T cells specific for a tumor antigen (either the transgenic oncogenic driver protein in the tumors or an antigen co-expressed with the oncogenic driver). In these models, tumor growth can be monitored in immunodeficient versus immunocompetent mice as well as expression of the cognate tumor antigen recognized by the transgenic T-cell receptor. In such a tumor model driven by Kras and p53 loss, tumors emerging in immunocompetent mice either lost antigen or MHC presentation capacity, whereas those emerging in immunodeficient mice did not.[61] In contrast, in a mouse model of spontaneous random oncogene activation, antigen-specific tolerance was generated in immunocompetent mice without evidence for antigen loss.[62] In some models, an intermediate result has been observed. For example, endogenous immune responses can, under some circumstances, establish an equilibrium state with the tumor in which the tumor is prevented from outgrowth in immunocompetent mice but is not completely eliminated.[63] Ultimately, given the model dependence of outcome (i.e., tolerance, versus surveillance versus editing versus equilibrium) it will be important to ascertain which mechanisms are operative in particular human cancers.

Immune Tolerance and Immune Evasion—the Immune Hallmarks of Cancer

Although controversy over the ultimate role of immune surveillance in natural modulation of cancer development and progression will undoubtedly continue into the future, one can summarize the current state of knowledge as supporting the notion that natural immune surveillance plays a much smaller role than originally envisioned by Thomas and Burnet. However, developing tumors need to adapt to their immunologic milieu in a manner that either turns off potentially harmful (to the tumor) immune responses or creates a local microenvironment inhibitory to the tumoricidal activity of immune cells that could inadvertently become activated in the context of inflammatory responses associated with tissue invasion by the tumor. These processes—tolerance induction and immune evasion—have become a central focus of cancer immunology efforts and will undoubtedly provide the critical information necessary for the development of successful immunotherapies that break tolerance to tumor antigens and break down the resistance mechanisms operative within the tumor microenvironment.

Evidence from murine tumor systems as well as human tumors strongly demonstrates the capacity of tumors to induce tolerance to their antigens. This capacity to induce immune tolerance may very well be the single most important strategy that tumors use to protect themselves from elimination by the host's immune system. Tolerance to tumors appears to operate predominantly at the level of T cells; B-cell tolerance to tumors is less certain because there is ample evidence for the induction of antibody responses in animals bearing tumors as well as human patients with tumors. However, with the exception of antibodies against members of the epidermal growth factor receptor family, there is little evidence that the natural humoral response to tumors provides significant or relevant antitumor immunity. In contrast, numerous adoptive transfer studies have demonstrated the potent capacity of T cells to kill growing tumors, either directly through cytotoxic T lymphocyte (CTL) activity, or indirectly through multiple CD4-dependent effector mechanisms. It is thus likely that induction of antigen-specific tolerance among T cells is of paramount importance for tumor survival.

The first direct evidence for induction of T-cell tolerance by tumors was provided by Bogen and colleagues, who examined the response of T-cell receptor (TCR) transgenic T cells specific for the idiotypic immunoglobulin expressed by a murine myeloma tumor.[64,65] They first demonstrated induction of central tolerance to the myeloma protein followed by peripheral tolerance. Using influenza hemagglutinin (HA) as a model tumor antigen, Levitsky and colleagues demonstrated that adoptively transferred HA-specific TCR transgenic T cells were rapidly rendered anergic by HA-expressing lymphomas and HA-expressing renal carcinomas.[66,67] Tolerance induction has been demonstrated in both the CD4 and CD8 compartment. In general, initial activation of tumor-specific T cells is commonly observed; however, the activated state of T cells is typically not sustained, with failure of tumor elimination as a frequent consequence. Tolerance induction among tumor antigen–specific T cells is an active process involving direct antigen recognition, although in some murine systems, tolerance to tumors appears to be associated with failure of antigen recognition by T cells—that is, the immune system "ignores" the tumor.[68,69] Beyond studies on transplantable tumors, more recent analyses of immune responses to tumor antigens in tumor transgenic mice developing spontaneous cancer have further emphasized the capacity of spontaneously arising tumors to induce tolerance among antigen-specific T lymphocytes. In a model of prostate tumorigenesis, Drake and colleagues evaluated CD4 responses to HA and double transgenic animals expressing HA and SV40 T antigen under the control of the prostate-specific probasin promoter.[70] The development and progression of prostate tumors did not result in enhanced activation of adoptively transferred HA-specific T cells. Tolerance to HA as a normal prostate antigen occurred largely through ignorance because there was no evidence for antigen recognition by HA-specific T cells. However, increased recognition was observed on either androgen ablation (which causes massive apoptosis within the prostate) or development of prostate cancer. Nonetheless, enhanced antigen recognition was not accompanied by activation of effector functions such as γ-interferon production. The consequences of transformation in additional tumor transgenic mouse systems have also been analyzed. As described earlier, Blankenstein and colleagues found that preimmunization of mice against the tumor-associated antigen prevented the development of tumors. However, nonimmunized mice developed spontaneous tumors without any significant evidence of natural immune surveillance in the absence of preimmunization. They further demonstrated that an initial antigen-dependent activation of tumor-specific T cells could be observed at the time of spontaneous tumor induction, but that this recognition ultimately resulted in an anergic form of T-cell tolerance similar to that observed by Drake and colleagues in the prostate system.[62]

The capacity of spontaneously arising tumors to tolerize T cells has not been uniformly observed. Ohashi and colleagues observed a contrasting result when LCMV GP33-specific TCR transgenic CD8 T cells were adoptively transferred into double transgenic mice expressing both SV40 T antigen and LCMV GP33 under the control of the rat insulin promoter.[71] These animals develop pancreatic islet cell tumors that express GP33. These investigators found that as tumors progressed in the mice, enhanced T-cell activation occurred. CD8 T-cell activation was demonstrated through bone marrow chimera experiments to occur exclusively via cross presentation in the draining lymph nodes. Despite the activation of tumor-specific T cells, the tumors grew progressively, indicating that the degree of immune activation induced by tumor growth was insufficient to ultimately eliminate the tumors. These results suggest that developing tumors can induce immune responses but may titrate their level of immune activation to one that ultimately does not keep up with tumor progression. Such a circumstance is highly susceptible to the immune editing concept put forward by Schreiber and colleagues in which the tumor edits itself genetically to maintain a sufficient level of resistance to induced immune responses. In the case of the LCMV GP33 T antigen transgenic mice, because neither anergic nor deletional tolerance was observed, animals treated with the dendritic cell stimulatory anti-CD40 antibody demonstrated significant slowing of tumor growth. Thus, it may be possible under some circumstances to shift the balance between tumor immune evasion and tumor immune recognition by agents that affect the overall activation state of either antigen-presenting cells or T cells (see later discussion).

It has been more difficult to obtain definitive evidence that human cancers tolerize tumor-specific T cells, because humans cannot be manipulated the way mice are. However, T cells that are grown out of patients with cancer tend either to be of low affinity for their cognate antigen or to recognize antigens that bind poorly to their presenting HLA (human MHC) molecule, resulting in inefficient recognition by T cells. Recently, a crystal structure of the TCR-peptide-MHC trimolecular complex has been solved for an MHC class II–restricted human tumor antigen.[72] Interestingly, the orientation of the TCR, which has low affinity for the peptide-MHC complex, is distinct from trimolecular complexes for viral (foreign) antigens and is partially similar to trimolecular complexes for a self-antigen. Thus, there may be fundamental structural features of tumor antigen recognition that lie between those of foreign antigen and self-antigen recognition.

As discussed later, one of the features of the tumor microenvironment that is likely central to the capability of tumors to tolerize tumor-specific T cells is the immature or inactive state of tumor-infiltrating dendritic cells (DCs). DCs are the major antigen-presenting cell that presents peptides to T cells to initiate adaptive immune responses. In the context of infection, microbial ligands or endogenous "danger signals" associated with tissue destruction activated DCs to a state in which they present antigens to T cells together with co-stimulatory signals that induce T-cell activation and development of effector function. However, in the absence of microbial products or danger signals, DCs remain in an immature state in which they can still present antigens to T cells but without co-stimulatory signals. These immature DCs function as "toleragenic" DCs, inducing a state of antigen-specific T-cell unresponsiveness (termed *anergy*). It is thought that steady-state presentation of self-antigens by immature DCs is an important mechanism of peripheral self-tolerance. Thus, if a tumor is able to produce factors that inhibit local DCs from becoming activated in response to the endogenous danger signals associated with tissue invasion, it could shift tumor-specific T cells from a state of activation to one of tumor-specific tolerance.

Inhibition of Antitumor Immunity by Regulatory T Cells

Over the past 10 years, regulatory T cells (Tregs) have emerged as a central player in maintenance of the tolerant state as well as general downregulation of immune responses to pathogens.[73,74] Not surprisingly, they appear to play a role in tolerance to tumor antigens as well as the resistance of tumors to immune-mediated elimination.[75,76] In contrast to the ephemeral CD8 suppressor cells of the 1970s that failed to withstand experimental scrutiny, the more recently defined $CD4^+$ Tregs are characterized by expression of a central master regulatory transcription factor—FoxP3—whose role in the gene expression programs of Treg is being actively studied.[77] Although $CD4^+$ Tregs selectively (but not specifically) express a number of cell-membrane molecules, including CD25, neuropilin, GITR, and LAG-3,[78-80] their overall genetic program and inhibitory capacity are absolutely dependent on sustained expression of Foxp3.[81,82] Mechanisms of immune suppression by Tregs vary and include production of inhibitory cytokines such as IL-10 and a recently described IL-12 family "hybrid" cytokine, IL-35, consisting of the alpha subunit of IL-12 and the beta subunit of IL-27.[104] In keeping with the emerging appreciation that tumors are by nature highly tolerogenic, numerous murine studies have demonstrated that Tregs expand in animals with cancer and significantly limit the potency of antitumor immune responses—either natural or vaccine induced. For example, in a study by Sutmuller and colleagues, a combination of GM-CSF transduced tumor vaccine plus anti-CTLA-4 antibodies was much more effective at eliminating established tumors when animals were treated with anti-IL-2 receptor alpha antibodies to eliminate $CD4^+$ Tregs.[83] It is now appreciated that treatment with low-dose cyclophosphamide is a relatively simple and reasonably effective way to temporarily eliminate cycling Tregs.[84-87] This appears to be a major mechanism by which pretreatment with low-dose cyclophosphamide before vaccination can significantly enhance the capacity of vaccines to break tolerance. As new cell membrane molecules that define Tregs are identified, the capacity to block regulatory T-cell activity with antibodies to these molecules presents new opportunities for immunotherapeutic strategies to break tolerance to tumor antigens. Because of their unusually high constitutive expression of high-affinity IL-2 receptors, IL-2 receptor–targeted antibodies and toxin-conjugated IL-2 molecules have been used therapeutically to eliminate Tregs in cancer patients.[88] This continues to be pursued, although its ultimate value will likely come through combination of Treg elimination with other immunotherapy strategies such as vaccination and checkpoint inhibition (see later discussion).

Suppression of Antitumor Immunity by Immature Myeloid Cells in the Tumor Microenvironment

As shown in Figure 52-2, the tumor microenvironment contains multiple inhibitory cells and molecules. Immature myeloid cells (iMCs),[89,90] often termed *myeloid-derived*

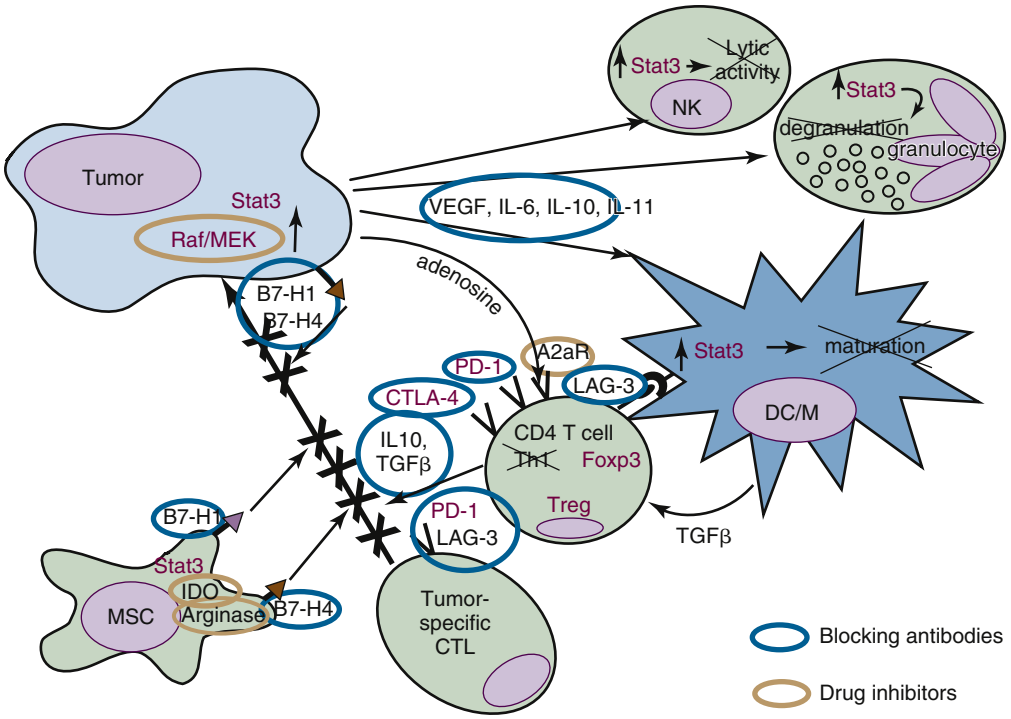

Figure 52-2 The immune microenvironment of a tumor expresses multiple molecules that inhibit immune responses Immune inhibition in the tumor microenvironment is mediated by upregulation of ligands that bind inhibitory receptors on helper T cells and cytotoxic T cells. Multiple immune inhibitory cells, such as myeloid-derived suppressor cells (MDSC) and regulatory T cells (Treg), as well as the tumor, express these inhibitory ligands. In addition, metabolic enzymes, such as IDO, consume nutrients critical for effector T-cell function and produce products inhibitory to T-cell activation. Expression of the molecules is driven by signaling pathways, such as Stat3, that are upregulated in many tumor types. Most of these inhibitory molecules are "druggable" with either small molecules or antibodies.

suppressor cells (MDSCs),[91-94] represent a cadre of myeloid cell types, somewhat overlapping with tumor-associated macrophages (TAMs), which share the common feature of inhibiting both the priming and effector function of tumor-reactive T cells. It is still not clear whether these myeloid cell types represent distinct lineages or different states of the same general immune inhibitory cell subset. In mice, iMCs and MDSCs are characterized by coexpression of CD11b (considered a macrophage marker) and Gr1 (considered a granulocyte marker) while expressing low or no MHC class II or the CD86 co-stimulatory molecule. In humans, they are defined as $CD33^+$ but lacking markers of mature macrophages, DCs, or granulocytes and are DR^-. A number of molecular species produced by tumors tend to drive iMC/MSC accumulation. These include IL-6, CSF-1, IL-10, and gangliosides. IL-6 and IL-10 are potent inducers of STAT3 signaling, which has been shown to be important in iMC/MDSC persistence and activity.

In addition to inhibitory cytokine production, myeloid cells of multiple type in the tumor microenvironment express a number of enzymes whose metabolic activity ultimately results in inhibition of T-cell responses within the tumor microenvironment. These include the production of reactive oxygen species (ROS) and/or reactive nitrogen species (RNS). Nitric oxide (NO) production by iMC/MDSC as a result of arginase and iNOS activity has been well documented, and inhibition of this pathway with a number of drugs can mitigate the inhibitory effects of iMC/MDSC. ROS, including H_2O_2, have been reported to block T-cell function associated with the down-modulation of the ζ chain of the TCR signaling complex,[95] a phenomenon well recognized in T cells from cancer patients and associated with generalized T-cell unresponsiveness.

Another mediator of T-cell unresponsiveness associated with cancer is the production of indoleamine 2,3-dioxygenase (IDO).[96] IDO appears to be produced by DCs either within tumors or in tumor-draining lymph nodes. Interestingly, IDO in DCs has been reported to be induced via backward signaling by B7-1/2 on ligation with CTLA-4.[97,98] The major IDO-producing DC subset is either a plasmacytoid DC (PDC) or a PDC-related cell that is $B220^+$[99]; however, IDO has been subsequently shown to be expressed by multiple cell types in the immune microenvironment, including tumor cells themselves.[100] IDO appears to inhibit T-cell responses through catabolism of tryptophan. Activated T cells are highly dependent on tryptophan and are therefore sensitive to tryptophan depletion. Thus, Munn and Mellor have proposed a bystander mechanism, whereby DCs in the local environment deplete tryptophan via IDO upregulation, thereby inducing metabolic apoptosis in locally activated T cells.[96] IDO has two isoforms, IDO-1 and IDO-2, encoded by distinct genes. The role of IDO-2 in human cancer is still unclear; a major IDO-2 polymorphism in humans encodes an inactive enzyme. A second tryptophan-metabolizing enzyme is TDO (tryptophan dioxygenase), which is upregulated commonly in human cancers—this may inhibit antitumor responses within the microenvironment similarly to IDO.[101] Finally, there has been greater appreciation that a major product of IDO and TDO metabolism of tryptophan—kynurenine—has potent

effects on T-cell differentiation. Under some circumstances, kynurenine can promote Treg development,[102] and under other circumstances, it can promote development of a class of a subset of T cells termed *Th17*,[103] known for its production of IL-17 and for its procarcinogenic properties (see later discussion). Ultimately, the relative role of tryptophan depletion versus kynurenine production in modulating the immune microenvironment remains to be determined.

A major inhibitory cytokine produced by iMC/MSC and by many other cell types that has been implicated in blunting antitumor immune responses is transforming growth factor beta (TGF-β), which is produced by a variety of cell types, including tumor cells, and which has pleiotropic physiological effects. For most normal epithelial cells, TGF-β is a potent inhibitor of cell proliferation, causing cell cycle arrest in the G_1 stage.[104] In many cancer cells, however, mutations in the TGF-β pathway confer resistance to cell cycle inhibition, allowing uncontrolled proliferation. In addition, in cancer cells, the production of TGF-β is increased and may contribute to invasion by promoting the activity of matrix metalloproteinases. In vivo, TGF-β directly stimulates angiogenesis; this stimulation can be blocked by anti-TGF-β antibodies.[105] A bimodal role of TGF-β in cancer has been verified in a transgenic animal model using a keratinocyte-targeted overexpression.[106] Initially, these animals are resistant to the development of early-stage or benign skin tumors. However, once tumors form, they progress rapidly to a more aggressive spindle-cell phenotype. Although this clear bimodal pattern of activity is more difficult to identify in a clinical setting, it should be noted that elevated serum TGF-β levels are associated with poor prognosis in a number of malignancies, including prostate cancer,[107] lung cancer,[108] gastric cancer,[109] and bladder cancer.[110]

From an immunological perspective, TGF-β possesses broadly immunosuppressive properties, and TGF-β knockout mice develop widespread inflammatory pathology and corresponding accelerated mortality.[111] Interestingly, a majority of these effects seem to be T-cell mediated, as targeted disruption of T-cell TGF-β signaling also results in a similar autoimmune phenotype.[112] Recent experiments by Chen and colleagues rather convincingly demonstrated a role for TGF-β in Treg-mediated suppression of CD8 T-cell antitumor responses.[113] In these experiments, adoptive transfer of $CD4^+$ $CD25^+$ Treg inhibited an antitumor CD8 T-cell effector response, and this inhibition was ameliorated when the CD8 T cells came from animals with a dominant negative TGF-β1 receptor.

Beyond inhibitory cytokines and immune inhibitory metabolic enzymes, the therapeutically most relevant inhibitory pathways in the tumor microenvironment are the so-called checkpoints. Immune checkpoints generally refer to membrane ligands that interact with inhibitory receptors on lymphocytes (see later discussion). Many of the checkpoint ligands are upregulated in the tumor microenvironment, either by tumor cells themselves or by myeloid cells within the tumor stroma. The best studies of the checkpoint ligands fall into the B7 family (discussed later), but a number of additional checkpoint ligands do not. Because activated T cells commonly express cognate inhibitory receptors, they are inhibited from mediating antitumor responses, even if they enter the tumor in an activated state. Antibodies against two checkpoint receptors, CTLA-4 and PD-1, as well as against the major PD-1 ligand, PD-L1 (B7-H1), have demonstrated clinical success and are transforming cancer immunotherapy into an accepted cancer treatment modality. These and other checkpoints of potential relevance in tumor immune evasion are covered in the last sections of this chapter.

Therapeutic Cancer Vaccines

Therapeutic vaccines, initially introduced a half century ago, are the most investigated approaches to cancer immunotherapy. Although they are often lumped under one term, the diversity of cancer vaccine formulations is enormous, ranging from cell lysate vaccines, to genetically engineered whole-cell–based vaccines, to dendritic cell vaccines, to peptide- or protein-based vaccines, to engineered viral and bacterial vaccines. The activity in cancer vaccine development translated into many clinical trials beginning in the 1980s and continuing today. As discussed next, newer generations of vaccine design that incorporate scientific principles of dendritic cell biology and T-cell activation are demonstrating more significant clinical benefit after an initial run of failed randomized trials.

Dendritic Cells—The Key Target of Cancer Vaccines

The central theme among cancer vaccination strategies is enhancement of modulation of antigen-presenting cell (APC) function. This is based on the concept that the quantitative and qualitative characteristics of T-cell responses to antigen depend on the signals they receive from the APC. Among the major bone marrow–derived APC subtypes (B cells, macrophages, and dendritic cells), the DC has emerged as the most potent APC type responsible for initiating immune responses.[114,115] As described earlier, DCs associated with cancer have altered properties that result in failure to activate T cells optimally. Cancer vaccines in essence seek to skew the function of DCs toward the generation of effector T-cell responses.

As virtually all phases of DC differentiation and function can be modulated by engineered vaccines, it is important to understand the molecular signals that regulate their role in activation of T-cell–dependent immunity. At sites of infection and inflammation, bone marrow–derived progenitor cells respond to both proliferative and differentiation signals. GM-CSF and other cytokines such as FLT-3L and IL-4 serve as mitogenic or comitogenic factors that induce an intermediate stage of DC differentiation, characterized by efficient antigen uptake and processing.[116-120] Once they have ingested antigens at inflammatory sites in the tissue, immature DCs differentiate in response to a number of distinct "maturation" signals. Although many diverse molecules induce DC maturation, most appear to signal DCs via binding to two classes of receptors—the Toll-like receptors (TLR) and the TNF receptor (TNFR) family. TLRs are "pattern recognition receptors" (PRR), which bind common chemical moieties expressed by pathogens termed *pathogen-associated molecular patterns* (PAMPs) such as lipopolysaccharide (LPS) and unmethylated CpG DNA sequences.[121] The two best characterized endogenous DC maturation factors are TNF-α itself and CD40L.[122-124] In addition to TLRs, intracellular PRRs, including PKR, RIGI, MDA-5, and NOD1/2, recognize PAMPs from intracellular bacteria and viruses that invade the cytosol.[125-127]

Maturation of DCs, which occurs as they traffic to draining lymph nodes, is characterized by transport of peptide-MHC complexes to the cell surface.[128,129] In addition to provision of high densities of peptide-MHC complexes for T-cell stimulation (termed *signal 1*), DCs regulate T-cell activation and differentiation through the provision of co-stimulatory signals in the form of cytokines, such as IL-12, and membrane-bound ligands of the B7 and TNF family (collectively termed *signal 2*). The ever-expanding panoply of co-stimulatory signals used by DCs to instruct T cells as to their pathway of differentiation and effector function defines a high degree of complexity to the communications that occur between APC and T cell. When immature DCs present antigens to T cells in the absence of co-stimulatory signals, the outcome is tolerance induction (Figure 52-3). This is a normal mechanism for the maintenance of tolerance to self-antigens. It is also a mechanism by which tumors can induce immune tolerance to their own antigens. As discussed throughout this chapter, tumor-induced immune tolerance is a major barrier to successful vaccination of established cancers. Each of the molecular events involved in proliferation, antigen presentation, and co-stimulation represents potential targets that are being exploited in the design of immunotherapy approaches.

Prior to the molecular identification of tumor-specific antigens, investigators used tumor cells themselves as a source of tumor antigen (Table 52-1). Efforts to modify

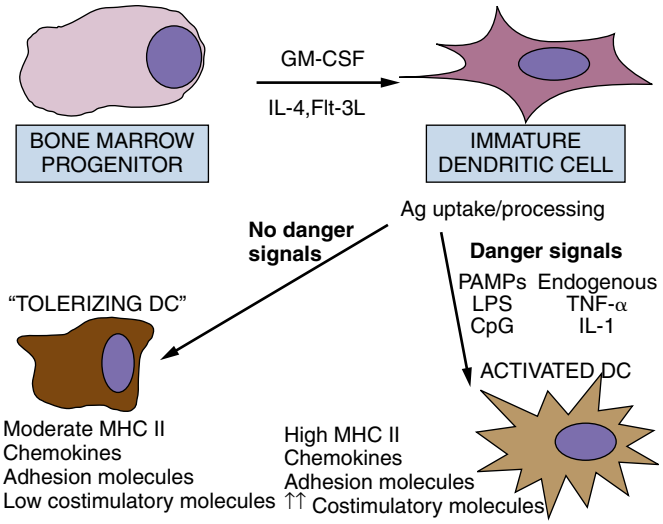

Figure 52-3 Dendritic cells can mediate immune tolerance or immune activation Dendritic cells (DCs), the sentinels of the immune system, develop from hematopoietic progenitors under the influence of cytokines such as granulocyte macrophage colony-stimulating factor (GM-CSF). In the presence of microbial infections, certain microbial products such as lipopolysaccharide (LPS)—often called danger signals—bind sensing molecules on the DC surface, phagosome or cytosol. This induces expression of high levels of MHC molecules and co-stimulatory molecules that aid in activation of T cells specific for ingested antigens. In the absence of these danger signals, DCs can also present antigens to T cells, but in the absence of co-stimulatory molecules. These DCs also express high levels of co-inhibitory molecules for so-called checkpoint receptors on T cells. The result is that T cells become refractory to activation, a state referred to as *anergy*. In some cases, anergic T cells die. Either of these fates generates immune tolerance specific for those antigens.

tumor cells as vaccines date back roughly half a century. Whole-cell tumor vaccines have been generated through mixing with adjuvants aimed at enhancing "immunogenicity" of tumor-specific or tumor-selective antigens incorporated therein, with clinical testing of these mixtures dating back to the 1980s.[130-134] Another approach has been to hapten modify whole tumor cells with chemicals such as dinitrophenol[135] or infect them with a virus.[136] The general concept is that increasing the immunogenicity of tumor cells using either adjuvants or expression of foreign antigens will enhance immune responses to the endogenous tumor antigens, thereby allowing the immune system to kill metastatic tumor deposits.

More recently, a new era in genetically engineered whole-cell vaccination has involved the modification of tumor cells through the transfer of genes encoding cell membrane immunostimulatory molecules or cytokines. Although most of the clinical activity related to adjuvanted whole-cell vaccines is diminishing significantly, active clinical investigation continues for cytokine gene-modified whole-cell vaccines, particularly with the GM-CSF gene (described later). Adjuvanted whole-cell tumor vaccines have been tested extensively in patients with melanoma, renal cell carcinoma, and colorectal carcinoma. Most of these vaccine strategies have

Table 52-1 General Formulations for Cancer Vaccines

Vaccine Type	Advantages	Disadvantages
Cell-based vaccines		
Autologous Allogeneic	Highly polyvalent antigenic content Vaccine antigens match those of patient's tumor Generic vaccine for all patients	Contains mostly self-antigens Individualized patient formulation Relies solely on shared antigens
Dendritic cell (DC)		
Peptide loaded Protein loaded Tumor lysate loaded RNA transduced	Can manipulate DC type and direct Ag loading Specific antigen and easy to synthesize Specific antigen and no need for HLA match Highly polyvalent antigenic content Can amplify from tiny amount of tumor	Individualized cell culture Must match patient's HLA type Loading of HMC I less efficient Contains mostly self-antigens Complex individualized process
Peptide + adjuvant	Very easy to produce	Limited immunogenicity
Protein + adjuvant	Moderately easy to produce	Potency adjuvant-dependent
DNA vaccine	Easy to produce, versatile construction	Limited immunogenicity
Viral vaccine	Moderately easy to produce, immunogenic	Neutralizing Ab limit revaccination
Bacterial vaccine	Easy production, immunogenic, incorporate many Ag	Regulatory challenges

involved the co-injection of either autologous or allogeneic tumor cells with adjuvants such as bacille Calmette-Guérin (BCG) and *Corynebacterium parvum*.[130-134,137] Although BCG and *C. parvum* were long known to represent reasonable vaccine adjuvants for the generation of antibody responses, a limitation of this vaccination approach has been their relatively poor capacity to generate T-cell responses, particularly in the face of established tolerance. Initially, nonrandomized clinical trials were performed that demonstrated hints of promise. In some of these studies that reported antitumor responses, the responses were shown to correlate with the return of delayed-type hypersensitivity (DTH) responses to recall antigens and more importantly with the development of DTH responses to autologous tumor cells.

The application of BCG-adjuvanted tumor cell vaccines to patients with bulky metastatic cancer demonstrated an insignificant clinical response rate. However, given the plethora of studies in animal models suggesting that cancer vaccination might be more effective in the setting of minimal residual disease, a number of studies employing BCG-adjuvanted tumor vaccines in clinical trials were undertaken in the minimal residual disease setting after resection of the primary tumor. Initial enthusiasm for a BCG-adjuvanted, autologous colon cancer vaccine in patients with resected stage II/III colon cancer[138] as well as a melanoma vaccine consisting of a mixture of irradiated allogeneic human melanoma lines with BCG used in melanoma patients with stage III and resected stage IV disease[139] was based on Phase II studies and limited single-institution Phase III studies. The concern in the interpretation of clinical outcomes of these Phase II studies is that it was unclear whether the untreated "historical controls" were truly comparable to the population of patients treated in the Phase II studies. In the absence of careful case-controlled comparisons, the ultimate acceptance of these vaccines depended on pivotal randomized Phase III studies in which both progression-free survival and overall survival were the relevant clinical endpoints. In the case of the autologous BCG-adjuvanted colon cancer vaccine, an initial randomized single-institution study in The Netherlands claimed a longer overall survival in patients with stage II but not stage III colon cancer.[140] Unfortunately, these findings were not reproduced in expanded multicenter trials, possibly owing in part to technical difficulties in consistent autologous tumor preparation as part of the patient-specific vaccine formulation.[141] After 20 years of Phase I and II studies with an allogeneic BCG-adjuvanted melanoma vaccine, a randomized Phase III clinical trial of BCG-adjuvanted allogeneic melanoma cells versus BCG control demonstrated no evidence of enhanced overall survival for the BCG plus tumor vaccine arm.[142] Although the Phase II studies claimed to have demonstrated significant survival benefit relative to case-matched controls, the case-matched controls demonstrated suspiciously short overall survival times relative to melanoma patients of similar stage from multiple other clinical studies. There were encouraging reports of responses to vaccination with BCG-adjuvanted DNP-modified allogeneic melanoma vaccines.[143] However, definitive randomized Phase III trials have not been completed at the time of this writing. Although a number of these studies reported that patients with enhanced DTH responses post vaccination had better disease outcomes than patients who did not, these studies were largely devoid of analyses of antigen-specific T-cell responses, and it is unclear whether the association between DTH responses and enhanced survival had anything to do with the vaccination. A similar fate befell the melanoma vaccine Melacine, a mixture of lysates from

multiple allogeneic melanoma cells admixed with the "detoxified" LPS derivative monophosphoryl lipid A (MPL) plus mycobacterial cell wall extracts. Despite encouraging reports from Phase II studies, a definitive Phase III study in patients with stage II/III operated melanoma failed to demonstrate a statistically significant effect on overall survival.[144] A retrospective subset analysis suggested that HLA-A2$^+$ and HLA-C1$^+$ patients had greater benefit, but this result has not been confirmed in a prospective trial.

One of the limitations of these trials is that none demonstrates definitive enhancement of T-cell responses against relevant antigens. In the case of melanoma, many tumor antigens recognizable by T cells are indeed well defined and responses to them should be measured as part of the development process. As described earlier, a more limited set of "immunorelevant" antigens are defined for other human cancers. In summary, the age of adjuvanted whole-cell or lysate tumor vaccines appears to be slowly drawing to a close and will likely be a historical footnote in the development of cancer immunotherapies.

Genetically Modified Tumor Vaccines

With the development of improved genetic techniques, emphasis shifted to genetic modification of tumor cells to express immunostimulatory molecules. Building on the original studies of Lindenmann and Klein,[145] who showed that vaccination with influenza virus–infected tumor-cell lysates generated enhanced systemic immune responses against challenge with the original wild-type tumor, Fearon and colleagues use direct gene transfer to introduce the immunogenic influenza hemagglutinin (HA) gene into murine tumor cells to create genetically engineered vaccines.[146] These HA transfectants induced a systemic immune response against challenge with the parental tumor. Gene transfer of viral antigens was eventually superseded by gene transfer of immune response–modulating genes. It is important to point out that although many of the strategies were designed with a specific mechanism in mind, it is becoming clear that genetic manipulation to alter expression of even a single gene product can result in a complex cascade of cellular responses in vivo that ultimately may affect multiple aspects of antigen processing, presentation, and co-stimulation.

There are many ways to genetically modify tumor cells to augment T-cell–mediated antitumor immunity. One involves the genetic modification of tumor cells to express cytokines that function as attractants or differentiating agents for dedicated APCs such as dendritic cells.[147] Recruited DCs ingest released tumor antigens at the site of vaccination and present them together with appropriate co-stimulation required for the activation of a tumor-specific T-cell response. Alternatively, the tumor cell can be genetically modified such that it becomes the APC itself.

Both ex vivo and in vivo methods of gene delivery have been employed in the development of genetically modified whole-cell cancer vaccines. Ex vivo gene delivery involves the modification of cultured cells. The genetically modified cells are subsequently administered to the host, typically after irradiation. Clearly, the most effective way to enhance expression of MHC molecules or to enhance expression of co-stimulatory molecules such as B7.1 or B7.2 is to genetically modify the tumor cell itself. However, when the goal is to deliver cytokines locally in a paracrine fashion, genetic modification of the tumor cells themselves is not necessary. A number of transduced bystander cytokine delivery systems have been developed.[148] The efficacy of bystander cytokine delivery systems is comparable to that of direct gene modification of the tumor cell for augmenting antitumor immunity. It is, however, necessary that the transduced bystander cells be admixed with the tumor cells in an appropriate ratio.

Genes that encode cytokines are the most common types of genes that have been introduced into tumor cells in order to generate genetically modified tumor vaccines.[147] Tumor cells transduced with cytokine genes alter the local immunologic environment at the vaccine site, enhancing either the presentation of tumor-specific antigens to the immune system or the activation of tumor-specific lymphocytes. Critically, the cytokine is produced at very high concentrations in the vicinity of the tumor, whereas systemic concentrations are relatively low. This paracrine physiology much more closely mimics the natural biology of cytokine action than does the systemic administration of recombinant cytokines. Since the initial reports of enhanced antitumor responses after vaccination with IL-2-transduced tumor vaccines,[149,150] many cytokine genes have been introduced into tumor cells with various effects on both tumorigenicity and immunogenicity. Some of these cytokines induce a local inflammatory response that results in elimination of the injected tumor. This local inflammatory response is predominantly dependent on components of innate immunity rather than the classic T cells. Ultimately, however, the most important outcome of vaccination is the generation of enhanced T-cell responses specific for the antigens expressed by the vaccinating tumor.

Among the vast array of cytokine gene–transduced tumor vaccine studies, GM-CSF–transduced tumor vaccines remain as the most actively pursued clinically, despite their recent failure in Phase III trials in prostate cancer. In the original study that identified GM-CSF, multiple cytokine, adhesion molecule, and co-stimulatory genes were introduced into the poorly immunogenic B16-F10 tumor using a replication-defective retroviral vector that produced consistent high levels of expression of each of the transgenes in the absence of

selection, thereby eliminating variability caused by different levels of gene expression and resultant cytokine expression. Animals were vaccinated with the irradiated transductants, followed by challenge with unirradiated wild-type B16-F10 cells to doses 3-4 logs higher than the minimal tumoricidal dose.[151] Although a number of cytokine genes in that study, such as IL-4 and IL-6, induced some measurable systemic antitumor immunity,[152,153] the most potent systemic antitumor effect was produced by GM-CSF–transduced tumor cells. Many subsequent studies in other murine tumor models have validated the potent systemic immunity induced by GM-CSF–transduced tumor vaccines. Antitumor immunity induced by GM-CSF–transduced vaccines has been shown to depend on $CD4^+$ and $CD8^+$ T cells. In addition to the classic MHC class I–restricted CTLs, other effector arms mediated by CD4 cells have been shown to participate in the generation of maximal antitumor immunity. TH1 and TH2 effector arms have been delineated.[154] The TH1 effector arm depends on IFN-γ and involves the activation of macrophages at sites of metastases to produce reactive nitrogen species such as NO, as well as reactive oxygen species (superoxides). Eosinophils appear to be important TH2 effectors that are dependent on the production of cytokines such as IL-4 and IL-5 by tumor-specific CD4 cells. The presence of eosinophils at DTH sites and in tumor metastases subsequent to vaccination with GM-CSF–transduced tumors is not only observed in animal models, but also has been a consistent observation in clinical trials with different tumor types.[155]

Clinically, non–patient-specific GVAX platforms that use GM-CSF–modified allogeneic tumor cells exclusively offer numerous advantages over their autologous cell counterparts including manufacturing issues, consistency of vaccine, and fewer limitations on vaccine quantity. Scientific data from both preclinical and clinical studies have provided support for the relevance of allogeneic GVAX immunotherapies and the seminal role of cross presentation of allogeneic tumor-associated antigens by host APCs in the initiation of a cellular antitumor immune response. The one drawback of allogeneic GVAX vaccines is that unique, patient-specific tumor antigens are not targeted.

Antigen-Specific Vaccines

The ultimate goal of cancer vaccine development is the use of antigen-specific vaccines that incorporate select tumor antigens into a vaccine vector(s) or adjuvanted formulation(s) (see Table 52-1). Antigen-specific vaccines have two intrinsic advantages over any type of cell-based vaccine. First, their formulation into a vaccine is much more versatile. Second, they do not contain the thousands of irrelevant or autoantigens included in cell-based vaccines. The control over antigenic makeup afforded by antigen-specific vaccines is significant but requires knowledge of the best antigens to incorporate. An ideal tumor antigen: (1) should be highly selectively expressed by the tumor relative to normal tissues and expressed at reasonably high density on the surface of the tumor cell (as peptide-MHC complexes for T-cell recognition); (2) should be shared among the majority of tumors of a particular type or ideally tumors with diverse histologies; (3) should provide a growth advantage for the tumor, ideally required for tumor growth or survival; and (4) should have a reasonable T-cell repertoire available in patients that has not been deleted and is not stringently tolerized. One of the major limitations in many of the antigen-specific vaccines tested clinically has been the application of antigens that do not meet these criteria. No one antigen may exist that does perfectly meet all these criteria. However, when planning to test a vaccine clinically, it is important to ask how well the candidate antigen(s) meet them. Ideally, antigen-specific vaccines should contain multiple "immunorelevant" antigens, particularly if they are not absolutely essential for tumor growth or survival. A final general principle is that a vaccine containing the best tumor antigen(s) will not enhance antigen-specific responses effectively if the vaccine vector or adjuvant is suboptimal. These principles will be evaluated in the later discussion of commonly studied antigen-specific vaccines.

Peptide Vaccines

The identification of T-cell–recognized tumor antigens at the peptide level spawned a major effort beginning in the 1990s to develop peptide vaccines.[156-158] The fundamental concept of peptide vaccination is that minimal peptides—particularly MHC class 1–restricted peptides that are recognized by CD8 killer cells—can efficiently load MHC molecules on the surface of cells without requiring internal antigen-processing routes. Early studies with peptide vaccines mixed with various adjuvants demonstrated the induction of peptide-specific T cells in vivo and in some cases antitumor responses.[159]

Clearly, one of the major advantages of peptide vaccines is that they represent the ultimate defined tumor antigen, and therefore the capacity to monitor induction of T-cell responses to the immunizing peptide is optimal. However, there are a number of disadvantages associated with peptide vaccination. First, individual peptides are selective for specific MHC alleles and therefore cannot be used generically. This limitation has been circumvented through the use of mixtures of peptides that bind to common MHC alleles, thereby ensuring that the vast majority of patients will express at least one MHC allele that can present the peptide in the vaccine mix. Another major issue with

minimal peptides as vaccinating antigens is that they not only load the MHC molecules of DCs that would activate immune responses, but also bind to MHC molecules on the surface of cells other than DCs just as efficiently. The consequences of peptide presentation by these cells can be tolerance induction because they do not supply the appropriate co-stimulatory signals necessary for T-cell activation.[160-162] Therefore it is possible that peptide vaccination could in fact be detrimental for immune responses. Indeed, Melief and colleagues have presented evidence in animal models that vaccination with long peptides that require processing is significantly superior to vaccination with minimal MHC binding peptides.[163] They have demonstrated that the advantage of vaccination with long peptides comes from the fact that only DCs can process long peptides, thus leading to selective antigen presentation by DCs over other APCs that could induce tolerance.

Another major factor in peptide vaccinations is the adjuvant that is used. Peptides themselves are intrinsically nonimmunogenic, and strong immunization with peptides in animal models is observed only when strong adjuvants capable of activating dendritic cells are mixed with the peptides. Peptides can also be loaded onto DCs grown ex vivo (see later discussion) and reinjected into the patient. The most common formulation used for peptide vaccines in clinical trials is incomplete Freund's adjuvant (IFA), an oil emulsion that does not contain any specific activators of DCs and is thus suboptimal. A few groups have reported enhanced immunogenicity of peptides conjugated to lipids (lipopeptide vaccines).[164,165]

Clinical trials with peptide vaccines in cancer have predominantly used HLA class I–restricted tumor antigen peptides, but some are including MHC class II–restricted peptides.[166] The inclusion of MHC class II–restricted peptides can involve either peptides derived from tumor antigens (such as tyrosinase in the case of melanoma), or those derived from foreign antigens that would nonspecifically stimulate CD4 helper cells, which theoretically would provide help for enhanced stimulation of tumor-specific CD8 T cells responding to the tumor-specific MHC class I–restricted peptides.

Clinical trials have been performed using peptide vaccines for many different cancer types, though vaccination for melanoma is the most common clinical target of peptide vaccines. A number of clinical trials using peptides either in the setting of bulky metastatic cancer or in the minimal residual disease setting have demonstrated induction of increased numbers of antigen-specific T cells using various methods with anecdotal clinical responses.[167,168] Some methods use staining with peptide-MHC tetramers to directly visualize antigen-specific T cells. Other methods such as ELISPOT or intercellular cytokine staining (ICS) seek to measure induction of functional T cells through the production of cytokines such as γ-interferon.

Among the most interesting clinical results highlighting the dichotomy between induction of expanded numbers of peptide-specific T cells and the absence of clinical activity are the vaccine trials in melanoma that have used an anchor-modified gp100 peptide to generate enhanced binding to HLA-A2.[169] These trials use repetitive vaccination with this peptide in IFA in patients with no evaluable disease (NED) after resection for stage II to stage IV melanoma. In these trials, Rosenberg and colleagues demonstrated the capacity to induce tremendous expansion of antigen-specific CD8 T cells, in some patients reaching 50% of the total circulating CD8 T cells as measured by staining with peptide-MHC tetramers and peptide-induced γ-interferon production. Nonetheless, there was no evidence that relapse rate was significantly different from the relapse rate in the same group of melanoma patients not receiving vaccination. In some cases, relapsed melanomas could be demonstrated to have lost HLA-A2 expression or expression of the gp100 antigen, possibly representing an example of evasion or escape from the T-cell responses induced by vaccination. However, many of the relapsed tumors expressed HLA-A2 and gp100, thereby suggesting that the expanded populations of HLA-A2/gp100-specific T cells induced by peptide vaccination were ineffective at eliminating relapsing tumors. Rosenberg and colleagues recently summarized the clinical experience with peptide vaccines, indicating that peptide vaccines as single agents in the advanced disease setting provide a meager 2% to 3% objective response rate.[170] However, more recent clinical studies, adding various adjuvants to peptide vaccines, mixing multiple MHC class I and MHC class II–restricted tumor peptides together,[171] and using "long peptides,"[172] suggest that the maximal potential benefits of peptide vaccines have yet to be realized. As more is learned about the regulation of T-cell responses, it is quite plausible to imagine that T cells expanded in suboptimal conditions (i.e., in the absence of appropriate proinflammatory or co-stimulatory signals) could upregulate expression of inhibitory molecules that would block them from developing the critical effector activity necessary to kill tumor cells. Thus, tumor antigen–specific cells could expand but not be effective against tumors.

Ex Vivo Loaded DC Vaccines

The ability to culture DCs ex vivo has led to a plethora of studies of ex vivo antigen-loaded DCs as tumor vaccines. Although DCs can be loaded with lysates of tumor cells, they are typically either loaded with peptides or recombinant protein or transduced with various vectors or RNA encoding specific antigens. Initially, it was demonstrated that loading of ex vivo cultured DCs with MHC class

I–restricted peptides, whole proteins, or tumor lysates followed by administration back into the animal led to the generation of immune responses against the loaded antigen as well as antitumor responses.[173-179] More recently, the advent of more efficient gene transfer vectors has led to approaches in which ex vivo cultured DCs are transduced with genes encoding relevant viral or tumor antigens.[180-182] A number of recombinant replication-defective viruses have been used to transduce DCs. In addition, Gilboa and colleagues have demonstrated that purified RNA can be used to effectively transduce DCs with resultant presentation of encoded antigens.[183] This strategy offers the interesting possibility that DCs could be transduced with the entire amplified transcriptome of a tumor cell, even when only tiny amounts of tumor tissue are available. At present, the paucity of direct comparative studies leaves open the question of which method of loading DCs ex vivo will be the most effective. Another major issue with ex vivo loaded DC vaccines is the degree of maturation that is induced in vitro and its relevance to homing and function of loaded DCs after reinjection. Maturation protocols used for DC vaccination are currently quite variable and range from monocyte conditioned medium to various defined agents such as TNF-α, IL-1, soluble CD40L, and prostaglandins.[184,185] Concern has been raised that full-blown maturation/activation of DCs ex vivo to a stage normally achieved once they are within paracortical regions of the lymph node will impair their ability to home to lymph nodes after reinjection. This has led to the suggestion that DCs should be loaded and reinjected in an immature state and allowed to mature in vivo. However, such an approach has potential negative consequences, as Steinman, Bhardwaj, and colleagues have demonstrated—immunization of patients with antigen-loaded immature DCs can actually result in tolerance or suppression of antigen-specific responses.[186]

Elucidation of proliferative and maturation signals for DCs has led recently to approaches in which DCs not only are loaded with antigen but are transduced with genes encoding proliferation and maturation signals. This would result in autocrine DC stimulation in vivo after reinjection. In one study, DCs loaded with antigen were transduced with genes encoding GM-CSF and CD40L. These genetically modified DCs resulted in much more potent stimulation of antitumor immunity than immunization with DCs loaded with antigen alone.[187]

Another approach aimed at providing DCs with a full complement of tumor antigens is the generation of DC-tumor fusion vaccines.[188-190] The concept behind this approach is to fuse autologous tumor cells with dendritic cells, thereby allowing for the coexpression of all relevant tumor antigens together with all relevant DC molecules within the same cell. One of the major limitations to clinically translating an approach of this type is the efficiency with which fusion can be achieved between DCs and tumor cells in the absence of selection. Ultimately, it is critical that both preclinical and clinical DC vaccine studies identify the critical parameters of DC growth and maturation as well as antigen loading that result in therapeutically relevant levels of T-cell activation in vivo.

Many clinical trials with DC vaccines have been performed using DCs cultured and activated in vitro by various methods and loaded with tumor antigens of various types. As with most cancer vaccines, melanoma is the most common target, although other cancers have been targeted as well. Induction of T-cell responses is commonly reported, and interesting anecdotal clinical responses have been reported in Phase I/II trials.[117] One of the more interesting clinical DC vaccine approaches involves transduction of DCs with RNA encoding telomerase that is targeted to the MHC class II processing pathway with the LAMP targeting signal.[191] Telomerase is the enzyme that restores telomeres, the ends of chromosomes. Without telomerase, cells will eventually stop growing when their telomeres are exhausted. Tumors typically upregulate telomerase, making it a tumor-selective antigen. Vaccination with DCs transduced with telomerase-LAMP RNA led to significantly enhanced CD4 and CD8 responses specific for telomerase.

Two Phase III clinical trials using DC vaccines have been negative, though one led to interesting politically motivated deliberations at the U.S. FDA. Schuler and colleagues compared DTIC chemotherapy with peptide-loaded DC vaccination in stage IV melanoma patients.[192] Objective responses were low in both arms (less than 5%), and there was no statistically significant difference in overall survival. A retrospective subset analysis suggested that HLA-$A2^+$/HLA-$B44^-$ patients might derive greater benefit from vaccination, but this has not been verified in a prospective manner. The Dendreon Corporation has recently reported results of a Phase III trial in patients with advanced prostate cancer comparing placebo with a DC vaccine prepared by crude enrichment of peripheral blood lymphocytes followed by culture with a prostatic acid phosphatase–GM-CSF fusion protein.[193] The primary endpoint of prolonged progression-free survival was not achieved, but continued evaluation of the patients demonstrated prolonged overall survival compared with placebo of 4.5 months. The quality of this trial was questionable because the small size precluded careful matching of patient characteristics and registration was applied for based on an endpoint different from that built into the original trial. In addition, the initial evaluation of a follow-up Phase III trial did not demonstrate even a significant trend toward improved overall survival in the DC-vaccinated group. Although a majority of the advisory

panel voted to approve the vaccine, the FDA ultimately chose to require additional supporting clinical data before approval.[194] However, a follow-up Phase III trial with overall survival as the endpoint has recently been reported to have met its endpoint (see later) and, at this writing, is in the process of Biologics License Application (BLA) filing.

Heat Shock Protein–Based Vaccines

Another interesting category of proteins that may target antigen effectively to DCs and furthermore into MHC processing pathways are the heat shock proteins (HSPs). It is now well established that complexing peptide antigens to certain HSPs such as gp96, hsp-70, calreticulin, and hsp-110 enhances their immunogenicity significantly.[195-202] HSPs were first used as tumor vaccines by purifying them from tumor cells followed by immunization. HSPs isolated from tumors are naturally complexed with a whole array of tumor-associated peptides. Other approaches to link antigen to HSP have included the production of recombinant fusion proteins in which antigenic peptides are covalently or noncovalently linked to the HSP[203] as well as DNA-based vaccines in which fusion genes between antigen and HSP gene are incorporated. In one direct comparative study using the human papillomavirus (HPV)-E7 antigen as a model, it was demonstrated that DNA vaccines encoding an E7-hsp70 fusion gene were 30-fold more effective than the wild-type E7 gene in generating $CD8^+$ responses.[204] Immunogenic HSPs complexed with antigenic peptides have been shown to efficiently load the MHC class I processing pathway (so-called in vitro cross presentation).[205] Although the intracellular pathway by which HSPs effectively load MHC class I molecules with their associated peptides has not yet been elucidated, Srivastava and colleagues have identified CD91, the α2 macroglobulin receptor, as an important receptor for several HSPs (gp96, hsp-70, hsp-90).[206] Ultimately, the immunogenicity of HSPs has been proposed to result from their ability to activate APCs and target antigens to MHC processing pathways. One report has suggested that hsp-70 can activate macrophages via CD14/TLR-4 (LPS receptor)–dependent and –independent pathways.[207] HSPs have also been reported to activate DCs,[208] although the receptors that mediate these putative activation functions have yet to be elucidated.

Clinical trials with HSPs have been ongoing. A Phase II trial vaccinating women with premalignant high-grade cervical dysplasia caused by HPV-16 using a bacterial hsp65-HPV16 E7 fusion protein demonstrated a 35% CR with induction of E7-specific T-cell responses in roughly half of the patients; however, the cohort was too small to determine whether this response rate was statistically different from the roughly 25% spontaneous regression rate observed in this patient group without treatment.[209] The only Phase III trial with HSP vaccines reported to date was in patients with operated stage II/III renal cancer, who were randomized to observation or treatment with autologous hsp96 purified from the resected primary tumor. This was a negative study in that no statistical difference was observed in either relapse-free survival or overall survival. A second Phase III trial of autologous hsp96 versus physician's choice (IL-2, resection, or chemotherapy) demonstrated no benefit relative to the physician's choice arm but found that patients receiving 10 or more vaccine administrations had a longer overall survival than those who received fewer administrations of vaccine.[210]

The Growing Armamentarium of Vaccine Vectors

For all of the added value that recombinant DNA technology provides in engineering elements into vaccine constructs that enhance their potency, nature itself provides a virtually limitless array of delivery systems in the form of diverse microbes with potent intrinsic immunologic properties. These immunogenic properties derive from their expression of PAMPs, which activate DCs via TLRs and intracellular sensing pathways such as PKR, RIGI, and MDA-5; their ability to induce proinflammatory cytokine expression by infected cells; and their ability to target intracellular MHC processing compartments. Of the three major microbial classes—virus, bacterium, and fungus—viruses and bacteria have been the most intensively investigated. A few reports of engineered yeast vaccines emphasize the potential immunologic utility of the third microbial class.

Engineered Viruses

Viruses are the most diverse and efficient gene transfer agents whose natural cell tropism and biologic features can significantly enhance the immunogenicity of antigens carried within them (see Table 52-1). Using standard recombination approaches, Moss and Paoletti were the first to explore recombinant viruses as vaccine vectors. They used vaccinia virus, a highly immunogenic virus related to smallpox that is relatively nonvirulent in immunocompetent individuals. In most cases, a single immunization with recombinant vaccinia carrying a gene expressing an antigen will generate significantly greater immune responses against that antigen than the corresponding protein or peptide epitopes mixed with standard adjuvants.[211-213] This is particularly true for CTL generation. To date, many viruses have been explored as recombinant vaccine vectors, including attenuated replication-deficient poxviruses (such as modified vaccinia ancara,

fowlpox, and canarypox), adenovirus, herpesviruses, and Venezuelan equine encephalitis virus.[214-217] Each of these viruses has various advantages and disadvantages, and no clear "winner" has emerged as the absolute vector of choice. Features of viruses that can enhance their potency as vaccine vectors include their ability to induce immunologic "danger" signals at sites of infection and to directly infect APCs. Features of viruses that can diminish their potency as vaccine vectors include the presence of virally encoded inhibitors of immunity. These include molecules that block processing and presentation in the MHC class I pathway (such as TAP inhibitors and inhibitors of MHC class I traffic out of the endoplasmic reticulum) and cytokine decoys, to mention a few.[218] Deleting immunologic inhibitory genes from recombinant viruses may further enhance their vaccine potency while attenuating their virulence.

A major barrier to virus-based vaccination are neutralizing antibodies in preexposed or prevaccinated individuals that inhibit the initial round of infection and replication, thereby quenching their ability to immunize. Individuals who have never been previously exposed to the vaccinating virus generate neutralizing antibody after the first vaccination, thereby precluding subsequent vaccination with the same vector. This finding has led to the concept of cycling different viral vectors in "prime-boost" formats. Dramatic enhancement of immunization potency has been observed in prime-boost formats between both different viruses such as vaccinia followed by fowlpox between DNA vaccines and recombinant viral vaccines.[219,220]

Among the large number of clinical trials with viral vaccine vectors, the most extensive have involved poxvirus vectors. Based on enthusiasm from preclinical experiments, a number of prime-boost studies have been performed using vaccinia followed by fowlpox.[221] A Phase III trial in patients with inoperable pancreatic cancer was performed using a vaccinia-fowlpox prime-boost schedule versus chemotherapy or supportive care. The viral vectors incorporated two antigens—carcinoembryonic antigen and MUC-1—and also included ICAM-1, LFA-3, and B7.1 genes to putatively enhance the co-stimulatory activity of infected DCs (though this has never been proven). The trial was negative. Phase II trials with a similar prime-boost regimen for advanced prostate cancer using prostate-specific antigen (PSA) as the antigen have provided interesting results, but clinical benefit has not been definitively demonstrated. Regulatory hurdles and the inability to vaccinate repetitively are likely to preclude further development efforts for viral vaccines in cancer.

Engineered Bacteria

Genetic engineering of intracellular bacteria such as BCG, *Salmonella*, *Shigella*, and *Listeria* has produced a number of interesting and promising vaccines.[222-224] In principle, bacteria that enter antigen-presenting cells may represent a good vehicle for delivery of recombinant antigens. In certain cases, such as *Listeria*, the bacteria exhibit complex life cycles that involve both phagolysosomal and cytoplasmic stages. Thus, recombinant *Listeria monocytogenes* (LM) engineered to secrete antigens will load the MHC class II processing pathway during the phagolysosomal phase and the MHC class I pathway during the cytosolic phase of the life cycle. In addition, a number of recombinant bacteria actively induce infected APCs to secrete proinflammatory cytokines such as IL-12. More recently, recombinant bacteria have been used as vectors for delivery of DNA vaccines.[223,224] Thus, bacterial vaccines containing plasmids with eukaryotic promoter and enhancer elements driving the antigen gene result in potent immunization. These results indicate that the bacteria can directly transfer plasmids into eukaryotic transcriptional compartments within infected APCs.

The LM vectors are among the most promising bacterial vectors being developed for therapeutic vaccination of cancer. Dubensky and colleagues have identified a number of approaches to dramatically attenuate the virulence of LM without diminishing its immunogenicity. One approach is to knock out the ActA and Internalin(Inl)B genes of LM.[222] Knockout of ActA does not prevent the initial infection of cells with LM, but eliminates the capacity for cell-to-cell spread necessary for the propagation of LM infections. Knockout of the InlB gene eliminates the capacity of LM to infect hepatocytes while not affecting the capacity of LM to infect APCs. Thus, infection with InlB mutant LM generates strong intrahepatic inflammatory responses with minimal destruction of hepatocytes. ActA/InlB double mutant LM are equivalently immunogenic to wild-type LM, but are 4 to 5 logs attenuated in their virulence. Another approach to virulence attenuation of LM (which is applicable to other bacterial vectors as well) involves the knockout of DNA repair genes together with limited DNA crosslinking using psoralen derivatives. Because the DNA repair system has been knocked out, bacteria can be inhibited from replicating themselves with as little as a single DNA crosslink per bacterial genome. This approach maintains metabolic activity while formally "killing" the bacteria. These killed but metabolically active (KBMA) organisms maintain significant immunogenicity but have highly attenuated virulence.[225]

Despite the diversity of vaccine platforms just described, anecdotal reports of vaccine-induced tumor regressions, and promising Phase I and II clinical trial results with cancer vaccines evaluated since the 1960s, a string of failures in randomized clinical trials bred significant skepticism as to the ultimate clinical value of therapeutic cancer vaccines.[170] However, in the past couple of years, a number of important clinical successes with cancer vaccines have dramatically altered the perception of their potential value.

The first successful randomized Phase III cancer vaccine trial used a putative DC vaccine, sipuleucel-T, to treat patients with advanced hormone-resistant prostate cancer.[226] This vaccine is based on the concept that optimal T-cell activation requires antigen processing and presentation by a specialized cell—the DC—with the capacity to concomitantly deliver strong co-stimulatory signals in the form of membrane ligands and secreted cytokines. Sipuleucel-T is a patient-specific vaccine produced by transiently incubating the patient's own peripheral blood mononuclear cells (PBMCs) with a fusion protein consisting of PAP (prostatic acid phosphatase—a prostate/prostate cancer–specific antigen) linked to the DC growth and differentiation factor GM-CSF. A 4-month overall survival (OS) benefit relative to the control arm (uncultured PBMCs without PAP-GM-CSF fusion protein) in the absence of objective tumor regressions or effect on time to progression emphasizes a developing paradigm: that immunotherapy can potentially provide OS benefits that are not reflected in progression-free survival (PFS) or objective response rate (ORR). The survival benefit of sipuleucel-T ultimately led to FDA approval in 2010.

Recently, three positive randomized cancer vaccine trials have been reported. First, a trial comparing a poxvirus-PSA prime/boost vaccine regimen plus GM-CSF versus non–antigen-expressing viruses in patients with advanced prostate cancer demonstrated a significant (8 month) OS benefit for the vaccine arm but no effect on PFS or ORR.[227] Second, a melanoma vaccine consisting of a modified gp100 peptide plus systemic IL-2 was compared to systemic IL-2 alone in patients with advanced melanoma,[228] yielding a statistically higher ORR in the vaccine + IL-2 arm, improved PFS, and improved OS ($P = .06$). Of note, the same peptide vaccine, when combined with anti-CTLA-4, demonstrated no improvement in patients with advanced melanomas relative to anti-CTLA-4 alone (see later discussion), underscoring the importance of context when evaluating vaccines as components of combinatorial therapies. In 2013, a randomized trial comparing a GVAX/*Listeria*-mesothelin prime-boost vaccine versus GVAX alone in patients with advanced chemotherapy refractory pancreas cancer demonstrated a strong statistical survival benefit for the GVAX/*Listeria*-mesothelin prime-boost arm (6.1 versus 3.9 months, HR = 0.55, $P = .013$; per-protocol analysis: 9.7 versus 4.6 months, HR = 0.44, $P = .01$).[229] This prime-boost strategy was based on preclinical data demonstrating that priming with GVAX and boosting with a *Listeria* vaccine, but not vice versa, produced strongly enhanced T-cell responses and antitumor responses in animal models. The choice of mesothelin as antigen to incorporate into the *Listeria* (ActA/Internalin B KO as described earlier) vaccine vector was based on earlier demonstrations that it is highly upregulated in all pancreatic cancer, provides an advantage to tumor growth (and thus cannot be easily down-modulated without cost to the tumor cells), is expressed at low levels in a limited subset of mesothelial cells, and can be a clear target for induced T-cell responses.

In addition to therapeutic vaccine trials for established cancer, premalignant lesions caused by chronic viral infection are excellent targets for therapeutic vaccines. The best example of such a situation is HPV-associated premalignant lesions of the cervix, vulva, anus, and orolaryngeal mucosa. In a single-arm clinical trial using long peptides (which are selectively processed and presented by DCs) derived from HPV-16 E6 and E7 antigens induced complete regressions in 9 of 19 patients with vulvar intraepithelial neoplasia, an HPV-associated preneoplastic condition with a spontaneous regression rate of less than 2%.[230]

Co-inhibitory Ligands and Receptors That Down-Modulate Tumor Immunity

Without question, the major molecules to be successfully targeted in clinical cancer immunotherapy are the growing class of ligand-receptor pairs commonly referred to as immune checkpoints. In considering the mechanism(s) of action of inhibitors of various checkpoints, it is critical to appreciate the diversity of immune functions that they regulate. For example, the two immune checkpoint receptors that have been most actively studied in the context of clinical cancer immunotherapy, CTLA-4 (CD152) and PD-1 (CD279), regulate immune responses at very different levels and by very different mechanisms. The clinical activity of blocking antibodies for each of these receptors implies that antitumor immunity can be enhanced at multiple levels and that combinatorial strategies can be intelligently designed, guided by mechanistic considerations and preclinical models. This section focuses particular attention on the CTLA-4 and PD-1 pathways because they were the two checkpoints whose inhibition has revolutionized clinical cancer immunotherapy. However, it is important to emphasize that multiple additional checkpoints represent promising targets for therapeutic blockade based on preclinical experiments, and inhibitors of many of these are under active development.

The CTLA-4 Checkpoint—a Global Regulator of T-Cell Activation

CTLA-4, the first immune checkpoint receptor to be clinically targeted, is expressed exclusively on T cells, where it primarily regulates the amplitude of the early stages of T-cell activation. CTLA-4 knockout mice die within 3 weeks from immune destruction of multiple organs, which attests to its critical role as an inhibitory regulator of T-cell–dependent immune responses. Primarily, CTLA-4 counteracts the

activity of the T-cell co-stimulatory receptor CD28.[231-233] CD28 does not affect T-cell activation unless the TCR is first engaged by cognate antigen. Once antigen recognition occurs, CD28 signaling strongly amplifies the TCR signal to activate T cells. CD28 and CTLA-4 share identical ligands—CD80 (B7.1) and CD86 (B7.2).[234-238] Because CTLA-4 has a much higher overall affinity for both ligands, its expression on the surface of T cells dampens the activation of T cells by outcompeting CD28 in binding CD80 and CD86, as well as by actively delivering inhibitory signals to the T cell.[239-244] The specific signaling pathways by which CTLA-4 blocks T-cell activation are still under investigation, although a number of studies suggest that activation of the phosphatases SHP2 and PP2A is important in counteracting kinase signals induced by TCR and CD28.[232] However, CTLA-4 also confers "signaling independent" T-cell inhibition through sequestration of CD80 and CD86 from CD28 engagement as well as active removal from the APC surface.[245] The central role of CTLA-4 in maintaining T-cell activation in check is dramatically demonstrated by the systemic immune hyperactivation phenotype of CTLA-4 knockout mice.[246,247]

Even though CTLA-4 is expressed by activated CD8 killer T cells, the major physiologic role of CTLA-4 appears to be through distinct effects on the two major subsets of CD4 T cells—down-modulation of helper T-cell activity and enhancement of regulatory T-cell suppressive activity.[231,248,249] CTLA-4 blockade results in a broad enhancement of immune responses dependent on helper T cells, and conversely, CTLA-4 engagement on Treg (Tregs) enhances their suppressive function. CTLA-4 is a target gene of the transcription factor Foxp3,[77,250] the expression of which determines the Treg lineage,[251,252] and Tregs therefore express CTLA-4 constitutively. Although the mechanism by which CTLA-4 enhances the inhibitory function of Tregs is not known, Treg-specific CTLA-4 knockout or blockade significantly inhibits their ability to regulate both autoimmunity and antitumor immunity.[248,249] Thus, in considering the mechanism of action for CTLA-4 blockade, both enhancement of effector CD4 T-cell activity and inhibition of Treg-dependent immune suppression are likely important factors.

Clinical Application of CTLA-4 Blocking

Blockade of CTLA-4 as a general strategy was initially questioned because there is no tumor specificity to expression of the CTLA-4 ligands (other than certain myeloid and lymphoid tumors) and also because the dramatic lethal autoimmune/hyperimmune phenotype of CTLA-4 knockout mice predicted a high degree of immune toxicity associated with blockade of this receptor. However, Allison and colleagues used preclinical models to demonstrate that a therapeutic window was indeed achieved when CTLA-4 was partially blocked with antibodies.[253] The initial studies demonstrated significant antitumor responses without overt immune toxicities when mice bearing partially immunogenic tumors, particularly melanomas, were treated with anti-CTLA-4 antibodies as single agents. Poorly immunogenic tumors did not respond to anti-CTLA-4 as a single agent but did respond when anti-CTLA-4 was combined with a GM-CSF–transduced cellular vaccine.[254] These findings suggested that, if there was an endogenous antitumor response present in the animals after tumor implantation, CTLA-4 blockade could enhance that endogenous response, which ultimately induced tumor regression. In the case of poorly immunogenic tumors, which do not induce significant endogenous responses, the combination of a vaccine and an anti-CTLA-4 antibody could induce a strong enough immune response to slow tumor growth and in some cases eliminate established tumors.

These preclinical findings encouraged the production and testing of two fully human anti-CTLA-4 antibodies, ipilimumab and tremelimumab, which began clinical testing in 2000. As with virtually all anticancer agents, initial testing was as a single agent in patients with advanced disease, not responding to conventional therapy.[255] Both antibodies produced objective clinical responses in roughly 10% of melanoma patients but also immune-related toxicities involving various tissue sites in 25% to 30% of patients, with colitis being a particularly common event.[256-258] The first randomized Phase III clinical trial to be completed was for tremelimumab in patients with advanced melanoma. In the trial, 15 mg/kg tremelimumab was given every 3 months as a single agent and compared to DTIC, a standard melanoma chemotherapy treatment. The trial showed no survival benefit with this dose and schedule relative to DTIC.[259]

However, ipilimumab fared better. Even though the two antibodies appear to have similar intrinsic activity, response rates in Phase II trials, and immune toxicity profiles, ipilimumab was more carefully evaluated at different doses and schedules. In addition, more careful definition of algorithms for improved clinical management of the immune toxicities (using steroids and TNF blockers) mitigated the overall morbidity and mortality associated with immunologic toxicities.

The toxicity rate for ipilimumab is quite significant (14% to 30% grade 3-5 in various studies) and is generally immunologic in nature, implying that it is "on target." This was predicted from the dramatic lethal hyperimmune/autoimmune phenotype of the CTLA-4 KO mice. The most common toxicities with both ipilimumab and tremelimumab are cutaneous (rash) and colitis. However, hepatitis, pneumonitis, hypophysitis, and thyroiditis are also observed.

Interestingly, although there is evidence that clinical responses might be associated with immune-related adverse events, this correlation is modest.[260]

Finally, in a randomized three-arm clinical trial of patients with advanced melanoma who received a melanoma-specific gp100 peptide vaccine alone, the gp100 vaccine plus ipilimumab, or ipilimumab alone, there was a 3.5-month survival benefit for patients in both groups receiving ipilimumab (i.e., with or without the gp100 peptide vaccine) compared with the group receiving peptide vaccine alone.[261] As the first therapy ever to demonstrate a survival benefit for patients with metastatic melanoma (DTIC was approved based on response rate and has never been shown to provide a survival benefit in melanoma), ipilimumab was FDA approved for the treatment of advanced melanoma in 2010.

More impressive than the mean survival benefit was the affect on long-term survival: 20% of the ipilimumab-treated patients survived beyond 2 years (compared with 5% of patients receiving the peptide vaccine alone).[261] In this and other studies, the proportion of long-term survivors is higher than the proportion of objective responders. The finding of ongoing responses and survival long after the completion of a relatively short course of therapy (four doses of 10 mg/kg over 3 months) supports the concept that immune-based therapies might reeducate the immune system to maintain tumors in check after completion of the therapeutic intervention.

As with all oncology agents that benefit a limited proportion of treated patients, much effort has been expended to define biomarkers predictive of clinical response to anti-CTLA-4 treatment. To date, no such pretreatment biomarker has been validated to the point where it could be applied as part of standard-of-care therapeutic decision making, though insights have emerged from the identification of certain posttreatment immune responses that seem to correlate with clinical outcome.[262-264]

An important feature of the anti-CTLA-4 clinical responses that distinguishes them from conventional chemotherapeutic agents and oncogene-targeted small-molecule drugs is their kinetics. Whereas chemotherapy and tyrosine kinase inhibitor (TKI) responses commonly occur within weeks of initial administration, the response to immune checkpoint blockers is slower and, in a number of patients, delayed (up to 6 months after treatment initiation). In some cases, metastatic lesions actually increase on computed tomography or magnetic resonance imaging scans before regressing. These findings demand a reevaluation of response criteria for immunotherapeutics that does not use conventional time-to-progression or RECIST objective response criteria, which were developed based on experience with chemotherapy agents and as the primary measure of drug efficacy.[265]

Biology of the PD-1 Checkpoint—a Pathway That Functions within the Tumor Microenvironment

Another immune checkpoint receptor, PD-1, is emerging as a promising target, emphasizing the diversity of potential molecularly defined immune manipulations capable of inducing antitumor responses by the patient's own immune system.

In contrast to CTLA-4, the major role of PD-1 is to limit the activity of T cells in the peripheral tissues at the time of an inflammatory response to infection and to limit autoimmunity.[266-272] This translates to a major immune resistance mechanism within the tumor microenvironment (Figure 52-4).[273-275] PD-1 expression is induced when T cells become activated.[267] When engaged by one of its ligands, PD-1 inhibits kinases involved in T-cell activation via the phosphatase SHP2,[266] although additional signaling pathways are also likely induced, and because PD-1 engagement inhibits the TCR stop signal, this pathway could modify the duration of T-cell/APC or T-cell/target cell contact.[276] Similar to CTLA-4, PD-1 is highly expressed on Tregs, where it may enhance their proliferation in the presence of ligand.[277] Because many tumors are highly infiltrated with Tregs that likely further suppress effector responses, PD-1 pathway blockade may also enhance antitumor responses by diminishing the number and/or suppressive activity of intratumoral Tregs.

The two ligands for PD-1 are PD-L1 (B7-H1, CD274) and PD-L2 (B7-DC, CD273).[266,278-280] These B7 family members share 37% sequence homology and arose via gene duplication, positioning them within 100 kb of each other in the genome.[280] Recently, an unexpected molecular interaction between PD-L1 and CD80 was discovered,[281] whereby CD80 expressed on T cells (and possibly APCs) can potentially behave as a receptor rather than a ligand, delivering inhibitory signals when engaged by B7-H1.[282,283] The relevance of this interaction in tumor immune resistance has not yet been determined. Finally, genetic evidence from PD-1–deficient T cells suggests that both PD-L1 and may bind to a co-stimulatory receptor expressed on T cells.[282] These complex binding interactions are reminiscent of the CD80/CD86 ligand pair, which binds the co-stimulatory CD28 expressed on resting T cells and the inhibitory CTLA-4 expressed on activated T cells, though, as stated earlier, PD-1 predominantly regulates effector T-cell activity within tissue and tumors, whereas CTLA-4 predominantly regulates T-cell activation. Understanding the role of these various interactions in given cancer settings is highly relevant for the selection of both antibodies and recombinant ligands for use in the clinic.

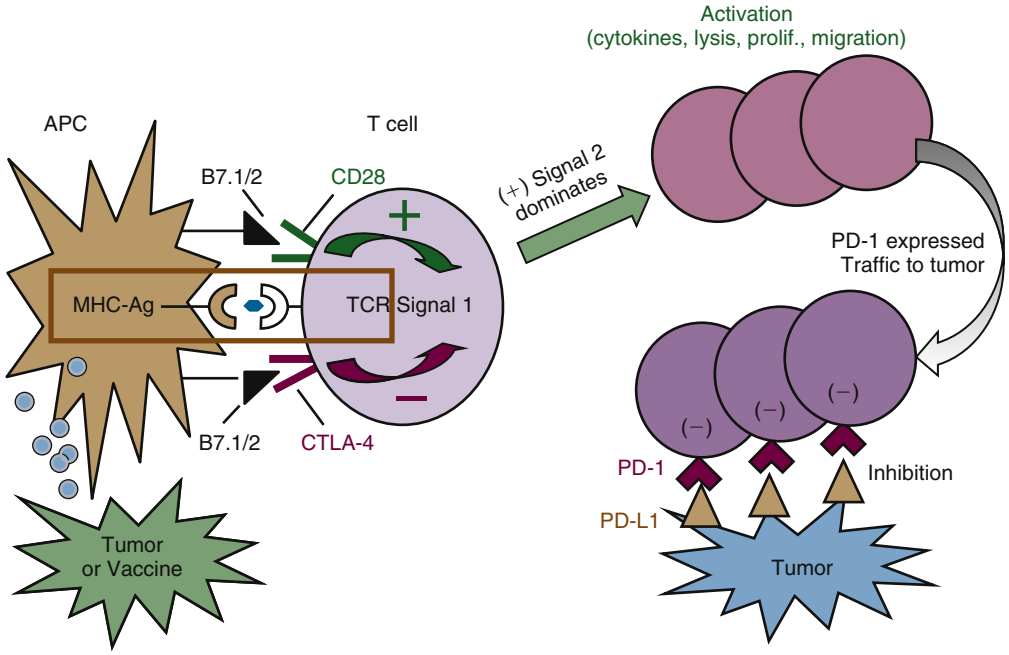

Figure 52-4 CTLA-4 and PD-1 checkpoints act to regulate different elements of the T-cell response to tumors Naïve T cells and resting T cells express little CTLA-4 or PD-1 on their surface. On initial T-cell activation via triggering of the T-cell receptor (TCR) by cognate peptide/MHC complexes together with engagement of CD28 by B7-1 and/or B7-2, CTLA-4 becomes expressed on the cell surface while the T cell is still engaged with its antigen-presenting cell (generally a dendritic cell), usually in the secondary lymphoid tissue. The greater the TCR stimulus, the more CTLA-4 is expressed on the surface. Inhibitory signals from CTLA-4 interaction of CTLA-4 with B7-1 and B7-2 results in a counterregulatory signal that down-modulates the ultimate amplitude of T-cell activation. Activated T cells then traffic into the tumor, where the PD-1 pathway becomes important. The PD-1 checkpoint primarily operates within the tumor where PD-1 ligands (PD-L1 and sometimes PD-L2) are upregulated.

PD-1 is more broadly expressed than CTLA-4; it is induced on other activated non–T lymphocyte subsets, including B cells and NK cells,[284,285] limiting their lytic activity. Thus, although PD-1 blockade is typically viewed as enhancing the activity of effector T cells in tissues and in the tumor microenvironment, it likely also enhances NK activity in tumors and tissues and may also enhance antibody production either indirectly or through direct effects on PD-1$^+$ B cells.[286]

In addition, chronic antigen exposure, such as occurs with chronic viral infection and cancer, can lead to high levels of persistent PD-1 expression, which induces a state of exhaustion or anergy among cognate antigen-specific T cells. This state, which has been demonstrated in multiple murine and human chronic viral infections, appears to be partially reversible by PD-1 pathway blockade.[287] Finally, although the PD-1 pathway plays its major role in limiting immune effector responses in tissues (and tumors), it can also shift the balance from T-cell activation to tolerance at early stages in T-cell responses to antigen within secondary lymphoid tissues (i.e., at a similar point compared to CTLA-4). Taken together, these findings imply a complex set of mechanisms of action for PD-1 pathway blockade.

PD-1 is expressed on a large proportion of tumor-infiltrating lymphocytes (TILs) from many different tumor types.[288,289] Some of the enhanced PD-1 expression among CD4 TILs reflects a generally high level of PD-1 on Tregs, which, as noted earlier, can represent a large fraction of intratumoral CD4 T cells. Increased PD-1 expression on CD8 TILs may reflect an anergic/exhausted state, as has been suggested by decreased cytokine production by PD-1$^+$ versus PD-1$^-$ TILs from melanomas.[288]

Just as PD-1 is highly expressed on TILs from many cancers, the PD-1 ligands are commonly upregulated on many different human tumors.[274,290] On solid tumors, the major PD-1 ligand to be expressed is PD-L1. Forced expression of PD-L1 on murine tumors inhibits local antitumor T-cell responses.[274,291] Indeed, this combination of findings provides the basis for PD-1 pathway blockade to enhance antitumor effector function in the tumor microenvironment. As immunohistochemistry (IHC) techniques and flow cytometry analysis of surface expression have been employed, it has become clear that the selective upregulation of PD-1 ligands in various human tumor types is heterogeneous at a number of levels.[275] Expression patterns of PD-1 ligands may very well be critical in choosing suitability for therapeutic blockade of this pathway, because its primary role in cancer is thought to be immune inhibition within the tumor microenvironment, and PD-1 inhibits lymphocyte function only when it is engaged by cognate ligand.

Initially, the majority of melanoma, ovarian, and lung cancer samples were reported to have high expression of PD-L1,[274,291,292] and subsequently, many other human

cancers were reported to upregulate PD-L1. In addition to tumor cells, PD-L1 is commonly expressed on myeloid cells in the tumor microenvironment.[293-295] An initial report in renal cancer demonstrated that expression of PD-L1 on either tumor cells or infiltrating leukocytes in primary tumors predicted a worse prognosis—that is, decreased overall survival relative to PD-L1$^-$ tumors.[296] Since that report, analyses of various tumors have suggested that PD-L1 status can correlate with poor prognosis or better prognosis or can show no correlation with prognosis.[275,297-301] Variability in IHC technique, cancer type, stage of cancer analyzed (most analyses are of primary, not metastatic lesions), and treatment history in the analyzed cohort all likely contribute to the wide range of reported outcomes.

Although most analyses of PD-1 ligand expression have focused on PD-L1, PD-1 has also been reported to be upregulated on a number of tumors. It is highly upregulated on certain B-cell lymphomas such as primary mediastinal, follicular cell B-cell lymphoma, and Hodgkin's disease.[299] Upregulation in these lymphomas is commonly associated with gene amplification or rearrangement to the CIITA locus, which is highly transcriptionally active in B-cell lymphomas.[302]

Given the heterogeneity of expression and potential relevance as a biomarker for blockade of the PD-1 pathway, it is important to understand the signals that induce expression of PD-1 ligands on tumor cells and also hematopoietic cells within the tumor microenvironment (Figure 52-5). Two general mechanisms for the regulation of PD-L1 have emerged: innate and adaptive. For some tumors such as glioblastoma, it has been demonstrated that PD-L1 is driven by constitutive oncogenic signaling pathways in the tumor cell. Expression on glioblastomas is enhanced on deletion or silencing of PTEN, implicating the PI3K-AKT pathway.[303] Similarly, constitutive ALK signaling, observed in certain lymphomas and occasionally in lung cancer, has been reported to drive PD-L1 expression via STAT3 signaling.[304]

The alternative mechanism for PD-L1 upregulation on tumors that has emerged from both clinical and preclinical studies reflects their adaptation to endogenous tumor-specific immune responses—a process termed *adaptive resistance*.[275] In adaptive resistance, the tumor uses the natural physiology of the PD-1 ligand induction for tissue protection in the face of an immune response to infection in order to protect itself from an antitumor response. Expression of PD-L1 as an adaptive response to endogenous antitumor immunity can occur because it is induced on most cancers in response to interferons—predominantly γ-interferon, similarly to epithelial and stromal cells in normal tissues.[305-307] This mechanism represents an alternative to the conventional drug resistance mechanisms that involve mutation of drug targets. It also contrasts with mechanisms of viral immune escape that involve mutation of immunodominant epitopes. The mechanism of adaptive resistance intrinsically implies that immune surveillance does exist even in some advanced cancers, but the tumor ultimately resists immune elimination by upregulating ligands for inhibitory receptors on tumor-specific lymphocytes that turn off antitumor responses within the tumor microenvironment.

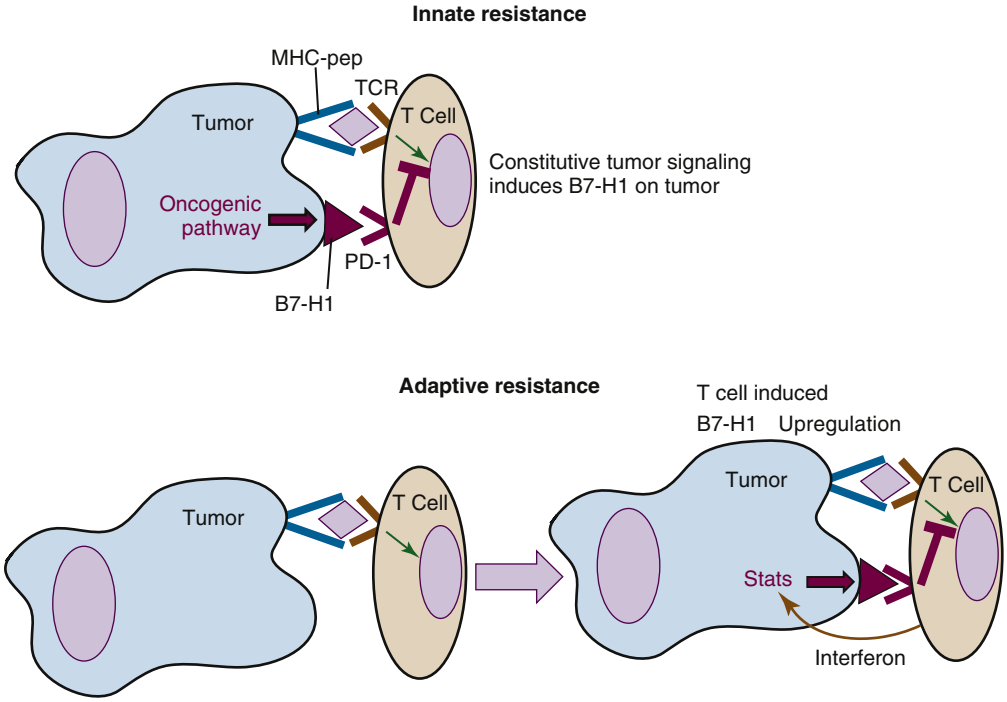

Figure 52-5 Two mechanisms for PD-L1 induction on tumors: innate and adaptive PD-L1 can be constitutively expressed on tumors as a consequence of oncogene-driven transcriptional activation. Alternatively, PD-L1 can be induced in an adaptive fashion when there are the right inflammatory cytokines in the tumor microenvironment consequent to an ongoing immune response to the tumor. This mechanism of tumor resistance to immune attack is coopted from physiologic PD-L1 expression for tissue protection in the setting of antimicrobial immune responses. Innate and adaptive mechanisms of PD-L1 expression on tumors can coexist. The adaptive resistance mechanism implies that PD-L1 expression is a "marker" of endogenous antitumor immunity.

A number of preclinical and clinical studies support the adaptive resistance hypothesis. Gajewski and colleagues have demonstrated that melanomas can be roughly divided into "inflammatory" and "noninflammatory" categories defined by expression of multiple inflammatory genes, including those involved in the interferon pathway.[308] A recent study in melanoma demonstrated a very high correlation between cell surface PD-L1 expression on tumor cells and both lymphocytic infiltration and intratumoral γ-IFN expression. This correlation was seen not only among tumors but within individual PD-L1$^+$ tumors at the regional level, in which regions of lymphocyte infiltration were exactly the regions where PD-L1 was expressed on both tumor cells and infiltrating leukocytes.[275]

Evidence of Clinical Activity for PD-1 Blockade

Taken together, the general findings of increased PD-1 expression by TIL and increased PD-1 ligand expression by tumor cells created an important rationale for the capacity of antibody blockade of this pathway to enhance intratumoral immune responses. This was validated through many murine tumor studies demonstrating enhanced antitumor immunity through antibody blockade of PD-1 or its ligands (see earlier discussion). Furthermore, the relatively mild phenotypes of PD-1, PD-L1, and PD-L2 knockout mice suggest that blockade of this pathway would result in less collateral immune toxicity than CTLA-4 blockade, a finding that appears to be the case in clinical trials.

Although the clinical experience with anti-PD-1 antibodies is less extensive than with anti-CTLA antibodies at this time, results look extremely promising. In the first Phase I clinical trial with a fully human IgG4 anti-PD-1 antibody, there were a number of cases of tumor regression, including mixed responses, partial responses, and a complete response.[309] Tumor regressions were observed in four of the five histologies examined—melanoma and colon, renal, and lung cancer—and were associated with significant increases in lymphocyte infiltration into metastatic tumor deposits. Results from a second larger clinical trial, sponsored by BMS and extending the treatment with anti-PD-1 (named nivolumab) to 2 years, demonstrated objective responses in 31% of patients with advanced melanoma, with an additional 7% achieving disease stabilization for more than 6 months. Similar response rates were observed in renal cancer with an additional 27% with disease stabilization for more than 6 months. Most surprisingly, there was an 18% response rate in non–small-cell lung cancer (NSCLC), with an additional 7% disease stabilization for longer than 6 months. Efficacy against melanoma, renal cancer, and lung cancer was also observed with an anti-PD-L1 antibody.[310]

Among 270 nivolumab-treated patients with lung, melanoma, or kidney cancer, 1- and 2-year landmark survival rates were 42%/14% for lung cancer, 62%/43% for melanoma, and 70%/50% for kidney cancer. Median overall survival in these heavily pretreated patients (47% with three to five prior systemic therapies) was 9.6, 16.8, and more than 22 months, respectively. Among all responders, median response duration was 74, 104, and 56 weeks, respectively. Among 19 responders who discontinued therapy for reasons other than disease and were followed for at least 4 months (range 4 to 14 months), 70% retained their response.[311]

As predicted by the distinct phenotypes of the PD-1 knockout versus CTLA-4 knockout mice, the frequency of immune-related toxicities from anti-PD-1 treatment appears to be less than from anti-CTLA-4. Grade 3/4 drug-related toxicity was less than 15% and was also largely immune related. In contrast to anti-CTLA-4, the most significant toxicity was pneumonitis, which produced a 1% mortality rate. Recently instituted protocols to manage pneumonitis with steroids and, when necessary, anti-TNF blocking antibodies appear to mitigate lung toxicity.

It is logical to imagine that the enhancement of antitumor immune responses on blockade of this pathway would depend in significant part on expression of a ligand for PD-1 within the tumor. Analysis of 42 patients treated with anti-PD-1 in the trial described earlier demonstrated a strong correlation between PD-L1 expression and response. None of 17 patients with no membrane PD-L1 expression on pretreatment biopsies responded to anti-PD-1, whereas 44% patients with more than 5% of tumor cells expressing membrane PD-L1 displayed either an objective or mixed response.[312] The lack of response in patients whose tumors exclusively expressed cytosolic PD-L1 was also notable, as cytosolic PD-L1 would fail to activate the PD-1 pathway. If validated in a larger series, this finding sets the stage for a broader assessment of immune checkpoint ligands and receptors as targets for antibody blockade as well as an assessment of ligand expression in the tumor as a biomarker for success in blockade of a specific checkpoint pathway.

There are a number of companies developing and testing antibodies that block the PD-1 pathway; a recent study with a different anti-PD-1 antibody produced by Merck (named lambrolizumab) demonstrated a 38% response rate in melanoma,[313] and an anti-PD-L1 antibody produced by Genentech gave similar response rates in melanoma and NSCLC (but a somewhat lower response rate in kidney cancer) to the BMS anti-PD-1 antibody.[314] These results validate the PD-1 pathway as an important target for immunotherapeutic targeting. Based on the known interactions between the PD-1 ligands, it is theoretically possible that a

PD-1 antibody would have distinct biologic activity from an anti-PD-L1 antibody—an anti-PD-1 antibody would block PD-1 interaction with both PD-L1 and PD-L2 but not the interaction between PD-L1 and CD80. Most anti-PD-L1 antibodies block the interaction between PD-L1 and CD80 and between PD-L1 and PD-1 but would not block PD-1 interaction with PD-L2. Thus, it is possible that, depending on which interactions dominate in a particular cancer, PD-1 and PD-L1 antibodies might not have redundant activity.

Based on the distinct roles of CTLA-4 and PD-1 in regulating distinct components of the immune response, it was postulated that combined blockade of these pathways might provide an additive or synergistic antitumor effect. Indeed, a recent study demonstrated a 41% response rate in melanoma patients treated concurrently with ipilimumab and nivolumab. A larger proportion of the responses were "deep" (more than 80%) than observed with nivolumab alone, and there were about 20% additional mixed responses and stable disease longer than 6 months. However, toxicity was also greater than with nivolumab alone, with a 53% grade 3/4 toxicity rate.[315] Although the ultimate long-term clinical benefit of this combination remains to be determined, the study emphasizes the potential for combinatorial blockade of multiple checkpoints.

Additional Checkpoints Participate in Tumor Immune Resistance and Tolerance

Successful clinical outcomes of CTLA-4 and PD-1 pathway targeting have garnered great interest in a number of additional checkpoints (Figure 52-6). Basic immunologic studies have demonstrated that a number of checkpoint receptors are expressed coordinately under circumstances of tolerance to self-antigens and chronic infections as well as in inflammatory settings. In addition to defined lymphocyte inhibitory receptors, a number of B7-family inhibitory ligands—in particular B7-H3 (CD276) and B7-H4—do not yet have defined receptors, but murine knockout experiments support an inhibitory role for both these molecules.[316] In addition, they are upregulated on tumor cells or tumor-infiltrating cells.[317] B7-H3 appears to be upregulated on endothelial cells of the tumor vasculature, and B7-H4 has been reported to be expressed on tumor-associated macrophages.[316] Preclinical tumor models have been used to demonstrate that blockade of many of these individual immune checkpoint ligands or receptors can enhance antitumor immunity and dual blockade of coordinately expressed receptors can produce additive or synergistic antitumor activity. Inhibitors for a number of these immune checkpoint targets either are entering the clinic or are under active development. Those described next are targets with currently available blocking antibodies or small-molecule inhibitors but do not represent a comprehensive list.

LAG-3 (CD223), 2B4 (CD244), BTLA (CD272), Tim-3, A2aR, and the family of killer inhibitory receptors have each been associated with inhibition of lymphocyte activity and in some cases induction of lymphocyte anergy. Antibody targeting of these receptors, either alone or in combination with a second immune checkpoint blocker, has been shown to enhance antitumor immunity in animal models of cancer. Because many tumors express multiple inhibitory ligands and TILs express multiple inhibitory receptors, there are many opportunities to enhance antitumor immunity via dual or triple blockade of immune checkpoints. Although human blocking antibodies specific for a number

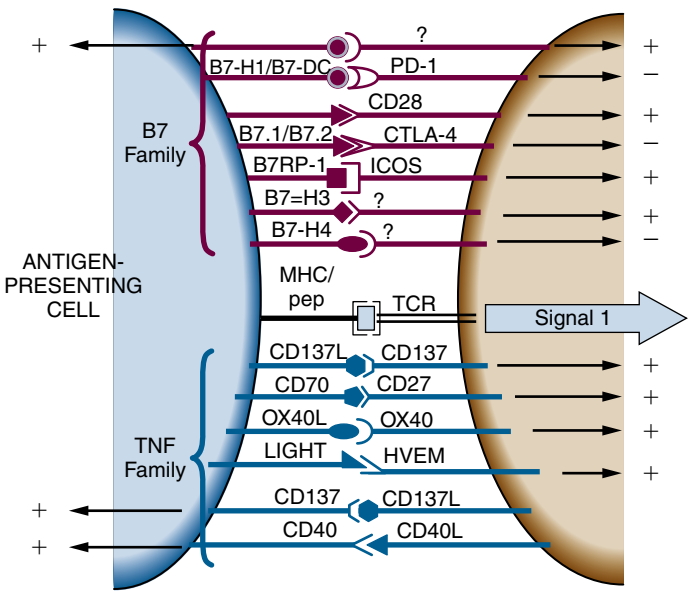

Figure 52-6 Multiple co-stimulatory and co-inhibitory ligand-receptor interactions ultimately determine the amplitude of T-cell activation and the potency of effector T-cell responses in tissue and tumor B7 family ligands and CD28 family receptors are shown in *purple* and TNF/TNFR family ligand-receptor pairs are shown in *blue*. There are additional inhibitory ligand-receptor pairs that do not fit into either of these families. Some of the receptors for B7 family members are not yet discovered. Whereas TNF/TNFR interactions are usually one-on-one pairs, B7 family ligands often interact with multiple receptors. HVEM is a TNFR family member—in addition to its interaction with the TNF member LIGHT, it also interacts with the inhibitory receptor BTLA, which is a member of the CD28 family. Additional signals of activation or inhibition are contributed by cytokines.

of these "second generation" inhibitory receptors are under development, none has entered the clinic at this time. Most of these receptors are induced on T-cell activation, in keeping with the biologic theme that they play roles in feedback inhibition of T-cell responses when their cognate ligands are present. In addition to providing inhibitory signals to activated effector T cells, some of these receptors such as LAG-3 are highly expressed on Tregs, where they are important to amplify their inhibitory activity.[79] This implies that, as with CTLA-4 and PD-1, these receptors play a dual role in ultimately inhibiting effector immune responses and blocking antibodies, and therefore have multiple potential mechanisms of action.

LAG-3 was cloned more than 20 years ago as a CD4 homologue,[318] but its function in the immune checkpoint was only defined in 2005, when it was shown to play a role in enhancing Treg function.[79,319] LAG-3 also inhibits CD8 effector function independently of its role on Tregs.[320] The only known ligand for LAG-3 is MHCII, which is upregulated on some epithelial cancers (generally in response to IFN-γ) but is also expressed on tumor-infiltrating macrophages and dendritic cells. The role of the LAG-3/MHCII interaction in LAG-3 mediated inhibition of T-cell responses is unclear because anti-LAG-3 antibodies that do not block the LAG-3/MHCII interaction nonetheless enhance T-cell proliferation and effector function in vitro and in vivo. The MHCII interaction of LAG-3 may be most important for its role in enhancing Treg function. LAG-3 is one of a number of immune checkpoint receptors coordinately upregulated on both Tregs and anergic T cells and simultaneous blockade can result in enhanced reversal of this anergic state relative to blockade of either receptor. In particular, PD-1 and LAG-3 are commonly coexpressed on anergic or exhausted T cells.[321,322] Dual blockade of LAG-3 and PD-1 provide synergy in reversing anergy among tumor-specific CD8 T cells as well as virus-specific CD8 T cells in the setting of chronic infection. Dramatic evidence of the effects of coordinate T-cell inhibition by PD-1 and LAG-3 comes from PD-1/LAG-3 double knockout mice, which completely reject even poorly immunogenic tumors in a T-cell–dependent fashion, but also develop autoimmune syndromes much more quickly than PD-1 or LAG-3 single knockouts that are ultimately fatal (though not as quickly as CTLA-4 knockouts).[323] These findings emphasize the balance between antitumor effects and autoimmune side effects that must be taken into consideration in all of the immune checkpoint blockade strategies.

Tim-3, the ligand of which is galectin-9 (a galectin reported to be upregulated in a number of cancer types such as breast cancer) inhibits Th1 responses,[324] and anti-Tim-3 antibodies enhance immunity.[325] Tim3 has also been reported to be coexpressed with PD-1 on tumor-specific CD8 T cells, and dual blockade of both molecules significantly enhances the in vitro proliferation and cytokine production of human T cells when stimulated by the cancer-testes antigen NY-ESO-1. In animal models, coordinate blockade of PD-1 and Tim3 was reported to enhance antitumor responses and tumor rejection under circumstances where only modest effects from blockade of each individual molecule were observed.[326-328]

BTLA was first identified as an inhibitory receptor on T cells based on enhanced T-cell responses observed in the BTLA knockout mice.[329] Subsequently, herpesvirus entry mediator (HVEM), which is expressed on certain tumor cell types (i.e., melanoma) as well as tumor-associated endothelial cells, was demonstrated to be the BTLA ligand.[330] This is a rare case in which a TNF family member interacts with an immunoglobulin supergene family member. BTLA expression on activated virus-specific CD8 T cells is relatively low, but it has been demonstrated to be much more highly expressed on TILs from melanoma patients. BTLA(hi) T cells are inhibited in the presence of its ligand, HVEM. Thus, BTLA may also be a relevant inhibitory receptor for T cells in the tumor microenvironment.[331] The system of HVEM-interacting molecules is complex—two additional interacting molecules, CD160 (an immunoglobulin superfamily member) and LIGHT (a TNF family member), appear to mediate inhibitory and co-stimulatory activity, respectively. It also appears that signaling can be bidirectional depending on the specific combination of interactions. The complexity of this system makes therapeutic inhibition strategies less straightforward than with other inhibitory receptors or ligands, although dual blockade of BTLA and PD-1 clearly enhances antitumor immunity.[332]

The A2a receptor for adenosine inhibits T-cell responses, in part by driving CD4 T cells to express Foxp3 and develop into Tregs.[333] Knockout of this receptor results in enhanced and sometimes pathologic inflammatory responses to infection. This receptor is particularly relevant in tumor immunity because the rate of cell death in tumors from cell turnover is high, and dying cells release adenosine. In addition, Tregs express high levels of the exoenzymes CD39, which converts extracellular ATP to AMP, and CD73, which converts AMP to adenosine.[334] Given that A2a receptor engagement by adenosine drives T cells to become Tregs, this can produce a self-amplifying loop within the tumor. Indeed, tumors grow more slowly in A2aR knockout mice, and tumor vaccines are much more effective against established tumors in these mice.[335] A2aR can be inhibited either by antibodies that block adenosine binding or by adenosine analogues, some of which are fairly specific for A2aR. Although these drugs have been used in clinical trials for Parkinson's disease, they have not yet been tested clinically in cancer patients.

Killer inhibitory receptors are a broad category of inhibitory receptors that can be divided into two classes based on structure: killer immunoglobulin receptors (KIR) and C-type lectin receptors, which are type II membrane receptors.[336-338] These receptors were originally described as critical regulators of the killing activity of NK cells, though many are expressed on T cells and APCs.[339] The importance of their inhibitory role on T cells and APCs (i.e., DCs) is less well studied, but the resulting activation of NK cells can provide potent antitumor activity. Many of the killer inhibitory receptors are specific for subsets of HLA molecules and possess allele specificity. However, other receptors recognize broadly expressed molecules—for example, the C-type lectin receptor KLRG1 recognizes e-cadherin. The potential value of NK cells in antitumor responses when their inhibitory receptors are not appropriately engaged is best exemplified by the significantly enhanced graft-versus-tumor effects in allogeneic bone marrow transplants elicited by mismatches between donor NK inhibitory receptors and recipient HLA alleles. The big question in therapeutic blockade of NK inhibitory receptors is which among the more than 20 receptors should be targeted.

Summary

After decades of research and clinical trials aimed at harnessing cancer patients' immune systems to attack their cancer, clinical efficacy with both vaccines and inhibitors of immune checkpoints has been demonstrated. The past few years have therefore become a turning point, establishing active immunotherapy as a viable approach to cancer therapy. These advances have been fueled by basic molecular and cellular discoveries related to immune system activation as well as study of the tumor microenvironment to identify resistance mechanisms that can be targeted directly. Future work will concentrate on targeting multiple pathways of immune regulation and developing rationally designed combinatorial approaches.

53 Interferons

Introduction

Interferons (IFNs) comprise a family of secreted α-helical cytokines induced in response to specific extracellular biomolecules through stimulation of Toll-like receptors (TLRs). Acting in paracrine or autocrine modes, IFNs stimulate intra- and intercellular networks for regulating innate and acquired immunity, resistance to viral infections, and normal and tumor cell survival and death (Table 53-1). Through high-affinity cell surface receptors, IFNs stimulate genes, employing signaling molecules also used in part by other cytokines first identified through studies of IFNs. Perturbations in these pathways can also make cells resistant to a given ligand, facilitating either progression or resistance of malignancy. IFNs act on almost every cell type and, through their cellular actions, can be effective in inhibiting tumor emergence and progression and in inducing regression (see Table 53-1).

Studies on the mechanisms by which IFNs exert their antitumor activity have helped to understand host resistance to tumor emergence and also define cellular actions of interferon-stimulated gene (ISG) products (see Table 53-1). These latter proteins underlie not only the antitumor and immunoregulatory actions but also the antiviral effects of IFNs. More than a thousand genes regulated through IFN signaling pathways now have been identified.[1,2] Suppression of IFNs and influences on their regulated gene products in and by malignant cells is emerging as an important contributor to the development of some human cancers (Table 53-2). Germ-cell mutation of an ISG *RNASEL* increases risk for prostate, breast, head and neck, and pancreatic carcinomas.[3-6] Gene expression profiling and cytogenetic analyses have identified somatic homozygous deletions in the locus for IFNs at 9p21 and mutations of ISGs in melanoma, colon, lung, and hematologic malignancies.[7-12] Epigenetic and genetic silencing of IFN signaling also likely influences tumor development.[11,13-15] Activated natural killer (NK) and T cells have a critical role in the production and action of IFNs for potent immunomodulatory roles in the protection from chemical carcinogenesis and in controlling the growth of syngeneic and transplanted tumors. In addition to being a primary source for the production of IFNs-α and IFN-β, dendritic cell maturation is also influenced by IFNs.[16-19] These actions of endogenous IFNs-α, IFN-β, and IFN-γ are probably the basis for the effectiveness of IFNs and/or inducers in suppressing tumor emergence and progression.[20-22] These immunomodulatory actions, however, may or may not be identical to those resulting in clinical tumor regression with IFNs administered as single agents or in conjunction with other modalities of therapy.

Before the development of recombinant DNA technology for protein synthesis in prokaryotes, only limited quantities of impure IFNs were available. IFNs were, indeed, the first proteins produced by recombinant technology that were not previously available for wide use in clinical medicine. A long-awaited milestone, U.S. Food and Drug Administration (FDA) approval for a defined human protein with potent cell regulatory effects for the treatment of human malignancy, was subsequently realized.[23,24] IFNs thus became the prototypic biologic response modifiers for clinical oncologic therapy. With an emphasis on studies in human cells, this chapter reviews the structure of this family of cytokines, receptor interactions, signal transduction pathways, mechanisms of action, the ISGs, and clinical antitumor activity.

Induction, Genes, Receptors, and Signaling

Interferon Genes, Proteins, and Their Induction

There are several types and families of IFNs, all of which have antiviral effects. Classification of IFNs is based on primary

structures as well as target receptors. Based on these similarities and differences, there are three types of IFNs.[23,25-27] Type I IFNs include the multiple subtypes of the IFN-α family with multiple subtypes, IFN-β, IFN-ω, IFN-τ, IFN-κ, and IFN-ε.[23,25-28] The sole type II IFN is IFN-γ.[29] The more recently discovered type III IFNs are also known as IFN-λ or IL-28/29; there are three known members, λ1 (IL-29) and λ2/3 (IL-28 A/B) produced by mucosal epithelial cells.[26] The type III IFNs share structural homology and induction characteristics with type I IFNs, with cell lineage distribution of their unique receptors restricted to mucosal epithelial cells and plasmacytoid dendritic cells (pDCs).[26]

The genes for the human type I IFNs lack introns; genes, including those encoding 14 subspecies of IFN-α, are clustered on chromosome 9.[23,25,27] The corresponding 13 murine genes are clustered on chromosome 4. At the protein level, the human IFN-α subspecies share about 50% sequence identity; IFN-β is 22% and IFN-ω is 37% identical to the IFN-α. IFNs-α and IFN-β have 186 to 190 amino acids and contain a cleavable signal peptide resulting in secreted protein of 165 or 166 amino acids. Two Cys-Cys disulfide bonds are conserved among the proteins. Structure-function analysis has implicated the NH_2 termini of IFN-α molecules as important for their biological activity.[30] The gene encoding IFN-γ, located on human chromosome 12 (mouse chromosome 10), has three introns and encodes a protein of 146 amino acids; it functions as a dimer.[29] The structural homology of IFN-γ with type I IFNs is minimal. NK and T cells are the major source of IFN-γ. Type I IFNs are produced predominantly by dendritic cells but can be induced in all other cell types, including T cells, monocytes, fibroblasts, and epithelial cells.

The specific isoforms induced depend on both the cell type and the inducing agent. Virus or microbial infection through their gene products, such as dsRNA, ssRNA, dsDNA viral envelope proteins or prokaryotic cell wall constituents, triggers type I IFN synthesis.[31-34] These viral and microbial pathogen-associated molecular patterns (PAMPs) are recognized by specific membrane proteins called Toll-like receptors (TLRs) that initiate the signaling process culminating in IFN synthesis (Table 53-3). dsRNA, a common by-product of viral replication, is recognized by TLR-3, a protein present in endosomal membrane.[34] dsRNA can also be recognized by two cytosolic RNA-helicases, RIG-I and Mda5, both of which are upregulated by type I IFNs.[35] Viral single-stranded RNAs are recognized by TLR7 and TLR8

and viral DNA by TLR9, all of which are also present in endosomal membranes.[32,33]

Induction also occurs in bacterial PAMPs such as lipopolysaccharides and unmethylated CpG DNA.[33,36-38] Low molecular weight synthetic molecules that can be agonists of TLRs 7 to 9 and produce IFNs and ISGs have also been identified.[39-41] Different adaptor proteins connect these receptor proteins to specific protein kinases, such as TBK1 and IKK, which activate transcription factors including NFκB, IRF3, IRF7, and AP-1. For IFN-β gene induction, NFκB, the AP-1 complex composed of ATF2/c-jun and IRF1, and IRF3 or IRF7 are needed. These phosphorylated proteins form the enhanceosome complex at the IFN-β promoter.[42,43] Synthesis of different members of the IFN-α family and IFN-β can be temporally staggered. IFN-β induces IRF7 synthesis, which in turn induces transcription of IFN-α1 and other IFN-α genes.[31] Synthesis of IFNs and their actions are, therefore, intimately linked; inhibition of IFN signaling blocks robust production of IFN-α. IRF5 and IRF8 can also participate in IFN-α gene induction in specific situations.[44,45]

Interferon regulatory factors (IRFs), a family of nine transcription factors, have common DNA binding domains in their N-terminal domains. Their C-terminal domains, resembling the SMAD transcription factors in most IRFs, were first identified through the role of IRF1 in inducing IFN-β.[45-47] Although IRF3 and IRF7 are more important in inducing type I IFNs, IRF-1 and possibly IRF-5 may determine which species of IFNs are induced by TLR activation. IRF1 is expressed constitutively and in response to IFN-γ, as is IRF8, whereas IRF7 is mostly produced by type I IFNs. IRF7 amplifies the initial phosphorylated activation of constitutive IRF3 and other IRFs through TLRs, leading to additional cascades of production of IFNs by homo- and heterodimers of mostly IRF3 and IRF7 and potentially also induction of specific ISGs such as CXCL10.[45-47]

Polyethylene glycol (PEG)-conjugated IFNs have superior pharmaceutical properties compared with their unconjugated counterparts as a result of greater protection against proteolytic degradation, better solubility, and slower catabolism and excretion.[48-52] Because the half-life of IFN-α2 ranges from 4 to 8 hours and little is detected in serum 24 hours after administration, daily injections of IFN-α are required to achieve sustained clinical efficacy. Two PEG-IFNs have been developed and taken forward to clinical regulatory approval: a 40-kDa branched PEG conjugated to IFN-α2a and a 20-kDa PEG conjugated to IFN-α2b. Although they have a somewhat less specific activity, probably as a result of lower receptor affinity, preclinical and clinical studies have established a prolonged human pharmacological profile enabling effective weekly dose for PEG-IFNα2 as compared with daily IFN-α2.[48,49,52]

IFN Receptors and Signaling

IFNs bind to species-specific, heterodimeric cell surface transmembrane proteins that trigger signaling through their cytoplasmic domains.[23,27,53-55] The signaling pathways used by IFNs and other cytokines partially overlap, reflecting their common structural motifs with other members of the class II cytokine receptor family. To elicit a cellular response, the receptor for IFNs-α and IFN-β requires two subunits, IFNAR-1 and IFNAR-2. IFNs-α and IFN-β use and compete for the same receptor complex, although IFN-β interacts with the receptor heterodimer in a different way than does IFN-α2.[56,57] The ligand-specific anchor points induce a different conformational change in IFNAR1 that can result in greater activation of a subset of ISGs.[54,55,58] IFN-γ binds to a different heterodimeric receptor consisting of two subunits, IFNGR-1 and IFNGR-2.[27] The receptor for IFNs-λ consists of a unique subunit IFN-λR1 and a second subunit IL-10R2, the latter also a component of the receptor complex for IL-10, IL-22, and IL-26.[26]

Signals are transmitted to the promoters of ISGs and transcription induced.[23,59] Many of the same genes are also directly induced by dsRNA and viruses, which in part use different signaling pathways. Synthesis of some of the proteins that mediate IFN signaling, such as IRF7 and STAT1, are induced by IFNs as well, thus eliciting positive feedback responses. Proteins, such as constitutively expressed IRF2, a stable nuclear factor, downregulate both production of type I IFNs and synthesis of ISGs such as PKR, OAS, and IRF7.[31] Suppressors of cytokine signaling (SOCS) proteins that block IFN signaling are also induced so that, even in the continuous presence of IFNs, signaling is transient.[60,61] The critical role of both of these proteins in damping ISG antiviral and antitumor responses has been confirmed in IRF2$^{-/-}$ cells and SOCS1$^{-/-}$ mice.[62-64]

The critical event in triggering signaling is the ligand-initiated dimerization of the receptors that results in cascades of tyrosine phosphorylation. The ligand-activated cytoplasmic domains of receptors for IFNs signal by binding to JAKs (Janus kinases) and STATs (signal transducers and activators of transcription).[27,60,65,66] The cytoplasmic domains activate the two nonreceptor protein tyrosine kinases, Tyk2 and JAK 1, which phosphorylate STAT1 and STAT2 (Figure 53-1). Phosphorylated STATs form homomeric or heteromeric dimers that bind to specific cis-acting DNA sequences in the promoters of ISGs (see Figure 53-1). The principal transcription factor activated by type I IFNs is ISGF3, composed of activated STAT1, STAT2, and IRF9, the last specifically recognizing the ISRE (IFN-stimulated response element). Thus, for type I IFN signaling, seven proteins are essential: IFNAR1, IFNAR2, JAK1, Tyk2, STAT1, STAT2, and

IRF9. For full activation of STATs, further phosphorylation at specific serine residues is required as well. A dephosphorylation switch through the histone acetylation, leading to binding of phosphatase DCP45, suppressed signaling.[67]

Protein tyrosine phosphatases (PTPs) also have a regulatory role in suppressing signaling by IFNs in NK, T, and tumor cells. Inhibition of these can prolong signaling and potentiate antitumor activities of IFNs.[68-70] Loss of function of a phosphatase modifying STATs resulted in melanocytic neoplasms in *Drosophila*.[71] Inhibition of the PTP SHP-1 can be accomplished by inhibitors with potentiation of effects of IFNs.[70,72,73] SHP-2 silenced NK cells have elevated cytolytic activity with increased production of IFN-γ consistent with immune activation.[74] SHP-2 suppression increased STAT1 tyrosine 701 phosphorylation, increased promoter activity, and enhanced anti-melanoma effects of IFN-α2b for a human xenograft in mice.[70,75]

In the IFN-γ signaling pathway, the two receptor subunits IFNGR1 and IFNGR2, JAK1, JAK2, and STAT1 are required to activate the transcription complex, GAF, which binds to the gamma-activated site (GAS).[23,27] Additional Ser phosphorylation of STAT1 is required for the optimum function of GAF. Because the intracellular component of IFNγR2 at a site separate from the JAK2 binding domain can be inhibitory of apoptosis without ligand activation,[76] additional functions of this and possibly other components of IFN receptors may be identified.

IFN-λ proteins signal through a different receptor that is composed of a unique IFN-LR1 subunit and the IL-10R2 chain of IL-10, IL-22, and IL-26 receptors.[77] Like other type I IFNs, IFN-λ uses the proteins JAK1, Tyk2, STAT1, and

STAT2 for signaling; additional pathways are probably activated as well. Another major difference is in the expression profile of the receptors. Whereas IFNAR1 and IFNAR2 are ubiquitously expressed on cells of all lineages, expression of IFN-LR1 has a more limited distribution on epithelial and dendritic cells.[26,77]

In addition to the STAT pathways outlined earlier, IFNs can activate signaling pathways through other transcription factors.[23,66,78] For example, just like IFN-γ, type I IFNs can trigger STAT1-dimer formation and gene induction by the GAS. Furthermore unphosphorylated STAT1, itself induced potently by IFNs, can prolong and increase expression of ISGs initially induced by pSTAT1.[79] Signaling cross talk between STATs is illustrated by the effectiveness of an inhibitor of STAT3 in augmenting IFN-α activity for a murine melanoma.[80] This finding is in accord with those identifying roles of heterodimers of other STATs with STAT1.[78,81]

Although different subspecies of IFNs-α and IFN-β signal through the JAK-STAT pathway using the same receptor, signaling pathways triggered by them may not be identical. A mutant cell line lacking Tyk2 still responded to IFN-β and IFN-α8, but not to IFN-α1 and IFN-α2.[82] Preferential induction of the *BR1* gene by IFN-β also supports the notion of additional IFN-β-specific pathways.[83] The receptors, which are glycosylated in their extracellular domains, are both necessary and sufficient for activities of IFNs. Binding to IFNAR-1 accounts for the affinity and differential actions of IFNs-α and IFN-β.[54,84,85] IFNAR1 is at least in part degraded by an E3 ubiquitin ligase; decrease in activity of the ubiquitin ligase increases IFNAR1 and decreases tumorigenicity for a human melanoma xenograft.[86]

To add to the complexity of the signaling cascade, other STATs, such as STAT3 and STAT5, are activated by IFNs and can form homo- and heterodimers that influence transcription.[66,87] Indeed, in chronic lymphocytic leukemia (CLL) cells with high-risk molecular features, STAT3 was activated by IFNs, resulting in increased cell size and number.[88] Furthermore, STAT2 influences gene expression independently from its phosphorylation, with binding identified before IFN-α2 on many ISGs.[89] IFN type I suppressed genes were marked by pSTAT2 and by repressive histone methylation marks on H3K27me3 together with STAT1 binding.[89,90]

Ancillary pathways, activated by type I IFNs, are also triggered by additional protein kinases such as PI3K and p38 MAPK.[66,78] PI3K and p38 MAPK signaling pathways are activated by type I IFNs, and responses can be inhibited by low molecular weight inhibitors.[83,91,92] Purified $CD34^+$ cells with a mutation in JAK2, derived from patients with polycythemia vera, had increased apoptosis from pegylated IFN-α2a, an effect mediated by p38 MAPK.[93] Furthermore, MAPK activation may play an important role in translational synthesis of ISGs and thus antiproliferative effects.[94]

Thus, the global impact on gene induction by IFNs is influenced by many factors, including cell lineage, basal transcription binding and methylation of promoters, and exposure of the cells to other cytokines and secondary cascades of signaling generated by genes induced in the primary response.

IFN Pathways and Molecular Oncogenesis

Genotypic variation in signaling components in IFN pathways can be important in initiation and progression of malignancy. Oncogenes such as RAS and HPV E6E7 downregulate TLR signaling pathways,[95,96] possibly enhancing cell transformation. Several viral oncoproteins can block IFN signaling, often by interfering with the function of ISGs or ISGF-3.[97,98] IFN-κ with 30% homology to other type I proteins has been identified in epidermal keratinocytes and imparts cellular protection against viral infections in a species- and tissue-specific manner, using the same receptors and signaling pathways as other type I IFNs. It was suppressed by human papillomavirus type 16 in keratinocytes in vitro and in human cervical carcinoma biopsies, suggesting its role in innate immunity.[99]

The potential importance of TLR signaling in oncogenesis has been suggested by the identification of gain-of-function mutations in an adaptor protein (MYD88) for TLR signaling in a subset of aggressive diffuse B-cell lymphomas, particularly those of mucosa-associated lymphoid tissue (MALT).[100] A population-based control study of more than 4000 individuals identified single-nucleotide polymorphisms (SNPs) in IRFs, IFN-γ, and IFN-γR2 as influencing colorectal carcinoma risk and progression.[8] With an increasing number of variant genotypes, the risk of colorectal carcinoma and hazard of dying increased linearly.

The initiation and progression of carcinogen-induced bladder or hepatocellular carcinomas in murine models was inhibited by IFN-β or IFN-γ, respectively.[101,102] In the bladder carcinoma model, both IFNs and an inducer were effective; IFN-β completely prevented tumor formation. Gastric carcinogenesis from *Helicobacter pylori* and hepatocarcinogenesis from a chemical carcinogen in murine models was suppressed by IFN-γ through autophagy, p53 activation, and alterations in the tumor immune microenvironment.[102,103] In the hepatocellular carcinoma studies, although infiltration of immune effector cells and chronic inflammation was present, inhibition resulted from activation in hepatocytes of p53 tumor suppressor function.

Evidence suggesting a direct role for IFNs on tumor cell viability and progression through apoptosis or inhibition of proliferation has resulted from mouse tumor model systems. Treatment with human IFN-α or IFN-β of immunodeficient nude mice implanted with human tumor cells

effectively controlled tumor growth and promoted tumor cell apoptosis.[104,105] Alteration of tumor phenotype by reversal of epigenetic silencing of gene expression made an IFN-resistant mouse tumor sensitive.[106] Because mouse cells do not respond to human IFNs, these antitumor effects were clearly direct. Furthermore, progression of a RAS transformed cell line could be reversed both in vitro and in vivo by exogenous IFN-β with or without retinoic acid.[107] RAS can, however, result in activation of endogenous IFN-β that may contribute to the transformed cellular phenotype.[108]

Conversely, other murine studies highlight the importance of immune effector cells in antitumor effects of IFNs. Equivalent antitumor effectiveness of IFNs in vivo has been identified for syngeneic tumor cells sensitive or resistant to antiproliferative effects of IFNs in vitro.[109,110] Additional evidence supporting a role for host immune effector cell response to IFNs comes from studies in which mice implanted with a syngeneic leukemia, or with human prostate and HeLa tumor xenografts, received neutralizing antibody to murine IFN.[111] These mice, in the absence of exogenous IFN, had enhanced tumor growth and transplantability, suggesting that neutralization of endogenous IFN removes aspects of host defense to tumor.

Subsequent studies, using genetically altered mice, have more rigorously suggested the potential importance of immune cell regulation in the antitumor effects of type I IFNs. *STAT1* knockout mice implanted with IFN-responsive tumors and treated with exogenous IFN-α did not survive longer than control mice.[112] Furthermore, wild-type (*STAT1*$^{+/+}$) animals implanted with *STAT1*-null tumor cells were able to mount an effective antitumor response following IFNs suggesting the importance of host cells.[113] Additional studies of either IFN-γR– or STAT1-deficient mice identified the development of spontaneous tumors of diverse histologies or chemically induced fibrosarcomas at substantially greater frequency than in controls.[114,115] Type I IFNs, endogenously produced, were required to prevent primary carcinogen-induced and transplantable tumors.[116] In contrast to IFN-γ, for which tumor cells were important targets, host hematopoietic cells (NK cells, dendritic cells) were critical targets for IFNs-α and INF-β during the development of protective antitumor responses leading to tumor elimination.[116,117] Particularly critical for mediating effects of type I IFNs may be CD8α^{+} dendritic cells.[118,119]

Mice lacking IRF8 develop a disease similar to chronic myelogenous leukemia (CML). Overexpression of IRF8 in Bcr-Abl transformed cells inhibited leukemogenesis as well as resistance to the tyrosine kinase inhibitor imatinib; this correlated with reduced bcl-2 expression.[120] IRF4 inhibits myeloid progenitor cell growth and granulocytic differentiation in vitro, and its absence enhanced progression of the CML-like disease that occurs in IRF8$^{-/-}$ mice.[121] In chronic lymphocytic leukemia, heterozygous mutations in the DNA binding domain of IRF4, which both is constitutively expressed and can be induced through TLR ligation, have been identified in a small proportion of patients.[122] Other genetic perturbations in IRF4 have been identified in a subset of germinal center B-cell lymphomas (a translocation) and cutaneous carcinomas (a germline SNP).[123,124] Similarly, overexpression of IRF5 in breast carcinoma cells inhibited in vitro and in vivo cell growth and was identified as downregulated in human breast carcinomas.[125]

Over the past decade, paradoxes and additional complexities in antitumor actions of IFNs have been identified. STAT1 has generally been considered the upstream initiator of a prodeath and tumor-suppressive pathway. However, emerging evidence suggests that STAT1 activation and its induction by IFNs can be associated with resistance to DNA-damaging agents and may mediate more aggressive tumor growth.[79,126-128] STAT1 was induced by ionizing radiation or doxorubicin and can also be identified together with other ISGs as constitutively present in human tumors. Indeed, presence of a subset of ISGs in breast cancers was adversely prognostic for metastasis-free survival following adjuvant radiation and chemotherapy.[128] Specific ISGs, such as ISG15 and G1P3, have been identified as constitutively expressed in breast carcinomas and associated with anti-apoptotic effects and adverse clinical prognosis.[129-131] Chronic induction of ISGs may be detrimental, possibly through unphosphorylated STAT1 after an initial protective burst of ISGs in response to pSTAT1.[79] Understanding these adverse patterns of ISG expression on resistance to DNA damage and patient outcome may, over the next several years, further explain why IFNs are not more effective clinically.

Regardless of the cellular mechanisms augmented and suppressed by endogenous and exogenous IFNs, underlying the immunoregulatory, antiproliferative/prodeath, and antiangiogenic effects of IFNs are the ISGs, which are regulated at the level of transcription.[132] Although the function of many of these ISGs has begun to be understood, many were identified initially as differentially expressed mRNAs after the treatment of cells with IFNs or more recently on expression arrays. Although overlap in function certainly exists, actions relevant to antitumor effects of the most studied and potently induced protein products of ISGs are summarized next.

Mechanisms of Antitumor Action of Induced Genes

Underlying the antitumor actions of IFNs are the transcriptionally regulated ISGs.[132] Almost 2000 genes are transcriptionally regulated, mostly stimulated (more than 1500) but

some suppressed (about 300), with varying patterns of temporal expression over 24 hours after IFNs.[1,2,133] They are relatively equally divided between those predicted to be nuclear or cytoplasmic in functional location and include structural proteins, transcription factors, adaptors, enzymes, metabolic factors, and secreted proteins.[2] Fundamental discoveries concerning regulation of RNA stability and editing, translational protein synthesis, and protein transport and turnover have emerged from studies of these gene products. The proteins induced influence and mediate the pro-apoptotic, immune modulatory, and anti-angiogenic effects. Realizing that ISGs may have more than a single biological effect, some of the most potently induced (10× to 50× at the RNA level) have been related to these antitumor mechanisms of action.

Direct Antigrowth and Pro-apoptotic Effects

Regardless of direct or indirect causes of stasis or regression of tumors, antigrowth and apoptotic effects must result in the transformed cell. Thus activities of ISG products that may mediate or influence this action have been one key focus of assessment of molecular actions (Table 53-4). Unlike the rapid apoptosis induced by cytotoxics such as camptothecin, programmed cell death through the intrinsic cascade in response to IFNs is a later effect, requiring 48 to 72 hours. Underlying this latency is probably the requirement for synthesis of protein products of ISGs that occur over 24 to 48 hours (many identified by expression profiling).[1,134]

An ISG product, Apo2L/TRAIL (TNF-related apoptosis inducing ligand) mediates apoptosis from IFNs in myeloma, melanoma, T cells, B cells, and hepatoma and lymphoma cells.[135,136] IFN-β induced Apo2L/TRAIL in melanoma and other cells more potently than did IFN-α2.[135] Coculture of cells with IFN and neutralizing TRAIL antibodies or TRAIL decoy receptors can inhibit IFN-induced apoptosis. Apo2L/TRAIL induction in breast cancer cells by IFN and retinoic acid was mediated through IRF1 activation of the Apo2L/TRAIL promoter.[137] Combination with IFN and retinoic acid synergistically induced Apo2L/TRAIL with potentiated antitumor effects.[137]

Table 53-4 IFN-Regulated Proteins Contributing to Apoptosis

Apo2L/TRAIL	Fas ligand
IRF-1	XAF-1
PML	DAPK
RNase L	Protein kinase R
p56 family proteins	IFI-16, AIM-2 (p200 family proteins)
IHPK2	

Other ISG protein products are needed as well to sensitize cells to the effects of Apo2L/TRAIL. Pretreatment with IFNs, particularly IFN-β or IFN-γ, enhanced apoptosis from recombinant Apo2L/TRAIL or its receptor agonists, even in cells otherwise resistant to Apo2L/TRAIL.[135] Indeed, a gene signature dominated by ISGs predicted sensitivity to TRAIL for 95 human cancer cell lines.[138] ISGs, such as the p200 family, PML, Fas L, and XAF1,[139-146] among others, also have substantial effects on cell proliferation and viability. XAF1 was correlated with the ability of cells to respond to the pro-apoptotic effects of Apo2L/TRAIL.[142] Through interactions with p53 and the inhibitor of apoptosis, XIAP,[142,143] XAF1 may allow Apo2L/TRAIL to fully activate downstream caspases. Possible importance of XAF1 clinically has been suggested by finding that its constitutive expression, assessed by immunohistochemistry (IHC), in renal carcinomas was low in patients with shortened survival times.[147] Another ISG product, IRF1, suppressed another anti-apoptotic protein, survivin.[144]

The nuclear protein PML, which acts as a tumor suppressor, may be involved in IFN-induced Apo2L/TRAIL expression in myeloma cells.[140,145] Mice deficient in PML were largely resistant to IFN-induced apoptosis. Nuclear bodies (NB), multiprotein complexes in the nucleus associated with acute promyelocytic leukemia and acquired immunodeficiency syndrome (AIDS), are made up of the PML protein, sp100, sp140, sp110, and the exonuclease ISG-20, all of which are ISG products.[145] In contrast to the pro-apoptotic actions of products of many ISGs, G1P3 (ISG6-16) inhibited apoptosis both in gastric and breast carcinomas and myeloma.[129,148,149]

In CML and multiple myeloma cells, induction by IFN-α of the death receptor Fas (CD95) resulted in apoptosis through activation of caspase-8/FLICE.[150] Intralesional administration of IFN-α into basal cell carcinomas increased Fas expression and led to regression.[151] Similarly, IFN-γ increased susceptibility of melanoma cells to apoptosis by Fas activators and breast carcinoma cells to doxorubicin.[152,153] Doxorubicin also induced STAT1.[152] Among other genes induced in an ovarian carcinoma xenograft regressing after paclitaxel were ISGs (G1P3, IFI16, IFI27, IFITM1, and ISG15).[154]

Treatment of cells with IFNs results in sustained activation of the latent endoribonuclease RNase L, which degrades ssRNA and triggers a mitochondrial pathway of apoptosis that eliminates virus-infected cells.[4,155,156] Genetic disruption of RNase L impairs this apoptotic response, which has raised interest in the possibility that such mutations might also contribute to malignancy (Figure 53-2).[157,158] In this regard, the hereditary prostate cancer 1 (*HPC1*) gene maps to the RNase L gene (*RNASEL*) and is implicated in controlling apoptosis of prostate cancer cells.[3]

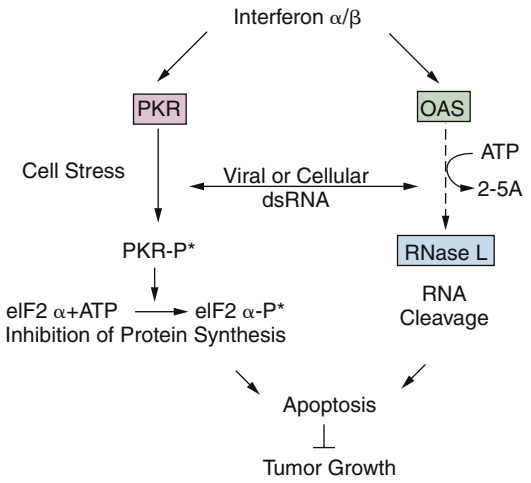

Figure 53-2 Interferon-regulated activation of 2-5A and PKR pathways and their mechanisms of action.

In a large, controlled sibling-pair study, an RNase L variant (R462Q) with decreased enzymatic activity was associated in up to 13% of unselected prostate cancer cases.[3] However, although case-controlled genetic and epidemiologic studies support the involvement of *RNASEL* (and notably the R462Q variant) in prostate cancer etiology,[3,5,6] others do not,[159,160] suggesting that either population differences or environmental factors such as infections may modulate the impact of *RNASEL* on prostatic carcinogenesis. A novel xenotropic murine retrovirus (XMRV) was identified in the prostate tumor-bearing tissues, almost exclusively in men with the homozygous, reduced activity variant of RNase L (R462Q).[161] Other findings suggest a wider tumor suppressor role of RNase L in additional malignancies.[162,163]

Activation of RNase L is the only well-established function of the ISG products 2′,5′-oligoadenylate synthetase (OAS).[164] The OAS-RNase L system (see Figure 53-2) in humans has four functional *OAS* genes (*OAS1-4*), resulting in 8 to 10 OAS isoforms because of alternative mRNA splicing.[164] When stimulated by double-stranded RNA (dsRNA), OAS proteins produce from ATP a series of short 5′-phosphorylated, 2′,5′-linked oligoadenylates collectively referred to as 2-5A [$p_x5'A(2'p5'A)_n$; x = 1-3; n ≥ 2]. Because dsRNA is a frequent viral PAMP, 2-5A often accumulates in IFN-treated and virally infected cells.[165] In contrast, OAS1 mRNA and other ISGs were reduced in prostatic malignancies.[166] OAS2 has been specifically associated with the fatigue and depression associated with chronic administration of IFN-α2 to patients.[167]

Another ISG, protein kinase R (PKR), mediates signal transduction, apoptotic, and tumorigenic responses (see Figure 53-2).[168,169] PKR, an IFN-inducible, dsRNA-dependent serine/threonine protein kinase that inhibits protein synthesis initiation, is activated by dsRNA, dimerization, and autophosphorylation.[170,171] PKR is a 551-amino-acid protein in which the N-terminal region contains two dsRNA binding motifs, whereas the catalytic domain is present in the C-terminal half.[172,173] In addition, a cellular protein (PACT) can directly activate PKR in the absence of dsRNA.[174] PKR is a p53-regulated gene with an influence on p53-mediated inhibition of translation, apoptosis, and tumor growth.[175] Phosphorylation by PKR of the protein synthesis initiation factor eIF-2α caused an inactive complex to form between eIF2-GDP and the recycling factor, eIF2B. These events result in global inhibition of rates of protein synthesis both viral and cellular; indeed, many viruses evade the IFN response by inhibiting PKR function.[97]

Mouse fibroblasts lacking PKR are resistant to apoptosis induced by TNF, dsRNA, or lipopolysaccharide.[169] Phosphorylation of eIF2α by PKR is required for the apoptotic responses to dsRNA, TNF-α, or serum deprivation.[176] Implantation into mice of NIH3T3 fibroblasts expressing a catalytically inactive, dominant negative PKR led to tumorigenesis.[177] Suggesting further its key role in mediating the growth-suppressive effects of IFN-γ for $CD34^+$ myeloid precursors was the finding that pharmacologic or siRNA-mediated ablation of PKR increased hematopoietic colony formation.[178] Deficiencies in PKR activity, but not protein levels, have been identified in B-cell chronic lymphocytic leukemia.[179] Because PKR is a key point of regulation in the protein synthetic machinery, is induced by p53 in addition to IFNs, and can cause apoptosis, strategies for selectively activating PKR have been explored. Like RNase L, PKR exists in a latent, inactive state, and thus drugs that act as molecular switches for these proteins might have potent antitumor and/or antiviral effects.[180]

Adenosine deaminases acting on RNA (ADAR), another family of ISGs, through their effects on dsRNAs, can modulate cellular effects of IFNs.[181] Through their RNA editing activity, ADARs can affect translational gene expression via regulation by miRNAs. In addition, ADAR 1 is essential for hematopoietic stem cell survival and can have anti-apoptotic effects, possibly through modification of dsRNA essential for actions of OAS and PKR.[182,183]

The ISGp56 gene (also known as IFIT1), as are other ISGs discussed in this chapter, is strongly transcriptionally induced (50× to 100×) by type I IFNs.[184] These proteins (including related p54, p56, and p60) contain multiple tetratricopeptide repeat (TPR) motifs that mediate protein-protein interactions.[184] Although the human p56 and the mouse p56 proteins have only 50% sequence identity, their six TPR motifs are positioned very similarly along the linear sequences of their amino acids. A major property of the p56 and p54 proteins is inhibition of initiation of protein synthesis.[185,186] This inhibition is mediated by binding to specific subunits of the translation initiation factor eIF3; human p56 binds to the e subunit, whereas p54 binds to both subunits.

Binding of these proteins to the e subunit blocks the ability of eIF3 to stabilize the ternary complex of eIF2, GTP, and Met tRNA, blocking CAP-dependent translation initiation. These alterations in protein synthesis may underlie the pro-apoptotic effects of IFIT2 through caspase 3 that can occur without IFN stimulation.[187] The subunit of eIF3 to which p56 bound was identical to *Int-6*, a gene whose disruption by the integration of the mouse mammary tumor virus gene caused mouse mammary carcinoma.[188] The cellular function of the eIF3e/Int-6 protein in this context could be different from translation initiation because the protein was present not only in the cytoplasm as a component of eIF3 but also in the nucleus.

The p200 family of ISG protein products, IFI-16, myeloid cell nuclear differentiation antigen (MNDA), and absent in melanoma 2 (AIM2), share a common 90-amino-acid, N-terminal pyrin domain and a partially conserved 200-amino-acid C-terminal domain important for protein-protein interaction.[189] p200 family members have a significant role in cellular growth regulation and differentiation.[141,189-194] They influence function of the tumor suppressor genes Rb and p53 and the transcription factor E2F. Inhibition of proliferation by these p200 gene products has resulted in loss of the transformed phenotype and decreased tumor formation in mouse models.[189] In an IFI16-null human tumor cell line, retroviral restoration of IFI16 expression reduced tumorigenesis significantly.[195] Similarly, AIM2 suppressed breast carcinoma and colorectal cell growth.[196,197] In human prostate carcinoma cells, overexpression of IFI16 resulted in a senescence-like phenotype with reduction in S-phase–specific cells and inhibition of colony formation.[198] Studies such as these have established the p200 family as among the most active in growth suppression and most pro-apoptotic of ISGs.[189]

Identified initially as an IFN-γ induced pro-apoptotic gene, death-associated protein kinases (DAPKs) are serine threonine kinases with ankyrin and death domains that induce caspase-independent cell death.[199] Reduced expression correlated with malignant progression, whereas restoration of expression led to apoptosis of mouse lung tumors.[200] Expression of DAPK can be suppressed in human malignancies, at least in part by epigenetic silencing.[201] IFN-γ resulted in induction of a novel growth suppressive pathway through the transcription factor C/EBPβ.[202] IFN-γ stabilized DAPKs through inhibiting its ubiquitination, thus identifying another mechanism by which IFNs promote apoptosis and autophagy.[203]

Immune Effects

Amplification of innate and specific immune responses results from both type I and type II IFNs.[20,57] The antitumor activity of IFNs in vivo is mediated by activation of immune effector cells, increased antigen processing, and enhanced immunogenicity of tumor cells (Table 53-5). Plasmacytoid dendritic cells have been identified to secrete high levels of IFNs-α and IFN-β in response to stimuli, have been found associated with the T-cell zone of lymphatic tissue, and have been identified in tumors of various types.[16,18,19,204-206] Production of type I IFNs is a process partially regulated by osteopontin and furthers dendritic cell maturation and induction of T cells into a Th1 pathway.

Table 53-5 IFN-Regulated Proteins Contributing to Immune Response

MHC Class I	MHC Class II
LMP-2, LMP-7	TAP
CEA	TAG-72
CCL chemokines	CXC and CXCL chemokines
Phospholipid scramblase	ISG-15

IFNs can stimulate activity of cytotoxic and helper T cells, NK cells, macrophages, and dendritic cells. Cytotoxic T-cell expansion was promoted by IFN-γ in part through upregulation of IL-2.[207] Activation of NK cells and macrophages has been identified both in vitro and in vivo.[208] Furthermore, IFNs induced expression of Apo2L/TRAIL on immune effector cell surfaces, sensitizing tumor cells to T-cell and NK-cell–mediated cytotoxicity.[209,210] Type I IFNs can also suppress T-cell function through inhibiting secretion of IL-17.[211,212] Type I IFNs can induce IL-10 in T cells, thus dampening both innate and adaptive immune responses.[213] Reduced responsiveness in T cells to IFN-α and IFN-γ also resulted from myeloid-derived suppressor cells through reduction in p-STAT1.[214]

In addition to both stimulating immune effector cells and constraining inhibitory immune subpopulations, IFNs upregulated major histocompatibility complex (MHC) antigens facilitating activation of $CD8^+$ cytotoxic T cells.[215-217] IFNs increased transcription of MHC class I genes but also coordinately induced expression of additional proteins required for the surface expression of the mature MHC class I complex. As nascent class I molecules are synthesized, they associate with β2-microglobulin, also an ISG, in the endoplasmic reticulum for transport to the cell surface. Augmentation of HLA class I–associated β2-microglobulin has been identified in patients after IFN-α2 or IFN-β.[218,219] The effects of IFNs in increasing HLA class II genes may be in part mediated by the HIN-200 family member AIM2, suggesting a novel role for this ISG in specific immune responses.[220]

Generation of antigenic peptides for loading onto class I molecules occurs in the proteasome. The three subunits, low molecular weight protein-2 (LMP-2), LMP-7, and LMP-10,

that make up the proteasome and the cytoplasmic transporter for processing (TAP) are all ISGs, can also be induced by IRF7, and are suppressed in some malignancies.[221-224] TAP transports the processed peptides from cytosol to the ER for loading onto class I molecules. The MHC class II transactivator factor (CIITA), the master regulator of MHC class II expression, is induced by IFN-γ.[57] In addition, three cathepsins, thought to be partly responsible for peptide antigen processing and loading onto MHC class II proteins, were upregulated by IFN-γ.[225] In addition to IFN-γ, type I IFNs can also drive MHC class II expression onto the plasma membrane and also maintained intracellular vacuolar expression for sustained dendritic-cell presentation of antigens.[226]

Through their immune effector functions, IFNs type I and IFN-γ can have an amplifying role for other immunomodulatory therapeutics. IFNs induced the tumor-associated antigens carcinoembryonic antigen and TAG-72 on the surface of tumor cells both in vitro and in vivo.[227] Type I IFNs induced by a vaccine protein linked to a TLR7/8 agonist markedly increased dendritic-cell antigen uptake.[228] This increase could be beneficial for either innate or adoptive immunotherapies targeting these tumor antigens, as suggested by studies combining IFN-α with a CEA poxvirus vaccine.[229] Offering the potential for use with targeted monoclonal antibodies directed at tumor proteins was the finding of the essential role of both type I IFNs and IFN-γ in mediating effectiveness of a monoclonal antibody binding to HER2/ErbB-2 in a murine breast carcinoma model.[230] This effect required TLR signaling through MyD88 and IFN-γ producing CD8 T cells but was independent of perforin, fas ligand, or IL17R signaling.

IFNs have increased expression of a number of chemokines that function as chemoattractants both in vitro and in patients.[231,232] IFN-induced chemokines include CCL5 (RANTES), CXCL10 (IP-10), CCL2 (MCP-1), CCL3 (MIP-1α), CXCL9 (MIG), and CXCL11(I-TAC). STAT1 induction of chemokines CXCL9, CXCL10, CXCL11, and CXCL16 controlled recruitment of protective, antigen-specific Th1 cells into peripheral tissues.[233] These ISGs and IRF-induced proteins are chemoattractive to both lymphocytes and monocytes and play a crucial role in recruiting these cells into tissues.[234]

Other ISG products, such as phospholipid scramblase 1 (PLSCR1), may play a role in providing macrophages with a signal for engulfment after tumor cell apoptosis.[235-237] PLSCR1 may increase expression of a subset of ISGs influencing apoptosis and other effects of IFNs.[235-237] Ovarian cancer cells overexpressing PLSCR1 grew more slowly in nude mice compared to vector-transfected cells, and resultant tumors were infiltrated by neutrophils and macrophages. Thus by inducing PLSCR1, IFNs may facilitate tumor cell phagocytosis by macrophages.

ISG-15, a secreted protein induced by IFNs-α and IFN-β, induced IFN-γ synthesis by T cells and proliferation of NK and lymphokine-activated killer (LAK) cells.[238] A genetic defect in ISG15 secretion resulted in impaired production of IFN-γ by NK and T cells and impaired protective immunity to mycobacteria.[239] Four of the top 36 expressed genes in an expression array of melanoma cells (ISG 15, USP18, UBE1L, UBE2L6) constitute part of a cascade of ubiquitin-related ISGs that influence both innate immunity for malignant cells and cellular signaling. These can conjugate intracellular proteins to influence action and extracellular cell function of IFNs.[240-244] Melanoma cells producing high levels of ISG-15 were those able to induce e-cadherin expression on dendritic cells.[241] Conjugation of ISG15 to components of the IFN-signaling pathway (STAT1 and JAK1) and other signaling pathways (ERK 1, phospholipase C, and heat shock proteins) suggest that targeted regulation of ISG 15 family molecules could have profound effects not only on tumor cells but also on host response.[244]

Consistent with the concept that ISG15-ylation of proteins is analogous to ubiquitination, most target identified proteins have decreased function with ISG15 conjugation.[244] However, an siRNA to the ISG USP18, the ISG that deconjugates ISG15 from target proteins, increased expression of TRAIL through its increased transcription and thus promoted apoptosis.[245] Consistent with this is the finding that immunization against ISG15 resulted in CD8 T-cell–mediated reductions in murine breast carcinoma growth.[246] Complexities in understanding the functional effects of the ubiquitin-like ISGs may be explained by ISGylation and deISGylation stabilizing or altering binding of a target protein to its typical interaction partner at the protein-protein or protein-RNA interface.[244,247]

Inhibition of Malignant Cell Motility and Invasion

An essential part of the malignant process is the motility of transformed cells and their invasion of normal tissues, a process inhibited by several of the highly induced ISGs. One of the genes highly induced by IFNs-α and IFN-β in most tissues is *MX1*. It encodes a GTPase MxA that inhibited motility and invasiveness of prostate carcinoma and melanoma in both in vitro and in vivo assessments.[248] IFIT2 (p54) inhibited migration of oral squamous carcinomas in vitro, possibly through interaction with cytokeratins.[249] Another ISG product, schlafen 5, when suppressed, increased melanoma cell invasiveness into three-dimensional collagen.[250] Because schlafen 5 was often suppressed in melanoma, it may contribute to antimelanoma effects of IFN-α2.[250]

Though less widely studied for its biological effects than some others, the products of the ISGs of the IFITM family are transmembrane proteins (IFITM1, 9-27; IFITM2, 1-8) of wide phylogenetic distribution, expression in most tissues, and lower molecular weight (approximately 14 to 17 kDa).[251] IFITM1 associates with cell surface CD81 in many human cells types, and the complex is involved in β1 integrin adhesion to extracellular matrix proteins.[252] It also interacts with the CD19/CR2 signal complex in lymphocytes and antibodies to IFITM1 and resulted in homotypic adhesion of T cells.[253,254] The antibody to IFITM1 has antiproliferative effects for leukemic B cells; thus IFITM1 contributes to growth control in lymphocytes.[255,256] Upregulation of IFITM1 and IFITM3 has been identified in more invasive breast, head and neck, and gastric carcinomas with promotion of invasiveness in vitro.[257,258] Also suggesting a role in homotypic adhesion and greater invasiveness was the lower level of IFITM1 and IFITM3 in metastatic melanomas.[259]

Angiogenesis Inhibition

IFNs inhibit angiogenesis both by altering the stimulus of tumor cells and by inhibiting endothelial cells through increase and decrease of proteins mediating the angiogenic process (Table 53-6). Following IFNs, vessels underwent coagulation necrosis.[260] Inhibition of angiogenesis by IFNs occurred before antiproliferative effects on tumor cells and has been identified in vivo within 24 hours of tumor-cell inoculation.[261] IFN-sensitive and IFN-resistant bladder carcinoma cells in mice had reductions in tumor cell growth after IFN-α in IFN-sensitive cells by directly regulating expression of the angiogenic cytokine basic fibroblast growth factor (bFGF).[262] Suppression of bFGF correlated with reduced vascularization and tumor growth.[262] Knockout studies confirmed signaling through STAT1 as necessary for reduction by IFNs of bFGF signaling. Compared with wild-type mice, IFNAR receptor knockout mice have increased angiogenesis and tumorigenesis.[263]

In addition to their action on bFGF, IFNs have inhibited angiogenesis by acting on other angiogenesis mediators. IFNs inhibited VEGF mRNA and protein expression in neuroendocrine tumors by regulating VEGF promoter activity.[264] Effects on VEGF promoters may in part be mediated by a reduction in one of its promoters, HIF-1α, that was reduced by IFN-γ.[265] Contributing to reductions in VEGFA by IFN-γ may be a novel conformational change in the VEGF-A RNA 3′ untranslated region to reduce VEGF-A translation through integration of hypoxia and STAT signaling.[266] IL-8, a mediator of angiogenesis, was inhibited in vitro and in vivo by IFN-α2b and IFN-β.[267,268] Other angiogenesis inhibitory members of the chemokine family that lack the ELR binding motif, CXCL9, CXCL10, and CXCL11, are also IFN-stimulated genes.[269,270]

Table 53-6 IFN-Regulated Proteins Contributing to Suppressive Events in the Microenvironment

bFGF decrease	VEGF decrease
GBP1	IL-8 decrease
CXCL 9, CXCL 10, CXCL 11	Tryptophanyl-tRNA synthetase
MXA	schlafen 5
TFITM family	

Guanylate binding proteins (GBPs), a family seven human GTPases of the dynamin superfamily potently induced by IFNs, modulated proliferation and spreading of endothelial cells in vitro.[271] In endothelial cells, hGBP1 functioned as an inflammatory response factor, inhibiting endothelial cell proliferation and angiogenesis through matrix metalloproteinases.[272] hGBP1 also inhibited proliferation of endothelial cells stimulated by VEGF or bFGF through its C-terminal alpha helices.[273] In contrast to endothelial cell inhibition by hGBP1 was its increase in malignant glioma cells through EGF receptor signaling resulting in increased matrix metalloproteinase 1 and glioma cell invasion.[274] Whether this latter effect is transformed-cell or tissue-type dependent remains to be determined; it does, however, emphasize that induction and action of ISGs can occur through unique and undiscovered pathways that are independent of IFNs as ligands. Thus, induction of ISGs such as GBP1 and IFI16 that function as angiostatic inhibitors, coupled with downregulation of other factors, may contribute to inhibition of angiogenesis by IFNs.[271,275,276]

Endogenous type I IFN signaling may therefore play a role as a negative regulator of angiogenesis, keeping the "angiogenic switch" in the off position. Indeed, mice lacking IFN-β (IFN-$\beta^{-/-}$) had faster growing melanomas and sarcomas with better developed blood vessels than did control mice.[277] Tumors from these mice had enhanced infiltration by neutrophilic cell population with phenotypic markers of myeloid-derived suppressor cells (MDSCs) and increased expression of VEGF and matrix metalloproteinase 9. These data suggest that endogenous IFN-β may play an important role in regulating tumor-induced angiogenesis. Further supporting this was the finding that in vitro treatment of tumor-infiltrating neutrophils with low levels of IFN-β reduced expression of pro-angiogenic factors to normal levels.[277] In this and other preclinical mechanistic studies, IFNs inhibited tumor vascularization and modulated expression of pro-angiogenic and anti-angiogenic genes at doses well within those that are therapeutically achievable.[278] Consistent with an important role for angiogenesis inhibition in the antitumor effects of IFNs is that, clinically, IFN-α2b has proven

effective in the treatment of infantile hemangiomas, hemangioblastomas, giant-cell tumor of the mandible, and Kaposi's sarcoma.[279-281]

Antitumor Effects in Humans

Because of their clinical effectiveness in reducing tumor cell mass, limiting virus replication, controlling disease symptoms, and prolonging survival, IFNs are now licensed in more than 50 countries for treatment of viral, malignant, and immune disorders. Global market sales approximated $5 billion in 2010 and are expected to continue to increase to $10 billion by 2015. IFNs as single agents can induce clinical regression in almost a dozen hematopoietic malignancies or solid tumors.[23] In CML, melanoma, renal cell carcinoma, bladder carcinoma, Kaposi's sarcoma, hairy-cell leukemia, lymphomas, myeloma, polycythemia vera, locally advanced basal cell carcinoma, and essential thrombocythemia, IFNs have had therapeutic value.

For example, use of IFN-α2 for hairy-cell leukemia and for CML resulted in a gradual decrease in bone marrow infiltration with malignant cells as well as a normalization of peripheral hematologic parameters.[282-286] In CML, in addition to reduction in leukemic cell mass, a decrease resulted in cells with the abnormal, activated bcr-abl kinase. The median survival for all patients with CML treated with IFN-α2 was extended to approximately 6 years, with over 90% of those with complete cytogenetic response in remission at 10 years. Frequency of cytogenetic response and survival were further enhanced by adding cytosine arabinoside to IFN-α2. The survival advantage for IFN-α2 has now been exceeded by the substantial effectiveness of the targeted tyrosine kinase inhibitors such as imatinib and nilotinib. However, the hematologic effectiveness and tolerability of IFN-α2 and pegylated IFNα2 have resulted in continued evaluation in combination with imatinib with higher and longer duration molecular responses, sustained immunologic effects, and possible improvements in survival.[287-290] Aberrant JAK2 expression, part of a protein complex driven by the Bcr-Abl translocation in CML, could be a target.[291] Because the activity of IFN-α2 in CML has not been elucidated on a molecular basis, tyk2 and JAK1 stimulation by IFN-α2 could be providing a lateral, suppressive shift in from JAK2 activity with subsequent inhibition of proliferation. Furthermore, with its clinical effectiveness and tolerance, pegylated IFN-α2 continues to be evaluated and used for other myeloproliferative disorders such as essential thrombocythemia and polycythemia vera, with beneficial clinical results confirmed by reduction in cells with pathogenic mutations in JAK2(V617F).[292]

Curative elimination of metastatic malignancies can result when systemic therapies are given to eliminate micrometastases in patients at highest risk for recurrence after surgical removal of a primary. Effectiveness of IFNs as adjuvant therapy after surgery of murine tumors has been demonstrated and is consistent with pioneering clinical studies of IFNs in therapy for osteosarcoma involved this approach.[293,294] IFN-α2 enhanced clinical benefit of surgery and resulted in effects equivalent to effective chemotherapy. To more rigorously define the role of pegylated IFN-α2 after surgery and chemotherapy for primary osteosarcoma, a randomized international trial involving cooperative groups in Europe and the United States is ongoing.

Elimination of micrometastases was the basis for evaluation of IFN-α2b for patients at high risk for recurrence of melanoma—those patients marked by deeply invasive primaries or nodal metastases. The initial positive findings have been largely further validated by subsequent trials of high-dose IFN-α2b for 1 year and by meta-analyses.[295,296] A multi-institutional randomized trial evaluated pegylated IFN-α2 in more than 1200 patients with stage III melanoma for a period of 5 years with dose adjusted for the side effect of fatigue to maintain full activity level.[297] Overall survival was not significantly different in the two groups, although the IFN-treated patients had a significant improvement in relapse-free survival (RFS) ($P = .01$), with subgroup analyses identifying the greatest improvement in RFS in patients with microscopic nodal disease ($P = .02$).[297] Subsequent analysis of this study in a combined database identified an improvement in both disease-free survival and overall survival in patients with ulcerated primaries, this group possibly reflecting those with the most marked invasiveness or vascularity.[297]

Adjuvant use of IFN-α2 has also proved effective after resection and/or ablation for hepatitis C virus–associated hepatocellular carcinoma in both individual Phase II and randomized controlled Phase III trials and a meta-analysis. In the meta-analysis, regardless of viral load, highly beneficial effects on both reduction in recurrence frequency and overall survival were identified.[298] Building on the therapeutic activity of IFNs in Phase II trials in metastatic renal cell carcinoma (RCC),[299] resection of a primary followed by IFN-α2 extended patient survival in each trial cohort and in a combined analysis.[300] However, addition of the antiangiogenic bevacizumab to IFNs has more recently failed to markedly improve outcomes in metastatic RCC.[301] Furthermore, as in CML, the orally active, targeted kinase inhibitors such as sunitinib and axitinib have changed the natural history of RCC carcinoma, extending survival in metastatic disease more than the injectable IFN-α2.[302] In follicular lymphomas in combination with chemotherapy, even relatively limited amounts of IFN-α2 can prolong survival.[303] Curative

effects with topical use have been seen in both ocular squamous neoplasia and superficial carcinoma of the bladder. The former, treated with ophthalmologic drops of IFN-α2b, results in complete clinical regression in more than 80% of treated eyes—even those with T3 tumors.[304]

IFN-γ has had only limited clinical utility in melanoma, renal, colorectal carcinomas, and other metastatic malignancies as a single agent.[133,305,306] It has also been assessed in resected stage I and stage II primaries in a randomized study of patients.[307] Compared with untreated patients, no improvements in outcome resulted. More recent insights have begun to offer some understanding of this unexpected lack of clinical effectiveness of IFN-γ. Murine melanomas after IFN-γ, for example, evaded CD8 T-cell cytotoxicity by producing large amounts of tumor antigen, noncognate MHC class I molecules on melanoma cells, limiting T-cell activation and effector function.[308] Immune evasion and progression of a UVB-induced melanoma in mice was facilitated by IFN-γ through macrophage trafficking by induced chemokines.[309] Furthermore, TLR signaling or IFN-γ can induce an immunosuppressive T-cell ligand, PD-L1, in tumor cells, induction by IFN-γ occurring possibly through a MAPK signaling pathway.[310,311] This occurred in a time- and dose-dependent manner with suppression of CD8 T-cell cytotoxicity.[310,311] It is thus conceivable that on balance, the potent immunologic effects of IFN-γ may be detrimental rather than beneficial in the tumor microenvironment.

As inducers of IFNs, agonists for TLR7-9, imiquimod and the phosphothioate oligoribonucelotide CpG7909, have immunomodulatory effects.[312,313] Imiquimod has proven effective topically both for venereal warts caused by papillomaviruses and for basal-cell carcinomas.[314,315] Newer TLR9 agonists have been combined with rituximab and a CEA vaccine.[316,317]

Perspective

Both as a product of nascent biotechnology companies and as one of the several advances in modulating the immune system to treat cancer, introduction and clinical use of IFNs has been one of the major advances in oncology over the past three decades. The 1980s saw the clinical introduction of these high purified pharmaceuticals as the first products of biotechnology for the treatment of cancer. The 1990s were marked by an expansion in clinical use and a clearer understanding of the molecular events that influence the biologic actions. During these two decades, IFNs were understood as fundamental cellular defense mechanisms against viral infections and cancer and thus critically important to the health of animals and humans. Through the action of specific ISGs reviewed in this chapter, IFNs were identified as the principal cytokine that blocks viral replication, important in resistance not only to acute but also chronic human infections, such as those with oncogenic hepatitis C virus and papillomaviruses. Because biologic effects of IFNs were identified as mediated primarily through STAT1 signaling and its induction and the action of other induced ISGs, attention over these final 20 years of the 20th century shifted to understanding how insights into the genes reviewed in this chapter might lead to more efficacious cancer and new antiviral therapeutics.

The first decade of the 21st century has been marked by an application of this knowledge to further understand mechanisms of action of IFNs. Complexities in STAT activation, signaling, and regulation, possibly in some instances detrimental to endogenous and exogenous antitumor effects, have been identified.[79,128] As part of the innate immune response and immune surveillance mediated through TLR activation, new insights into the essential role of both type I and type II IFN signaling have, however, been identified.[20-22] Tumor cells that are not eliminated are kept dormant by a suppressive host response, both as the result of essential type I IFNs and IFN-γ.[20,21] Consistent with these murine observations, suppression or downregulation of STAT1-induced genes in tumor-infiltrated T cells and in peripheral blood of patients with metastatic melanoma has been clinically associated with worse outcome.[318,319]

Many important questions thus remain unanswered. What roles do endogenous triggering of TLRs play in antitumor responses? What specific roles do the multiple isoforms of IFN-α have in host defenses? How do STAT proteins regulate apoptosis, cell growth, immunity, and cytotoxic drug resistance? What are the functions of the many still-uncharacterized ISGs? Which of the ISGs are most important for the antitumor effects—and through what cellular mechanisms: immune augmentation, cell stasis and death, inhibition of angiogenesis? What mechanisms cause the difficult spectrum of clinical side effects of fatigue and anorexia? What causes resistance to IFNs in cancer? Can effective oral systemic inducers of IFNs or ISGs be identified? Answers to these questions will continue to stimulate future advances.

Acknowledgment

This chapter is revised and updated from the same chapter in the prior edition of *Molecular Basis of Cancer*. That chapter was written by the author together with R. Silverman and G. Sen of the Cleveland Clinic, whose prior contributions provided important elements of this update.

Gene Therapy and Oncolytic Viruses

Introduction

Genetic alterations are the driving force behind cancer development and progression. It follows that cancer could potentially be treated by correcting these alterations using gene therapy or by agents that kill cells by mechanisms based on these genetic alterations. Approaches of these kinds have a number of potential advantages. Vectors and viruses can be engineered in countless ways to achieve specificity and potency (Table 54-1) and can be designed and tested using tools that are routine in contemporary molecular biology laboratories. For these reasons, a dazzling array of creative concepts has been described over the past 20 years. However, few of these have been tested extensively in the clinic, and none has yet completed a successful Phase III clinical trial in the United States or Europe. Therefore, gene therapy and oncolytic viral therapy have not yet lived up to their promise and have not yet entered the mainstream of medical oncology, by any means. In this chapter, we discuss the potential and challenges of these novel technologies. We focus on the main strategies that have been evaluated clinically. These include the design of agents that kill cancer cells by gene replacement or by disruption of oncogenic signaling pathways. For example, therapeutic agents have been developed that reintroduce the wild-type p53 tumor suppressor gene or destroy RNA encoding oncogenic K-RAS. The delivery of toxic genes and genes that convert prodrugs into toxic metabolites has undergone extensive clinical testing and has produced exciting results. Furthermore, we highlight strategies that aim at modulating the immune response in order to achieve anticancer effects. Finally, we discuss the basic and clinical aspects of the use of replication-competent viruses, either in their natural configuration or genetically modified, to selectively kill cancer cells (Table 54-2).

Killing Cancer Cells by Gene Replacement and Gene Knockout

Gene Replacement

Cancers develop through loss of function of key regulatory genes known as tumor suppressors as well as through activation of proto-oncogenes. Loss of *p14*, *p16*, *p53*, or *PTEN* occurs at high frequencies in most tumor types. Loss of Adenomatous Polyposis Coli (*APC*) occurs in the majority of colorectal cancers, and loss of *RB* is frequent in small-cell lung cancers, among many other examples.[1,2] Mutations or deletions inactivate products of these genes, or their expression is suppressed by hypermethylation. Clonal evolution of tumors depends on loss of these functions: replacement of functional versions of these genes should therefore reverse this process. Indeed, when tumor suppressors are reexpressed in tumor cells by gene delivery, tumor cells die or growth is arrested. This has been shown for *APC*, *p16*, *p21*, *p27*, *RB*, *p14ARF*, *p53*, *PTEN*, *APC*, and *BRCA1*, *BRCA2*, among others.[3]

In contrast, normal cells receiving additional copies of these genes appear to be unaffected, at least in the cases that have been tested so far. This has been documented most clearly for p53: delivery of this tumor suppressor to normal bronchial epithelial cells had no effect on cell growth, suggesting a therapeutic window of more than 2 orders of magnitude.[4] This may be because tumor cells have additional defects that make them more sensitive to the effects of reexpressing p53. For example, almost all tumor cells have a defect in the RB checkpoint and therefore are less able to undergo growth arrest. Normal cells, in contrast, undergo G_1 arrest when p53 is active, and this can protect them from apoptosis. In addition, the negative regulator of p53,

Table 54-1 Gene Therapy and Oncolytic Viruses—Basic Concepts

		Class	Example
Vectors	Viral	Naturally cancer-selective viruses	Reovirus, Newcastle disease virus (NDV), vesicular stomatitis virus (VSV), measles, vaccinia virus
		Engineered viruses	Adenovirus: ONYX015; herpes simplex virus (HSV): OncoVEXGM-CSF; vaccinia virus: JX-594
	Nonviral	Bacteria	*Listeria monocytogenes*: CRS-207
		Plasmids	Plasmid encoding IL-12
		RNAi	siRNA against RRM2: CALAA-01
Strategies to achieve tumor killing	Cell lysis/killing via viral replication		All replication-competent viruses
	Direct targeting of tumor genetics: knockdown of oncogenes or essential pathway components, reexpression of tumor suppressor genes		KRasG12D: siG12D LODER; p53: AdCMV-p53
	Delivery of cytotoxic or pro-apoptotic genes		Bcl-2; Survivin
	Delivery of immune-stimulatory genes		GM-CSF: JX594, OncoVEXGM-CSF; TNF: TNFerade
	Activation of innate and adaptive immunity, induction of memory		OncoVEXGM-CSF, JX594
	Delivery of anti-anti angiogenic genes and enzymes		Anti-FLT1 ribozyme
	Delivery of prodrug converting enzymes		Thymidine kinase, carboxylesterase, cytosinedeaminase
	Delivery of transporters		Sodium-iodide symporter (NIS)
	Chemosensitization by viral replication		All replication-competent viruses
Strategies to achieve tumor selectivity	Vector size: preferential exit from leaky tumor vasculature (fenestrations of ~100-400 nm); enhanced permeability retention effect (EPR)		CALAA-01 (70-nm diameter); vaccinia virus (200 nm)
	Vector engineering to match specific tumor genetics		Rb: adenovirus Delta24
	Targeting cell surface receptors overexpressed by cancer cells for delivery		Transferrin receptor: CALAA-01 siRNA delivering nanoparticles with transferrin as a targeting ligand
			$\alpha_v\beta$-Integrin: Adenovirus RGD
	Deletion of viral genes inducing S-phase, and/or other genes required for replication in quiescent cells		Adenovirus: E1A and E1B deletions; vaccinia: thymidine kinase deletion
	Use of tumor- and/or tissue-specific promoters		Adenovirus CG0070: E2F-1 driven expression of E1A

FLT1, Fms-like tyrosine kinase 1, VEGFR1; *RGD*, Arg-Gly-Asp; *RRM2*, ribonucleotide reductase subunit M2.

Mdm2, is itself a p53 effector.[5] In tumor cells lacking p53, mdm2 levels are often low. In normal cells, Mdm2 constantly degrades p53 and maintains low p53 activity. Therefore, p53 expressed ectopically in normal cells is degraded, whereas in cancer cells it is relatively stable. In addition, p53 promotes a bystander effect on uninfected tumor cells, possibly through antiangiogenesis,[6] secretion of soluble proapoptotic proteins,[7] and immune upregulation.[8,9] In agreement with these theoretical considerations, clinical safety and some evidence for anti-tumor activity of an adenoviral vector expresses wild-type p53 under the control of a Rous-sarcoma-virus promoter (Gendicine) have been demonstrated and led to approval of this agent in China for use in head and neck cancer.[10] Fever and flu-like symptoms were the main adverse events; no severe side effects occurred.[10] Long-lasting responses with this agent were observed in studies in patients with head and neck cancer. Very high response rates, including 64% complete responses, were observed following intratumoral injection of Gendicine in combination with radiation therapy.[11,12] However, a similar virus that delivers wild-type p53 under the control of a constitutively active CMV promoter (AdCMV-p53; Advexin) failed to complete a Phase III clinical trial successfully in the United States, and development of this agent stopped in 2008. This example illustrates the fact that poor delivery systems and inefficient access to tumor cells have limited the potential of gene-replacement therapy for treating cancer, despite compelling theoretical arguments for its development.

Gene Knockout

Antisense

Activation of proto-oncogenes such as *Ras*, *B-Raf*, *Myc*, or *EGFR* through various mechanisms is a key factor in carcinogenesis. For example, mutations of the *Ras* oncogene occur in many types, including pancreatic cancer, where about 90% of cases carry a mutation of the K-ras gene.[13,14] Knockout of oncogenes driving tumor development in transgenic mouse models of cancer can lead to complete regression, confirming

Table 54-2 Cancer-Selective Viruses in Clinical Trials

Virus Genus	Virus Product Name/Strain	Genome	Basis of Selectivity	(Other) Genetic Modification(s)	Clinical Phase	Route of Administration	Ref.
Enterovirus: Coxsackievirus A21, CVA21	CAVATAK	ssRNA$^+$	High levels of CAV21 receptors (ICAM1, DAF) expressed by cancer cells	None	Phase II malignant melanoma	Intratumoral	NCT00832559
Newcastle Disease Virus (NDV)	NDV-HUJ	ssRNA$^-$	Defective IFN response in transformed cells	None	Phase I/II glioblastoma, sarcoma, neuroblastoma	IV	122 NCT01174537
Parvovirus H-1 (apathogenic rat virus)	ParvOryx01	ssDNA	Defective IFN response in transformed cells; viral replication only in proliferating cells	None	Phase I/IIa glioblastoma multiforme	Intratumoral/ intracerebral or IV/intracerebral	123,124 NCT01301430
Reovirus		dsRNA	PKR suppression by Ras and oncogenic EGFR	None			
	Respiratory enteric orphan virus (REOLYSIN)				Phase II NSCLC; Phase II prostate cancer; Phase II colorectal cancer; Phase II pancreatic adenocarcinoma; Phase II melanoma; Phase II lung squamous cell carcinoma; Phase II head and neck carcinoma; Phase III head and neck carcinoma	IV	50,125 126 NCT00861627; NCT01619813; NCT01622543; NCT00998322; NCT00984464; NCT00998192; NCT00753038; NCT01166542
	Wild-type reovirus				Phase II fallopian tube cancer, ovarian cancer Primary peritoneal cavity cancer; Phase II pancreatic cancer	IV	NCT01199263; NCT01280058
Seneca-valley virus/ senecavirus	Senecavirus-001, NTX-010	ssRNA$^+$			Phase II NSCLC	IV	NCT01017601
Adenovirus	CG0070	DNA	E2F-1 promoter-driven expression of E1A	GM-CSF$^+$	Phase II/III Non–muscle-invasive bladder cancer	Bladder instillation	127 NCT01438112
Herpes Simplex Virus	OncoVEX GM-CSF	DNA	ICP34.5$^-$ (ICP34.5 related to eIF2 phosphatase regulatory subunit GADD34, involved in translational regulation)	ICP47$^-$ (immune stimulating, as ICP47 blocks antigen processing in HSV-infected cells), GM-CSF$^+$ (immune stimulating)	Phase III Malignant melanoma	Intratumoral	128,129 NCT01368276, NCT00769704

their potential value as drug targets.[15] Antisense technology has been studied as a strategy to knock down expression of oncogenes. This approach is based on the possibility of inhibiting transcription of a particular mRNA by transfecting short double-stranded DNA oligonucleotides into target cells that bind and inactivate the target mRNA in a sequence-specific manner.[16] The development of oligonucleotides with modified DNA backbone that increases the stability of the molecule in vivo allowed for the development of clinical protocols involving intravenous application of antisense molecules targeting, for example, mutant Kras or the anti-apoptotic genes *BCL-2* and *Survivin*.[17] Clinical trials with oblimersen sodium (G3139), an antisense oligonucleotide directed against BCL-2, have demonstrated increased survival of patients with advanced melanoma in combination with chemotherapy compared to chemotherapy alone.[18] An interesting variant of the antisense approach that is currently being tested clinically is GRN163L, a lipid-modified 13-mer DNA-oligonucleotide that acts as a telomerase RNA template antagonist.[19]

RNAi

The discovery of the possibility of silencing gene expression in mammalian cells with high efficiency using RNA interference (RNAi) has spurred renewed interest in the gene knock-down as a therapeutic strategy. This approach, first described in the worm *Caenorhabditis elegans*, takes advantage of a cellular gene silencing machinery that involves the RNA-induced silencing complex (RISC) and degrades double-stranded RNAs with high efficacy.[20] The introduction of short RNAs with complementary sequence to any cellular transcript activates this mechanism. RNAi can silence target genes with high efficacy. However, off-target effects that result in sequence-specific though unpredictable knock-down of additional genes represent a potential problem that has not been fully resolved at this point.[21] Nevertheless, novel targeting and delivery mechanisms have been developed that hold the promise of therapeutic application of RNAi-based agents in cancer.[20] For instance, a recently reported nanoparticle-based delivery system shows great promise for systemic delivery of siRNA. These synthetic nanoparticles consist of a cyclodextrin-based polymer, a human transferrin protein (TF) targeting ligand displayed on the exterior of the nanoparticle to engage TF receptors (TFR) on the surface of the cancer cells, a hydrophilic polymer (polyethylene glycol [PEG] used to promote nanoparticle stability in biological fluids), and siRNA designed to reduce the expression of the Ribonucleotide Reductase subunit M2 (RRM2). Tumor-specific targeting is achieved via the interaction of the TF targeting ligand with TFR, which is known to be upregulated in malignant cells.[22] Moreover, the size of these nanoparticles, about 70 nm in diameter, favors their exit from the bloodstream in leaky tumor vasculature and accumulation in the tumor bed via the enhanced permeability and retention (EPR) effect. RRM2, an enzyme catalyzing a rate-limiting step in DNA synthesis, is an established anticancer target.[23] These particles (CALAA-01), currently in Phase I clinical studies, have been administered systemically to humans and have shown specific gene inhibition—a reduction in both mRNA and protein.[24]

Another well-established anticancer target is the *KRAS* oncogene. Most pancreatic adenocarcinomas are caused by a somatic mutation in *KRAS*, most commonly *KRAS G12D*. In vitro and animal studies suggest that selective inhibition of the mutant, but not the WT *KRAS* expression, leads to apoptosis of targeted cancer cells. An siRNA specifically targeting mRNA encoding KRAS G12D, coated by a biodegradable polymeric matrix, siG12D LODER (Local Drug EluteR), is currently in Phase 0/I to evaluate its safety and tolerability. Apart from these two particular RNAi therapeutics, at least another six are currently undergoing clinical testing, thanks to recent advancements in the understanding of RNAi biology and in the areas of RNAi specificity, stability, and delivery. Most are delivered employing synthetic carriers, such as cationic liposomes, anionic liposomes, and polymeric particles. As more attention is focused on safe and effective methods for delivering siRNA to tumors, the clinical value of this approach will likely increase dramatically. siRNA-based therapy has the potential of addressing undruggable oncogene targets, combinatorial approaches to cancer cell killing, and drug resistance, but this potential will not be realized until the challenges of delivery and uptake have been fully addressed.

Killing Cancer Cells by Delivering Prodrug Converting Enzymes and Other Enzymes

For more than 60 years chemotherapeutic agents have been used for the treatment of cancer. However, their use is often limited by damage to normal cells, drug resistance, and low chemical stability. One strategy to overcome limitations of classical chemotherapeutic agents is the use of prodrugs. A prodrug is a fairly nontoxic compound that needs to be transformed before acting as a pharmacon. Such a transformation can be catalyzed by endogenous enzymes, in which case tissue distribution of such endogenous enzymes dictates where the active pharmacon is produced. Alternatively, gene-directed enzyme prodrug therapy (GDEPT) can specifically deliver such enzymes to diseased cells where they can activate nontoxic prodrugs into toxic agents. Progress in this field has been reviewed recently by Duarte and colleagues.[25]

Thymidine Kinase

The first GDEPT system described was the thymidine kinase gene of the herpes simplex virus (HSV-TK) in combination with the prodrug nucleoside analog ganciclovir. The enzyme thymidine kinase (TK) is naturally present in bacteria, viruses, and mammals, where it is involved in the salvage pathway of nucleotide biosynthesis. Thus, high TK activity is found in proliferating cells such as cancer cells. TK also converts ganciclovir to ganciclovir monophosphate, which is subsequently converted by cellular kinases into the toxic ganciclovir triphosphate nucleotide. The HSV-TK is three orders of magnitude more efficient than any human kinase catalyzing this first activation step. Hence, several gene therapy approaches combining HSV-TK and ganciclovir have been developed.

For instance, retroviral vectors were used to deliver HSV-TK in a brain tumor model. Because retroviruses integrate only in proliferating cells, gene delivery and expression would be tumor selective in the context of normal, nonproliferating brain cells.[26] A further advantage of this approach was thought to result from the "bystander effect," the killing of uninfected neighboring cells that occurs when HSV-TK–expressing cells are exposed to ganciclovir, which can be observed in vitro and in vivo.[27] To increase transduction of target cells with retroviruses, virus-producing cells (VPCs) were used to inoculate target tumors instead of virus suspension. Preclinical studies in a rat glioma model demonstrated that this delivery of a retrovirus expressing HSV-TK resulted in high transduction levels and frequent tumor regressions following ganciclovir administration.[28] Initial clinical studies were promising and demonstrated in responses of small glioblastomas following VPC injection.[29] However, when standard therapy (surgical resection and radiotherapy) was compared to standard therapy plus injection of retrovirus-producing cells in a Phase III trial, no differences in progression-free and overall survival were observed between the two groups.[30] Smaller, preoperative studies suggested that lack of transduction of tumor cells is the dominant reason for the failure of this approach.[31] Despite the disappointing results of this trial, it represents an early and innovative effort to use gene therapy to kill cancer cells selectively.

Cytosine Deaminase

In contrast to thymidine kinase, the enzyme cytosine deaminase (CD) is not present in mammalian cells, but in several bacteria and fungi. It catalyzes the amidine hydrolysis of cytosine to uracil and ammonia, and several cytosine analogs such as halogenated cytosines are substrates as well. One such substrate is the prodrug 5′-fluorocytosine (5′-FC) which is activated by CD to 5′-fluorouracil (5′-FU). 5′-FU kills cells mainly by inhibition of thymidilate synthetase and by incorporation into DNA. The safety and efficacy of a CD and 5′-FC prodrug therapy are currently being assessed in Phase I/II trials in which 5′-FC and a recombinant *Bifidobacterium longum* (a live bacterium normally found in the digestive tract) that has been modified to produce CD are given orally to patients with various solid tumors.

Carboxylesterase

Another well-studied prodrug-converting enzyme is carboxylesterase (CE). CE expression is widely distributed in human tissues; nonetheless, targeted gene delivery to enhance CE expression specifically in tumor cells is a promising approach to increase the local availability of cytostatic drugs. CE is involved in the activating metabolism of various commonly used chemotherapeutics: It activates paclitaxel-2-ethylcarbonate to the microtubule-stabilizing agent paclitaxel/taxol and is involved in the multistep conversion of capecitabine to the pyrimidine analog 5′-fluorocytidine (5′-FC). Moreover, CE converts the relatively nontoxic camptothecin analog CPT-11/irinotecan to SN38, a potent topoisomerase I inhibitor. Because the human CE is comparatively inefficient in catalyzing this conversion, several gene therapeutic strategies using the more effective rabbit CE were developed and shown to be successful in tissue culture and animal models. Also, secreted mutants of this enzyme are being studied to enhance the spread of the toxic metabolite and thereby the bystander effect. For instance, Oosterhoff and colleagues show increased killing of colon carcinoma cells on infection with adenovirus expressing secreted CE (Ad5-Δ24-sCE) combined with CPT-11 treatment.[32] Even though CPT-11 also reduced viral replication, the overall cytotoxicity of virus combined with CPT-11 was still higher than cell killing achieved by the virus alone. Nonetheless, this exemplifies the complications of using chemotherapeutic agents in combination with oncolytic viruses; it is crucial to know the kinetics of both viral replication and drug metabolism to design a suitably timed treatment regimen. This is not only essential for oncolytic viruses as vectors for GDEPT, but for the combination of any oncolytic virus with chemotherapeutic agents.[33]

Sodium-Iodide Symporter

Not only prodrug-converting enzymes are being pursued as gene therapeutics. Several vectors have been developed

to deliver genes for various other enzymes, including the one for the sodium iodide symporter (*NIS*). The endogenously expressed NIS is an integral plasma membrane glycoprotein that mediates active I^- transport into thyroid follicular cells. The rationale for its use in gene therapy approaches is twofold: targeted expression of *NIS* in cancer cells renders these cells susceptible to uptake of radioactive iodine, which, depending on the isotope used, can be harnessed to kill and/or to image targeted cells. For instance, measles virus (MV) strains that have been engineered to express the human NIS (MV-NIS) have shown significant antitumor activity against various cancer lines and orthotopic xenografts. Expression of NIS in infected glioma cells resulted in effective concentration of radioactive iodine, which allowed for in vivo monitoring of localization of MV-NIS infection by measuring uptake of ^{123}I and led to a significant increase of MV-NIS antitumor activity.[34] A Phase I study is ongoing to establish the safety of intrapleural administration of this MV-NIS in patients with malignant pleural mesothelioma.

Another interesting approach is the retroviral delivery of a multidrug resistance pump (*MDR1*) gene into peripheral blood progenitor cells (PBPCs). The rationale behind this is not to kill cancer cells, but to prevent some of the toxicities of an intensive chemotherapy regimen in patients. PBPCs are isolated from the patient, genetically modified ex vivo, and transferred back into the patient. The hope is that introduction of the *MDR1* gene into the patients' PBPCs renders these cells and their offspring resistant to the toxic effects of certain chemotherapeutic agents, by pumping out chemotherapeutic agents before they can exert a cytotoxic effect.[35-39]

Many other strategies have been devised to express prodrug-converting enzymes, or other potentially toxic genes, in cancer cells selectively. Most of these depend on tumor-selective gene expression to drive the gene of interest, such as the promoters for the androgen receptor or prostate-specific antigen (PSA),[40-42] for tyrosinase (selective for melanoma),[43] or for alpha-lactalbumin (selective for breast cancer).[44] More generic tumor-selective–specific promoters include E2F-1, which is upregulated through loss of the RB checkpoint, and telomerase reverse transcriptase (TERT), which is also upregulated in most cancers.[45,46]

Genes That Boost the Immune System

Although oncolytic viruses can kill cancer cells directly via viral replication and by delivery of cytotoxic genes or prodrug-converting enzymes, it is becoming more and more evident that the great potential of viruses as gene therapeutic vectors lies in their immune-modulatory capability. This feature can be further enhanced by the addition of immune-modulatory genes into the viral genome. For virus-based therapies to be successful, both host immune system avoidance and potent immune stimulation need to be combined. One approach to boosting antitumor immune responses involves the administration of cytokines to increase the activity of immune effector cells systemically or to enhance the presentation of antigens in tumor cells themselves. A wide range of cytokine genes have been engineered into an equally wide range of vectors and viruses. IL-2, IL-4, and IL-12 have been studied extensively, as well as interferons, members of the tumor necrosis factor (TNF) family, and granulocyte-macrophage colony-stimulating factor (GM-CSF).

TNF

TNFerade is an exciting example of this approach. This replication-incompetent adenovirus expresses TNF under the control of the Early Growth Response Factor 1 (EGRr-1) promoter, which is strongly activated in response to cellular stress such as iodizing radiation or chemotherapy.[47] TNFerade was injected in Phase I studies to up to 4×10^{11} pu (particle units) without dose-limiting toxicities occurring. In agreement with this favorable safety profile, serum TNF levels remained consistently low. However, in esophageal cancer, relatively high rates of thromboembolic complications occurred that were potentially induced by the study medication. This problem was not observed in trials of this agent in pancreatic cancer. In this disease the maximum tolerated dose (MTD) of TNFerade in combination with chemoradiation treatment was determined to be 4×10^{11} pu. At that dose level, clinical responses and evidence for prolonged median survival were seen in an interim analysis of a Phase III study in locally advanced pancreatic cancer in combination with chemoradiotherapy.[48]

GM-CSF

Of cytokines tested in oncolytic virus and vaccine models so far, GM-CSF seems to be the most potent at generating antitumor immune responses. HSV-, adenovirus-, and vaccinia virus–based vectors encoding GM-CSF have shown great promise in early clinical trials, and studies are still ongoing (see Table 54-2). Arming viruses with GM-CSF aims to activate the immune system primarily by attracting and activating dendritic cells (DCs). GM-CSF has been clinically tested in peptide and whole-cell vaccine strategies as well as oncolytic virus approaches. Notably, only virus-based

GM-CSF expression seems to generate a potent and sustained antitumor immune response, suggesting that the context in which GM-CSF is expressed is crucial. Virus-based GM-CSF expression and DC recruitment are tightly coupled to tumor cell death and subsequent release of a vast array of tumor antigens. Remarkably, for both HSV and vaccinia expressing GM-CSF, not only injected but also noninjected tumors responded. The studies mentioned earlier are among the first to combine oncolysis with immune system activation using armed, replication-competent viruses. Further exploitation of the immune system is a focus of current gene therapy and vaccine studies.[49]

Naturally Occurring Viruses That Replicate Selectively in Cancer Cells

Cancer cells provide an environment that is permissive for replication of a number of naturally occurring viruses. This is because checkpoints and defense mechanisms are disabled in cancer cells, allowing them to grow and survive and to evade detection by the immune system. In some cases these mechanisms are also used to defend normal cells against virus replication. Cancer cells may therefore be vulnerable to virus infection while normal cells are protected. Because infection usually leads to cell death, this vulnerability could potentially be exploited for cancer therapy. Indeed, several naturally occurring viruses are under clinical evaluation in a variety of cancer indications (see Table 54-2).

Reovirus

Reoviruses replicate selectively in many cancer cells. During infection of normal cells, their double-stranded RNA genomes activate a cellular protein kinase (PKR) that restricts viral replication by blocking translation of viral mRNA. For reasons that are unclear, this kinase activity is suppressed in cancer cells in which the Ras pathway is hyperactivated, allowing productive viral replication.[50] Based on this selectivity, and the capacity of reoviruses to replicate quickly and kill infected cells, reoviruses are undergoing clinical evaluation. One of these, Reolysin, is being tested in Canada, the United Kingdom, and the United States using clinical protocols that include local or systemic delivery of Reolysin as a monotherapy, and local delivery in combination with radiation therapy for patients with advanced cancers. Intravenous administration of this virus was well tolerated in a Phase I study. Although no objective tumor responses were observed, disease stabilization of up to 6 months was observed in a subset of patients.[51]

Vesicular Stomatitis Virus

The rhabdovirus vesicular stomatitis virus (VSV) has a single-stranded RNA genome. Selectivity for cancer cells is thought to be the result of their failure to elicit a protective interferon response, thus allowing lytic replication. VSV variants with mutations in the matrix (M) protein enhance VSV's effectiveness, at least in animal models.[52] Systemic delivery of VSV has been shown to be effective and safe against laboratory models of multifocal and invasive malignant gliomas.[53] M protein mutant viruses have also shown efficacy against prostate cancer cell lines and others.[52]

Measles

Measles viruses, like VSV, contain negative-stranded RNA genomes but are members of the paramyxovirus family. Replication-competent attenuated Edmonston B measles vaccine strain (MV-Edm) is nonpathogenic and has potent antitumor activity against several human tumors. The virus is selectively oncolytic, eliciting extensive cell-to-cell fusion and ultimately leading to cell death. An attenuated strain of MV has been genetically engineered to produce carcinoembryonic antigen, which can be used as a serum marker of virus replication.[12] This virus had potent antitumor activity against gliomas in vitro, as well as in animal models.[54] This virus is undergoing clinical evaluation in patients with glioblastoma multiforme and multiple myeloma.

Newcastle Disease Virus

Lytic strains of the avian paramyxovirus Newcastle disease virus (NDV) selectively kill cancer cells in culture and in mouse models.[55] The molecular basis of selectivity is not fully understood, but appears to be facilitated by high levels of N-myc, at least in neuroblastoma cells. Cytotoxicity is due to multiple caspase-dependent pathways of apoptosis independent of interferon signaling competence.[55,56] Several Phase I studies of intravenously infused NDV have been performed using various doses and administration schedules.[57,58] Main toxicities included moderate flu-like symptoms and mild gastrointestinal symptoms. Interestingly, a two-step intrapatient dose-escalation of the NDV strain PV701 aiming at desensitizing resulted in significant reduction of the intensity of adverse events. Patients developed only moderate levels of neutralizing antibodies, and the serum clearing of virus was not significantly different during the course of treatment.[59] Disease stabilization as well as objective tumor responses were observed in Phase I studies, in particular in patients

who had received higher doses. A complete remission was observed in a patient with glioblastoma multiforme treated with the NDV strain NDV-HUJ.[57]

Viruses Engineered to Replicate Selectively

In addition to naturally occurring viruses, many efforts have been made to engineer viruses to replicate in tumor cells selectively. Such agents kill cells through lytic mechanisms and potentially spread from one infected cell to another, amplifying the dose of the selective killing agent. Selectivity for cancer cells can be achieved by several strategies. The first uses DNA synthetic enzymes produced by proliferating tumor cells to support replication of DNA viruses that are otherwise defective. The second takes advantage of genetic defects in cancer cells that supply functions that have been specifically deleted from the oncolytic agent, and the third uses tumor-selective promoters to drive replication of conditionally replicating viruses.

Herpes Simplex Viruses

One of the first viruses designed to replicate in cancer selectively were HSVs that had been engineered so that they were unable to express viral genes necessary for DNA replication, such as thymidine kinase or ribonucleotide reductase. Proliferating cells would provide these essential functions, whereas resting normal cells would not. HSV G207 is an example of such an oncolytic virus. In addition to inactivation of a subunit of the viral ribonucleotide reductase gene, both copies of the neurovirulence gene, the gamma(1)34.5 gene, are deleted to further reduce replication in normal tissues.[60] Although direct tumor cell killing represents a major mechanism of action of these viruses, evidence from experiments in immunocompetent mouse models suggests that also a vaccination effect mediated by activated T lymphocytes contributes to the effect.[61] Phase I clinical trials of G207 and a related virus, HSV1716, have been completed and demonstrated the safety of these viruses.[62] Another related HSV mutant, NV1020, has been tested in a Phase I study in patients with hepatic metastases from colorectal cancer. The virus was administered into the hepatic artery in a Phase I study. Only mild toxicity was observed, and a decline in CEA levels was suggestive of some antitumor activity.[63] Many innovative approaches have been employed to improve the clinical value of HSV viruses, including expression of prodrug-converting enzymes to elicit bystander cells and the addition of genes encoding cytokines to boost immune recognition of tumor cells. The latter approach has been taken into the clinic in the form of the HSV mutant OncoVex(GM-CSF), a conditionally replicating HSV-1 mutant that expresses the cytokine GM-CSF. A Phase I/II trial with intratumorally injected Oncovex GM-CSF demonstrated that this agent is well tolerated.[64] Side effects included mainly fever, flu-like symptoms, and inflammation at the injection site. Clinical evidence for tumor necrosis was found; however, no detailed objective response assessments have been published at this point.

Vaccinia

Using a similar strategy, attenuated strains of another large DNA virus, vaccinia, have been created and shown to replicate selectively in cancer cells.[65] Vaccinia virus (VV) strains have several attributes that render them ideally suited for their use as oncolytic agents. First, VV vectors are derived from vaccine strains that have been used safely in millions of children worldwide for immunization against smallpox. Thus, their safety profile, genetic stability, and other pharmacological parameters are extremely well documented. Second, these viruses have several suitable biological properties: vaccinia has evolved mechanisms for stability in the bloodstream and spread to distant sites, including resistance to antibody and complement-mediated neutralization. Moreover, because of their relatively large size (about 200 nm), vaccinia virions preferentially accumulate in tumor tissues, where neovasculature has increased permeability ("leaky tumor vasculature"). The relatively large size also results in a large transgene capacity (25 to 50 kb), which allows for the expression of several therapeutic and monitoring genes. Last but not least, VV replication is promoted by EGFR/Ras pathway signaling,[66,67] which is frequently hyperactivated in cancer cells. A genetically engineered vaccinia that has shown great promise in recent clinical trials is JX-594.[68] This virus is a derivative of a smallpox-vaccine strain carrying an inactivated *TK* gene to increase tumor specificity, and two transgenes: one encoding GM-CSF to stimulate antitumor immune responses and the other β-galactosidase, as a surrogate marker for viral gene expression. JX-594 has demonstrated great success on local-regional and intravenous delivery to patients in terms of safety, cancer selectivity, oncolysis, chemosensitization, and induction of immune and antitumor responses (Figure 54-1, Table 54-3). Notably, in a Phase I clinical trial, intravenously delivered JX-594 was capable of replicating selectively in metastases from a variety of tumor types, representing a milestone in the development of oncolytic agents for systemic administration. Moreover, intravenous JX-594 therapy led to a reduction in the outgrowth of new metastases in patients over time. Seven Phase I and II clinical trials are currently ongoing to test this agent's safety and efficacy further in various solid tumors.[69,70]

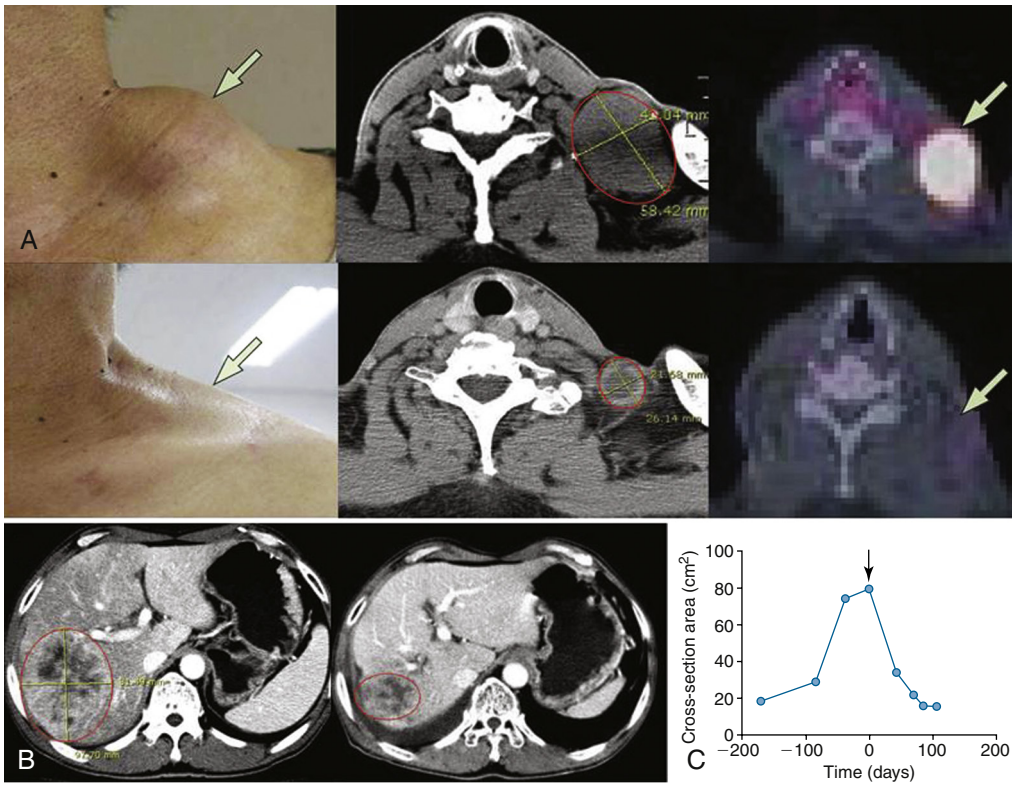

Figure 54-1 Representative tumor response to JX-594 treatment **(A)** Patient 201 with a primary hepatocellular carcinoma received direct intratumoral injections into the liver tumor, which led to a RECIST PR. Direct injection of a previously noninjected tumor in the neck, after four previous cycles of JX-594 treatment in the liver, led to RECIST and Choi response at this site as well, despite the presence of high concentrations of neutralizing antibodies to JX-594. Physical examination and CT and PET-CT scans of the metastatic tumor in the neck region, before and after induction of high-titer antibodies, illustrate this response. **(B, C)** Patient 103 with metastatic squamous cell carcinoma of the lung received six rounds of JX-594 intratumoral injections. **(B)** CT scan and **(C)** tumor cross-section areas before and after treatment. *Arrow* indicates initiation of JX-594 treatment. *CT,* Computed tomography; *PET,* positron emission tomography; *PR,* partial response; *RECIST,* Response Evaluation Criteria in Solid Tumors. *(Adapted from Park BH, Hwang T, Liu TC, et al. Use of a targeted oncolytic poxvirus, JX-594, in patients with refractory primary or metastatic liver cancer: a phase I trial.* Lancet Oncol. *2008;9:533-542.)*

Table 54-3 Representative Patient Response to JX-594

Patient ID	Tumor	Injected	Response	
			RECIST*	Choi criteria**
201	Primary tumor: hepatocellular carcinoma (HCC)	Yes	Partial response (PR)	+ (30% decrease in diameter)
	Secondary tumor: neck	Yes	PR	+ (57% decrease in diameter; see Figure 54-1A)
103	Primary tumor: lung squamous cell carcinoma	Yes	PR	+ (51% decrease in diameter; see Figure 54-1B, C)
	Metastasis: liver	No	Stable disease (SD)	+ (22% decrease in HU†)

Adapted from Park BH, Hwang T, Liu TC, et al. Use of a targeted oncolytic poxvirus, JX-594, in patients with refractory primary or metastatic liver cancer: a phase I trial. *Lancet Oncol.* 2008;9:533-542.
*RECIST: Response Evaluation Criteria in Solid Tumors: Partial response (PR) is a maximum diameter decrease of ≥30%, progressive disease (PD) is an increase of ≥20%, and stable disease (SD) is a change in diameter between these two cutoffs.
**Choi criteria: response (+) is maximum diameter decrease of ≥10% or density decrease of ≥15%.
†HU: Hounsfield units, also CT units: related to the composition and nature of the tissue imaged, represents the density of tissue.

Adenovirus

Whereas G207 and related viruses were engineered to take advantage of permissive conditions in cancer cells relative to quiescent cells, ONYX-015 was designed to exploit lack of functional p53 in tumor cells. ONYX-015 is an adenovirus that lacks the E1B 55K gene. This gene encodes a protein that binds p53 and targets it for degradation. In the absence of E1B 55K, ONYX-015 was expected to replicate poorly in normal cells, in which functional p53 could abort lytic,

productive replication. In contrast, cancer cells should be permissive for ONYX-015 because E1B 55k should be unnecessary in cells that lack p53.[71]

Extensive analysis of the molecular mechanisms underlying ONYX-015 replication revealed that the virus does indeed replicate selectively in tumor cells. Whereas replication of this virus is mediated through the p53 pathway, tumor selectivity is mostly based on the ability of tumor cells to complement other functions of E1B 55K unrelated to p53.[72-74] These functions relate to the ability of E1B 55K to facilitate the export of viral mRNAs and shut down host protein synthesis. Nonetheless, ONYX-015 advanced to Phase III trials in the United States, after encouraging signs of safety and efficacy. The analysis of clinical tumor specimens obtained following injection of ONYX-015 provided unambiguous evidence for its tumor selectivity. Replicating virus was found (1) in head and neck cancer following intratumoral injection, (2) in liver metastases from gastrointestinal cancer after intra-arterial injection, and (3) in lung tumors following intravenous injection.[75-77] Furthermore, objective tumor responses were observed in several clinical Phase II studies. Single-agent treatment with ONYX-015 induced objective responses in 14% of patients with recurrent head and neck cancer.[77] In a subsequent study, the virus was combined with standard chemotherapy. Only a single tumor was injected with ONYX-015, leaving a subgroup of patients with additional uninjected control lesions. Interestingly, the response rate of tumors injected with the virus was significantly greater than those of noninjected lesions, and the time to progression was significantly longer for injected tumors.[75] Further evidence of antitumor activity of ONYX-015 was found in three patients with 5-FU/leucovorin-refractory liver metastases from colorectal cancer that experienced minor responses (30% to 48% shrinkage) following intra-arterial infusion of ONYX-015 into the hepatic artery.[78]

Meanwhile, a closely related adenovirus, H101, has recently been developed by Shanghai Sunway Biotech and approved for treatment of head and neck cancer in China[3] after a clinical Phase III study demonstrated a dramatically higher tumor response rate in patients who had received H101 in combination with cisplatin and 5-fluorouracil (78.8% versus 39.6%, respectively).[79]

Delta-24 (also known as *dl*922-947 or ONYX-838) is another adenovirus mutant that targets cancer cells selectively.[80] The E1a region contains a small deletion that prevents binding to RB. As a result, this virus cannot replicate efficiently in normal cells, because RB represses E2F activity that is essential for replication (in addition to transcribing genes involved in DNA synthesis, E2F activates transcription of the viral E2 region; this is how E2F was first named and identified). In cancer cells, E2F activity is not repressed by RB, because RB itself is mutated or inactivated indirectly through loss of p16INK4a, amplification of cyclin D1, or by other means. Tumor cells therefore provide a permissive environment for replication of Delta-24. A modified version of Delta-24 has entered clinical trials for the treatment of glioblastoma.[81,82] This virus, Delta-24 RGD, has been engineered to increase infectivity by the addition of an RGD sequence in its fiber gene.[83] Likewise, adenoviruses designated KD1 and KD3 contain two small deletions in E1A that abolish its binding to pRB but leave the ability of E1A to transactivate viral genes intact. These have been shown to replicate with great efficiency in tumor cells, but fail to replicate efficiently in normal cells.[84]

A second-generation version of Delta-24 was engineered to express human p53.[85,86] Ad24-p53 more effectively killed most human cancer cell lines tested in vitro than did its parent Ad24 and had significant activity against xenografts in vivo.[85] To further improve potency of this virus, the p53 transgene was engineered so that it is resistant to degradation by Mdm2.[85] Adenoviruses have also been engineered to take advantage of unregulated TCF transcriptional activity, a characteristic of colorectal cancer cells that lack the APC tumor suppressor or contain activating mutations in beta-catenin.[87,88]

An array of creative approaches has been employed to make viruses replicate selectively based on abnormal transcription activity in cancer cells. These include viruses that use unregulated E2F activity resulting from loss of the RB tumor suppressor pathway to drive the E2F-1 promoter, the telomerase promoter, prostate-specific promoters and regulatory elements to drive proliferation in prostate cancer cells, and many others. These approaches have been reviewed recently by Fukazawa and colleagues.[89]

Challenges and Future Perspective

Preclinical Development

Gene therapeutic agents and oncolytic viruses have highly diverse physical and biological properties and act through complex molecular mechanisms, making predictions about their pharmacological and pharmacodynamic behavior in humans difficult. Preclinical model systems are therefore particularly important elements in the selection process for further clinical development.

Mouse xenograft tumor models of human cancer cell lines in nude mice allow for efficient assessment of antitumor activities of novel gene delivery and oncolytic agents in a broad variety of human tumor types. However, these models have significant limitations due to the lack of a functional immune system and differences in structure and composition

of the tumor stroma. To address these limitations, immunocompetent tumor models have been developed. Such models have been instrumental for assessing the impact of immunemodulatory genes in the genome of oncolytic adenoviruses on virus replication and antitumor effect.[90] In addition, orthotopic implantation of allografts in immunocompetent models allows for testing novel vectors in tumors growing an organotypic microenvironment that more closely resembles the situation in humans.[91-93] Despite these improved murine models, limitations remain. For example, normal and malignant mouse tissues only poorly support replication of human adenoviruses. Another example is the difference between the sequences of human and mouse cytokines, which makes the generation of mouse-specific variants of immune-modulatory agents necessary. Other species offer potentially advantageous features. For example, normal and malignant Syrian hamster cells support adenovirus replication. Using this model, intratumoral injection of an oncolytic adenovirus resulted in suppression not only of the primary tumor but also of distant metastases following virus entry into the bloodstream.[94] Similar results were obtained in cotton rats.[95] In addition, replication-competent viruses for use in canine models have been developed.[96]

Biodistribution and systemic effects of novel gene therapy and oncolytic viral agents are fundamentally different from small-molecule or antibody-based anticancer therapies and therefore difficult to predict. To address this, novel in vivo imaging strategies allowing for real-time monitoring of the effects of such agents in animals as well as in humans have been developed and will play a major role in the further development of this therapeutic approach. Distribution of nonviral and viral particles can be directly assessed by radioactive or fluorescent labeling. The biodistribution of liposomes, for example, can be followed after labeling with radioactive isotopes (e.g., ^{99m}Tc) or gadolinium by scintigraphy or magnetic resonance imaging, respectively.[97,98] A variety of strategies have been pursued to monitor viral agents. Green-fluorescent protein and firefly luciferase are transgenes that allow for the detection of cells infected with viruses carrying an expression cassette for either of these genes through the detection of fluorescent light or bioluminescence, respectively—in animal models, at least.[99,100] The use of prodrug-converting enzymes opens the possibility of using the enzyme activity for imaging purposes. The most developed approach is expression of the prodrug converting enzyme HSV-TK, which not only converts ganciclovir into cytotoxic phosphorylated derivatives but also phosphorylates uracil derivatives labeled with radioactive iodine and acylguanosines labeled with radioactive fluorine, which are then also retained within the cell and detectable by positron emission tomography (PET). This approach has been successfully used in a variety of vectors in small animals. Recently, it has also been demonstrated to be an effective imaging strategy in a pilot study in patients with liver cancer.[101] A similar approach involves the vector-mediated delivery of receptors with only limited physiologic expression, such as the dopamine D2 receptor or the somatostatin receptor subtype 2. PET imaging probes for both receptors are already clinically available for imaging of neuroendocrine tumors. A third technology has been developed using the sodium-iodide symporter, which is a transmembrane transporter protein that is physiologically predominantly expressed in the thyroid gland.[102] Ectopic expression of this protein leads to accumulation of radioactive iodine, which can be detected by radionuclide imaging using a gamma camera or PET. The potential advantage of this approach is that cytotoxic radionuclides such as ^{131}I can be used therapeutically.[103]

The complexity of the host-vector interaction and the resulting dynamics of virus and tumor cell replication are theoretically amenable to in silico modeling of virus and tumor cell population dynamics. Such mathematical models created important insights into the kinetics of human immunodeficiency virus (HIV) infection and treatment[104,105] and have been, at a theoretical level, developed for oncolytic viruses and their interaction with tumor cells and the host immune system.[106,107] Experimental validation of these models is currently being actively pursued by several laboratories.

Safety and Toxicity

The use of viruses either as vectors for the delivery of therapeutic genes or, in mutant form, as therapeutics themselves raised significant concerns not only in regard to the safety of individuals treated with such agents but also because of the potential risks for others. In particular, the occurrence of recombinant viruses that regain wild-type properties or demonstrate even greater toxicity was feared. For this reason, extensive safety studies were performed. For example, the biohazard potential of AdCMV-p53 was investigated in France in the context of clinical trials of this virus in head and neck cancer. No evidence for any environmental risk from intratumoral injection of the virus was found.[108]

Immune and Cytokine Response

A major concern with respect to the use of viral particles as therapeutic agents is the induction of neutralizing antibodies that could limit the efficacy of such agents. In the case of adenovirus this is of particular relevance, as at least 50%

of patients present with preexisting antibodies against adenovirus type 5, resulting from earlier infections.[75-78,109,110] It is therefore not surprising that almost all of the patients treated with viral agents developed high titers of neutralizing antibodies following the first administration of the virus. Preclinical studies suggest that the presence of such antibodies might reduce the efficacy of adenoviral treatments.[111] At this point, this has not been clearly demonstrated clinically. In contrast, following intra-arterial infusion of ONYX-015 into the hepatic artery or intravenous administration, the virus was cleared rapidly from the bloodstream.

Improving Tumor Killing by Improving Tumor Cell Access

Viral vectors and oncolytic agents have been engineered to improve their ability to infect cancer cells, either to increase selectivity or to increase potency. Adenoviruses have been the focus of many of these efforts. This is because it is believed that the utility of adenovirus vectors is limited because of the low expression of CAR, the high-affinity receptor that is necessary for efficient attachment to the cell membrane.[112] This is of particular concern in many advanced cancers, in which CAR levels are often low relative to normal cells or well-differentiated cancers.[113,114] Many attempts have been made to address this problem. Wickham and co-workers[115] modified the C terminus of the adenoviral fiber protein by the addition of either an RGD-containing peptide or seven lysine residues. Dmitriev and colleagues[116,117] have also shown that the incorporation of an RGD-containing peptide in the H1 loop of the fiber knob domain results in the ability of the virus to utilize an alternative receptor during the cell entry process. The modified virus was able to infect primary tumor cells and tumor cell lines more efficiently than unmodified virus.[116,118] The RGD/fiber modification was subsequently introduced into the Delta-24 virus, described above. Gu and associates have successfully redirected cell binding and uptake of an adenovirus through fibroblast growth factor receptors (FGFRs), suggesting that redirecting the native tropism of adenovirus may offer therapeutic benefit.[119]

Conclusion

Virotherapy and other gene-therapeutic approaches represent a novel class of targeted anticancer agents that is distinct from traditional treatment modalities.

The initial focus of this field was to invent and test new agents that kill cancer cells selectively, based on the genetic lesions that cause this disease. This goal has been achieved using a rich variety of viruses, vectors, genes, and approaches, in laboratory and animal model settings. Some of these approaches have been translated into clinical research projects; however, until very recently, clinical results have been disappointing in terms of increased survival or meaningful patient benefit.[120] Although most treatment regimens have shown great safety, some early gene therapeutic trials raised serious concerns in this regard—the death of a patient with ornithine transcarbamylase deficiency, and the leukemia caused by gene therapy in four severe combined immunodeficiency (SCID) patients.[121] These rare adverse effects and the initial lack of compelling clinical activity, together with the potential risk and cost of manufacturing these agents, has dampened the initial enthusiasm in this field, as well as interfered with significant investments. However, substantial advances in our understanding of cancer biology and validation of targets, as well as the promise shown by some of the very recent gene therapeutic clinical trials, have led to a paradigm shift: anticancer gene therapy is now on an upswing again.

Nonetheless, significant hurdles still exist and need to be addressed. One of the biggest remaining challenges is delivery, including delivery to the tumor site, spread within the tumor, undesired clearance by the liver, neutralizing antibodies, and complement. Another significant difficulty for many of the approaches currently in development is the lack of appropriate preclinical models.

For gene therapy strategies to be clinically successful, they likely have to be included in multimodality treatment approaches and go far beyond killing cancer cells: they need to be anti-angiogenic and immune-modulatory, and they must prevent or overcome resistance to therapy. Intelligent vector design and clever combination regimens will, it is hoped, bring us closer to achieving this goal. Recent studies have demonstrated synergistic effects of combination therapies consisting of conventional chemo- or radio- and virotherapy. Moreover, combinatorial therapies with more "modern" approaches, such as the use of nanotechnology and cellular carriers, hold great promise. For instance, polymer-coated adenoviruses have shown a significantly enhanced half-life when compared to naked viruses, and the use of appropriate cellular carriers has been demonstrated to improve delivery and induction of desirable immune responses against the tumor.

Furthermore, clinical studies will likely yield better patient benefits and increase the chance for approval if factors can be pinpointed that predict efficacy—such as tumor type, histology, and molecular signatures.

Taken together, the recent advances in cancer biology, virology, biotechnology, and nanotechnology, as well as interdisciplinary collaborations, will expedite the development of this therapeutic platform and, we can hope, improve patients' lives in the very near future.

RNA as a Therapeutic Molecule

Cancer represents the most complex genetic disease. Despite decades of investigation and the expenditure of vast resources, mortality from cancer has not decreased significantly worldwide, particularly in developed countries.[1] Many explanations have been offered, but the basic point is that we do not yet deeply understand the mechanisms by which tumorigenesis occurs. A decade ago, a new layer of genetic complexity was discovered in malignant cells by the addition of noncoding RNAs (ncRNAs; RNAs that do not code for proteins) to the list of cancer genes, and exploiting this research could provide a great treatment opportunity. Globally, during the most recent 5 years for which there are data available (2004 to 2008), overall cancer incidence rates declined slightly in men (by 0.6% per year) and were stable in women, while cancer death rates decreased only by 1.8% per year in men and by 1.6% per year in women.[1] This was largely because of the advances in early detection of breast cancer and the reduction in tobacco use over the past four decades; the therapeutic advances were less significant. For example, the oligoantisense strategy was considered for many years as an optimal alternative for developing drugs to inhibit the proteins overexpressed in cancer cells (for a review, see Reference 2). This is the case with the BCL2 antisense oligonucleotide (ASO[3,4]), but until now no other ASO agents had shown consistent and reproducible beneficial effects in clinical trials. Various publications in the past decade reported clinical studies regarding trials in Phase II (to determine whether a new treatment works) or III (to study whether a new treatment is better than standard treatment) performed on more than 1000 patients using aprinocarsen (Affinitak, LY 900003, ISIS 3512; Isis Pharmaceuticals, Carlsbad, Calif[5-10]). This is a 20-mer oligonucleotide acting as an ASO that binds to the 3′ untranslated region (3′-UTR) of human messenger RNA (mRNA) for protein kinase Cα (*PKCa*). It acts by forming an mRNA-ASO duplex through Watson-Crick binding, and it leads to RNAse-H–mediated cleavage of the *PKCa* mRNA. In all trials but one, no significant effects were identified in patients with advanced non–small-cell lung cancer, metastatic colorectal cancer, or relapsed low-grade non-Hodgkin lymphoma. Therefore, there are major reasons for developing new therapeutic modalities to cure cancer.

Cancer as a Genetic Disease of Protein-Coding Genes and Noncoding RNAs

Why the need for RNAs as therapeutic molecules? One of the most unexpected and fascinating discoveries in the past few years in molecular oncology is that in a specific tumor, abnormalities in both protein-coding genes (PCGs) and ncRNAs can be identified, and the interplay between them is causally involved in the initiation and progression of human cancers.[11-13] The "classic" molecular oncology dogma was that cancer is a genetic disease involving tumor suppressor and oncogenic proteins. Recent findings that small noncoding RNAs called microRNAs (miRNAs) are involved in the pathogenesis of most cancers reveal a new layer of complexity in the molecular architecture of human cancers (Table 55-1).

MicroRNAs represent a new class of small ncRNAs able to regulate gene expression.[14,15] MicroRNAs are distinct from, but related to, small interfering RNAs (siRNAs), which have been identified in a variety of organisms (for reviews, see References 15 and 16). These small 19- to 24-nucleotide (nt) RNAs are transcribed as long primary transcripts of several kilobases (kb) in length, named pri-miRNA. Pri-miRNAs are processed in the nucleus into precursor hairpin RNAs (70 to 100 nt in length) named pre-miRNA by the double-stranded RNA-specific ribonuclease Drosha.[17] The hairpin RNAs are transported to the cytoplasm, via an exportin-5–dependent mechanism, where they are digested by a second double-stranded specific ribonuclease named Dicer. In animals, single-stranded miRNAs bind specific mRNA through a low complementary binding site located in the target mRNA, mainly at their 3′ UTR.[14] By a mechanism that is not fully characterized, the bound mRNA remains untranslated, resulting in reduced levels of

Table 55-1 MicroRNAs as Oncogenes and Tumor Suppressors (Main Examples)

Human microRNA (location)	Putative Function/Involved Pathways	Deregulation in Tumors	Putative Functions and Targets	Molecular Regulation	Diagnostic and Prognostic Markers
let-7 family (various)	*Anti-tumorigenic:* Self-sufficiency in growth signals Insensitivity to antigrowth signals Angiogenesis	Downregulation in lung, breast, gastric, ovary, prostate, and colon cancers, CLL, and leiomyomas Downregulation of *miR-98* in head and neck cancer cells Point mutation in the *let-7e* precursor sequence affects maturation	*Molecular mechanism:* Represses cell proliferation/growth *let-7f* promotes angiogenesis *Targets:* CCND1, CDC25a, CDK6, CRD-BP, HOXA9, IMP-1, MYC, RAS, TLR4	*Regulation:* MYCN positively regulates *let-7b* transcription PPARalpha inhibits *let-7c* transcription Notch pathway regulates *let-7a* *mmu-let-7a* is highly edited after transcription LIN-28 regulates the maturation of *let-7a*	*Poor prognosis:* *let-7a-2* low expression (lung and ovarian cancer patients) *let-7b* discriminates high-risk uveal melanomas *Drug resistance:* *let-7i* affects chemotherapy potency *Therapy:* Intranasal delivery of *let-7a* adenovirus reduces growth of Ras-induced lung tumors in mice
	Oncogenic: Self-sufficiency in growth signals Apoptosis	Hypomethylation of *let-7a-3* in lung adenocarcinomas Overexpression in AML	*Molecular mechanism:* *let-7a* represses NF2 and decreases chemotherapy-induced apoptosis in vitro	*Regulation:* IL-6 dependent STAT-3 survival signaling positively regulates *let-7a*	
miR-16-1/15a cluster (13q14.3, intron 4 ncRNA *DLEU2*)	*Anti-tumorigenic:* Self-sufficiency in growth signals Evasion of apoptosis	Downregulation in CLL, DLBCLs, multiple myeloma, pituitary adenoma, prostate, and pancreatic cancers Germline mutations in B-CLL patients and NZB mouse strain	*Molecular mechanism:* Induce apoptosis in leukemia cells *miR-16* regulates cell cycle by downregulation of G0/G1 proteins *Targets:* ACVR2A (*X. tropicalis*), BCL2, CARD10, CCND1, CDK6, CDC27, CGI-38, DMTF1, MCL1, NGN2, VEGF, WNT3A	*Regulation:* Wnt/βcatenin pathway negative regulates *xtr-miR-15a/16*	*Poor prognosis:* *miR-15a* and *miR-16* higher expression in de novo aggressive CLL *Drug resistance:* *miR-16* affects chemotherapy potency and modulates sensitivity to vincristine in gastric cancer cell lines
miR-21 (17q23.1, 3′UTR TMEM49)	*Oncogenic:* Self-sufficiency in growth signals Evasion of apoptosis Invasion and metastasis	Overexpression in glioblastomas; breast, lung, prostate, colon, stomach, esophageal, and cervical carcinomas; uterine leiomyosarcoma; and DLBCL	*Molecular mechanism:* *miR-21* knockdown induces apoptosis in glioblastoma cells *miR-21* induces invasion and metastasis in colorectal cancers *Targets:* BCL2, MASPIN, PDCD4, PTEN, TPM1, RECK	*Regulation:* STAT3 regulates *miR-21* at the transcriptional level REST negatively regulates mir-21 in mouse ES TGFβ and BMP promote mir-21 maturation in human vascular smooth muscle cells AP-1 induces mir-21 in response to RAS activation in thyroid cells	*Poor prognosis:* *miR-21* high expression (in colon and breast cancer) *Good prognosis:* *miR-21* high expression in de novo DLBCL *Drug resistance:* *miR-21* affects chemotherapy potency in NCI60 cells
miR-155 (21q21.3, exon 3 ncRNA BIC)	*Oncogenic:* Evasion of apoptosis	Overexpression in pediatric BL, Hodgkin's disease, primary mediastinal lymphomas, and DLBCL, as well as in breast, lung, colon, and pancreatic cancers	*Molecular mechanism:* Pre–B-cell proliferation and lymphoblastic leukemia/high-grade lymphoma in *miR-155* transgenic mice *Targets:* AGTR1, AID, TP53INP1		*Poor prognosis:* *miR-155* high expression (in lung cancer, DLCBL, and aggressive CLL)

AML, Acute myeloid leukemia; *BL*, Burkitt's lymphoma; *CLL*, chronic lymphocytic leukemia; *DLBCL*, diffuse large B-cell lymphoma; *ES*, Ewing sarcoma.

the corresponding protein—and/or the bound mRNA can be degraded, causing a decrease in the transcript and consequently, in the corresponding protein. The role of miRNAs was proven to be important in essential biologic processes for the eukaryotic cell such as pancreatic cell insulin secretion (*miR-375*), adipocyte development (*miR-375*), cell proliferation control (*miR'125b* and Iet-7), brain patterning (*miR-430*), hematopoietic B-lymphocyte lineage fate (*miR-181*), or B-lymphocyte survival (*miR-15a* and *miR-16-1*).[12,13]

MicroRNAs were found to be involved in the pathophysiology of all types of analyzed human cancers.[18] Among the new paradigms of molecular oncology are the following:

1. Several genome-wide profiling techniques (for review, see References 13, 19, and 20), such as oligonucleotide miRNA microarray, bead-based flow cytometric technique, and quantitative reverse-transcriptase-polymerase chain reaction (qRT-PCR) for precursor and active miRNA or the miRAGE (serial analyses of gene expression for miRNAs), were performed on various cancer histotypes, including chronic lymphocytic leukemia (CLL), breast cancer, glioblastoma, thyroid papillary carcinoma, hepatocellular carcinoma, lung cancer, colon cancer, and endocrine and exocrine pancreatic tumors. From these studies it has become clear that in cancer cells the main alteration of the microRNome (defined as the full complement of microRNAs present in a genome) is represented by aberrant gene expression, consisting of abnormal levels of expression for mature and/or precursor miRNA sequences compared with the corresponding normal tissues.
2. Germline and somatic mutations in miRNAs[21] or polymorphisms in the protein coding mRNAs targeted by miRNAs[22] may also contribute to cancer predisposition, initiation, and progression. In somatic cells, miRNA alterations could initiate or contribute to tumorigenesis, whereas germline mutations could represent cancer-predisposing events.
3. MiRNA profiling achieved by various methods has allowed the identification of signatures associated with diagnosis, staging, progression, prognosis, and response to treatment of human tumors (for review, see Reference 13). Therefore, miRNA "fingerprinting" represents a new addition to the diagnostic and prognostic tools to be used in medical oncology.

Other types of ncRNAs (such as ultraconserved genes [UCGs] and long intergenic noncoding RNAs [lincRNAs]) have also been linked to human cancers.[23] One of the most intriguing characteristics of miRNAs is the near-complete conservation of orthologous genes. For example, the active molecules of the *miR-16-1/miR-15a* cluster, shown to be an essential player in the initiation of CLL,[21] are completely conserved in humans, mice, and rats and highly conserved in 9 of 10 primate species sequenced. Comparative sequence analysis represents an essential tool in the identification of genomic DNA regions with important biologic functions. Several of these highly conserved genomic sequences were considered not genic (not producing a transcript) and were called *conserved nongenic sequences*.[24] A special subset of conserved sequences named *ultraconserved regions* (UCRs) include, by definition, intra- and intergenic sections of the human genome that are absolutely conserved (100% identical with no insertions or deletions) between orthologous regions of the human, rat, and mouse genomes.[25] Because of the high degree of conservation, the UCRs have been demonstrated to have fundamental functional importance for the ontogeny and phylogeny of mammals and other vertebrates. Recently, it was proved that most UCRs are transcribed and that hundreds of UCGs are consistently altered in a significant percentage of analyzed leukemias and carcinomas. UCGs are frequently located at fragile sites and genomic regions involved in cancers. It has also been proven that the inhibition of an overexpressed UCG induces apoptosis in colon cancer cells, and that the expression of some UCGs may be regulated by miRNAs abnormally expressed in CLL.[26] These new regulatory mechanisms support a model in which various types of noncoding genes are actively involved and cooperate with protein-coding genes in human tumorigenesis. Gathering all these notions together makes it clear that noncoding RNA genes, once seen as second-level genomic elements, are now at the center of attention in cancer research. Therefore, it is reasonable to attempt to expand the anticancer ammunition with RNA molecules capable of attenuating or completely abolishing the function of overexpressed ncRNAs—or, alternatively, to reexpress at physiologic levels the deleted or downregulated ncRNAs.

Main Types of Therapeutic RNA Molecules

Three different types of RNA molecules—the ribozymes, the siRNAs, and the anti-miRNA agents—have passed preclinical testing for efficiency in downregulating a target and now are entering clinical trials. At least two more types of RNA molecules recently added to the expanding list of anticancer ammunition—the miRNA-mimic agents and the 8-mer anti-miRNA LNA (locked nucleic acid) molecules—are going through preclinical tests. The antisense oligonucleotide (ASO) strategy was primarily developed using DNA molecules (for detailed discussion, see References 2 and 27). Although the history of RNAs as therapeutic

Table 55-2 Glossary of Terms in RNA-Inhibition Strategies

ASO: An antisense oligonucleotide is a single-stranded, chemically modified DNA-like molecule that is 17 to 22 nt in length and designed to be complementary to a selected messenger RNA and thereby specifically inhibit expression of that gene.
Messenger RNA (mRNA): The form of RNA that mediates the transfer of genetic information from the cell nucleus to ribosomes in the cytoplasm, where it serves as a template for protein synthesis. It is synthesized from a DNA template during the process of transcription.
Noncoding RNAs (ncRNAs): Any RNA molecule that is not translated into a protein.
Open reading frame (ORF): A section of a sequenced piece of DNA that begins with an initiation (methionine ATG) codon and ends with a nonsense codon. ORFs all have the potential to encode a protein or polypeptide; however, many may not actually do so.
Phase III clinical trials: Designed to study whether a new treatment is better than standard treatment by including hundreds of patients in the study and control groups.
Phase II clinical trials: Designed to determine whether a new treatment works by including tens of patients in the study or control groups.
Pol II: RNA polymerase II (also called RNAP II) catalyzes the transcription of DNA to synthesize precursors of mRNA and most small nuclear RNA.
Pol III: RNA polymerase III (also called RNAP III) transcribes DNA to synthesize 5S rRNA and other small RNAs. The genes transcribed by RNA Pol III fall in the category of "housekeeping" genes whose expression is required in all cell types and most environmental conditions.
Sense/antisense: Referring to the strand of a nucleic acid that directly specifies the product or referring to the strand of a double-stranded molecule that does not directly encode the product but is complementary to it.
Transcription: The process whereby RNA is synthesized from a DNA template.
Translation: The process of protein synthesis whereby the primary structure of the protein is determined by the nucleotide sequence in mRNA. The ribosome-mediated production of a polypeptide whose amino acid sequence is derived from the codon sequence of an mRNA molecule.
Untranslated region (UTR): The 5′ UTR is the portion of an mRNA from the 5′ end to the position of the first codon used in translation. The 3′ UTR is the portion of an mRNA from the 3′ end of the mRNA to the position of the last codon used in translation.
Watson-Crick pairing: The A-T and G-C pairing between the four types of DNA nucleotides.

molecules is two decades long, too few clinical trials have yet been conducted on large numbers of cancer patients to allow any convincing conclusion to be drawn. The first hints are encouraging and support the development of new and larger clinical trials. Most of the clinical and preclinical data were gathered from patients with viral infections, such as human immunodeficiency virus type-1 (HIV) or chronic hepatitis C virus (HCV). For a glossary of terms used in RNA inhibition strategies, see Table 55-2.

Ribozymes

In 1982, the first two ribozymes, the self-splicing intron of the *Tetrahymena* pre-rRNA and the RNaseP, were discovered by Cech's group[28] and Altman's group,[29] respectively. Both shared the Nobel prize in medicine in 1989 for this discovery. A naturally occurring or laboratory-prepared RNA enzyme, ribozyme is an RNA molecule that can catalyze a chemical reaction of substrate cleavage. The mechanism of action consists of three steps that are cyclically repeated. The first is represented by the Watson-Crick base pairing to a complementary target sequence, the second by the site-specific cleavage of the substrate, and the third by the release of the cleavage products. Although there are now seven naturally occurring classes of ribozymes,[30] the most commonly used class of ribozymes as therapeutic agents are the hammerhead (Hh) ribozymes. The Hhs are short-length RNAs, not more than 40 nt long, and are made of two substrate-binding arms plus a conserved catalytic domain of 24 bases.[31]

Angiozyme (RPI.4610; Sirna Therapeutics Inc, Boulder, Colo), an angiogenesis inhibitor, is an Hh ribozyme targeting a conserved region of human vascular endothelial growth factor receptor (VEGFR-1), selectively downregulating the VEGFR-1 by cleavage of its mRNA. It is the first synthetic ribozyme to be tested as a therapeutic agent in human cancer. Angiozyme was used in a Phase I clinical trial as a single agent in patients with biopsy-proven refractory solid tumor and showed promising results. The disease was stable in 25% of 28 eligible patients for a period of more than 6 months, with the longest treatment duration of more than 16 months, and showed no significant adverse reactions.[32] In another study, the same drug was combined with carboplatin and paclitaxel, indicating that this multidrug regimen can be administered in patients with advanced solid tumors with no substantial pharmacokinetic interactions.[33] The most common adverse effects were neutropenia, thrombocytopenia, pain, anemia, and fatigue. Angiozyme was well tolerated after intravenous (IV) infusion or a single subcutaneous (SC) bolus in healthy volunteers.[34] Combined with the data from the Phase I clinical trial, new studies will be designed and conducted to assess efficacy in various human cancers. Furthermore, as inhibition of either VEGFR-l or VEGFR-2

signaling can only partially block tumor angiogenesis and growth, simultaneous inhibition of both VEGFR-l and VEGFR-2 signaling could be highly effective in retarding the growth of some tumors.[35]

One obvious question is why, in spite of years of effort to decipher the structure and function of ribozymes, data accumulated in cancer patients are so scarce. One reason is the sequence specificity requirements of targeted RNAs that limit the amount of putative targets: for example, the Hh ribozymes work at their best on GUC and AUG triplets. Another reason is the limited accessibility of the drug to the mRNA complementary sequence due to the internal base pairing, producing secondary structures, and to the proteins that physically associate with the RNA. Furthermore, differences in targeted mRNA half-lives could affect the efficacy of the silencing, it being easier to eliminate a target with a shorter half-life than targets with a much longer half-life.

To improve the efficiency of ribozymes in cancer cells, a hybrid construct was produced, referred to as maxizyme.[36] This is a dimer of minimized ribozymes (minizymes) that can cleave two target sites located in two different mRNAs. The maxizyme also can allosterically cleave the target RNA only when it recognizes two target sites. For example, two distinct oncogenes, cyclin Dl (*CCND1*) and fibroblast growth factor 4 (*FGF4*, also named *HST-1*), which are overexpressed in breast cancer cells, were used as targets of a maxizyme. *CCND1* activity is required for cell cycle G_1/S transition, whereas *FGF4* is involved in tumor growth and invasion, and therefore blocking these genes could target a wide spectrum of pathways in malignant cells. When conventional ribozymes were used for suppression of expression of these genes, mRNAs in cancer cells and in normal cells were affected, whereas the trans-maxizyme cleaved these mRNAs only in the breast cancer cells. Whether such a drug can have similar results in clinical trials in patients with breast cancer is still an open question.

siRNAs and shRNAs

In 1998 Mello and Fire discovered RNA interference (RNAi) in vertebrates,[37] for which they received the Nobel prize in medicine in 2006. RNAi is a form of posttranscriptional gene silencing (PTG) in which double-stranded RNA (dsRNA), named *siRNA*, catalyzes the degradation of complementary mRNA targets. An *siRNA* is a dsRNA homologous to an mRNA of a target gene. In cytoplasm, the dsRNAs are processed by a complex consisting of Dicer and several other proteins into siRNAs, which are loaded into Argonaute 2 and RNA-induced silencing complex (RISC). The siRNA guide strand recognizes target sites to direct mRNA cleavage, which is carried out by the catalytic domain of AG02. The processing of the siRNAs is similar to that of miRNAs, which is viewed as the "endogenous" process of RNA duplex maturation.[38,39]

A small-hairpin RNA (shRNA) represents an siRNA-like molecule expressed from a vector.[40] DNA cassettes encoding RNA polymerase III promoter-driven siRNA-like shRNAs allow long-term expression of therapeutic RNAs in targeted cells. One advantage over the ribozyme technology is the higher efficiency in targeting specific messengers. For example, when the efficiency of the shRNAs was compared with adenoviral delivery of an anti-MDR1 (multidrug resistance) ribozyme construct, the shRNA's downregulation of mRNA and protein expression was accompanied by a complete inhibition of the pump activity of MDR1 and a reversal of the multidrug-resistant phenotype. The ribozyme construct weakly affects gene expression, confirming that adenoviral delivery of shRNAs is much more effective than adenoviral delivery of ribozymes and that adenovirus-based vectors can be very powerful agents for the efficient delivery of therapeutic RNA molecules.[41]

Oncogenes expressed at abnormally high levels represent the main targets of siRNA-directed therapy. Results from preclinical studies are promising and show clear efficacy. For instance, in a mouse model of ovarian cancers overexpressing the tyrosine kinase receptor *EphA2* gene, the administration of liposomal-delivered siRNA targeting *EphA2* combined with paclitaxel determined a reduction of tumor size greater than 50% with intravenous or intraperitoneal routes of delivery. These data support the idea that chemotherapy and siRNA together can provide a powerful anticancer combination.[42] In another example, adenovirus-mediated siRNA against a *K-ras* mutated messenger (K-ras codon 12 GGT to GTT) markedly decreased *K-ras* gene expression and inhibited cellular proliferation of lung cancer cells that express the relevant mutation, but produced only minimal growth inhibition in cells that lack the specific abnormality.[43]

Although there are promising preclinical data, siRNA cancer therapy is overshadowed by few, but significant, concerning issues. The first involves the low bioavailability: in aqueous solution, siRNAs are extremely hydrophilic and heavily hydrated because of the exposure of the sugar-phosphate backbone to water, thus reducing their diffusion to the target tissue. Furthermore, because of degradation by serum nucleases, the in vivo half-lives of siRNAs are short. Chemical modifications of siRNAs to overcome these deficiencies include the conformationally "locked" nucleotide analog (LNA), which substantially increases the serum stability, without adversely affecting interactions with cellular silencing machinery. Introduction of a 2′-*O*-methyl group (2′-*O*-Me) and 2′-fluoro nucleotides enhances plasma stability and increases potency by several hundredfold in vivo

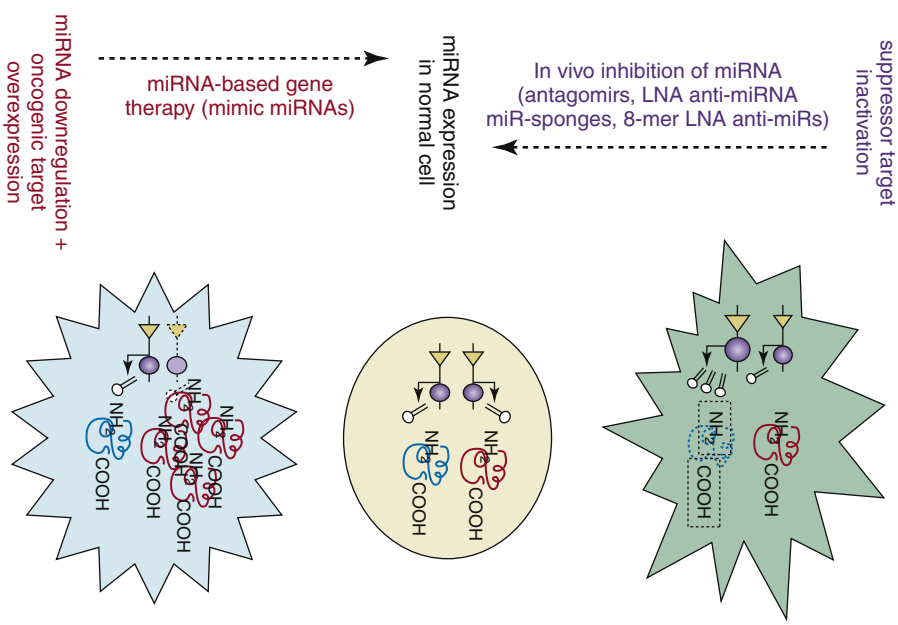

Figure 55-1 MicroRNAs (miRNAs) and anti-miRNAs as new therapeutic agents The type of therapeutic intervention is different with respect to the type of genetic alteration. If overexpressed, agents that specifically reduce miRNA expression to normal levels should be used, whereas if downregulated, agents that restore miRNA expression must be used. *(Modified from* Pharmacogenomics. *2007;53:521-537.)*

over the unmodified, "naked" siRNAs.[44] Another unsolved problem is represented by off-target effects (OTEs), meaning that, in addition to the complementary target, a specific siRNA can induce the silencing of several other imperfect complementary mRNAs that can be important for cell homeostasis. OTEs have been demonstrated by transcriptional profiling studies, and the nonspecific genes differentially expressed between treated and nontreated cells contain complementary regions to one of the two strands in the siRNA duplex. Chemical modification of nucleotides within this region of homology, by the introduction of a 2′-O-Me group, reduces the OTE without decreasing the silencing activity on messenger RNAs. Finally, a major concern is the stimulation of the innate immune system and the production of high amounts of interferon in response to siRNA duplexes. Sugar modifications (such as 2′-*O*-Me) and LNAs seem to reduce the immunostimulatory effects of siRNAs (for a comprehensive review of this topic, see Reference 44).

ASOs/AMOs Anti-miRNAs, LNAS Anti-miRNAs, and Antagomirs

A rationale for considering miRNAs as potential therapeutic targets is offered by the fact that miRNA overexpression in cancer cells has a pathogenic effect (see preceding sections). Therefore, several types of agents targeting miRNAs are now under development and ready to be tested for their in vivo effects and in clinical trials (Figure 55-1).[45,46]

Anti-miRNA oligonucleotides (AMOs) represent ASOs, single-stranded, chemically modified DNA-like molecules that are 17 to 22 nt in length and designed to be complementary to a selected miRNA. Thus they are able to specifically inhibit expression of that gene. Mechanistically, AMOs can be described as ASOs against miRNAs and therefore produce an ASO-miRNA duplex through Watson-Crick binding, leading to RNAse-H–mediated cleavage of the target miRNA gene. Important for potential clinical use, ASOs harboring a complete 2′-*O*-methoxyethyl and phosphorothioate modification have been demonstrated to silence in vivo *miR-122* in mouse liver.[47] The LNAs' anti-miRNAs represent modified antisense single-stranded oligonucleotides 17 to 22 nt in length, with a methylene bridge connecting the 2′ and 4′ carbons. *miR-21,* shown to be strongly overexpressed in glioblastomas, was silenced in vitro by using LNA-modified antisense oligonucleotides, leading to a significant reduction in cell viability and elevated intracellular levels of caspases.[48]

The antagomir represents RNA therapeutic molecules originally designed to inhibit miRNAs.[49,50] These are chemically modified and cholesterol-conjugated single-stranded 23-nt RNA molecules complementary to the targeted miRNAs. The modifications were introduced to increase the stability of the RNA and protect it from degradation. When intravenously administered to mice, antagomirs against *miR-122* (antagomir-122), a miRNA highly expressed in liver, induced a marked, specific, and persistent (up to 23 days) reduction of endogenous miRNA gene expression. The same was true for antagomir-16, targeting the ubiquitously expressed *miR-16*. Silencing of miRNAs by these new agents was followed by physiologic effects, such as a decrease in plasma cholesterol levels after antagomir-122 administration. The only tissue where antagomirs did not act when injected systemically was the brain—probably because of the difficulty

of crossing the blood-brain barrier—but they efficiently targeted miRNAs when injected locally into the mouse cortex. One clear advantage with respect to siRNA technology is that antagomirs did not induce an immune response.

A recent addition to this expanding category of therapeutic agents are the 8-mer LNA antimiRs, specifically designed to target the 5′ "seed" region of miRNAs. It was shown that an 8-mer LNA antimiR-155 oligonucleotide targeting miR-155 inhibits Waldenström macroglobulinemia (WM) and CLL cell proliferation in vitro, whereas systemically delivered antimiR-155 showed significantly decreased tumor growth in vivo.[51] Another approach is the use of "miRNA sponges" or "miRNA decoys"—transcripts expressed from strong promoters and containing multiple artificial miRNA binding sites that compete with the endogenous miRNA targets for miRNA binding.[52] Finally, "miRNA masks" are novel gene-specific anti-miRNAs that can selectively inhibit the interaction of the target miRNA with a specific mRNA. These consist of 2′-*O*-methyl-modified ASOs with locked 3′ and 5′ ends that effectively mask the specific mRNA from the endogenous miRNA and thus prevent its repression.[53]

miRNA-Mimic Agents

There are no reports in clinical practice of using the mimic miRNA agents that reproduce the effects of endogenous miRNAs and include all the chemical modifications necessary for stability and processing. However, the restoration of the expression of specific miRNAs abnormally expressed because of genomic deletions, hypermethylation, or other causes could be clinically used in the future. Several studies have validated the efficiency of miRNA mimics in in vitro and in vivo models. For example, intranasal administration of let-7 (which negatively regulates *RAS*) in a K-ras mutant mouse effectively inhibited tumor growth.[54] Similar studies have been performed for miR-34a in a prostate cancer model,[55] and for miR-26 in a liver cancer model.[56] Thus administration of miRNA-mimetic agents in patients might be a new avenue for clinical cancer management.

In Search of the Right Way and the Right Type of Delivery

Two practical issues regarding the use of RNAs as therapeutic molecules should be further dissected: the selection of the most adequate formula and the most efficient method of administration (local vs. systemic). Naked RNA delivery or vehicle delivered and viral vehicle versus nonviral delivery are the most important questions in the formula type debate. Initial therapeutic applications used 21-nt siRNA duplexes, with 2-nt 3′ overhangs, as well as longer siRNAs of 27 mers and shRNAs (29 nt). These drugs are able to induce only transient gene silencing, because their intracellular concentrations diminish with every cell division.[38] However, despite improvements in siRNA stability, naked siRNAs are of little therapeutic use and are likely to require some form of targeted delivery vehicle for sufficient tissue specificity and cellular uptake. Long-lasting and stable knockdown of target transcription is achieved by expression of shRNAs from various types of vectors, including viral vectors, with Pol II or Pol III promoters. Although therapeutically useful, the continuous expression can cause harmful side effects due to the saturation of the endogenous silencing pathway; thus abundant shRNA expression could be toxic. For example, the use of an adeno-associated virus (AAV) vector with a U6 promoter (Pol III type) induced high expression levels of shRNAs and caused death in about half of treated mice.[57] Different lentiviral vectors (LVs), adenoviral vectors (AVs), and AAVs are being tested. LVs efficiently integrate into the genome of nondividing cells, such as pancreatic islets or terminally differentiated cells. In contrast to LVs, AVs do not integrate into the host genome; they do, however, efficiently transduce dividing and nondividing cells. Different AAV serotypes can be potentially used for organ-directed miRNA expression. Another option is to use nonviral delivery vehicles for shRNAs. Liposomes, lipid complexes with small molecules, polymers, proteins, and antibodies were tested as potential delivery options and all have certain advantages (but also clear disadvantages[58]). With these delivery partners, the efficacy of shRNA is increased and doses reduced, but the cytotoxic effects are much greater (Table 55-3).

A second practical issue is the selection of local versus systemic administration of RNA drugs. Local administration has certain advantages, such as the need for lower doses with consequent lower adverse/toxic reactions and better bioavailability of the drug to the target tissue. Numerous publications have described the delivery of siRNA molecules directly to tumors in vivo, including direct applications of siRNA into to the peritoneal cavity, testes, or urethra (reviewed in Reference 59). In other instances, such as leukemias, local administration cannot be achieved and therefore systemic delivery is mandatory.

A Strategy for Using RNA as Therapeutic Molecules

RNA molecules are now at the center of molecular oncology, with applications for diagnosis and therapy beginning to

Table 55-3 Delivery Methods for RNA-Interference–Based Therapeutics

Method	Molecule Delivered	Advantage	Disadvantage
Nonviral Delivery			
Cholesterol	siRNA	Systemic delivery, stable	Nonselective delivery
SNALP	siRNA	Systemic delivery, highly stable	Nonselective delivery
Fab	siRNA	Selective delivery	Relatively complex formulation
Aptamer	siRNA	Selective delivery	Large-scale sequence screening required
Nanoparticle	siRNA	Receptor-specific, self-assembling	Sophisticated preparation required
Viral Delivery			
Lentivirus	RNA (shRNA produced)	Stable expression, transduces nondividing cells	Gene-disruption risk, localized delivery
Adenovirus	dsDNA (shRNA produced)	Episomal, no insertional mutagenesis	Immunogenic, dose-dependent hepatotoxicity, transient expression
AAV	ssDNA/dsDNA (shRNA produced)	Episomal, low genomic integration	Immunogenic, small sector capacity, transient expression

dsDNA, Double-strand DNA; *SNALP*, stable nucleic acid-lipid particle; *ssDNA*, single-strand DNA.

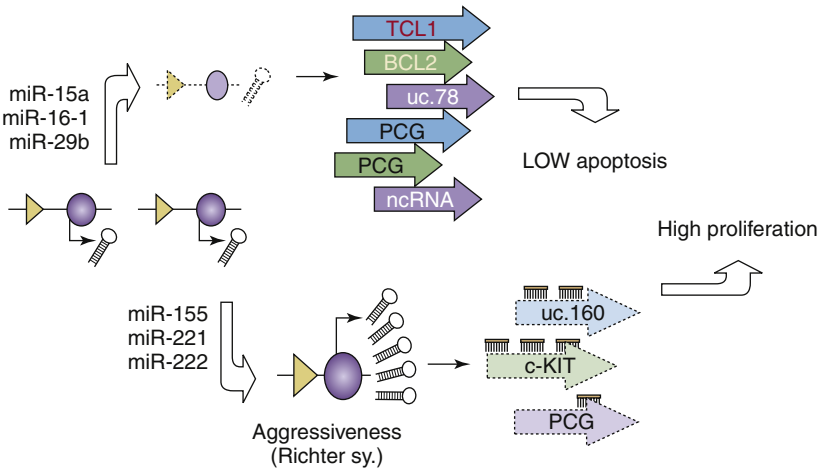

Figure 55-2 Chronic lymphocytic leukemia (CLL) as the best known example of interplay between noncoding RNAs (ncRNAs) and protein coding genes (PCGs) and the therapeutic implications During the initiation and progression of B-cell CLL alteration in at least three different types of genes, PCGs, microRNAs (miRNAs), and ultraconserved genes (UCGs) were identified. These are not independent, as complex regulatory interactions between miRNAs and PCGs and between miRNAs and UCGs occur. Furthermore, we postulate the existence of interactions between UCGs and PCGs, although these have not yet been demonstrated.

be proposed. Although exciting and full of promise, the field of RNA as a therapeutic molecule is not free of obstacles. Therefore, a good practical option is to attempt to improve strategies to optimize the efficiency of this new anticancer tool in the light of the unfulfilled promises of other types of new therapies. One approach to cancer therapy is to target various molecular defects in the multistep pathways of specific cancers—the *multiplex RNA inhibition targeting strategy*. Another strategy is to focus on a major molecular alteration clearly linked to disease pathogenesis by using multiple agents—the *Sandwich RNA inhibition strategy*. For example, to highlight, let us use the example of B-cell chronic lymphocytic leukemia (B-CLL), the most frequent adult leukemia in the Western world[60] and one of the best studied models of interplay between coding and ncRNAs in human cancers.[21] B-CLL is characterized by predominantly nondividing malignant B cells overexpressing the anti-apoptotic Bc12 protein. Deletion or downregulation of the *miR-15a/miR-16-1* cluster located at chromosome 13q14.3 represents an early event directly involved in the regulation of *BCL2* expression.[61] During the evolution of malignant clones, other miRNAs are deleted (such as *miR-29*) or overexpressed (such as *miR-155* or the cluster *miR-221/miR-222*), contributing to the aggressiveness of B-CLL (Richter syndrome). Such abnormalities influence the expression of other protein-coding genes: reportedly *miR-221* and *miR-222* directly down-modulate *c-KIT* receptor and *miR-29* regulates the levels of *TCL1* oncogene[62] or targets other ncRNAs such as UCGs *uc.160* and *uc.78* (Figure 55-2[26]). The consequences of this steady accumulation of abnormalities are represented

initially by low apoptosis and high survival of malignant B cells and later by the evolution of more aggressive clones with a higher proliferative capacity and survival by the overexpression of BCL2 and TCL1 oncogenes. Therefore, a mixed strategy of targeting both these oncogenes at the same time and using combined RNA drugs could be proposed. For example, designing a maxizyme anti-BCL2 and anti-TCL1 could be an option. Combining the systemic delivery of *miR-15* and *miR-16* family members targeting BCL2, together with *miR-29* and *miR-181* family members against TCL1, could increase the efficacy of therapeutic oncogenic downregulation. Furthermore, taking advantage of genome-wide profiling technologies, these therapies could be provided to only the subset of CLL patients having both types of lesions, specifically offered only to patients with *BCL2* overexpression and *mi-R15* and *miR-16* downregulations (the indolent form of CLL), or only to patients with *TCL1* overexpression and *miR-29* and *miR-181* downregulation (the aggressive form of CLL).

Finally, in light of the newly discovered interactions between various categories of ncRNAs, targeting not only miRNAs but also ultraconserved genes or lincRNAs regulated by miRNAs begins to be an alternative option. The competing endogenous RNA (ceRNA) hypothesis asserts that RNA transcripts can indirectly regulate each by competing for binding to miRNAs.[63] For example, synthetic RNA molecules that form hairpin structures simulating DNA transcription factor binding elements can be generated to target and regulate transcription factor activity, whereas synthetic lncRNAs that contain mutant miRNA binding sites can sequester and reduce expression levels of miRNAs.[64] Certainly, this is an exciting time for the RNA therapeutics, and we look forward to many more results of clinical studies investigating such strategies.

Heat Shock Protein 90 and the Proteasome: Housekeeping Proteins That Are Also Molecular Targets for Cancer Therapy

Introduction

Cancer is a disease of genetic instability. Although only a few specific alterations seem to be required for generation of the malignant phenotype, at least in colon carcinoma there are approximately 10,000 estimated mutations at time of diagnosis.[1,2] The genetic plasticity of cancer cells allows them to frequently escape the precise molecular targeting of a single signaling node or pathway, making them ultimately nonresponsive to molecularly targeted therapeutics. Even Gleevec (Novartis Pharmaceuticals Corp.), a well-recognized, clinically active Bcr-Abl tyrosine kinase inhibitor, can eventually lose its effectiveness under intense, drug-dependent selective pressure, because of either mutation of the drug interaction site or expansion of a previously existing resistant clone.[3] Most solid tumors at the time of detection are already sufficiently genetically diverse to resist single-agent molecularly targeted therapy.[4] However, such an enhanced rate of mutation suggests that cancer cells should be highly dependent on efficient chaperoning and degradation of terminally misfolded proteins, because unchecked accumulation of misfolded proteins can initiate apoptosis.[5] Further, a multipronged attack on tumor cell signaling is likely to prove more efficacious than is targeting individual molecular pathways. Thus, pharmacologic agents that inhibit a cancer cell's ability to dispose of misfolded protein, allow for simultaneous attack of multiple signaling nodes, or possess both properties simultaneously should be of benefit. Hsp90 inhibitors and proteasome inhibitors display these characteristics and are actively being developed as novel anticancer agents.

Hsp90: a Chaperone of Cancer

A number of signaling proteins that are Hsp90 clients (see the website maintained by D. Picard, http://www.picard.ch/DP/downloads/Hsp90interactors.pdf, as well as several excellent reviews[6-8]) also mediate acquisition of the eight hallmarks of cancer[9] and promote cancer cell survival in the face of environmental stress (Figure 56-1). Therefore, it is not surprising that inhibition of Hsp90 may collapse or significantly weaken a cancer cell's "safety net." Several excellent reviews provide an in-depth description of the many signaling nodes regulated by Hsp90.[10-16]

Cancer cells are subjected to extreme environmental stress, such as hypoxia and acidosis, as well as the exogenously applied environmental stresses of chemotherapy or radiation. These stresses tend to generate free radicals that can cause significant physical damage to cellular proteins. Given the combined protective role of molecular chaperones toward damaged proteins and the dependence of multiple signal transduction pathways on Hsp90, it is therefore not surprising that molecular chaperones in general, and Hsp90 in particular, are highly expressed in most tumor cells. Hsp90 may provide a unique molecular target in cancer cells for an additional reason. In *Drosophila* and *Arabidopsis* model systems, Hsp90 has been suggested to be a buffer of genetic mutation.[17,18] Extrapolating this function to genetically unstable cancer cells, it is tempting to speculate that Hsp90 may be critical to a cancer's ability to survive in the presence of a constitutively high mutation rate.[19] Indeed, a recent study identified the Hsp90 inhibitor tanespimycin (17-AAG) in an unbiased in vitro screen for drugs active against aneuploid cancer cell lines.[20]

The benzoquinoid ansamycin antibiotics, first isolated from the actinomycete *Streptomyces hygroscopicus* var. geldanus var. nova,[21] include geldanamycin (GA) and its semisynthetic derivatives, 17-allylamino-17-demethoxygeldanamycin (17-AAG, tanespimycin) and the more water-soluble 17-dimethylaminoethylamino-17-demethoxygeldanamycin (17-DMAG, alvespimycin) and 18,21-didehydro-17-demethoxy-18,21-dideoxo-18,21-dihydroxy-17-(2-propenylamino) geldanamycin (IPI-504, retaspimycin) (Figure 56-2). These small molecules were the first identified inhibitors of Hsp90,[22,23] and they (and

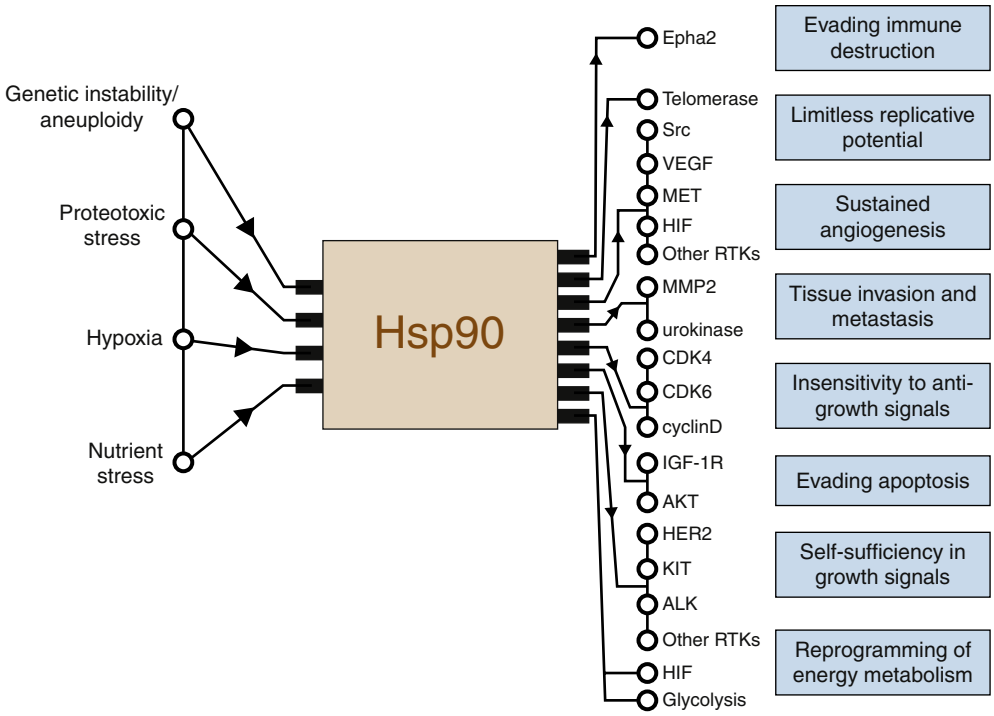

Figure 56-1 Hsp90 function is required for the establishment and maintenance of each of the eight hallmarks of cancer. Importantly, Hsp90 function is also critical for cancer cells to survive the genetic instability on which acquisition of the eight hallmarks depends, and the environmental stresses to which they are frequently subjected.

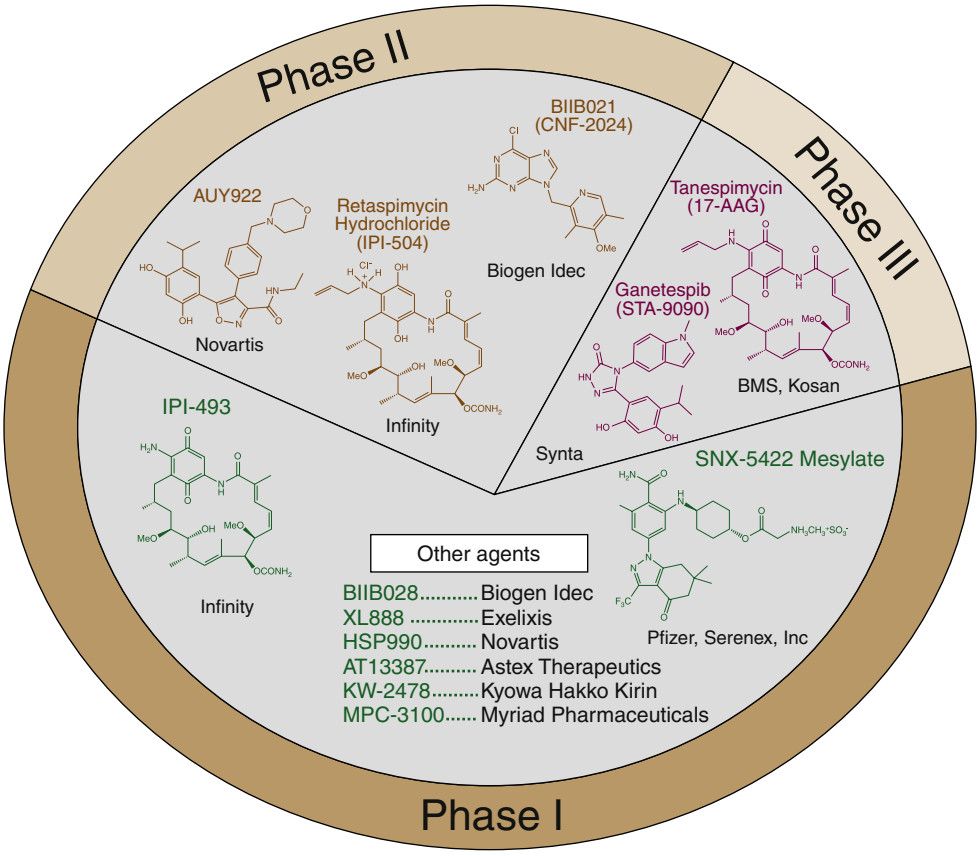

Figure 56-2 Hsp90 inhibitors in clinical development. See text for further details.

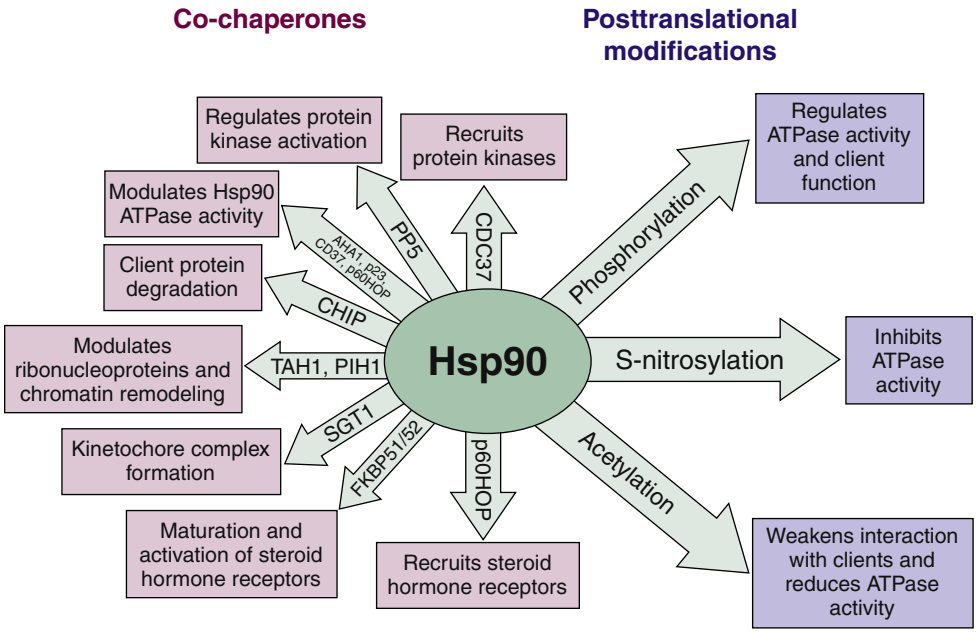

Figure 56-3 Co-chaperones and posttranslational modifications affect Hsp90 function. In eukaryotes, Hsp90 activity requires the contribution of numerous co-chaperones, each with a specific function. Acetylation, phosphorylation, and nitrosylation of specific residues on Hsp90 affect its interaction with client proteins and co-chaperones.

second-generation Hsp90 inhibitors) have shown activity in cancer clinical trials.[24,25] In particular, RECIST responses have been documented in patients with HER2$^+$ breast cancer previously treated with trastuzumab (Herceptin), and in EML4-ALK$^+$ non–small-cell lung cancer. Activity has also been seen in bortezomib-naïve and refractory multiple myeloma.

Several recent, excellently detailed reviews of the mechanics of Hsp90 function are in the scientific literature.[11,13,14,26-28] Hsp90 is a conformationally flexible ATPase that associates with a distinct set of co-chaperones depending on ATP binding to an amino-terminal purine binding pocket. Identification of this pocket as the GA binding site led Chiosis and colleagues to design a series of highly potent purine scaffold Hsp90 inhibitors with markedly improved drug-like properties.[29-32] Workman and colleagues used a high-throughput screen based on inhibition of Hsp90 ATPase activity to identify 3,4-diarylpyrazoles as a novel class of Hsp90 inhibitors.[33,34] Other groups have developed and validated a number of structurally distinct inhibitors of this purine pocket.[35] As of early 2012, more than 10 Hsp90 inhibitors had reached clinical trial (see Figure 56-2).

Hsp90 ATPase Activity and Chaperone Function

A model of Hsp90 function has emerged in which ATP binding to the amino-terminal pocket initiates a series of conformational changes that endow Hsp90 with ATPase activity. This process involves participation of a number of co-chaperones that interact with Hsp90 to form a "super-chaperone machine."[36] Certain co-chaperones play specific roles in this dynamic process (Figure 56-3). ATP hydrolysis completes the chaperone cycle, at which point the process (which is frequently iterative) can begin again. Many Hsp90 client proteins first associate with an Hsp70/Hsp40 chaperone complex.[37] This assemblage associates with Hsp90 via p60Hop, an Hsp90/Hsp70 interacting protein. At this point, when the client protein is being loaded on Hsp90, the chaperone is thought to be in an apo (nucleotide-free) conformation. ATP binding alters Hsp90 conformation, causing it to release p60Hop and the Hsp70/Hsp40 complex, and to recruit another set of co-chaperones, including p23 and certain immunophilins. In the case of kinase client proteins, the co-chaperone p50Cdc37 usually delivers the client to Hsp90. Although ATP hydrolysis is essential for chaperone activity, the ATPase activity of Hsp90 is very weak. Association of the co-chaperone Aha1 is necessary to increase Hsp90 ATPase activity sufficiently to drive the chaperone cycle forward.[38-41] In higher eukaryotes, the ordered association/dissociation of client proteins and co-chaperones is also affected by a series of sequential phosphorylation events.[42] Other posttranslational modifications also affect Hsp90 chaperone activity or client binding (see Figure 56-3).[43-45]

Hsp90 Inhibitors Target Client Proteins to the Proteasome

A highly orchestrated and tightly regulated process drives the ATP-dependent Hsp90 super-chaperone machine. Hsp90 inhibitors block the chaperone cycle by displacing ATP from the amino-terminal purine pocket, inducing client

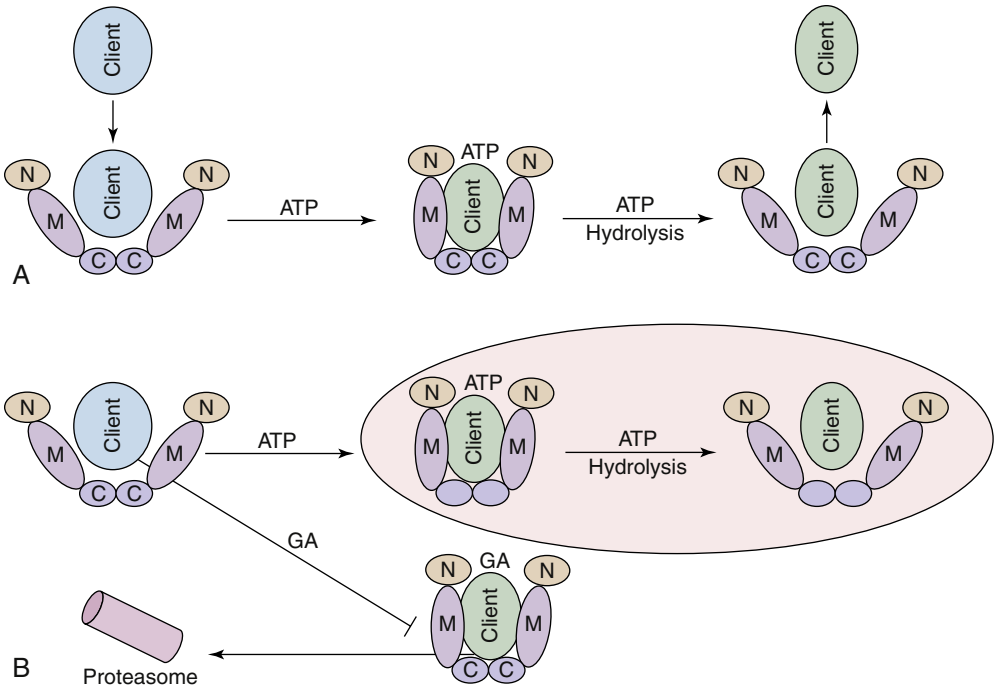

Figure 56-4 The Hsp90 chaperone machine **(A)** Client proteins associate weakly with an Hsp90 dimer in the absence of ATP. On ATP binding to an amino-terminal pocket in the chaperone, the N-lobes of each Hsp90 monomer transiently dimerize, resulting in tight binding of the client protein to Hsp90 and in acquisition of ATPase activity. On ATP hydrolysis, stimulated by various co-chaperones, the N-lobes of Hsp90 dissociate, releasing the now-folded client protein. **(B)** Geldanamycin (GA) and other N-terminal Hsp90 inhibitors block ATP binding to Hsp90, preventing dimerization and maintaining Hsp90 in a conformation that weakly associates with client protein. In the absence of ATP binding, the client protein dissociates from Hsp90, becomes polyubiquitinated by chaperone-dependent E3 enzymes, and is ultimately degraded by the proteasome.

protein ubiquitination and proteasome-mediated degradation (Figure 56-4). Although the mechanics of this process are not well understood, they appear to involve a "handing-off" of the client from inhibitor-bound Hsp90 to an Hsp70-ubiquitin ligase complex.[46] E3 ubiquitin ligases that have been implicated in mediating Hsp90 inhibitor-induced client protein ubiquitination in mammals include CHIP and Cullin 5.[47,48] Importantly, even if the proteasome is inhibited, client proteins are not rescued from Hsp90 inhibition, but instead accumulate in a misfolded, inactive state in detergent-insoluble subcellular complexes.[49] A selection of several oncogenic Hsp90 clients (in addition to HER2 and EML4-ALK, mentioned earlier) is shown in Table 56-1. The reader is directed to the references therein for more detailed information.

Hsp90 itself is also subject to ubiquitination and degradation. Wee1-mediated phosphorylation of a conserved tyrosine residue (Y38 in human Hsp90α) determines the ubiquitination and degradation of a nuclear pool of the chaperone, with consequences for Hsp90 function.[44,50]

Table 56-1 List of Selected Hsp90 Clients Involved in Cancer

Cancer	Hsp90 Client	References
Anaplastic large cell lymphomas	NMP-ALK	103, 104
Acute myeloid leukemia	FLT3	105, 106
Chronic myelogenous leukemia	BCR-ABL	107, 108
Human mastocytosis Gastrointestinal stromal tumors	KIT	109
Melanomas	B-RAF EGFR	89, 110-113
Prostate cancer	Androgen receptor	114-116
Clear cell renal cell carcinoma (ccRCC) Nonhereditary sporadic ccRCC	HIF1-α	117, 118
Glioblastoma	VEGF	119
Leukemia	BCL2 APAF	120
Small-cell lung cancer	MET	121-124
Multiple endocrine neoplasia type 2 (MEN2A, MEN2B) Familial medullary thyroid carcinoma (FMTC) Papillary carcinoma of thyroid	RET	125-128

Hsp90 Inhibitors May Prevent Oncogenic Switching

Recent studies have identified development of resistance to tyrosine kinase inhibition (TKI) as a significant roadblock to effective targeted therapy. One mechanism of resistance recently appreciated involves "oncogene switching," or the reactivation of signaling pathways by one or more redundant upstream activators. In breast cancer models, ErbB TKIs such as gefitinib have been shown to lose the ability to modulate ErbB-driven signaling pathways over time, even though ErbB inhibition is maintained.[51] Similarly, ErbB kinase activation has been reported to confer resistance to MET TKIs in MET oncogene-addicted gastric cancer cells.[52] This model of "oncogene plasticity" does not rely

on kinase mutation or on drastic changes in gene expression but merely on the inherent redundancy of biological systems, and it may explain some of the disappointing results seen in previous TKI clinical trials. Using several models, we and others have found that Hsp90 inhibition prevents oncogene switching and is itself a targeted therapy that is not prone to this phenomenon.[53-55] Although Hsp90 inhibitors may have single-agent activity in cancers that are strongly dependent on an Hsp90 client (e.g., HER2 or ALK), these drugs may find a broader role in combination with TKIs that target Hsp90 clients.

The Proteasome as an Anticancer Molecular Target

Regulated degradation of intracellular proteins is mediated by the proteasome, a 2.4-MDa molecular machine comprising approximately 60 subunits that together account for 2% of total cell protein. Not only do proteasomes regulate the half-lives of many signaling proteins in response to environmental stimuli, another primary function of the proteasome is to rapidly degrade hopelessly misfolded proteins that, if allowed to accumulate, can lead to apoptosis. Although the process leading from aggregation of misfolded proteins to cell death is not well understood and is likely to be multifactorial, one hypothesis is that accumulation of aggregated proteins results in the sequestering of numerous cellular chaperones and proteasome components in an insoluble and nonfunctional state, thus negatively affecting normal cell homeostasis and promoting cellular apoptosis. Deregulated protein aggregation has been shown to cause mitochondrial membrane depolarization, release of cytochrome c, and activation of caspase cascades. Indeed, deficiency in proteasome processing of misfolded proteins underlies a number of neurodegenerative diseases characterized by abnormal deposition of insoluble misfolded proteins that cause the apoptotic death of neuronal cells. The frequent acidosis and hypoxia to which cancer cells are subjected cause free radical–mediated damage to cellular proteins. If this damage cannot be repaired, such proteins are cleared from the cell via degradation in the proteasome. Thus, in order to maintain homeostasis, cancer cells are highly dependent on the ability of the proteasome machinery to operate with maximal efficiency.

The proteasome is composed of a 20S core particle containing three proteolytic activities that recognize hydrophobic, basic, and acidic amino acids, respectively. The 26S proteasome is composed of a 20S core particle capped on either end by a 19S ubiquitin chain recognition particle that also uses ATP to unwind substrate protein, allowing it to enter the 20S core where it is degraded into small peptides 2 to 25 residues in length. On exiting the proteasome, these small peptides are rapidly degraded to their amino acid components by cytosolic peptidases. The polyubiquitin chain is also removed and disassembled to monoubiquitin for reuse. The interested reader is referred to several excellent reviews on proteasome function and on validation of the proteasome and ubiquitination machinery as drug targets.[56-58]

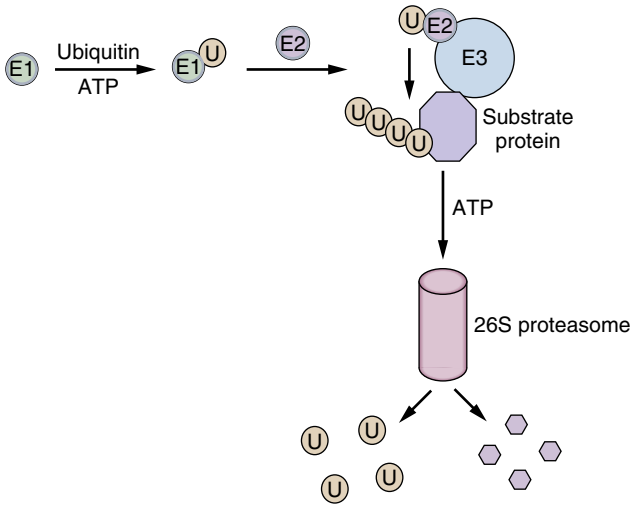

Figure 56-5 The ubiquitin-proteasome pathway Using ATP, a series of enzymes (E1, E2, and E3) attach multiple units of the small protein ubiquitin to a substrate protein destined for degradation. Substrate specificity is provided by the E3 complex. Once polyubiquitinated, the substrate protein is recognized by the 19S cap of the 26S proteasome and in an ATP-dependent process is unwound and fed into the proteasome for degradation. The 19S core of the proteasome contains chymotryptic, tryptic, and caspase-like proteolytic activities, thus ensuring efficient degradation of the substrate protein into small peptides that, on exiting from the proteasome, are cleaved to their constituent amino acids by cytosolic peptidases. Polyubiquitin chains are disassembled to resupply the cellular monoubiquitin pool. Proteasome inhibitors inhibit one or more enzymatic activities of the 19S core (see text).

As stated earlier, the 26S proteasome recognizes polyubiquitin chains, and most proteins destined for proteasomal degradation are first tagged by sequential covalent addition of four or more ubiquitin moieties (a 76-amino-acid, highly conserved protein present in the cytoplasm and nucleus of all eukaryotes). This process involves ATP-dependent charging of a ubiquitin-activating enzyme (E1), which then transfers ubiquitin to a ubiquitin-conjugating enzyme (E2), which in the presence of a ubiquitin-ligating enzyme (E3) transfers a single ubiquitin moiety to the protein to be degraded (Figure 56-5). Interestingly, there is only one E1 enzyme in mammalian cells, approximately 50 E2 enzymes, but perhaps 1000 E3 enzymes. Thus, substrate specificity is primarily regulated by the selectivity of the E3 enzyme. Interaction of the E3 ubiquitin ligase with its substrate is frequently dependent on posttranslational modification (e.g., phosphorylation) of the substrate protein or, in the case of misfolded proteins, on initial interaction of the substrate protein with one or more molecular chaperones, including Hsp90.

Anticancer Activity of the Proteasome Inhibitor Bortezomib

Bortezomib, a dipeptidyl boronic acid–based reversible inhibitor, was the first proteasome inhibitor to enter clinical trials in hematologic malignancies. It has shown significant activity toward multiple myeloma, and in 2005 the U.S. Food and Drug Administration (FDA) approved its use in patients with relapsed multiple myeloma. Multiple additional clinical trials are currently under way examining the efficacy of this agent in various hematologic and solid tumors.[59] Preliminary data suggest promising activity in mantle-cell lymphoma and follicular lymphoma. Several clinical trials are also testing bortezomib in combination with other therapeutic agents, including dexamethasone, doxorubicin, melphalan, and Hsp90 inhibitors. For an in-depth review of bortezomib's possible mechanism(s) of action and clinical evaluation, the reader is referred to an excellent review by Roccaro and colleagues.[59] A comprehensive review of the current status (as of 2012) of proteasome inhibitors in multiple myeloma is also recommended.[60]

Second-Generation Proteasome Inhibitors

In recent years, several second-generation proteasome inhibitors have been developed and are being evaluated in the clinic. MLN9708, like bortezomib, is a boronate derivative, but it has demonstrated greater tissue penetration in preclinical studies and is the first orally available proteasome inhibitor to be evaluated in multiple myeloma.[61] Preliminary clinical data reveal encouraging activity, and durable responses have been seen in heavily pretreated patients.[62] CEP-18770 is a third boronate derivative, also orally active, that is in development.[63]

Carfilzomib, an epoxyketone, is an irreversible proteasome inhibitor that is structurally and mechanistically distinct from the boronate-based drugs. Carfilzomib has demonstrated reduced off-target activity compared to bortezomib, and, importantly, activity has been seen against bortezomib-resistant cell lines and primary multiple myeloma cells.[64,65] Carfilzomib has demonstrated durable antitumor activity in patients with relapsed/refractory multiple myeloma and, unlike bortezomib, has caused limited neurotoxicity.[66] An analog of carfilzomib, ONX-0912, is also under development.[67]

Marizomib (NPI-0052), a natural product lactone isolated from a marine bacterium, unlike the boronate compounds and carfilzomib, is an irreversible proteasome inhibitor that abrogates both the chymotrypsin-like and trypsin-like protease activities while only minimally affecting the caspase-like activity of the proteasome. As a result, it does not exhibit cross resistance with other proteasome inhibitors, has a unique safety profile, and has demonstrated antitumor activity in preclinical models of multiple myeloma, other hematologic diseases, and solid tumors.[68-70] Marizomib also demonstrates oral bioavailability.

Combined Inhibition of Hsp90 and the Proteasome

Proteasome-mediated degradation is the common fate of Hsp90 client proteins in cells treated with Hsp90 inhibitors.[71,72] Thus, at first glance, combining a proteasome inhibitor with an Hsp90 inhibitor may seem counterintuitive. However, proteasome inhibition does not protect Hsp90 clients in the context of chaperone inhibition—instead, client proteins become insoluble.[49,73] Because the deposition of insoluble proteins is toxic to cells,[74,75] interest has arisen in combining proteasome and Hsp90 inhibitors, the goal being to promote enhanced accumulation of insoluble proteins and trigger apoptosis. This hypothesis is particularly appealing given the clinical efficacy of proteasome inhibitors alone.[59] Initial experimental support for such a hypothesis was provided by Mitsiades and colleagues,[76] who reported that Hsp90 inhibitors enhanced multiple myeloma cell sensitivity to proteasome inhibition. Clinically, a combination of tanespimycin and bortezomib has been associated with durable responses in heavily pretreated patients with multiple myeloma, including those with bortezomib-refractory disease.[77-80] Additional Hsp90 inhibitors are being evaluated in this setting.[81-83]

Importantly, transformed cells are more sensitive to the cytotoxic effects of this drug combination than are nontransformed cells. Thus, 3T3 fibroblasts are fully resistant to the combined administration of 17-AAG and bortezomib at concentrations that prove cytotoxic to 3T3 cells transformed by *HPV16* virus encoding viral proteins E6 and E7.[84] In the same study, Mimnaugh and co-workers demonstrated that the endoplasmic reticulum is one of the main targets of this drug combination. In the presence of combined doses of both agents that show synergistic cytotoxicity, these investigators noted a nearly complete disruption of the architecture of the endoplasmic reticulum. Because all secreted and transmembrane proteins must pass through this organelle on their route to the extracellular space, it is not surprising that a highly secretory cancer such as multiple myeloma would be particularly sensitive to combined inhibition of Hsp90 and the proteasome. One might speculate that other highly secretory cancers, including hepatocellular carcinoma and pancreatic carcinoma, would also respond favorably to this drug combination.

Additional Rationales for Inhibiting the Ubiquitin-Proteasome System in Cancer

As stated earlier, the proteasome inhibitor bortezomib has demonstrated single-agent activity in multiple myeloma and in other hematologic malignancies. Although general interference in the clearance of misfolded proteins is likely to be a major contributor to the efficacy of this agent, other more specific effects of proteasome inhibition should also be considered.[59] In these hematologic cells, the transcription factor NFκB plays a particularly important role. Not only does it inhibit apoptosis, but it actively upregulates transcription of growth factors such as interleukin 6 and angiogenic factors such as VEGF. As a transcription factor, the activity of NFκB requires nuclear entry. This in turn is regulated by targeted, proteasome-mediated degradation of IκB, a protein that interacts with NFκB and restricts it to the cytosol. Treatment of cells with bortezomib has been shown to prevent the degradation of IκB, thus resulting in retention of NFκB in the cytosol.

Other important tumor suppressor proteins degraded by the proteasome include p53 and p27. Thus, proteasome inhibition promotes the accumulation of these proteins. Recently, investigators have identified more specific approaches to prevent inappropriate p53 and p27 degradation by searching for inhibitors of the E3 ligases that recognize these proteins. The E3 interacting with p53 is termed *MDM2* (double minute protein 2). Two small molecules that interfere with MDM2/p53 interaction have recently been identified.[85,86] Although mechanistically distinct, these agents both result in accumulation of wild-type p53 in tumor cells in vitro and shrink tumors growing in mice. The tumor suppressor p27 is degraded by the E3 ligase SKP2 (S phase kinase-associated protein 2). SKP2, which also targets other antiproliferative molecules in the cell—including the retinoblastoma family protein p130, the cyclin-dependent kinase inhibitors p21 and p57, and the inhibitory transcription factor FoxO (forkhead box protein O)—is overexpressed in many human cancers.[57] Molecular knockdown of SKP2 using RNA interference techniques or intracellular injection of SKP2-specific antibodies slows the proliferation of cancer cells in vitro.[57,87] Thus, SKP2 is a valid therapeutic target in its own right, and drug discovery efforts specifically targeting this ubiquitin ligase are under way.[88]

Why Are Tumor Cells Uniquely Sensitive to Hsp90 and Proteasome Inhibition?

It is apparent, from both preclinical and clinical observations, that Hsp90 inhibitors can be administered in vivo at doses and schedules that significantly affect tumor growth but display acceptable target-related toxicity in normal tissues or in the whole organism. This is the case for several small-molecule inhibitors, including 17-AAG and 17-DMAG, the synthetic purine mimetic PU24FCl, and is even true for a novel peptidomimetic inhibitor of the N-terminal Hsp90 nucleotide binding site, shepherdin.[89-93] When murine model systems are examined in vivo, Hsp90 inhibitors are found to concentrate in tumor tissue, while being rapidly cleared from normal tissue with a half-life similar to that of drug in plasma.[89,90,92,93] The Hsp90 inhibitor 17-AAG also has been reported to actively concentrate in tumor cells in vitro.[94]

Because preferential accumulation of Hsp90 inhibitors in tumor versus normal tissue may provide the observed therapeutic (or at least biologic) index, it is important to understand the reason for this phenomenon. A possible explanation put forth by Kamal and colleagues suggests that enhanced drug binding to tumor cell Hsp90 reflects the activity state of the Hsp90 chaperone machine in tumor versus normal cells.[95] They proposed that the enhanced ATPase activity of the chaperone in tumor cells, which is dependent on preferential recruitment of Hsp90 to a multicomponent chaperone complex, is responsible for the increased affinity of Hsp90 inhibitors in tumor cells. More recently, the suggestion that tumor cell Hsp90 more avidly binds Hsp90 inhibitors compared to the Hsp90 in nontransformed cells has received experimental support,[96] and posttranslational modifications of Hsp90 that affect drug binding have been described.[43,44]

The expression of NAD(P)H:Quinone Oxidoreductase I (NQO1), also known as DT-diaphorase, dramatically enhances cellular sensitivity to 17-AAG.[89,97] NQO1 generates the hydroquinone form of 17-AAG, which has been shown to bind more avidly to Hsp90 when compared to 17-AAG itself.[98] Further, the presence of NQO1 in a cell seems also to lead to increased total accumulation of intracellular ansamycin molecules, presumably reflecting the increased Hsp90 affinity of 17-AAG hydroquinone. The presence of NQO1 in tumor cells dramatically affects cellular sensitivity to 17-AAG.[89,97,98] Because high levels of NQO1 have been observed in diverse tumor types (e.g., liver, lung, colon, breast) compared to normal tissues of the same origin,[99] these data suggest an explanation for the disparate sensitivity of tumor and normal tissue to 17-AAG and to retaspimycin (IPI-504), a stabilized hydroquinone form of 17-AAG that is in clinical trial.[100,101] A similar preference of non-ansamycin Hsp90 inhibitors for tumor cell Hsp90 supports the hypothesis that unique modifications of Hsp90 in tumor versus normal cells also contribute to this phenomenon.

Proteasome inhibitors also display selective cytotoxicity toward tumor cells, both in vitro and in vivo. Why are they not more toxic to normal cells? Kisselev and colleagues[102]

have recently shown that, at therapeutic doses of bortezomib in vivo, and following the intermittent schedule of administration approved for patients, only the chymotryptic activity of the proteasome is significantly inhibited and the overall rate of protein degradation is reduced by less than 40%. Because cancer cells may require their proteasomes to be at full capacity in order to handle the load of continually generated misfolded proteins, moderate reduction in proteasome activity, even for a brief period, may prove deleterious. In contrast, nontransformed cells may be able to tolerate reduced proteasome function for an extended period of time. Some of our data described earlier in this review support this hypothesis. In the preclinical studies in which we observed dramatically enhanced toxicity (and dramatically enhanced insoluble ubiquitinated protein deposition) by combining low-dose Hsp90 inhibitors with bortezomib, we found that maximal benefit of the combination required only a 50% reduction in proteasome activity.[84] Importantly, the satisfactory safety profiles of second-generation irreversible inhibitors—including marizomib, which inhibits two of three proteasome-associated protease activities—suggest that nontransformed cells may be able to tolerate prolonged, significantly reduced proteasome activity, further amplifying the therapeutic index of these drugs.

Conclusion

The proteasome and Hsp90 together comprise approximately 4% of total cellular protein. Separately and together they regulate critical mechanisms responsible for maintaining cellular homeostasis in the face of severe environmental stress and constitutive genetic instability. Although Hsp90 and the proteasome certainly can be labeled as "housekeeping" proteins, both proteins have proven to be exciting and clinically relevant anticancer molecular targets. Because it is now clear that cancer cells, by their very nature, are more dependent on optimal function of homeostatic mechanisms compared to normal cells, further exploitation of these pathways as drug targets will likely provide additional therapeutic strategies to attack this disease.

Hematopoietic Growth Factors and Cytokines

Growth factors regulate the essential cellular process of proliferation and differentiation. Overproduction of growth factors is a common feature of tumor cells, stimulating unregulated proliferation of themselves in an autocrine fashion, and of adjacent cells in a paracrine fashion. More specifically, hematopoietic growth factor is a common term for the family of glycoproteins that regulate proliferation and differentiation of hematopoietic cells. Cytokines are a subtype of growth factors that are produced by hematopoietic and immune cell types and include interferons and interleukins. The term *cytokine* refers to a chemical messenger protein that carries a biochemical signal between cells, usually of the immune system, and the rest of the body. *Interleukin* designates any soluble protein or glycoprotein product of leukocytes that regulates the responses of other leukocytes. The pleiotropic nature of many cytokines and interleukins allows them to influence virtually all organ systems. In addition to their vital role in promoting hematopoietic cell growth, differentiation, and activity, these molecules are vital to the proper functioning of the central nervous system, cardiorespiratory system, and liver, as well as to bone remodeling, lipid metabolism, and embryogenesis and maintenance of pregnancy. Interestingly, many of these molecules have pleiotropic effects on numerous organ systems. For example, stem cell factor influences hematopoiesis and neurogenesis, and prolactin promotes multiproduction and erythropoiesis. Cytokines may have their own private receptor but may also share a "public" receptor with other cytokines (Table 57-1[1,2]), perhaps explaining some of the redundancy in their effects (Figure 57-1).

The identification and cloning of hematopoietic growth factors and cytokines have revolutionized medical practice. Raising white blood cell counts in patients with neutropenia was unimaginable until the discovery of granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). Today, growth factors are routinely used to alleviate neutropenia and, to a lesser extent, thrombocytopenia and anemia after chemotherapy. They can also help mobilize stem cells for transplantation, and they may have the potential to mobilize the immune system against infection or cancer.

Herein, we give an overview of the biologic characterization of the known clinically relevant interleukins and selected cytokines, the rationale for their use in therapy for patients with cancer, and the clinical experience with them.

Erythropoietin

Erythropoietin is produced by juxtaglomerular cells of the kidney. It is the most important hormone regulator of erythropoiesis. It has an accepted place in the treatment of anemia caused by a variety of illnesses (Table 57-2[3]). Because its primary production source is the kidney, it is not surprising that EPO has its best established role in the treatment of anemia due to the EPO-deficient state in kidney disease. However, many patients with anemia due to cancer also have a relative deficiency in endogenous EPO and respond to EPO. Interestingly, certain cases of familial erythrocytosis have been attributed to the presence of EPO-hypersensitive cells. This heightened EPO response results from the formation of a truncated EPO receptor that is missing a negative regulatory domain.[1]

EPO: Clinical Trials/Applications

EPO is most useful in those anemias in which there is an absolute or a relative deficiency in endogenous EPO levels, such as in renal failure and cancer, respectively (see Table 57-2). The quality of life for patients with anemia due to renal failure or cancer who respond to EPO is clearly improved. Although EPO has generally been used for patients with hemoglobin below 10 g/dL, the maximum improvement in the quality of life actually

Table 57-1 Receptors, Natural Antagonists, and Chromosomal Locations of Growth Factors and Cytokines

	Receptor	Natural Antagonists	Chromosomal Locations
Erythropoietin (EPO) (136)	EPO receptor	Soluble EPO receptor	7q21
GM-CSF	Type I receptor with α and β subunits		5q31.1
G-CSF	G-CSF receptor		17q11.2-q12
M-CSF	Fms		1p21-p13
Stem cell factor	c-kit	Soluble c-kit receptor	12q22-12q24
Thrombopoietin	Mp1		3q27-q28
IL-1	IL-1RI and IL-1RII? Extended family of 10 members including IL-18R	Soluble IL-1RI and IL-1RII and IL-1RA	2q13
IL-2	$\alpha\beta\gamma$ heterotrimeric complex		4q26-q27
IL-3	IL-3 receptor (heterodimer of IL-3 specific α subunit and β subunit)		5q31
IL-4 and IL-13	IL-4 and IL-13 receptors share subunits Type 1 IL-4 receptor (IL-4Rα and IL-2 receptor γc chain subunits) transduces IL-4; type II IL-4 receptor (IL-4Rα and the IL-13Rα1 subunits) transduces IL-4 and IL-13; IL-4Rα and IL-13Rα2 complex or two IL-13Rα transduce IL-13	Soluble IL-4 and IL-13 receptors exist	5q31
IL-5	Consists of IL-5Rα (IL-5-specific) and a β subunit. β subunit is common to IL-3 and GM-CSF complexes		5q31
IL-6	IL-6Rα together with gp130		7p21
IL-7	Composed of IL-7Rα (CD127) and the common γc chain subunits		8q12-q13
IL-8	IL-8Rα and IL-8Rβ exist		4q12-q13
IL-9	IL-9 receptor		5q31.1
IL-10	IL-10 receptor interferon receptors		1q31-q32
IL-11	IL-11Rα and gp 130 subunits gp 130 = CD130 on 5q11 IL-6, oncostatin M, and leukemia inhibitory factor also use gp130 subunit		19q13.3-q13.4
IL-12	IL-12Rβ1 and IL-12Rβ2 chains are related to gp 130	IL-12 p40 homodimers	IL-12A:3p12-q13.2 IL-12B:5q31.1-q33.1
IL-15	High-affinity receptor requires IL-2Rβ and γ chains and IL-15Rα chain		4q31
IL-16	Requires CD4 for biologic activities		15q26.1
IL-17	IL-17 receptor		2q31
IL-18	IL-18 receptor	IL-18 binding protein exists	11q22.2-q22.3
IL-19	IL-20Rl and IL-20R2		1q32
IL-20	IL-20R1 and IL-20R2		1q32
IL-21	IL-21 receptor		4q26–27
IL-22	IL-22R1 and IL-10R2		12q14
IL-23	IL-12Rb1 and IL-23R		12q13
IL-24	IL-20R1 and IL-20R2 IL-22R1 and IL-20R2		1q32
IL-25	IL-17BR		14q11
IL-26	IL-20R1 and IL-10R2		12q14
IL-27	TCCR/WSX-1 and GP130		12q13

Table 57-1 Receptors, Natural Antagonists, and Chromosomal Locations of Growth Factors and Cytokines—cont'd

	Receptor	Natural Antagonists	Chromosomal Locations
IL-28A, 28B, and 29	IL-28R1 and IL-10R2		19q13
IL-31	IL-31 receptor A and oncostatin M receptor		12q24
IL-32	Proteinase 3		16p13.3
IL-33	ST2		9p24.1
IL-35	IL-12Rβ2 and gp130		3 E 1
IL-36	IL-1Rrp2 and IL-1RAcP		IL36A:2q12-q14.1 IL36B:2q14 IL36G:2q12-q21 IL36RN:2q14

IL-38	IL36R		2q13

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IL,* interleukin; *M-CSF,* macrophage colony-stimulating factor.

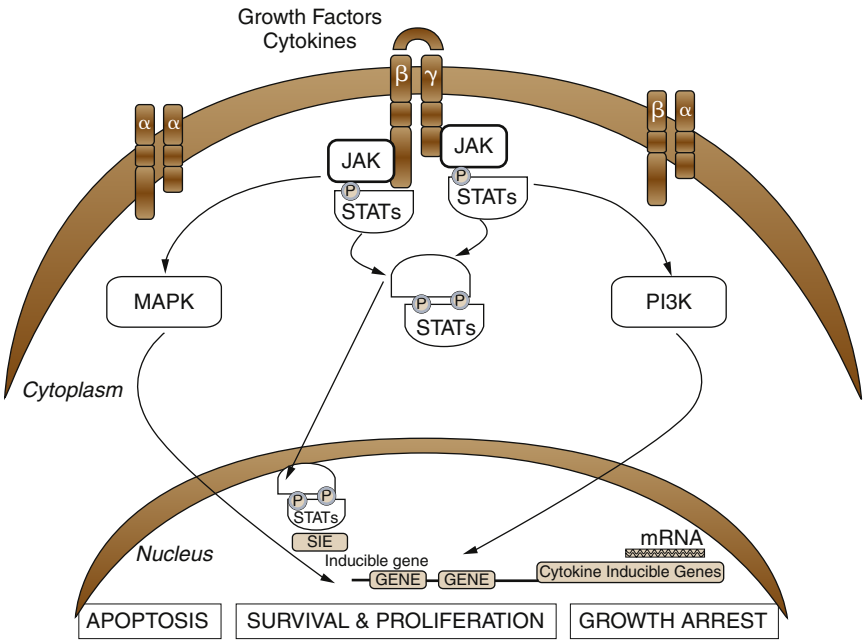

Figure 57-1 Actions of cytokine/growth factors binding to their receptors on the cell surface Cytokines and growth factors are the messengers that mediate intercellular communication. The regulation of cellular and nuclear functions by cytokines and growth factors is initiated through the activation of cell surface receptors. All receptors have a ligand-binding domain that ensures ligand specificity and an effector domain that initiates the generation of the biologic response on ligand binding. The activated receptor may then interact with other cellular components to complete the signal transduction process. Briefly, cytokine binding to receptor subunits induces homo- or heterodimerization resulting in the activation of Jaks that are bound to the receptor chains. The Jaks in turn phosphorylate tyrosine-based docking sites on the receptor. STATs bind via their SH2 domains. The STATs are then phosphorylated, form homo- or heterodimers, and translocate to the nucleus, where they bind target sequences, thereby regulating gene expression.

occurs in patients with higher hemoglobin levels (11 to 13 g/dL[1]). In the case of cancer, however, not all patients respond, and those with the highest levels of endogenous EPO are probably less likely to benefit. A recently discovered complicating factor to defining optimal EPO treatment has been the finding of decreased survival in some patients treated in randomized trials with "optimization" of hemoglobin.[4]

Erythropoietin-stimulating agents (ESAs) have been shown in clinical trials to decrease the transfusion requirements and increase the hemoglobin in patients with chemotherapy-induced anemia.[5-7] However, these trials have not shown that ESAs prolong survival or improve quality of life in these patients.[8] Moreover, ESAs have been associated with a number of unwanted outcomes in cancer patients, including an increased risk of stroke and venous thromboembolism, worse cancer outcomes, and increased mortality. With these findings of worse outcomes in patients treated with ESAs, the U.S. Food and Drug Administration (FDA) issued warnings against the use of ESA. The 2010 ASH/ASCO (American Society of Hematology/American Society of Clinical Oncology) Guidelines recommend a thorough workup for other causes of anemia before initiation of ESAs as well as discussion of the potential benefits and harms of ESAs.[7]

Table 57-2 Growth Factors and Cytokines in the Clinic*

Major Clinical Trials	
Erythropoietin (EPO) (136)	• Anemia of renal failure • Anemia of zidovudine therapy of HIV (with endogenous EPO level <500 mU/mL) • Anemia of cancer, especially after chemotherapy of solid tumors • Reduction of blood transfusions in elective surgery • Potentiation of autologous blood donation • Anemia of prematurity • Maximum quality-of-life improvement is at hemoglobin of 11-13 g/dL • Hyperglycosylated EPO (darbopoietin alfa) has prolonged half-life and can be administered less frequently • Postulated to offer neuroprotection after neurologic damage since EPO/EOP receptors are present in the central nervous system
GM-CSF	• Neutropenia due to myelosuppressive chemotherapy or bone marrow transplantation (BMT) • Peripheral blood stem cell mobilization • Graft failure • After induction therapy for acute myelocytic leukemia (AML)
G-CSF	• Neutropenia due to chemotherapy or BMT • Chronic and cyclic neutropenia • AIDS-related neutropenia • Autoimmune neutropenia • Peripheral blood stem cell mobilization • G-CSF reduces morbidity from high-risk febrile neutropenia treated with antibiotics
M-CSF	• Enhances hematopoietic recovery after chemotherapy or transplantation • Attenuates neutropenia in chronic neutropenia • Lowers serum cholesterol • May be useful in therapy of fungal infections
Stem cell factor (SCF)	• Peripheral blood progenitor mobilization (SCF + G-CSF better than SCF alone) • Aplastic anemia (trilineage responses seen after SCF)
Thrombopoietin	• Accelerates platelet recovery after chemotherapy • Increases platelet yield from normal donors for platelet transfusions • Enhances mobilization of peripheral blood progenitor cells by G-CSF • Nonimpressive effects on platelet recovery after myeloablative therapy
IL-1	IL-1α and IL-1β • Modest reduction in postchemotherapy neutropenia or thrombocytopenia; numerous side effects • No significant antitumor activity in melanoma or renal cell carcinoma IL-1RA • No clear-cut reduction in mortality in sepsis patients • Amelioration of rheumatoid arthritis and graft-versus-host disease
IL-2	• Antitumor activity in melanoma and renal cell carcinoma • IL-2 diphtheria fusion toxin (DAB-IL-2) approved for used in cutaneous T-cell lymphomas
IL-3	• Increases stem cell mobilization when used with G-CSF or GM-CSF • In combination with GM-CSF, hastens bone marrow recovery after transplant • Sequential IL-3 and GM-CSF produces multilineage responses in some marrow failure patients • Induces occasional sustained remissions in Diamond-Blackfan anemia
IL-4 and IL-13	• Only minor antitumor activity has been seen in a variety of human cancers of IL-4
IL-5	• IL-5 antagonists may be useful in the treatment of allergy and asthma. However, a trial of monoclonal antibody against IL-5 was not effective in asthma
IL-6	• Response rates 8%-14% in melanoma and renal cell carcinoma • Modest platelet-enhancing ability after chemotherapy or autologous transplant with significant toxicity • Antibody to block IL-6 is entering clinical trial
IL-8	• Antibodies to block IL-8 are entering clinical trial
IL-10	• Trend toward efficacy in rheumatoid arthritis, inflammatory bowel disease, and autoimmune diseases
IL-11	• Approved for use to prevent chemotherapy-induced thrombocytopenia
IL-12	• Potential use in vaccine development • No benefit in hepatitis C trial • Modest antitumor activity with significant toxicity in melanoma and renal cell carcinoma
IL-16	• May have potential use in HIV infection
IL-20	• May have potential for chronic inflammatory skin disease

Table 57-2 Growth Factors and Cytokines in the Clinic*—cont'd

Major Clinical Trials—cont'd	
IL-21	• Because it controls adaptive immune responses, its use in a clinical setting may prove efficacious for the treatment of cancer and infectious disease
IL-24	• Clinical trials for the treatment of melanoma are under way
IL-25	• Potent inflammatory activity and its association with various human disease states suggest this cytokine family as an important contributor to the pathophysiology of pulmonary diseases
IL-28A, 28B, and 29	• Alternative therapeutic choice to type 1 IFNs
IL-32	• Potential therapeutic target in rheumatoid arthritis

AIDS, Acquired immunodeficiency syndrome; *EOP*, erythropoietin; *G-CSF*, granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *M-CSF*, macrophage colony-stimulating factor; *HIV*, human immunodeficiency virus; *IFN*, interferon; *IL*, interleukin.
*Many of the listed applications refer to clinical trials and are not approved uses.

Granulocyte-Macrophage Colony-Stimulating Factor

Two hematopoietic growth factors, granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), regulate the production and deployment of neutrophils. Both CSFs stimulate cell division and accelerate marrow transit times. Autonomous production by the tumor of GM-CSF (or G-CSF) has also been implicated as a pathophysiologic mechanism underlying leukemoid reactions in cancer patients. GM-CSF is used clinically for the treatment of neutropenia after chemotherapy or transplantation, for the treatment of graft failure, and for peripheral blood stem cell mobilization (see Table 57-2[9,10]).

GM-CSF: Clinical Trials/Applications

GM-CSF is safe and effective in the treatment of patients with acute myelogenous leukemia (AML) who are undergoing induction therapy. GM-CSF decreases the neutropenic period and the rate of serious infections in the elderly. This molecule is also indicated for accelerating myeloid reconstitution after allogeneic bone marrow transplantation. It also increases survival in patients who have engraftment failure or delay after allogeneic or autologous transplantation, and it can be exploited to enhance stem cell mobilization for transplant.

Granulocyte Colony-Stimulating Factor

G-CSF has revolutionized the treatment of neutropenia and its sequelae (infection). It has been used by millions of patients worldwide and is remarkably effective and virtually devoid of side effects (see Table 57-2[11]). Some patients with solid tumors present with significantly increased leukocyte counts due to G-CSF secretion. Finally, point mutations in the gene for the G-CSF receptor have been described anecdotally in patients with AML that evolved from severe congenital neutropenia.

G-CSF: Clinical Trials/Applications

G-CSF promotes a rapid increase in neutrophilic leukocytes, which lasts about 24 hours. Despite the multitude of patients who have received G-CSF, few side effects have been reported. Even very long-term G-CSF administration seems fairly innocuous; the most common toxicity is bone pain.

A summary of current American Society for Clinical Oncology (ASCO) guidelines suggests that CSF can be used for primary prophylaxis of febrile neutropenia after chemotherapy if the risk is about 20%. It is also recommended for patients at high risk, based on age, medical condition, disease characteristics, and myelotoxicity of chemotherapy. Prophylaxis is also recommended for diffuse aggressive lymphoma in patients older than 65 treated with curative therapy. Patients exposed to lethal radiotherapy should also receive CSF.[12,13] In the transplantation setting, the administration of G-CSF reduces neutropenia and infection. G-CSF also mobilizes autologous peripheral blood progenitor cells; these cells are used to accelerate hematopoietic recovery in patients who have received myeloablative or myelosuppressive chemotherapy. Finally, in patients with acquired immunodeficiency syndrome (AIDS), G-CSF reverses and prevents zidovudine-induced neutropenia.[11] Of interest, G-CSF may also be useful in enhancing the defenses of nonneutropenic patients with AIDS who have bacterial infections. However, studies have shown only modest benefit for G-CSF in the setting of nonneutropenic infection in normal individuals.

Macrophage Colony-Stimulating Factor

M-CSF affects a variety of organ systems, but its cardinal effect remains its ability to influence most aspects of monocyte/macrophage development and function (Table 57-3[14]). In addition to its hematopoietic effects, M-CSF and Fms (the M-CSF receptor) are expressed in the brain. This cytokine induces microglial proliferation, activation, and survival. In malignancy, mutations in Fms have been reported at codon 969 in about 10% of cases of human myeloid malignancies.

M-CSF: Clinical Trials/Applications

M-CSF given to patients with AML after consolidation chemotherapies shortened the periods of neutropenia and thrombocytopenia after chemotherapy and reduced the incidence and shortened the duration of febrile neutropenia.[14] Similar salutary effects have been reported after chemotherapy or bone marrow transplantation. M-CSF can elevate neutrophil counts in children with chronic neutropenia.

Stem-Cell Factor

Stem-cell factor (SCF) is also known as kit ligand, mast cell growth factor, or steel factor. It functions as a hematopoietic cytokine that triggers its biologic effect by binding to c-kit (the SCF receptor; see Table 57-3[15-18]). The average concentration of SCF in normal human serum is 3.3 ng/mL. Serum SCF concentrations are not elevated in patients with aplastic anemia, myelodysplasia, or chronic anemia or after marrow ablative therapy. Thus, the level of SCF in the circulation, unlike the level of EPO, is not inversely related to the number of hematopoietic cells. Alterations in the local distribution of SCF within the skin have been implicated in the pathogenesis of cutaneous mastocytosis.[1] Point mutations in the c-kit receptor cytoplasmic domain have been identified in murine and human mast cell lines and in hematopoietic cells from patients with mast-cell disorders. Finally, activating mutations in kit, a kinase receptor, characterize a type of leiomyosarcoma known as gastrointestinal stromal tumor. This finding has led to new targeted therapies of tremendous impact.

SCF: Clinical Trials/Applications

SCF seems to be reasonably well tolerated by patients, with the predominant side effects being transient local erythema and long-lasting hyperpigmentation at injection sites. The most worrisome toxicity is a mast cell effect resulting in allergic-like reactions characterized by urticaria, with or without respiratory symptoms.[1]

Of special interest is the role of mutations in the SCF receptor (kit) in gastrointestinal stromal tumors. These mutations activate the kinase enzymatic activity of kit. Kinase inhibitors targeted against kit (imatinib and sunitinib) have been found to be dramatically effective in these notoriously chemotherapy-resistant tumors.[16]

Thrombopoietin

The cytokine basis of megakaryocyte and platelet production has been more enigmatic than that of other lineages (see Table 57-3[19-26]). Factors that have now been implicated in at least some aspects of thrombocyte development include interleukin-3 (IL-3), IL-6, IL-9, IL-11, G-CSF, GM-CSF, SCF, leukemia inhibiting factor, and thrombopoietin (TPO). The last molecule is believed to be of paramount importance in the physiologic regulation of platelet production. Unfortunately, however, compared with the striking effects of the granulopoietic factors in neutropenic patients, use of the thrombopoietic molecules in the clinic setting has been disappointing. It has been suggested that the temporal pace of the thrombopoietic response is physiologically ordained to be considerably slower than the myelopoietic response, and that may explain why short courses of thrombopoietins seem to be ineffective.[13]

TPO: Clinical Trials/Applications

Two forms of TPO have entered clinical trials[20]: (1) TPO (the full-length polypeptide) and (2) polyethylene glycol (PEG)-conjugated recombinant human megakaryocyte growth and development factor (PEG-rHuMGDF). Because its biologic action is prolonged, parenteral administration of TPO for 7 to 10 days increases platelet production 6 to 16 days later.[21] Results of clinical trials of PEG-rHuMGDF or recombinant human TPO in patients with cancer who were receiving chemotherapy, albeit with regimens that produce only moderate thrombocytopenia, suggest that platelet counts return to baseline significantly faster and that the nadir platelet counts are higher.[22] However, the effectiveness of these molecules in accelerating platelet recovery after myeloablative therapy has not been impressive.[23] Furthermore, in most patients with delayed platelet recovery after peripheral-blood stem-cell or bone marrow transplantation, recombinant human TPO did not significantly raise platelet counts.[24] TPO can result in

Table 57-3 Major Biologic Activities of Growth Factors and Cytokines

	Biologic Activities
Erythropoietin (136)	• Promotes the proliferation, differentiation, and survival of erythroid precursors
GM-CSF	• Stimulates growth of multilineage progenitors, BFU-E, granulocyte, macrophage, and eosinophil colonies • Induces migration and proliferation of vascular endothelial cells • Activates mature phagocytes (neutrophils, macrophages, eosinophils)
G-CSF	• Regulates production and function of neutrophils
M-CSF	• Influences most aspects of monocyte/macrophage development and function • Stimulates hematopoiesis • Induces osteoclast production • Helps maintain pregnancies • Lowers cholesterol levels • Affects microglial function
Stem cell factor	• Promotes hematopoiesis at multiple levels • Influences primordial germ cell and melanocyte migration during embryonic life • Affects immunoregulatory cells (B and T cells, mast cells, natural killer [NK] cells, dendritic cells) • Influences hematopoietic cell adhesive properties
Thrombopoietin	• Major regulator of platelet production • Acts in synergy with EPO to stimulate growth of erythroid progenitors • Acts in synergy with IL-3 and SCF to stimulate proliferation and prolong survival of hematopoietic stem cells
IL-1	• Induces production of multiple cytokines • Upregulates cell-surface cytokine expression • Synergizes with other cytokines to stimulate hematopoietic progenitor proliferation • Influences immune regulation (T- and B-cell responses) • Modulates endocrine function • Affects bone formation • IL-1 R acts as a cofactor in neural transmission • IL-1 is probably not critical for normal hematopoiesis; it is, however, central in disease states
IL-2	• Induces proliferation and activation of T cells, B cells, and NK cells
IL-3	• Stimulation of multilineage hematopoietic progenitors, especially when used in combination with other cytokines (SCF, IL-1, IL-6, G-CSF, GM-CSF, EPO, TPO)
IL-4 and IL-13	• Both IL-4 and IL-13 are involved in allergic reaction (induce switch to IgE)
IL-5	• Regulates production, function, survival, and migration of eosinophils • Enhances basophil number and function
IL-6	• B- and T-cell development and function • Thrombopoiesis • Acute-phase protein synthesis • Inhibition of hepatic albumin excretion • Osteoclastic bone resorption • Neural differentiation
IL-7	• Critical for T- and B-cell development
IL-8	• Potent chemoattractant agent for a variety of leukocytes, especially neutrophils • Suppresses colony formation of immature myeloid progenitors • Increases keratinocyte and endothelial cell proliferation • Increases adhesiveness of melanoma cells
IL-9	• Supports clonogenic maturation of erythroid progenitors • Acts as a mast cell differentiation factor • Protects lymphomas from apoptosis • Cooperates with IL-4 in B-cell responses • Enhances neuronal differentiation
IL-10	• Inhibits cytokine synthesis by Th1 cells and monocytes/macrophages • Stimulates B cell proliferation • Involved in transformation of B cells by Epstein-Barr virus and tumor necrosis factor (TNF) receptors
IL-11	• Best known as a thrombopoietic factor • Stimulates multilineage progenitors, erythropoiesis, myelopoiesis, and lymphopoiesis • Decreases mucositis in animal models • Stimulates osteoclast development • Inhibits adipogenesis • Stimulates proliferation of neuronal cells

Continued

Table 57-3 Major Biologic Activities of Growth Factors and Cytokines—cont'd

Biologic Activities—cont'd	
IL-12	• Proinflammatory cytokine important in resistance to infections • Th1 development • Stimulatory and inhibitory effects on hematopoiesis
IL-15	• Triggers proliferation and immunoglobulin production in preactivated B cells • Number of $CD8^+$ memory T cells may be controlled by balance of IL-15 (stimulatory) and IL-12 (inhibitory) • Stimulates proliferation of NK cells and activated $CD4^+$ or $CD8^+$ T cells • Facilitates the induction of LAK cells and CTLs • Stimulates mast cell proliferation • Promotes proliferation of hairy-cell leukemia and chronic lymphocytic leukemia cells
IL-16	• Chemoattractant for $CD4^+$ cells (T cells, monocytes, eosinophils) • May be involved in asthma and in granulomatous inflammation • Has antiviral effects on HIV-1
IL-17	• May mediate, in part, T-cell contribution to inflammation • Stimulates epithelial, endothelial, fibroblastic, and macrophage cells to express a variety of inflammatory cytokines • Promotes the capacity of fibroblasts to sustain hematopoietic progenitor growth • Promotes differentiation of dendritic cell progenitors • May be involved in the pathogenesis of rheumatoid arthritis and graft rejection
IL-18	• Promotes production of IFN-γ, TNF • Targets are T cells, NK cells, and macrophages • Promotes Th1 responses to virus
IL-19	• Induces IL-6 and TNF-α
IL-20	• Induction of genes involved in inflammation such as TNF-α, MRP14, and MCP-1
IL-21	• Mainly regulates T-cell proliferation and differentiation • Regulates cell-mediated immunity and the clearance of tumors
IL-22	• Upregulates the production of acute-phase reactants • Induces the production of ROS in resting B cells
IL-23	• A unique function of IL-23 is the preferential induction of proliferation of the memory subset of T cells
IL-24	• Induces IL-6, TNF-α, IL-1b, IL-12 and GM-CSF • Functionally it has the opposite effects with IL-10 • Infection with Ad-IL24 results in down-regulation of Bcl-2 and Bcl-XL (anti-apoptotic proteins) and upregulation of Bax and Bak (pro-apoptotic proteins) in cancer cells
IL-25	• IL-25 induces IL-4, IL-5, and IL-13 gene expression and protein production
IL-26	• Immune-protective role against viral infection
IL-27	• Early Th1 initiation • Synergizes with IL-12 in inducing IFN-γ production by T cells and NK cells
IL-28A, 28B, and 29	• Antiviral activities
IL-31	• Responsible for promoting the dermatitis and epithelial responses that characterize allergic and nonallergic diseases
IL-32	• Induces other proinflammatory cytokines and chemokines such as TNF-α, IL-1β, IL-6, and IL-8 • Induces IκB degradation • Phosphorylates p38 MAPK signaling pathway
IL-33	• Activates NF-κB and MAP kinases • Drives production of Th2-associated cytokines from in vitro polarized Th2 cells • Induces the expression of IL-4, IL-5, and IL-13 • Leads to severe pathologic changes in mucosal organs
IL-35	• Contributes Treg suppressor activity • Induces IL-10 and IFN-γ serum levels • Reduces induction of IL-17
IL-36	• Activates NFκB and MAP kinases • Play important role in skin biology • Involved in the initiation and regulation of immune responses
IL-37	• Regulates inflammatory responses
IL-38	• Reduces IL-36γ induced IL-8 production

AIDS, Acquired immunodeficiency syndrome; *BFU-E*, burst-forming unit-erythroid; *CTL*, cytotoxic T lymphocyte; *G-CSF*, granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *HIV*, human immunodeficiency virus; *IFN*, interferon; *IL*, interleukin; *LAK*, lymphokine-activated killer; *M-CSF*, macrophage colony-stimulating factor; *NK*, natural killer; *ROS*, reactive oxygen species; *SCF*, stem-cell factor; *TNF*, tumor necrosis factor; *TPO*, thrombopoietin.

multilineage mobilization of peripheral blood progenitor cells. The kinetics of progenitor release differs from that after G-CSF. Following G-CSF, peripheral blood progenitors increase almost immediately, peak at day 5 to 6, and decrease with G-CSF cessation. In contrast, PEG-MGDF resulted in a late and sustained increase in progenitors, with levels first detected on day 8 and climbing on day 12, despite cytokine discontinuation.[26] PEG-rHuMGDF has also been given to healthy subjects in a single dose of 3 mg/kg of body weight. Administration of this molecule increased the yield of platelets by a factor of nearly 4 and was associated with a quadrupling of platelet counts in the recipients of the apheresed platelets.[25]

Interleukin-1

Interleukin-1 (IL-1α and IL-1β) is the prototypic multifunctional cytokine with numerous roles in both physiological and pathological states (see Table 57-3[27-32]). This molecule influences nearly every organ system. Because IL-1 is a highly inflammatory cytokine, the margin between salutary effects and serious toxicity is exceedingly narrow.

High levels of IL-1 are seen in patients with infections (viral, bacterial, fungal, and parasitic), intravascular coagulation, and cancer (both solid tumors and hematologic malignancies). IL-1RA, a naturally occurring receptor antagonist, may also be dysregulated in inflammatory and neoplastic disease. Ultimately, it is the balance between agonist and antagonist that is probably important in determining disease manifestation.

The tumor microenvironment consists of tumor, immune, stromal, and inflammatory cells, which produce cytokines, growth factors, and adhesion molecules that promote tumor progression and metastasis. IL-1, as a pleiotropic cytokine, is known to be upregulated in many tumor types and has been implicated as a factor in tumor progression via the expression of genes associated with metastatic and angiogenic functions and growth factors. Solid tumors in which IL-1 has been shown to be upregulated include breast, colon, lung, head and neck cancers, and melanomas. Patients with IL-1–producing tumors have generally poor prognoses.[33-36]

Therefore the role of IL-1RA, as a potential novel therapeutic in cancer treatment, is being actively investigated. It currently is an approved treatment for patients with rheumatoid arthritis. This naturally occurring protein has been shown to decrease tumor growth, angiogenesis, and metastases in mouse models. There are other agents that are capable of inhibiting the inflammatory and tumor promoting effects of IL-1 such as anti-IL-1 monoclonal antibodies, the soluble IL-1R type II, and IL-1β–converting enzyme inhibitors. They are currently being used for the treatment of rheumatoid arthritis, but additional studies are necessary to determine their applicability as a novel therapy in cancer treatment.

IL-1: Clinical Trials/Applications

IL-1α and IL-1β have also been administered in clinical trials, mainly involving cancer patients.[27] In general, the acute toxicities of either isoform of IL-1 were greater after intravenous injection than after subcutaneous injection. Subcutaneous injection was associated with significant local pain, erythema, and swelling. Dose-related chills and fever were observed in nearly all patients, and even a 1-ng/kg dose was pyrogenic. Nearly all patients receiving intravenous IL-1 at doses of 100 ng/kg or greater experienced significant hypotension, probably because of induction of nitric oxide. IL-RA has been approved by the FDA for the treatment of rheumatoid arthritis.[37] Its use in metastatic disease to reduce IL-1 activity, particularly IL-1β, in cancer is being actively discussed. The most compelling design could be to add an IL-1 blocking approach to anti-VEGF or antibodies to VEGF receptors in order to reduce toxic side effects by increasing the anti-angiogenic efficacy.

Interleukin-2

IL-2 was discovered more than 30 years ago and acts as a T-cell growth and activation factor. To a lesser extent, B cells, natural killer (NK) cells, and lymphokine-activated killer (LAK) cells also respond to this cytokine (see Table 57-3[38]). Following binding of IL-2 with the trimeric receptor complex, internalization occurs and cell-cycle progression is induced in association with the expression of a defined series of genes. A second functional response occurs through the IL-2βγ dimeric receptor, also known as the intermediate affinity dimeric complex (10^{-9} kDa), and involves the differentiation of several subclasses of lymphocytes into LAK cells.[39] This response occurs in patients with cancer who receive IL-2[40,41] and was originally considered to be a critical part of the anticancer effect of IL-2. LAK cells recognize and kill tumor cells, regardless of the histocompatibility expression status of fresh human tumor cells tested.[42] The multiple biologic effects of IL-2 on immune cells include the induced proliferation of antigen-stimulated T cells and induction of cytotoxicity in major histocompatibility complex (MHC)-restricted, antigen-specific T-lymphocytes, NK cells leading to non–MHC-restricted LAK cell activity, and activation of

tumoricidal monocytes. It is not clear what roles any of these effector systems have in vivo.[43]

IL-2: Clinical Trials/Applications

Because of its potent ability to stimulate cytotoxic T cells and NK cells, IL-2 has been an attractive candidate for immunotherapy of metastatic cancer, such as melanoma and kidney cancer, although with relatively low response rates and at the cost of considerable toxicity. For instance, overall response rates of renal cell cancer to IL-2 are in the range of 15% to 25%, with a complete remission rate of 5% to 10%. Complete response rates and response duration seem to favor high-dose rather than low-dose regimens. In melanoma biochemotherapy, regimens combining IL-2 and interferon-α with, for instance, cisplatin, vinblastine, and dacarbazine produce response rates of up to 60%, but this has yet to be translated into a confirmed survival effect.[38] IL-2 has also been given to leukemic patients in a variety of doses and schedules, with hints that it might be useful in remission maintenance.[38] Development of second-generation IL-2 analogs that do not induce the same high levels of secondary cytokines provides promise for further reduction of toxicities, providing that the efficacy is not dependent on these secondary effects.[44] Another approach to therapy has been to use IL-2 attached to a toxin to target and kill cancer cells bearing the IL-2 receptor. DAB389IL-2 is an IL-2 receptor (IL-2R)-specific fusion protein. It contains the enzymatic and translocation domains of the diphtheria toxin fused to human IL-2. This chimera is able to direct the cytocidal action of the diphtheria toxin enzymatic region only to cells that bear the IL-2R. DAB389IL-2 has been approved for the treatment of cutaneous T-cell lymphomas that are CD25 (IL-2 receptor) positive. Antitumor effects may also be seen in patients with other lymphoid diseases bearing the IL-2 receptor.[1]

Recent advances for the use of low-dose IL-2 therapy is promising on chronic graft-versus-host disease (GVHD), which develops in some patients who have undergone allogeneic hematopoietic stem-cell transplantation for the treatment of lymphomas and leukemias. Chronic GVHD, a systemic inflammatory disorder with pleomorphic autoimmune features, is associated with considerable morbidity and mortality. In this setting, it has been shown that IL-2 promotes both effector and regulatory T-cell responses without impairing other immune functions in the patients.[45]

About half of patients showed clinical improvement, even including an improvement in GVHD manifestations in some. These studies may provide a path for the effective use of IL-2 as a regulatory component of immunotherapy. However, the number of subjects in these trials needs to be expanded, and combinations of IL-2 with other directed immunotherapies, such as the infusion of ex vivo expanded Treg cells, could be considered as alternative approaches. However, the results of low-dose IL-2 regimens as an immunotherapy approach in cancer have been disappointing, presumably because of the combined effects of the expansion of the $CD25^+$ Treg cell population and the poor stimulation of $CD25^-$ antitumor T cells. In contrast, as a single agent or in combination with tumor vaccines, the use of high-dose IL-2 in patients with metastatic melanoma or metastatic renal cell carcinoma has led to significant therapeutic responses in up to 20% of cases and to long-term survival beyond 10 years in approximately 10% of cases. In a recent randomized, multicentral Phase III trial in advanced melanoma, the response rate was higher and progression-free survival longer with vaccine [gp100:209-217(210M) peptide vaccine] and interleukin-2 than with interleukin-2 alone.[46]

Interleukin-3

IL-3 stimulates multilineage hematopoietic progenitors (see Table 57-3[47-50]). In vitro data from supernatants of long-term bone marrow cultures suggest that marrow stromal cells produce reduced levels of IL-3 in patients with aplastic anemia.[1] IL-3 has also been implicated in patients with acute lymphocytic leukemia (ALL) with a (5:14)(q31;q32) translocation.[1] In two such patients, the translocation resulted in juxtaposition of the IL-3 gene and the Ig heavy-chain gene, and excess IL-3 transcripts were produced by the leukemic cells, perhaps explaining the eosinophilia seen in these patients.

IL-3: Clinical Trials/Applications

IL-3 has been studied in clinical trials of peripheral blood stem cell mobilization, as well as for postchemotherapy and post-transplantation cytopenias and for bone marrow failure states. Most studies have shown only modest effects of IL-3 by itself; in conjunction with other growth factors, however, significant benefits have been demonstrated. For instance, in patients with bone marrow failure treated with IL-3 followed by GM-CSF (IL-3 dosages greater than 1.2 μg/kg/d), 7 (44%) of 16 patients with severe pancytopenia had multilineage responses with normalization or near-normalization of blood counts. Although prolonged therapy was necessary to achieve maximal hematopoietic recovery, responses were durable for up to 4 years after discontinuation of treatment.[49,51] Side effects of IL-3 include dose-dependent fever, rash, fatigue, diarrhea, rigor, musculoskeletal pain, chills, headache, conjunctivitis, edema, chest pain, dyspnea, decreases in platelet counts, increases in basophilic counts, marrow fibrosis, and pulmonary edema. The tolerance to IL-3 seems to be severalfold better in patients with bone marrow failure states compared with those treated after chemotherapy.[49]

Interleukin-4 and Interleukin-13

IL-4 and IL-13 are closely related.[52] They share biologic and immunoregulatory functions on B cells, monocytes, dendritic cells, and fibroblasts. The major regulatory sequences in the IL-4 and IL-13 promoters are identical, thus explaining their restricted expression pattern in activated T cells and mast cells. Furthermore, the IL-4 and IL-13 receptors are multimeric and share at least one common chain, IL-4RA. This, together with similarities in IL-4 and IL-13 signal transduction, explains the remarkable overlap of biologic properties between these two cytokines (see Table 57-3[52-54]). The inability of IL-13 to regulate T-cell differentiation due to a lack of IL-13 receptors on T lymphocytes, however, represents a major difference between these cytokines. Therefore, despite the impact redundancy of these two molecules, regulatory mechanisms are in place to guarantee their distinct functions.

IL-4: Clinical Trials/Applications

Despite the preclinical promise of IL-4, to date clinical trials of this molecule have found the molecule to be safe and nontoxic in humans but with only sporadic antitumor activity.[54]

Interleukin-5

IL-5 is a T-cell–derived cytokine involved in the pathogenesis of atopic diseases. It specifically controls the production, activation, and localization of eosinophils. Eosinophils mediate allergic and asthmatic symptoms. T cells purified from the bronchoalveolar lavage and peripheral blood of persons with asthma secrete an elevated amount of IL-5. Therefore, agents that suppress the production or activity of IL-5 would be expected to ameliorate the pathologic effects of the allergic response (see Table 57-3[55]). Interestingly, IL-5 is secreted from Reed-Sternberg cells and may therefore be the cause of eosinophilia in patients with Hodgkin disease.[1]

Interleukin-6

IL-6 exhibits functional pleiotropy and redundancy (see Table 57-3[56-59]). IL-6 is involved in the immune response, inflammation, and hematopoiesis. Indeed, before its complete characterization, this molecule was variously referred to as interferon-β2, B-cell stimulatory factor 2, human plasmacytoma growth factor, or hepatocyte stimulatory factor. The biologic effects of IL-6 include synthesis of acute-phase reactants in the liver, as well as effects on the hypothalamic-pituitary axis, bone resorption, and both the humoral and cellular arms of the immune system.[1] As a major inducer of the acute-phase response, this cytokine may play a role in the pathogenesis of sepsis. IL-6 acts as a growth factor for myeloma/plasmacytoma, keratinocytes, mesangial cells, renal cell carcinoma, and Kaposi sarcoma and hematopoietic stem cells. On the other hand, IL-6 also inhibits the growth of myeloid leukemic cell lines and certain carcinoma cell lines.

IL-6 has been implicated as a mediator of B symptoms in lymphoma.[56] Elevated serum IL-6 concentrations have also been associated with an adverse prognosis both in Hodgkin lymphoma and in non-Hodgkin lymphoma (NHL[57,58]). In diffuse large-cell lymphoma, IL-6 levels were found to be the single most important independent prognostic factor selected in multivariate analysis for predicting complete remission rate and relapse-free survival.[57] IL-6 levels may also be exploitable as a prognostic factor in numerous solid and hematopoietic cancers.

IL-6: Clinical Trials/Applications

In patients undergoing chemotherapy or autologous transplantation, IL-6 has minimal to no platelet-enhancing activity at tolerable doses. Toxicity includes fever and anemia.[1] IL-6 has also been tested as an antitumor agent in melanoma and renal cell carcinoma. Response rates have been low (less than 15%). IL-6 inhibitors have entered the clinic. An antibody against IL-6 receptor (MRA) has been approved in Japan for the treatment of Castleman disease. An antibody against IL-6 (CNTO328) is being studied in the United States, and preliminary results show encouraging activity in lymphoma and Castleman disease. CNTO-328 is also being tested in a number of Phase I/II clinical trials in transplant-refractory myeloma and castration-resistant prostate cancer.[60] Initial results suggested that declining C-reactive protein levels during treatment may reflect biologic activity.

Interleukin-7

IL-7 promotes the proliferation of B-cell progenitors in the absence of stromal cells (see Table 57-3[61-64]). It is secreted by stromal cells in the bone marrow and thymus and is irreplaceable in the development of both B and T cells.[1] High IL-7 levels are found in states of T-cell depletion and may therefore play a role in promoting T-cell expansion.[64] High

levels of IL-7 are also found in chronic lymphocytic leukemia and in Burkitt lymphoma, and transgenic mice overexpressing the IL-7 gene show dramatic changes in lymphocyte development, which can result, in some instances, in the formation of lymphoid tumors.[1] A recent Phase I study with recombinant hIL-7 administration in refractory malignancies showed that IL-7 has potent biologic activity over a dose range that is well tolerated in humans and suggests further exploration of its possible therapeutic applications.[65] It induced a marked expansion of the T-cell mass resulting in a rejuvenated T-cell profile with an increased T-cell repertoire diversity and a decreased proportion of regulatory T cells.

Interleukin-8

IL-8 is a potent, proinflammatory chemokine that induces trafficking of neutrophils across the vascular wall (chemotaxis; see Table 57-3[66,67]). This molecule belongs to a chemokine superfamily that includes neutrophil-activating peptide-2, platelet factor-4, growth-related cytokine (GRO), and interferon inducible protein-10, all of which are responsible for the directional migration of various cells.[66] Interestingly, the IL-8 receptor demonstrates strong homology to a gene encoded by human herpesvirus-8 (HHV-8; implicated in the etiology of Kaposi sarcoma[1]). IL-8 can induce tumor growth, an effect attributed to its angiogenic activity, a property that promotes vascularization. On the other hand, antitumor effects of IL-8 have also been reported. Of interest in this regard is the fact that increased levels of IL-8 have been observed in lung carcinomas and in melanomas. IL-8 may be a growth factor for pancreatic cancer and for melanoma.[66] In melanomas, IL-8 levels correlate with the growth and metastatic potential of the tumor cells, and exposure of the cells to interferon decreases IL-8 levels and cancer cell proliferation.[67] Blocking IL-8 or IL-8R has been suggested as a therapeutic strategy.[66]

Interleukin-9

Human IL-9 was originally identified as a mitogenic factor for a human megakaryoblastic leukemia. More recently, IL-9 targets were found to encompass a wide range of cells (see Table 57-3[68,69]). There is an interesting paradox between the unresponsiveness of normal T cells to IL-9 and the potent activity of this molecule on lymphoma cells. This contrast is illustrated by the observation that murine T cells acquire the ability to respond to IL-9 after a long period of in vitro culture, while they simultaneously acquire characteristics of tumor cell lines. Observations made with transgenic mice also demonstrate the oncogenic potential of dysregulated IL-9 production, because 5% to 10% of mice that overexpress this cytokine develop lymphoblastic lymphomas.[69] In line with these findings, constitutive IL-9 production by human Hodgkin lymphomas and large-cell anaplastic lymphomas has now been clearly documented.[68]

Interleukin-10

IL-10 is a pleiotropic cytokine, initially discovered as an activity produced by murine type 2 helper T cells (Th2; see Table 57-3[70-74]). It was first called cytokine synthesis inhibitory factor because of its ability to inhibit the production of certain cytokines by Th1. Of interest, IL-10 exhibits strong DNA and amino acid sequence homology to an open reading frame—BCRF1—in the Epstein-Barr virus (EBV) genome.[1] Indeed, *BCRF1* has been called viral IL-10. The protein product of *BCRF1* (viral IL-10) exhibits properties similar to those of human IL-10. The ability of EBV to transform human B cells may be, at least in part, a ramification of the ability of viral IL-10 to stimulate B-cell proliferation.

IL-10 may have a role in the development of lymphoma through several mechanisms, including its proliferation-stimulating properties on B cells and its immunosuppressive properties that impair viral control and tumor immunosurveillance. This role has been demonstrated in a severe combined immunodeficiency (SCID) mouse model for lymphomagenesis.[1] Of interest, primary B lymphoma cells from both HIV-positive and HIV-negative patients with lymphoma (NHL) secrete substantial amounts of IL-10. Indeed, several groups of investigators have evaluated the role and prognostic significance of IL-10 in patients with NHL.[73,74] A series of studies has demonstrated that IL-10 levels are elevated in lymphoma patients and that high IL-10 levels correlate with prognosis, if an assay that detects both human and viral IL-10 is used. Assays that detect only human IL-10 yield no correlation with prognosis. These studies raise additional questions about the participation of EBV in lymphomagenesis.

In general, the biologic role of IL-10 in cancer is quite complex. The presence of IL-10 in advanced metastases and the positive correlation between serum IL-10 levels and progression of disease support the negative regulatory role of IL-10 in the tumor microenvironment. Therefore, inhibition of IL-10 could be a useful therapeutic approach as a novel cancer immunotherapy. The combination of IL-10 antagonism and immunostimulatory approaches such as cancer vaccines could also be considered as an attractive

design. However, because of its various biologic functions in the tumor microenvironment, careful clinical investigation to define the administration of anti-IL-10 agents is critically important.

Interleukin-11

IL-11 was originally characterized as a thrombopoietic factor, but it is now known to be expressed and have activity in a multitude of other systems, including the intestine, testes, and central nervous system (see Table 57-3[75,76]). Clinically, this cytokine has been approved by the FDA for amelioration of chemotherapy-induced thrombocytopenia.

IL-11 acts as a synergistic factor with IL-3, GM-CSF, and SCF to stimulate proliferation of human primary leukemia cells, myeloid leukemia cell lines, megakaryoblastic cell lines, and erythroleukemic cell lines and to stimulate leukemic blast colony formation. IL-11 mRNA expression in leukemic cells and inhibition of leukemic cell growth by IL-11 antisense oligonucleotides suggest that IL-11 may function as an autocrine growth factor in leukemic cell lines. Although IL-11 stimulates the proliferation of murine plasmacytoma cells and murine hybridoma cells, the effect of IL-11 on the growth of human myeloma/plasmacytoma cells is controversial.[75]

IL-11: Clinical Trials/Applications

A multicenter, randomized, placebo-controlled clinical trial of IL-11 versus placebo showed that IL-11 reduced the need for platelet transfusion after chemotherapy. This led to its FDA approval. Edema was the most common clinical problem associated with IL-11. Some patients developed pleural effusions, shortness of breath, and/or atrial arrhythmias.[1] Lower dosages of IL-11 (10 μg/d subcutaneously) have been reported to be safe for prolonged administration and to effectively raise platelet counts in patients who had a variety of bone marrow failure states.[76] Given the high expression of IL-11Rα protein and the proposed role of IL-11/IL-11Rα signaling in bone metastasis, it has been considered as a candidate target for primary and metastatic osteosarcoma. In animal models of osteosarcoma, it has been shown that IL-11Rα within the bone microenvironment is accessible to a circulating particle displaying a mimic of the native ligand, IL-11, and strongly accumulates within the tumor. The data indicated that IL-11Rα is a candidate target in human osteosarcoma and may serve as a target for ligand-directed delivery of agents against this disease.[77] More recently, it has been also shown that the intravenous injection of IL-11Rα-CAR T cells induced the regression of established osteosarcoma lung metastases by an ex-vivo model using genetically modified T cells targeting IL-11Rα.[78]

Interleukin-12

IL-12 is an NK cell stimulatory factor and is crucial to the development of Th1 cells.[79] There seems to be a common pathway leading from the innate immune response to adaptive immunity-intracellular pathogens to stimulate macrophages to produce IL-12, which then promotes the development of Th1 cells from a naïve cell population. This pathway may be exploitable in the design of novel immunotherapies and vaccines (see Table 57-3[79-81]). IL-12 is a potent proinflammatory molecule that is essential for resistance to bacterial, fungal, and parasitic infections. It is produced within a few hours of infection, activates NK cells, and, through its ability to induce interferon (IFN)-γ production, enhances the phagocytic and bacteriocidal activity of phagocytic cells and their ability to release proinflammatory cytokines, including IL-12 itself. IL-12 is also a key immunoregulatory molecule, especially of Th1 responses. It is produced during the early phases of infection and inflammation and sets the stage for the ensuing antigen-specific immune response, favoring differentiation and function of the Th1 T cells while inhibiting the differentiation of the Th2 T cells. IL-12 also enhances the generation of cytotoxic T cells and LAK cells. IL-12 synergizes with other hematopoietic factors to promote survival and proliferation of early multipotent hematopoietic progenitor cells and lineage-committed precursor cells.[1] Although IL-12 has mostly stimulatory effects on hematopoiesis in vitro, IL-12 treatment in vivo decreases bone marrow hematopoiesis and both transient anemia and neutropenia.

IL-12: Clinical Trials/Applications

IL-12 has the potential for exploitation in the treatment of allergy and as an adjuvant for infectious disease therapy.[80] In addition, the ability of IL-12 to revert existing states of tolerance or anergy makes it a candidate for use in the composition of vaccines for infectious agents or tumors. Phase I clinical trials have begun in oncology (with an emphasis on melanomas, renal cell carcinomas, and cutaneous T-cell lymphomas) as well as in the setting of HIV infection and chronic hepatitis B and C. In early clinical testing, IL-12 has shown limited benefit in patients with almost any malignancies. Moreover, in a clinical trial

testing a combination of IL-12 and rituximab in patients with follicular B-cell non-Hodgkin lymphoma, those treated with IL-12 showed a lower response rate.[82] Further studies showed that extended exposure to IL-12 induced T-cell exhaustion and contributed to the poor prognosis in these patients.[83] Long-term exposure of freshly isolated human CD4+ T cells to IL-12 caused T-cell dysfunction and induced expression of TIM-3 (a T-cell immunoglobulin and mucin domain protein with a known role in T-cell exhaustion), in vitro. TIM-3 was required for the negative effect of IL-12 on T-cell function. Importantly, TIM-3 also was highly expressed on intratumoral T cells that displayed marked functional impairment. These findings identify IL-12– and TIM-3–mediated exhaustion of T cells as a mechanism for poor clinical outcome when IL-12 is administered to follicular B-cell non-Hodgkin lymphoma patients.

Interleukin-15

IL-15 shares biologic activities with IL-2 (see Table 57-3[84,85]). Like IL-2, IL-15 is able to trigger both proliferation of and immunoglobulin production by normal B lymphocytes. IL-15 also stimulates the proliferation of NK cells and activated CD4+ and CD8+ T cells, and it facilitates the induction of cytolytic effector cells (such as LAK cells). Finally, the numbers of CD8+ memory T cells are maintained in animals by a balance between the stimulatory effect of IL-15 and the suppressive effects of IL-12. IL-15 responsiveness distinguishes malignant B cells from normal B lymphocytes. In contrast to normal B lymphocytes, which require preactivation in order to proliferate in response to IL-15, leukemic cells from patients with chronic B-cell malignancies proliferate in response to IL-15 regardless of in vitro preactivation. Two decades after its discovery, IL-15 is now one of the most promising new candidates in cancer immunotherapy, as well as for the treatment of infectious diseases. IL-15 is considered as a strong potential cancer therapeutic because of its ability to stimulate NK and CD8+ T cells without inducing capillary leak syndrome. Moreover, it does not trigger Tregs or suppressor cells that might alter its therapeutic benefits. The Phase I study of recombinant hIL-15 in refractory metastatic malignant melanoma and metastatic renal cell cancer is an active first-in-humans study conducted by the National Cancer Institute's Center for Cancer Research.

Interleukin-16

Cruikshank and Center first described IL-16 in 1982 (see Table 57-3[86]). They found that this molecule was a lymphocyte chemoattractant factor expressed by mitogen-stimulated human peripheral blood mononuclear cells (PBMCs). IL-16 has been implicated in several conditions, including asthma and granulomatous inflammation.[86] It may also have antiviral effects in the context of HIV-1.[1]

Interleukin-17

Human IL-17 was originally identified by Rouvier and colleagues (see Table 57-3[87,88]). Of interest, this molecule has 72% overall sequence identity at the amino acid level with open reading frame 13 of herpesvirus saimiri.[1] Although limited in number, studies suggest that IL-17 may be a soluble factor by which T cells induce or contribute to inflammation,[88] IL-17 can also stimulate epithelial, endothelial, and fibroblastic cells and macrophages to express a variety of cytokines. The cytokines released after exposure to IL-17 seem to be cell specific. For instance, fibroblast cells produce IL-1, G-CSF, IFN-γ, IL-6, and IL-8 in response to IL-17, and macrophages produce tumor necrosis factor (TNF)-α, IL-1β, IL-1Rα, IL-6, IL-10, and IL-12. IL-17 also exhibits indirect hematopoietic activity by enhancing the capacity of fibroblasts (through stimulation of growth factor release) to sustain the proliferation of CD34+ hematopoietic progenitors and their differentiation into neutrophils.[88] IL-17 can also promote the maturation of dendritic cell progenitors. Because IL-17 acts to differentiate early dendritic cells, it has been implicated in host T-cell allostimulation and graft rejection.[1]

Interleukin-18

IL-18 (IFN-inducing factor) was first described as a serum activity that induced IFN-γ production in mouse spleen cells.[1] It is related to the IL-1 family of genes (see Table 57-3[29,89,90]). IL-18 has a molecular weight of 18 to 19 kDa and has homology to IL-1.[89] Like IL-1β, IL-18 is initially synthesized as an inactive precursor molecule (pro-IL-18) lacking a signal peptide and is cleaved by ICE to yield an active molecule.[1] T lymphocytes, NK cells, and macrophages are primary targets for IL-18. For example, IL-18 directly stimulates the production of TNF in human blood CD4+ T lymphocytes and NK cells and plays an important role in promoting a long-lasting Th1 lymphocyte response to viral antigens. IL-18 does not seem to be an endogenous pyrogen but may nevertheless contribute to inflammation

and fever because it is a potent inducer of TNF, chemokines, and IFN.[90] In the case of IFN-γ induction, IL-18 acts as a costimulant with mitogens or IL-2. Indeed, mice deficient in ICE, the molecule that cleaves pro-IL-18 to its mature form, fail to produce IFN-γ in response to endotoxin.

More specifically in cancer, IL-18 plays a pivotal role in inflammation and immune responses during cancer progression. In patients with various cancers, increased IL-18 serum levels accompany tumor progression and have a negative prognostic impact. In the absence of Th1-like cytokines, IL-18 alone accelerates tumor progression. Moreover, IL-18 could drive the expression of PD-1 (Programmed Death-1) on mature NK cells with immunosuppressive functions that could act as negative regulator of general NK responses.[91] Therefore, systemic depletion of IL-18 by a binding protein is vital to stimulate NK cell–dependent immunosurveillance in tumor models. Because of this definition of IL-18 as an immunosuppressive cytokine in cancer, it is important to include this information in our novel clinical implementations of anti-PD-1 antibodies in human malignancies that produce IL-18.

Interleukin-19

IL-19 is one of the members of the human IL-10 family of cytokines (see Table 57-3[92]). IL-19 shares 21% amino acid identity with IL-10, and the exon/intron structure of IL-19 is similar to that of the human IL-10 gene, comprising five exons and four introns within the coding region of the IL-19 cDNA. The expression of IL-19 mRNA can be induced in monocytes by lipopolysaccharides or GM-CSF.

Interleukin-20

IL-20 was discovered as another IL-10–related cytokine. It induces keratinocyte proliferation and causes aberrant epidermal differentiation in the skin.[93] The IL-20 receptor complex is described as a heterodimer of two orphan class II cytokine receptor subunits termed *IL-20Rα* and *IL-20Rβ* (see Table 57-3[93-95]). Recombinant IL-20 binds to its receptor on keratinocytes and stimulates a STAT3-containing signal transduction pathway.[95] Experimental evidence suggests a role for IL-20 and its receptor in psoriasis, a multigenic skin disease characterized by increased keratinocyte proliferation and differentiation. Clinical applications are currently under consideration.

Interleukin-21

IL-21, a cytokine most closely related to IL-2 and IL-15 (see Table 57-3[94,96,97]), is involved in the proliferation and maturation of NK cell populations from bone marrow, as well as in the proliferation of mature B-cell and T-cell populations.[96] IL-21 has been implicated in the activation of innate immune responses and in the Th1 response. IL-21 also plays a critical role in regulating immunoglobulin production of B cells.[97]

IL-21 is emerging as a key T-cell and NK cell immunoregulatory cytokine with multiple effects.[98-100] It is produced mainly by activated $CD4^+$ T cells, $CD4^+$ follicular helper cells, and activated NK cells. In NK cells, IL-21 is a cell growth factor that induces NK cell expansion[101] and promotes cytotoxic activity, especially through antibody-dependent cellular cytotoxicity (ADCC) in cancer.[99,102,103] IL-21 also helps drive cytotoxic $CD8^+$ T-cell activity by enhancing the expression of perforin and granzymes.[99,103] However, in T cells, the effects of IL-21 can be pleiotropic and may depend on the state of differentiation of the T cell. In naïve and memory T cells, IL-21 promotes the maintenance of a memory phenotype by facilitating the stable expression of CD28 and other memory T-cell markers associated with the preservation of robust proliferative potential of the effector-memory cells after initial antigen-specific expansion.[98,104] IL-21 has also been found to inhibit Foxp3 expression and increase the expansion of cytolytic $CD8^+$ T cells during an immune response.[105] Another mechanism of action of IL-21 that has emerged recently is telomerase. In both NK cells and T cells, IL-21 has been shown to induce or maintain telomerase expression and prevent telomere erosion during cell expansion.[101] Nevertheless, by itself, IL-21 is a relatively poor driver of T-cell division. However, combinations of IL-21 with other gamma chain cytokines, such as IL-2 and IL-15, have been found to synergize in driving T-cell division and maintenance of an effector-memory phenotype. This has been demonstrated during the activation and expansion of tumor antigen–specific T cells in melanoma, for example, where IL-21 maintained CD28 expression in the primed MART-1–specific T cells and in tumor-infiltrating lymphocytes (TIL) expanded with IL-21 in synergy with IL-15.[104,106] Another key function for IL-21 in human T cells seems to be in facilitating the expression of effector molecules in $CD8^+$ T cells. For example, IL-21 was found to restore and increase perforin expression in $CD8^+$ T cells from HIV-infected patients.[107,108] Clinical trials with IL-21 have begun recently.

IL-21: Clinical Trials/Applications

A number of small Phase I and Phase II clinical trials with recombinant IL-21 (Denenicokin from Zymogenetics) have been completed with a dose range between 1 and 300 μg/kg given either subcutaneously or intravenously.[109] A recent Phase I dose-escalation clinical trial using subcutaneous IL-21 injection (3 to 300 μg/kg) 3 days a week for 8 or 16 weeks in metastatic cancer patients (melanoma and renal cell carcinoma) found that it was relatively well tolerated with a maximum tolerated dose of 200 μg/kg.[110] Interferon-γ, perforin, and granzyme B mRNA expression in peripheral blood and granzyme B protein expression in both $CD8^+$ T cells and NK cells were found at the higher dose range, consistent with the activation of cytotoxic lymphocytes.[110] Some clinical responses were also noted. Similar results were found in a Phase I trial using intravenous IL-21 infusion.[111,112] Other clinical trials are now combining IL-21 with tumor cell targeting monoclonal antibodies, such as anti-EGFR, to facilitate ADCC by driving NK cell activation. A regimen of IL-21 with cetuximab (anti-EGFR) in colorectal cancer patients was well tolerated, with some clinical benefit noted.[113] However, in other circumstances, dose-limiting hematologic toxicities in combination with other agents, such as sunitinib in renal cell carcinoma patients, have been found.[114] Overall, IL-21 is a promising agent against cancer, and its immunological mechanism of action suggests that it should be tested in combination with targeted monoclonal antibodies to accentuate ADCC[102] or with prior cytotoxic therapy to release tumor antigens and also activate NK cells, where the cytokine can then enhance an induced NK cell or T-cell response.

Interleukin-22

IL-22 was originally described as an IL-9–inducible gene and called IL-TIF.[155] IL-22 activities include induction of the acute-phase response in hepatocytes. These activities are mediated through a heterodimeric receptor composed of the IL-22R subunit and the chain of IL-10R.[116] In addition to its cellular receptor, IL-22 binds to a secreted class II cytokine receptor family member that acts as a natural IL-22 antagonist (see Table 57-3[115,116]). IL-22 is mainly produced by activated T-cell subpopulations (Th22, Th1, Th17), and TNF-α, IL-17, and IFN-α amplify its effects on cells of the skin and gastrointestinal and respiratory systems. Blood and lesional skin samples from psoriasis patients demonstrate high levels of IL-22; it acts principally on keratinocytes and does not influence the immune system.[117] IL-22 probably plays the main role in the induction of psoriatic epidermal alterations, and therapeutic approaches that counteract IL-22 are under consideration as of today.

Interleukin-23

IL-23 is a member of the IL-6 family of cytokines and is closely related in structure to IL-12. IL-23 and IL-12 are heterodimeric cytokines that share the p40 subunit, and each has a unique second subunit, IL-23p19 and IL-12p35, respectively (see Table 57-3[118]). In addition to the close structural relationship between IL-23 and IL-12, their heterodimeric receptors share the IL-12Rb chain, and these cytokines have similar properties.[118]

Interleukin-24

When IL-24 was discovered, it was designated as melanoma differentiation–associated gene-7 (mda-7), because it was identified by subtractive hybridization after the treatment of melanoma cells with IFN-β and mezerein, which caused their terminal differentiation and growth arrest.[119] Later, it was recognized that mda-7 encodes a secreted protein that exhibits significant homology to IL-10 (see Table 57-3[94,120-124]). Then, this molecule was officially designated as IL-24.[120] Human IL-24 is secreted by activated PBMCs and is the ligand for two heterodimeric receptors, IL-22R1/IL-20R2 and IL-20R1/IL-20R2.[121] IL-24 also acts as a tumor suppressor gene, and the protein product was found to be constitutively expressed by melanocytes, nevus cells, and some primary melanomas but not metastatic lesions of melanoma.[122,123] It is an example of a tumor suppressor gene exhibiting immune stimulatory properties.[124]

IL-24: Clinical Trials/Applications

Because of the tumor suppressor characteristics of IL-24, it may potentially be used for cancer treatments in the clinic. Gene transfer of IL-24 was studied in the Phase I setting using intratumoral injections of Ad-mda7/IL-24 (INGN 241) in 28 patients with resectable solid tumors.[125] It has been reported that intratumoral administration of INGN 241 is well tolerated and induces apoptosis in a large percentage of tumor cells.[125,126] Future clinical approaches will

be required to determine whether IL-24 represents a viable therapeutic in cancer and whether it could be rationally combined with other cancer therapeutics to improve tumor killing in patients.

Interleukin-25

IL-25 was recently identified as a cytokine that is structurally related to IL-17 and induces IL-4, IL-5, and IL-13 gene expression (see Table 57-3[127]). The induction of these cytokines results in Th2-like responses marked by increased serum IgE, IgG1, and IgA concentrations, blood eosinophilia, and epithelial cell hyperplasia. Little is known about this newly discovered cytokine besides the fact that IL-25 is derived from Th2 T cells and that it can amplify allergic-type inflammatory responses by its actions on other cells.

Interleukin-26

Subtraction hybridization coupled with representational differential analysis identified IL-26/AK155 as a gene upregulated in human T cells following infection with herpesvirus saimiri (HVS[1]). It has the capacity to transform these cells in culture (see Table 57-3[94,128]). The IL-26 protein has 24.7% amino acid identity and 47% amino acid similarity with human IL-10. Structural analysis revealed that IL-26 contains six helices with four highly conserved cysteine residues, which are assumed to be relevant for dimer formation, as is the case with IL-10. It was determined that IL-26 mRNA is specifically overexpressed by T cells after HVS transformation.

Interleukin-27

In 2002, Pflanz and colleagues[129] described a new heterodimeric cytokine related to IL-12. This cytokine was designated IL-27. IL-27 acts together with IL-12 to trigger IFN-γ production by naïve $CD4^+$ T cells (see Table 57-3[129,130]). They also identified IL-27 as the ligand for TCCR/WSX-1, a novel member of the class I cytokine receptor family shown to be important for Th1 development.[1] Recent studies have found that IL-27 has the ability to induce tumor-specific antitumor activity and protective immunity and that the antitumor activity is mediated mainly through $CD8^+$ T cells and IFN-γ.[130] IL-27, similar to IL-12, shows antitumor activity in different tumors via induction of NK and CTL response or inhibition of angiogenesis by the induction of CXCL9 and CXCL10.[131,132] It has also an antiproliferative effect on melanoma cells,[133] which express its receptor (and multifunctional antitumor roles in multiple myeloma[134]).

Interleukin-28 and Interleukin-29

The IL-28 family has been identified from the human genomic sequence, and the member cytokines have been designated interleukin 28A (IL-28A), IL-28B, and IL-29. These molecules are distantly related to type I IFNs and the IL-10 family. IL-28 and IL-29 are induced by viral infection and show antiviral activity. Moreover, IL-28 and IL-29 interact with a heterodimeric class II cytokine receptor that consists of IL-10Rβ and an orphan class II receptor chain, designated IL-28Rα. This newly described cytokine family may serve as an alternative to type I IFNs in providing immunity to viral infection (see Table 57-3[135]). Their antiviral effects and gene-inducing activities have been compared with those of IFNs, but the data are very limited at present. Their clinical use has the potential for the treatment of hepatitis C virus (HCV) infection based on comparative analyses of their transcriptome and antiviral properties.[136]

Interleukin-31

IL-31 has been identified as a four-helix bundle cytokine that is preferentially produced by T-helper type 2 cells. IL-31 signals through a receptor composed of IL-31 receptor A and oncostatin M receptor. Expression of IL-31 receptor A and oncostatin M receptor mRNA was induced in activated monocytes, whereas epithelial cells expressed both mRNAs constitutively (see Table 57-3[137]). More specifically, the data indicated that IL-31 might be involved in promoting the dermatitis and the epithelial responses that characterize allergic and nonallergic diseases. It is also known that binding of IL-31 to its receptor activates JAK/STAT, PI3K/AKT, and MAPK pathways.[138]

Interleukin-32

IL-32 is a recently discovered proinflammatory cytokine that induces TNF-α, IL-1β, IL-6, and chemokines (see Table 57-3[139]). The proinflammatory activity of IL-32 seems to take place after degradation of IKβ, leading to activation of

NFκB as well as phosphorylation of mitogen-activated protein p38.[139] IL-32 was originally identified as a transcript, NK cell transcript 4 (NK4), the expression of which was increased in activated NK cells. It has been very recently demonstrated that NK4 is secreted from several cells on the stimulation of some inflammatory cytokines, such as IL-18, IL-1β, IFN-γ, and IL-12.[140] The gene encoding IL-32 resides at chromosome 16 p13.3, and six mRNA transcripts resulting from mRNA splicing are presently known, but the functional differences between these isoforms remain unknown.[141] The interaction between tumor and immune cells is responsible for overall tumor progression or regression. Cytokines can act as inducers via activation of T cells and NK cells in the tumor tissues, which results in the apoptotic cell death of tumor cells. A recent study revealed the role of IL-32 in STAT3 and NFκB pathways during cancer development, which are known to stimulate prosurvival, proliferative, anti-apoptotic, and pro-angiogenic genes in cancer development.[142] This study showed that IL-32 inhibits constitutively activated STAT3 and NFκB signaling, reduces the production of pro-inflammatory cytokines, and increased production of anti-inflammatory cytokines in colon cancer and melanoma cells. At this point, it is clear that IL-32 may play significant pathophysiological roles in cancer development.

Interleukin-33

IL-33, a member of the IL-1 family, which mediates its biologic effects via IL-1 receptor ST2, activates NFκB and MAP kinases, and it drives production of T(H)2-associated cytokines from in vitro polarized T(H)2 cells. In vivo, IL-33 induces the expression of IL-4, IL-5, and IL-13 and leads to severe pathologic changes in mucosal organs (see Table 57-3[143]). Analysis of a panel of human and mouse cDNA libraries by real-time quantitative polymerase chain reaction (PCR) showed that IL-33 mRNA is broadly expressed in many tissues. At the protein level, it is expressed by many cell types following pro-inflammatory stimulation, such as fibroblasts, epithelial cells, and endothelial cells.[144] In the absence of pro-inflammatory stimuli, IL-33 localizes to the nucleus.[145,146] Nuclear localization of full-length IL-33 is mediated by the amino terminus, which contains a nuclear localization sequence and a short chromatin-binding motif. IL-33 has a dual role in disease; it is associated with host protection against infections by promoting T(H)2 cells but can also aggravate T(H)2 and mast cells in inflammatory diseases.[144] The role of IL-33 in bacterial and viral infections remains to be explored, and its contribution to many inflammatory diseases is vital not only for inflammation but also for many cancers, which could be caused by chronic inflammation via induction of genetic and epigenetic aberrations in affected cells.

Interleukin-35

IL-35 represents a new member of the heterodimeric IL-12 cytokine family. It is a novel inhibitory cytokine that is produced by Treg cells and contributes to their suppressive activity.

In vivo studies showed that IL-35 reduces the incidence of arthritis and pathologic features of collagen-induced arthritis in mice by regulating serum levels of IL-10, IFN-γ, and IL-17.[147] Because IL-35 may be secreted exclusively by Treg cells and other cell populations with regulatory potential, it represents a novel potential target for the therapeutic manipulation of Treg activity to treat cancer and autoimmune diseases.

Interleukin-36

IL-36α, IL-36β, and IL-36γ are members of the IL-1 family of cytokines. They signal through the IL-1 receptor family members IL-1RL2 and IL-1RAcP to activate NFκB and MAPKs[148] and play an important role in skin biology. Similar to the classical IL-1 cytokines, IL-36 cytokines are also involved in the regulation of immune responses. IL-36s are expressed in a restricted manner, primarily in the skin, airway, and other epithelial tissues, whereas the receptors are more commonly expressed,[149] such as in the lung, joint, gut, kidney, and brain.

Interleukin-37

Since the discovery of IL-1 in 1977, the nomenclature has been continuously evolving, and there have been proposals for the assignment of new members to the IL-1 family.[150] IL-37 was originally defined as IL-1 family member 7 (IL-1F7), and transcripts are detected in lymph nodes, thymus, bone marrow, lung, testis, uterus, and placenta.[149] The anti-inflammatory features of IL-37 have been demonstrated in vitro. TGF-β and several Toll-like receptor (TLR) ligands induce production of high levels of IL-37 by PBMCs; proinflammatory cytokines such as IL-18, IFN-γ, IL-1β, and TNF moderately increase IL-37 levels.[151] In addition, expression of IL-37 in monocytic cells has been shown to reduce several intracellular kinases important for transducing proinflammatory

signals, such as focal adhesion kinase (FAK), STAT1, p38 MAPK, and c-jun. Therefore IL-37 is considered as one of the many key modulators of inflammation.

Interleukin-38

IL-38, originally named IL-1 family member 10, is one of 11 members of the family. Earlier studies show that IL-38 polymorphisms are associated with psoriatic arthritis and ankylosing spondylitis and suggested a role in the pathogenesis of these inflammatory diseases.[152,153] It has recently been shown that IL-38 binds to the IL-36R, as does IL-36Ra, and that IL-38 and IL-36Ra have similar biologic effects on immune cells and reduce the production of IL-17 and IL-22, which is similar to that caused by the IL-36 receptor antagonist in the same PBMC cultures.[154]

Conclusion

Many, if not most, cytokines and their respective natural inhibitors are ubiquitously expressed and have myriad biologic properties that influence virtually every organ system. It is already apparent that these molecules may also be effective in allergic, inflammatory, and autoimmune diseases, as well as in cancer therapeutics. The emerging understanding of their role and the availability of recombinant molecules for clinical therapeutics suggest that their application is still evolving and will ultimately affect many areas of medicine.

58 Cancer Chemoprevention

Chemoprevention is the use of pharmacologic interventions to reduce the risk of cancer or to treat or reduce the risk of intraepithelial neoplasia (IEN[1]) developing into cancer. As a noninvasive lesion representing an often pathologically discernable intermediate state between normal and malignant tissue, IEN has a substantial cancer risk.[2] The molecular biology of preinvasive carcinogenesis and drug interventions was substantially advanced by translational research of a few pioneering groups, including studies by Hong and colleagues in head and neck carcinogenesis and its response to retinoids.[1,3-7] These early studies presaged the emergence of molecular-targeted approaches, which have not only become a mainstay in therapeutic drug development but are also the major focus of chemopreventive drug development today.[8]

Molecular-Targeted Prevention

Molecular-targeted drug development is based on the concept that neoplasia is a multistep process, which involves accumulating genetic and epigenetic alterations driven by genomic instability, and a multifocal process, which involves field carcinogenesis and clonal spread.[1,9] Hallmarks of these processes include evasion of apoptosis, self-sufficiency in growth signals, insensitivity to antigrowth signals, strong replicative potential, and sustained angiogenesis. These molecular alterations and hallmarks can develop in IEN. Major advances in molecular-targeted chemoprevention include the drugs tamoxifen and raloxifene (targeting the estrogen receptor [ER]), finasteride (targeting 5α-reductase), and celecoxib (targeting cyclooxygenase-2 [COX-2][10-16]).

Biomarkers play a major role in all aspects of molecular-targeted chemoprevention, including as (1) molecular targets for identifying new agents; (2) targets to help determine the biologically active doses delivered to tissue; (3) cancer risk, prognosis, or predictive markers for selecting (or stratifying) study patients; (4) endpoints of Phase Ib and Phase II drug activity trials; and (5) surrogate efficacy and toxicity endpoints in Phase III cancer prevention trials. Although receiving keen interest, surrogate biomarkers are extremely complicated and may yet be a long way from validation as primary endpoints of Phase III trials.[17,18] Encouraging results on potential new surrogate endpoint biomarkers are emerging from work on proteomic and genomic profiling in trials of the selective COX-2 inhibitor celecoxib,[19,20] highlighting the convergence of molecular markers in chemoprevention with those of early-detection research. Spira and colleagues[21] were the first to define the reversible and irreversible genetic effects of cigarette smoke using gene expression profiling on human airway epithelial cells. Given that cigarette smoke creates a field of injury throughout the airway, they identified an 80-gene biomarker that distinguishes smokers with and without lung cancer. This biomarker panel had approximately 90% sensitivity for stage I cancer across all subjects and 95% sensitivity when combined with lower airway cell cytopathology, demonstrating a potential cancer-specific airway-wide response to cigarette smoke.[22] Also exciting is the discovery that the miRNA profile derived from serum and plasma of various tissues/organs shows immense promise as a novel noninvasive biomarker for the diagnosis of cancer and other diseases.[23] Because surgical pathology specimens from lung biopsies are stored as formalin-fixed, paraffin-embedded blocks and are widely available, miRNA expression and hypermethylation of genes can be successfully extracted as candidate biomarkers for the early detection of lung cancer.[24] Molecular biomarkers also can be used to confirm IEN response, the importance of which was suggested by genetic abnormalities that persisted at the site of head and neck IEN that had responded completely (clinically and histologically) in a chemoprevention trial.[25,26]

Molecular biomarkers also are used in the emerging field of preventive pharmacogenomics. Germ-line *BRCA2* mutations in people receiving tamoxifen, *SRD5A2* polymorphisms in people receiving finasteride, cyclin D1 polymorphisms in people receiving retinoids, *CYP2C9* genotypes in people receiving nonsteroidal anti-inflammatory drugs

(NSAIDs), and epidermal growth factor receptor (*EGFR*) tyrosine kinase (TK) domain mutations in patients receiving EGFR TK inhibitors (TKIs) are important examples of pharmacogenomic biomarkers.[27-31]

Prevention-Therapy Convergence

Molecular-targeting research is blurring the distinction between malignancy and premalignancy and between cancer therapy and prevention. A new generation of targeted drugs with acceptable therapeutic indices for prevention and therapy is emerging from the molecular study of neoplasia (IEN and cancer), drug effects on relevant pathways, and cancer risk/prognosis.[3] Targeted drugs can move from therapy to prevention (exemplified by tamoxifen, aromatase inhibitors, and EGFR inhibitors) or vice versa (celecoxib). It is likely that tamoxifen both prevented and treated subclinical cancer in the Breast Cancer Prevention Trial (BCPT) and adjuvant breast cancer trials. Always problematical, the distinction in cancer survivors between a second primary tumor (SPT), which is a prevention endpoint, and recurrence, which is a therapy endpoint, has been blurred further by molecular studies in breast and head and neck neoplasia. The distinction between cancer and IEN is blurred in definitively treated oral cancer patients who develop IEN at a very high risk of a new cancer because of genomic instability and loss of heterozygosity (LOH[32,33]). Furthermore, it is very difficult to determine if the new cancer developing in these patients is an SPT or a recurrence. Rigorous clinical determinations of SPT or recurrence following curative treatment of head and neck cancer have been questioned by genetic profiling that revealed substantial molecular ambiguity regarding the origins of the subsequent cancers. For example, more than 50% of the clinically defined SPTs were molecularly determined to be recurrences (i.e., to have genetic profiles consistent with clonal spread of the original tumor[34,35]).

In recent years, the paradigm in which "at-risk" tissue is visualized by autofluorescence has evolved and progressed from the lungs into the oral cavity as well as other major organ sites. New developments coupling autofluorescence with digital imaging/processing have the potential to become an important diagnostic adjuvant and make a significant impact on detection and evaluation of tissue alterations associated with neoplastic development. An exciting new imaging modality recently provided proof-of-principle in the ability of noninvasive optical imaging to accurately identify neoplastic tissue and premalignant lesions.[36-39] Using novel biomedical optics technology, microvascular blood content in the proximity of a neoplasia can be measured and evaluated for field effects and can play a potential role in distinguishing various stages of neoplasia.[40]

Convergent Trial Designs

Two convergent trial designs involving molecular-targeted agents are (1) a Phase I design in which toxicity and pharmacodynamic effects (e.g., optimal biologic doses) are assessed to determine the dose of an agent for subsequent Phase II testing in either prevention or therapy and (2) a therapy design with embedded prevention endpoints (e.g., IEN) for agents with preventive potential based on mechanistic and safety characteristics.[3] The Phase I design can include assessments of pharmacodynamic effects on tumor and surrounding or surrogate tissue. The embedding design can include Phase II or III trials in cancer settings with a prevalent IEN, for example, rectal aberrant crypt foci (ACFs) in single-agent colon cancer trials. ACFs can be identified by magnifying endoscopy (e.g., flexible sigmoidoscopy in the rectum) and are thought to be precursors of adenomas. ACFs often show Apc loss, K-ras mutations, and EGFR and erbB2 upregulation, and the number, size, and dysplastic features of ACFs correlate with the number of adenomas. ACFs appeared to be suppressed by NSAIDs in observational studies, by EGFR TKIs in preclinical studies, and by metformin in an early clinical trial.[41,42] Another embedded convergence approach is to assess at-risk tissue in adjuvant trials—for example, bronchoscopic studies in adjuvant lung cancer trials. A recent study detected *EGFR* TK domain mutations and increased estrogen receptor expression in histologically normal lung tissue surrounding a primary lung adenocarcinoma with *EGFR* mutations.[43,44] This apparent field effect raises important biologic issues and may help identify patients more likely to benefit from adjuvant therapy with EGFR TKIs. Drug activity in high-risk IEN is relevant to the therapy setting; prevention trials in high-risk settings and therapy trials have similar sizes, durations, costs, and ethical considerations (high cancer risk justifies potential adverse drug effects, as does cancer prognosis[45]). The highest risk IENs, such as familial adenomatous polyposis and oral IEN with LOH, are promising settings for convergent drug development.

Short-term trials in patients before a scheduled surgery also can be used for early-phase convergent drug development, as illustrated by recent studies of EGFR TKIs in breast neoplasia. The EGFR TKIs gefitinib and erlotinib reduced cell proliferation in randomized presurgical trials in women with ductal carcinoma in situ or early-stage breast cancer.[46,47] Although not involving therapy, a novel convergent approach is to embed prevention endpoints in a screening study. A recent randomized trial of inhaled budesonide was embedded within a spiral computed tomography (CT) screening study involving high-risk people with peripheral lung nodules (presumed precursors of adenocarcinoma). Although this study yielded negative results, the treatment was well tolerated. This novel trial design was the first formal

clinical assessment of preventive effects on adenocarcinoma precursors in the peripheral airway.[48]

Promising Convergent Targets and Drugs

Many promising targets for cancer prevention and therapy are in preclinical studies related to drugs currently in clinical testing (Table 58-1). Some of the major signaling pathways with promising molecular targets are discussed in the following sections.

EGFR Signaling

EGFR is upstream of several major targets/pathways, including COX-2, PI3K, and vascular endothelial growth factor (VEGF), and has complex interactions with retinoic acid signaling and the IGF axis (discussed later). (EGFR also is upstream of cyclin D1, signal transducer and activator of transcription-3 [STAT3], and Src.) The importance of EGFR as a prevention-therapy target is illustrated in lung carcinogenesis. High *EGFR* (*ErbB1*) gene copy number and protein expression occur in lung IEN and have been associated with a poor prognosis in resected non–small-cell lung cancer. EGFR inhibitors have activity in a mouse lung cancer prevention model and in non–small-cell lung cancer therapy (in association with high EGFR). *EGFR* TK domain mutations (which are associated with EGFR TKI response) have been detected in high-risk nonmalignant lung tissue.[43] EGFR is a potential target for convergent drug development in several sites and, as discussed in the following paragraphs, EGFR signaling has complex pathway interactions and feedback loops that make it very promising for use in combination targeting approaches.

Polyunsaturated Fatty-Acid Metabolic Signaling

Membrane phospholipids including arachidonic acid (AA) and linoleic acid (LA) are converted by a series of enzymes to a variety of eicosanoids, which differ markedly in their biological activities. The cyclooxygenase (COX) pathway leads mostly to the generation of prostaglandins (PGs), prostacyclins, and thromboxanes (TXs), whereas the lipoxygenase (LOX) pathway leads to the formation of leukotrienes, hydroxyeicosatetraenoic acids (HETEs), lipoxins, and hydroxyoctadecadienoic acid (HODEs). These biologically active lipids orchestrate the complex interactions between transformed epithelial cells and the surrounding stromal cells and play crucial roles in chronic inflammation and cancer (as reviewed in Reference 49). The enzymes involved in AA metabolism (COX1/2, 5-LOX, and 12-LOX) have been among the most extensively studied targets for anticancer therapy and prevention. In addition to its other effects, aspirin (a nonselective NSAID) has been shown to be an especially effective chemopreventive agent for colorectal neoplasia, through its actions as an inhibitor of the COX-2 pathway, which is overexpressed in 80% to 85% of colorectal cancers.[50-52] The LOX pathway enzymes (5-LOX, 12-LOX, and 15-LOX-1/2) also have an important role in tumor progression and survival. The 15-LOX-1 enzyme and its products (15-S-HETE and 13-S-HODE) induce apoptosis, and losses of 15-LOX-1 expression and enzymatic activity were the only significant changes in LOX metabolism that related to the loss of cell differentiation and apoptosis in colon cancer cells in vitro and in polyps of familial adenomatous polyposis patients.[53,54] Pharmacologic or genetic restoration of 15-LOX-1 induces apoptosis and suppresses tumorigenesis in vivo. 15-LOX-1 interacts with GATA-6, protein kinase G, histone deacetylase (HDAC), methyltransferase (upstream 15-LOX-1 regulators), and PPAR-δ and -γ (downstream 15-LOX-1 mediators) to induce apoptosis and suppress carcinogenesis.[53-56] 13-S-HODE downregulates PPAR-δ to activate PPAR-γ and induce apoptosis, indicating that polyunsaturated fatty acid oxidative metabolism can influence the balance between PPAR-δ and PPAR-γ. Understanding the roles of prostaglandins and leukotrienes in epithelial-derived tumors and their microenvironment may help to develop cancer biomarkers and chemopreventive and/or therapeutic agents with minimal side effects compared to NSAIDs.

Nuclear Receptor Signaling

Members of the nuclear receptor (NR) superfamily of ligand-dependent transcription factors are implicated in a broad spectrum of physiologic and pathophysiologic processes. As well, NRs have widespread anti-inflammatory roles in the cells of the immune system that contribute to the tumor microenvironment. Evidence exists for an increased risk for cancer development among patients with chronic inflammatory diseases such as diabetes or ulcerative colitis. That NRs and their ligands play a prominent role in modulating the microenvironment and inhibiting tumor-promoting inflammation makes them promising therapeutic targets for high-risk populations when used in combinatorial or chemopreventive strategies.[57]

Promising convergent targets also are emerging from studies of retinoid signaling through retinoic acid receptor (RAR) and retinoid X receptor (RXR) types, subtypes, and isoforms.[1,4] Retinoids modulate cell growth and gene expression by activating nuclear RARs and RXRs, each of which

Table 58-1 Molecular Targets and Their Agents in Development for, or Relevant to, Cancer Prevention and Therapy

Molecular Targets	Agents
Prevention and Therapy	
ER-α*	Tamoxifen,* raloxifene,* arzoxifene
5α-reductase**	Finasteride,** dutasteride**
COX-2*	Celecoxib,* rofecoxib
Ornithine decarboxylase	DFMO
p53	INGN201, ONYX-015
5-LOX	Zileuton
Prostacyclin	Iloprost
Aromatase	Exemestane, letrozole, anastrozole
Androgen receptor	Flutamide
PPAR-γ	Rosiglitazone
Retinoic acid receptor/ retinoid X receptor	9-*cis*-Retinoic acid
Retinoid X receptor	Bexarotene
EGFR	Gefitinib, erlotinib, cetuximab
Therapy†	
Farnesyl transferase	Tipifarnib, lonafarnib
mTOR	RAD-001, CCI-779, metformin
DNA methyltransferase	Azacytidine
Histone deacetylase	SAHA
PI3K/Akt	Deguelin, myo-inositol
MMP	Marimastat (broad), matlystatin B (MMP-1), metastat (MMP-2/9)
TRAIL	Apo2L/TRAIL
CDK	Flavopiridol (cdks 4/6,2,1); BMS 387032, seliciclib (cdks 2,1)
HER-2	Trastuzumab
VEGF	Bevacizumab, VEGF trap
VEGFR	Sorafenib, sunitinib, AZD2171, ZD6474, AMG 706, PTK 787
PDGFR	Imatinib, sunitinib, AZD2171, PTK 787
c-KIT	Imatinib, sunitinib, AZD2171, PTK 787
RET	ZD6474, sunitinib, sorafenib, AMG 706
IGF-1R	CP751871, 12, IGFBP3, metformin
FGFR	BIBF1120, BMS 582664
MEK	AZD6244, CI-1040
B-Raf	Sorafenib
Src	Dasatinib, AZD0530
HIF-1α	17-AAG
Proteosome	Bortezomib

*Target and agent involved in U.S. Food and Drug Administration–approved cancer risk reduction or IEN treatment.
**Target and agent involved in established cancer-risk reduction/chemoprevention.
†Therapy targets and agents with potential for chemoprevention.
5-LOX, 5-Lipoxygenase; *CDK,* cyclin-dependent kinase; *DFMO,* difluoromethylornithine; *EGFR,* epidermal growth factor receptor; *ER,* estrogen receptor; *FGFR,* fibroblast growth factor receptor; *HIF-1α,* hypoxia-inducible factor-1 alpha; *IGF-1R,* insulin-like growth factor-1 receptor; *MEK,* mitogen-activated protein kinase/extracellular signal-regulated kinase kinase; *MMP,* matrix metalloproteinases; *mTOR,* mammalian target of rapamycin; *PDGFR,* platelet-derived growth factor receptor; *PPAR-γ,* peroxisome proliferator-activated receptor gamma; *SAHA,* suberoylanilide hydroxamic acid; *VEGF,* vascular endothelial growth factor; *VEGFR,* VEGF receptor.

exists in several isoforms and possesses distinct functions. For example, the RAR-β_2 subtype is a putative tumor suppressor, whereas RAR-β_4 has oncogenic properties. RAR-β_2 suppresses COX-2 expression and frequently is methylated in tobacco-related and other neoplasias. Recent studies have identified a novel RAR-β_2–induced gene, RRIG1, which encodes a cell membrane protein that binds to and inhibits RhoA activity and mediates the effects of RAR-β_2 on cell growth and gene expression.[58,59] These findings highlight molecular pathways involving RAR-β_2, RRIG1, COX-2, and RhoA—all of which are promising convergent targets.

IGF Axis

Targeting the insulin-like growth factor (IGF) axis continues to be an important area of research for both prevention and therapy, as illustrated by recent data in the aerodigestive tract. Elevated levels of IGF-1 and reduced levels of IGF binding protein 3 (IGFBP-3) are associated with increased risk and poor prognosis in lung and other cancers[60]; IGF-1 is a mitogen for a number of neoplastic cells types. The IGF-1 receptor (IGF-1R) is activated during lung carcinogenesis in vitro and in vivo in animals. Targeting IGFR and its downstream pathways (e.g., by the use of IGFBP-3) inhibits survival of premalignant and malignant bronchial epithelial cells and vascular endothelial cells, decreases tumor growth and angiogenesis, and for this reason may be effective for cancer chemoprevention.[61] However, several recent Phase III chemotherapy trials using IGF-1R-targeting antibodies to target late-stage solid tumors have failed to demonstrate signs of clinical efficacy,[62] suggesting that the need to identify potential biomarkers that could help parse out patients who would benefit most is critical. Despite the poor therapeutic outcome with the anti-IGF1R trials, encouraging results from studies targeting the IGF axis in a combinatorial fashion (e.g., STAT3 or IL-6) may be an alternative strategy for chemoprevention.[63]

PI3K/Akt/mTOR Signaling

Targeting the PI3K/Akt/mTOR signaling pathway is another promising approach, especially in the lung. Tobacco carcinogens induce Akt activation and lung carcinogenesis. The Akt pathway is activated in bronchial premalignancy (both proximal airway and alveolar epithelium) in smokers and patients with lung IEN or cancer. Preclinical in vivo studies show that deguelin and myo-inositol have preventive activity in lung tumorigenesis, in part via suppressing the PI3K/Akt pathway, disrupting Hsp90 function, and inhibiting HIF-1α expression.[64-66] The kinase mammalian target of rapamycin (mTOR) is downstream of Akt, and the mTOR inhibitor CCI-779 blocked malignant progression of premalignant lesions with activated mTOR arising in the alveoli of mice that develop lung cancer because of activated K-ras.[67] The mechanism by which CCI-779 inhibited tumorigenesis was unexpected. These lesions were infiltrated with macrophages, shown immunohistochemically to have prominent activation of mTOR signaling. A similar pattern of macrophage infiltration occurred in human alveolar premalignant lesions (atypical alveolar hyperplasia). Treatment with CCI-779 induced apoptosis of macrophages, which coincided with the chemopreventive effect. In vitro, CCI-779 had no effect on LKR-13, a lung adenocarcinoma cell line derived from this mouse, whereas it did induce apoptosis of macrophages, and conditioned media from macrophages directly stimulated the proliferation of LKR-13 cells. In summary, mTOR is activated in lung premalignancy and is required for malignant progression in the lung. This kinase drives tumorigenesis in part through macrophages, a prominent component of the tumor microenvironment, and the antitumor effect of mTOR inhibition required the presence of the tumor microenvironment. These findings have two important implications: mTOR is a potentially important kinase target, and the tumor microenvironment is crucial in malignant progression and a source for novel targets in chemoprevention. An mTOR inhibitor also has reversed Akt-dependent prostatic IEN in transgenic mice.[68]

Metformin belongs to the biguanide class of antidiabetic drugs and activates the LKB1/AMPK axis (mediating glucose and energy homeostasis) and inhibits cancer cell viability through the inhibition of mTOR. Metformin can also downregulate mTOR and subsequent cell growth through AMPK-independent mechanisms[69] (Figure 58-1). A recent study using mouse models of lung cancer to assess the protective effect of metformin suggested two possible mechanisms: decreased levels of circulating insulin and lowered energy stress leading to inhibition of mTOR.[70] Owing to the fact that studies show metformin is associated with a decreased risk of cancer incidence compared with other treatments (such as insulin) among diabetic patients,[71] metformin is rightfully garnering interest for its role in cancer prevention and therapy and supports further testing in the clinical setting.

Looking at new targets of the antineoplastic activities of metformin yields some surprising and unique mechanisms. In paraquat-treated mice, metformin reduced the levels of mitochondrial ROS in an AMPK-independent manner while also reducing DNA double-stranded breaks.[72] A recent compelling study suggests the molecular mechanism by which metformin can elicit its biologic effects in pancreatic cancer stem-like cells (CSCs) is mediated through reexpression of miRNAs and decreased expression of CSC-specific genes.[73] Indeed, these novel mechanisms may help to explain reduced cancer incidence associated with metformin therapy.

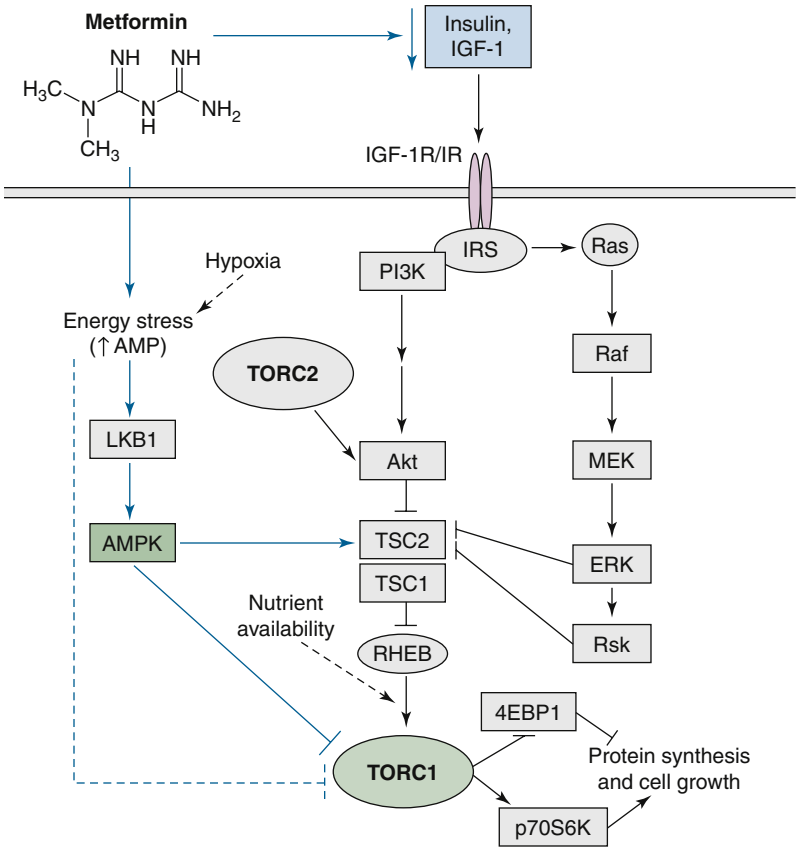

Figure 58-1 mTOR exists in the intracellular complexes TORC1 and TORC2. Growth factor signaling (through PI3K/AKT and ERK/ribosomal S6 kinase [Rsk] signaling) and energy homeostasis (through AMPK) directly lead to TSC2 phosphorylation. In vivo, metformin down-regulates TORC1 via several potential mechanisms including AMPK-dependent and AMPK-independent mechanisms. *IRS,* insulin receptor substrate; *LKB1,* liver kinase B1; *MEK,* mitogen-activated protein kinase. *(Reprinted by permission from the American Association for Cancer Research: Engleman JA, Cantley LC. Chemoprevention meets glucose control.* Cancer Prev Res (Phila). *2010;3:1049-1052.)*

The Angiogenic Switch

The angiogenic switch is a critical regulatory switch (at the level of Ras) within neoplastic cells that targets the endothelium/microenvironment or bone marrow–derived cells recruited to the neoplastic site to reverse endothelial quiescence, thus facilitating pathological angiogenesis. Dysplastic foci and microscopic tumors in various organs can remain undetectable and asymptomatic for years in the absence of inflammation and angiogenesis—both processes key targets for chemoprevention.[74,75] Potential drugs targeting various angiogenic switch regulators such as VEGF receptors (VEGFR including VEGFR1-3), chemokine receptors (CXCR-2 and CXCR-4), miRNAs (e.g., miR-132), and matrix metalloproteinases (e.g., MMP9) can be strategized according to risk to optimize the blockage of vascularization of incipient tumors. Some of these drug targets are under clinical development in therapy as well as for prevention.[76,77]

Combinations and Multiple Targets

Drugs designed to target a single pathway cannot usually combat multigenic diseases such as cancer. Combination drugs that affect multiple targets simultaneously are better at manipulating complex disease systems and are less likely to develop drug resistance. This multidrug treatment modality has become the standard of care in many important therapeutic areas. To that end, cancer chemoprevention using low-dose combinations of different agents instead of a single agent has been suggested to synergistically enhance the preventive effect with less toxicity and fewer side effects (as reviewed in Reference 78). Several promising combinations are listed in Table 58-2, and data supporting a few of these combinations are cited here. Methyltransferase inhibitors plus HDAC inhibitors have been shown to be highly active in vitro and in suppressing lung tumorigenesis in vivo.[79] Many studies support COX-2-inhibitor combinations, and there is extensive preclinical data suggesting that COX-2 inhibition is an attractive target for overcoming resistance to EGFR inhibition. COX-2 inhibitors plus EGFR inhibitors (e.g., in the colon) or aromatase inhibitors (in the breast) involve positive feedback loops. COX-2 inhibitors also block prostaglandin activation of EGFR and induction of aromatase, possibly allowing lower doses and less toxicity of each agent.[80,81] In a recent report, HDAC inhibitors can increase the sensitivity of oral adenomatous squamous carcinoma cells to EGFR inhibitors (possibly via effects on the epithelial-to-mesenchymal transition).[82]

Table 58-2 Promising Molecular-Targeted Combinations for Prevention and Therapy

EGFR inhibitors with:
COX-2 inhibitors
RXR agonists
IGF-1R inhibitors
mTOR inhibitors
VEGF/VEGFR inhibitors
HDAC inhibitors
PPAR-γ agonists
STAT3 inhibitors
COX-2 inhibitors with:
5-LOX inhibitors
12-LOX inhibitors
15-LOX modulators
Aromatase inhibitors
IGFBP-3
IGFBP-3 with:
FTase inhibitors
PI3K/Akt inhibitors
HDAC inhibitors with:
DNMT inhibitors
PPAR-γ agonists
DNMT inhibitors with:
RAR agonists
IGFBP-3

5-LOX, 5-lipoxygenase; *COX-2*, cyclooxygenase-2; *DNMT*, DNA methyltransferase; *EGFR*, epidermal growth factor receptor; *FTase*, farnesyltransferase; *HDAC*, histone deacetylase; *IGF-IR*, insulin-like growth factor-1 receptor; *IGFBP-3*, IGF binding protein-3; *mTOR*, mammalian target of rapamycin; *PI3K*, phosphoinositide 3-kinase; *PPAR-γ*, peroxisome proliferator-activated receptor-gamma; *RAR*, retinoic acid receptor; *RXRs*, retinoid X receptors; *STAT3*, signal transducer and activator of transcription-3; *VEGF*, vascular endothelial growth factor; *VEGFR*, VEGF receptor; *DNMT*, DNA methyltransferase.

Biomarker Cancer Risk Models

The identification of high-risk IEN is a major priority for targeted preventive drug development. This work can include the identification of molecular aberrancies in exfoliated cells and the use of novel imaging technologies. Genetic instability and clonal selection create the risk of cancer development and can be marked by LOH. The 3-year oral cancer risk of oral IEN with LOH at 3p14 and/or 9p21 is 25%.[6,83-88] Genes implicated in this cancer risk include the *FHIT* tumor suppressor gene (found at 3p14) and the p16/p15/p14 tumor suppressor genes (found at 9p21). The cancer risk increases to at least 35% with the addition of LOH at any other site of a known or candidate tumor suppressor gene (e.g., *TRAIL-R1* and *TRAIL-R2* at 8p21 and p53 at 17p13, respectively). The cancer risk associated with LOH in oral IEN has been confirmed by the consistent results of three independent groups. Recently, the oral IEN risk predictor model was further refined with the addition of another two markers (loci on 4q/17p).[85] LOH at 3p and/or 9p in IEN associated with curatively treated oral cancer has a 69% risk of a new oral cancer in 3 years. There are various biomarker-based models for predicting the oral cancer risk of oral IEN that integrates p53, LOH, and chromosomal polysomy,[89] or combines LOH and nuclear phenotypic score (as measured by the Quantitative Tissue Phenotype Imaging System),[90] or uses gene expression profiling.[91] Recent reports outline similar biomarker panels for the cancer risk of esophageal IEN (Barrett's esophagus[92-95]).

Novel risk assessment models are emerging from the joint efforts of neoplasia biology (e.g., to identify somatic genetic alterations) and molecular epidemiology (to identify constitutional genetic alterations). This work demonstrates that studies of a single gene or signaling pathway can identify germline polymorphisms for assessing risk and carcinogen susceptibility and can recognize epigenetic or genetic events for early detection and prognosis. These studies can also help in understanding the mechanisms of preventive drug response or resistance. Genes first explored for aberrations in tumors have been explored later for germline aberrations contributing to cancer risk and vice versa, providing new targets for cancer prevention. For example, germline type-II 5AR gene (*SRD5A2*) alterations have been associated with cancer risk, somatic *SRD5A2* mutations have been associated with carcinogenesis, and the SRD5A2 protein is the target of finasteride for preventing prostate cancer.[13]

Breast Cancer Risk Models

Current guidelines for breast cancer risk assessment are predominantly based on a modified Gail model as well as a modified Rosner and Colditz model. In 1989, a landmark study by Gail and colleagues[96] described the first prediction model, which estimated the risk of developing breast cancer (in a given time period) of an American woman at a given age based on six risk factors: age, age at first live birth, age at menarche, history of breast cancer in first-degree relatives, number of previous breast biopsies, and history of atypical hyperplasia. The Gail model was subsequently modified several times to include larger, more diverse cohorts (using U.S. and international registries) and other unconsidered risk factors such as mammographic breast density and hormonal replacement therapy as additional predictive factors. The Rosner and Colditz model[97] developed in 1996 was based on the assumption that relevant breast tissue aging variables played a larger role in risk assessment. However, that model underwent numerous modifications and validations and later included serum estradiol, which improved discriminatory accuracy. These newer models and others offered relatively higher discriminatory accuracy when compared to the original Gail and Rosner-Colditz models. However, a recent systematic review of breast cancer prediction models reports that, despite the substantial efforts invested in developing prediction models, only modest improvements in discriminatory power were realized, because observer bias and variability typically dilute the predictive and discriminative abilities of the model.[98] Nonetheless, the U.S. Preventive Services Task Force recommends breast cancer risk estimation for all

women considering chemoprophylaxis.[99] The Gail model has been shown to reliably predict risk at the population level, but its discriminatory accuracy at the individual level is modest. Thus, future prospective studies incorporating variables that are easily measured and readily available in routine practice will help minimize measurement bias, and using lessons learned from these prior and ongoing efforts will be useful for improving prediction models of breast cancer incidence and the design of successful intervention trials.[100]

Lung Cancer Risk Models

Lung cancer (LC) is the leading cause of cancer-related deaths in the United States. Although tobacco smoking accounts for the majority of LC, approximately 10% to 15% of patients with LC in the United States are lifelong never smokers. The World Health Organization estimates that 25% of LC worldwide occurs in never smokers.[101] Although cigarette smoking continues to impose substantial health and economic burdens on society, the development of reliable risk prediction tools for estimating lung cancer probability by smoking status holds immense public health implications, especially in light of the increased incidence of LC in the never-smoker cohort. However, there are daunting challenges for estimating LC risk, such as determining the risk factors for the 15% of LCs that occur in lifetime never smokers and identifying ever (former and current) smokers who have the highest risk of developing LC. The ability to estimate an individual's absolute risk could be used to guide preventive interventions and to motivate modifications in lifestyle and behavior in the ever-smoker cohort. A few risk-prediction models have been developed in the past decade to estimate an individual's absolute LC risk. The shared risk factors among these models include smoking duration and occupational exposure to asbestos, but differences surface when including family history or lung-related comorbidities.[102] Although the risk models for estimating LC are predominantly smoking-based, Foy and colleagues[103] were able to fit a two-stage clonal expansion (an essential stage in carcinogenesis) model to predict LC risk based on gender and smoking history. Their fitted model (assuming the requirement of two unique mutations) was validated against the control (placebo) arm of the CARET cohort (beta-CArotene and Retinol Efficacy Trial; lung cancer incidence endpoint), where it demonstrated accuracy in predicting the number of LC deaths observed during the trial (after adjusting for healthy volunteers effect). By using data from control subjects in the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO), Tammemagi and associates developed and tested predictive models for the general population and a subcohort of ever smokers. These models were externally validated in PLCO intervention arm participants,[104] and although the models demonstrated high predictive accuracy when applied for subsamples of women, men, whites, and nonwhites separately, the models may not be generalizable to other populations because of the average higher socioeconomic status of the PLCO study participants. However, in developing LC risk prediction models with increasing accuracy, these newer models might help reduce LC mortality by identifying current smokers at high risk who might benefit from intensive smoking cessation programs.

Chemoprevention Trials

Nonmolecular-Targeted Trials

Although too toxic for long-term use, high-dose isotretinoin provided the proof-of-principle of chemoprevention in a randomized trial showing that it prevented second primary cancers in patients after definitive treatment of a first head or neck cancer.[105,106] A subsequent trial of low-dose isotretinoin unfortunately did not reduce second primary cancers, recurrences, or mortality in head/neck cancer[107] and lung cancer.[108] These nontargeted trials did help develop many potential targets discussed previously (Promising Convergent Targets and Drugs). Despite consistent epidemiologic data suggesting that β-carotene is associated with a lower risk of lung cancer, β-carotene supplements alone or combined with vitamin A or E increased lung cancer risk in two randomized controlled trials (RCTs) in nearly 50,000 smokers and/or asbestos workers.[109,110] These RCTs suggested that harm correlated with smoking intensity: no evidence from RCTs indicated that β-carotene increased lung cancer risk in nonsmokers, former smokers, or moderate (less than one pack per day) smokers. Another large-scale, nutrient approach RCT (based on prior epidemiologic and laboratory evidence and significant secondary endpoints) testing the whether selenium and vitamin E alone or together decrease prostate cancer (SELECT; Selenium and Vitamin E Cancer Prevention Trial) showed that neither selenium nor vitamin E prevented prostate cancer in a heterogeneous population of healthy men.[111] The longer follow-up of SELECT participants yielded even more dire results: healthy men who took a common dose and formulation of vitamin E alone had a significantly increased risk of prostate cancer.[112] Notwithstanding the generally negative results with vitamin and mineral supplements in developed countries, the combination of β-carotene, vitamin E, and selenium significantly reduced the incidence of gastric cancer and all cancers as well as mortality from cancer in a randomized trial involving 29,581 people in Linxian, China, possibly reflecting the restoration of healthful nutrient levels in an undernourished population.[113,114]

The only proven chemopreventive approach for Barrett's esophagus is photodynamic therapy (PDT). A recent RCT found that PDT doubled the rate of regression of high-grade disease to a lower grade of dysplasia or normal-appearing epithelium (77% vs. 39%) and halved the rate of cancers (13% vs. 28%) at 2 years.[115,116] The PDT group had a rate of adverse events of 94% (vs. 13% in a control group). Complications of PDT in this trial included mild phototoxicity (68%) and significant stricture formation (36%) as well as vomiting, chest pain, constipation, and pyrexia. In mid-2003, the U.S. Food and Drug Administration (FDA) approved and granted orphan drug designation to a photosensitizing porphyrin mixture (Photofrin) in conjunction with PDT for ablation of high-grade disease in patients with Barrett's esophagus who are unable or unwilling to undergo esophagectomy.

Several RCTs of the NSAID aspirin presaged the COX-2–specific targeting trials discussed in Molecular-Targeted Trials. Aspirin (325 mg/d) in 635 colorectal cancer survivors significantly reduced the number of patients with incident adenomas and caused a significant delay in the time to the first adenoma (vs. placebo[117]). An RCT of low-dose (81 mg/d) and high-dose (325 mg/d) aspirin in 1121 patients with prior adenomas showed that only low-dose aspirin reduced the risk of adenomas (especially advanced adenomas[118]). A secondary analysis of the Physicians Health Study (PHS) (involving 22,071 U.S. male physicians) found that aspirin (325 mg every other day) for an average of 5 years did not reduce colorectal cancer risk but slightly (and nonsignificantly) reduced adenomas.[119] The Women's Health Study (WHS) (involving 39,876 U.S. women) found that low-dose aspirin (100 mg every other day) for an average of 10.1 years did not reduce the risks of colorectal cancer or all or other cancers. The International CAPP Consortium recently conducted the largest reported clinical trial in familial adenomatous polyposis (FAP) patients and reported that a daily aspirin (600 mg/d) regimen for more than 1 year resulted in a nonsignificant reduction in polyp load (number and size), lending additional support for an anticancer benefit of aspirin.[120] In addition, a meta-analysis of four RCTs that evaluated aspirin for the secondary prevention of colorectal adenomas indicated that aspirin reduces the risk of recurrence in individuals with a history of these lesions.[121]

Calcium modestly reduced the risk of sporadic adenomas in two randomized trials but did not reduce colorectal cancer in a large-scale trial of calcium plus vitamin D.[122] The incidence of colorectal cancer also was reduced by 37% in the Women's Health Initiative randomized trial of combined estrogen and progestin (vs. placebo) in 16,608 randomized postmenopausal women, but at the expense of an absolute increase in adverse cardiovascular outcomes. In carriers of Lynch syndrome, the most common form of hereditary colorectal cancer, the CAPP2 study (RCT of aspirin chemoprevention with cancer as the primary endpoint) reported substantial protection by aspirin (600 mg/d for a mean of 25 months) against colorectal cancer, making a clear case for the prescription of aspirin to this high-risk group.[123] As well, a pooled analysis of individual patient data from RCTs of daily aspirin versus control for the prevention of vascular events in the United Kingdom bore out aspirin's already known anticancer benefits.[124]

Although, strictly speaking, chemoprevention involves specific compounds (including extracted or synthetic nutrients), foods in the diet also can influence the risk of cancer. Epidemiologic studies of food and diet are conflicting, and randomized trials do not indicate that reduced dietary fat is associated with a reduced risk of breast cancer or that diets high in fruits and vegetables or fiber are independently associated with reduced risk of colorectal neoplasia.[125,126] In a randomized (noncomparative) Phase II trial in high-risk Chinese patients with esophageal dysplastic lesions, lyophilized strawberry powder (60 g/d for 6 months) significantly reduced the histologic grade of patients' precancerous dysplastic lesions as well as protein expression of localized biomarkers, suggesting the protective effects of small fruits and vegetables.[127] Despite disappointing results from recent large-scale randomized prevention trials such as SELECT, results from clinical cancer prevention trials using broccoli sprout–derived beverages for detoxification of airborne pollutants in Qidong, China,[128] and green tea extract to prevent oral cancer in the United States[129] have provided proof-of-principle in a clinical cancer prevention setting and lay the groundwork for future investigations.

Molecular-Targeted Trials

SERMs and Aromatase Inhibitors

The BCPT compared the selective estrogen receptor (ER) modulator (SERM) tamoxifen (20 mg/d) with placebo in preventing breast cancer in 13,388 women at a higher-than-average risk of breast cancer. At a median follow-up of 55 months, tamoxifen reduced the incidence of invasive breast cancer by 49% and noninvasive breast cancer by 50%.[10] These risk reductions were similar for all age and risk groups and were limited to ER-positive tumors. Tamoxifen also reduced the risk of osteoporotic fractures but increased the risk of endometrial cancer, thromboembolism, and cataracts. There was no effect on cardiovascular disease or mental function. Another major tamoxifen prevention trial, the International Breast Cancer Intervention Study (IBIS)-I, found a significant 32% risk reduction with tamoxifen (vs. placebo) in 7410 randomized women.[130] Tamoxifen (20 mg/d for 5 years) received supplemental approval from the FDA for reducing the risk of breast cancer in premenopausal and postmenopausal women with a 5-year predicted risk of at least 1.66%.

The FDA also has approved tamoxifen to reduce the risk of contralateral cancer in breast cancer patients or of invasive breast cancer in women with ductal carcinoma in situ.

Based on suggestive breast-cancer-risk-reduction data from trials in older women to prevent or reduce osteoporosis, the Study of Tamoxifen and Raloxifene (STAR) randomly tested the SERM raloxifene (60 mg/day) against FDA-approved tamoxifen (20 mg/day) for 5 years for reducing the risk of invasive breast cancer and other disease outcomes in 19,747 postmenopausal women (with increased 5-year breast cancer risk). This large, definitive prevention trial showed that raloxifene was equivalent to tamoxifen in effects on invasive breast cancer, had a higher number of noninvasive breast cancers, and had fewer uterine cancers.[11,12] The two drugs were equivalent in effects on other invasive cancer sites, ischemic heart disease events, stroke, and osteoporotic fractures. Raloxifene was associated with fewer cases of pulmonary emboli and deep vein thrombosis and was previously FDA approved and widely used for the prevention and treatment of osteoporosis in postmenopausal women. Raloxifene is now FDA approved based on the results of the STAR trial for reducing the risk of invasive breast cancer.

Tamoxifen and raloxifene illustrate the critical issue of risk-benefit profile for effective, acceptable chemoprevention. Tamoxifen in BCPT reduced invasive breast cancer by 49% (noninvasive by 50%)—however, at the expense of a 2.5-fold increased risk of endometrial cancer and threefold increased risk of pulmonary embolism. Raloxifene in STAR was associated with 38% less endometrial cancer and 36% less pulmonary embolism than was tamoxifen and an equivalent low rate of invasive breast cancer in STAR. Therefore, raloxifene improves the risk-benefit profile in women at risk of invasive breast cancer. A model of these comparative risk-benefit profiles is presented in Figure 58-2. Tamoxifen had

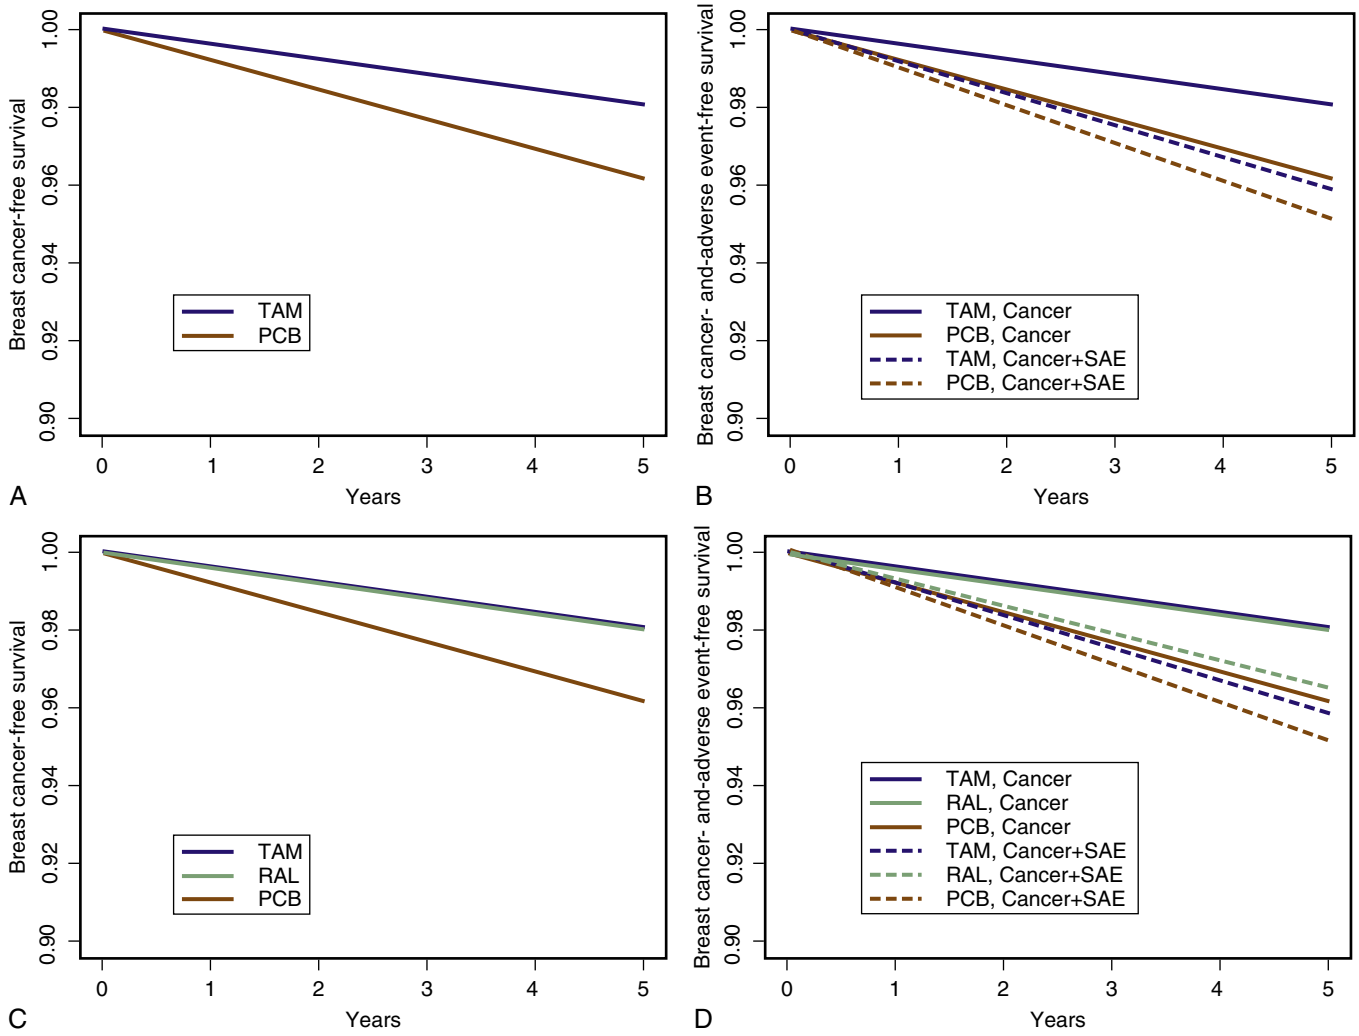

Figure 58-2 Risk-benefit comparisons for tamoxifen (TAM) and raloxifene (RAL) versus placebo (PCB) in breast cancer prevention. (A, B) Comparison of TAM versus PCB without and with the consideration of severe adverse events (SAEs) including the increased risk of endometrial cancer and embolic/vascular events. **(C, D)** Comparison of TAM versus RAL versus PCB without and with the consideration of SAEs. The assumed hazard rates for PCB, TAM, and RAL with the consideration of SAEs are 0.0097, 0.0082, and 0.00687, respectively. These hazard rates are based on data from the primary reports of the Breast Cancer Prevention Trial and Study of Tamoxifen and Raloxifene.

a 14.8% reduced risk overall (including cancer and severe adverse events [SAEs] vs. placebo), and raloxifene had a 29.9% reduced overall risk (including cancer, SAEs, vs. placebo; see Figure 58-2, *D*). SAEs are a major risk of chemoprevention itself, and raloxifene illustrates how to reduce this risk through reducing SAEs. Another way to counter this risk is by identifying target populations with very high cancer risks (discussed earlier in this chapter) who are more SAE tolerant.

Aromatase inhibitors produced greater reductions than tamoxifen in contralateral breast cancer incidence in adjuvant RCTs[131] with fewer endometrial cancer and thromboembolic events and are under active study in prevention. Although less toxic than tamoxifen, these agents have increased risks of osteoporosis and fatal myocardial infarctions, which require further examination in long-term outcome data. A recent double-blinded RCT using exemestane in postmenopausal women at high risk for breast cancer reported a 65% reduction in the diagnosis of invasive breast cancer in women after a median follow-up of 3 years. Exemestane was also associated with no serious toxic effects, supporting its use as an option for risk reduction in postmenopausal women with a high risk of breast cancer.[132]

Large randomized prevention trials show that SERMs can reduce the risk of ER-positive but not ER-negative breast cancer. Extensive data (non-RCT prevention trials) on aromatase inhibitors suggest that these agents will also prevent ER-positive and not ER-negative disease. Three such approaches are RXR agonists, COX-2 inhibitors, and EGFR TKIs, all of which can prevent ER-negative breast cancer in animal models.[133-135] Recent encouraging results from clinical Phase II/III trials demonstrate the utility of anti-EGFR therapies in both adjuvant and neoadjuvant settings.[136-138]

5α-Reductase Inhibitors

The Prostate Cancer Prevention Trial (PCPT) tested finasteride (5 mg/day), which inhibits type II 5α-reductase, the enzyme that converts testosterone to the more potent androgen dihydrotestosterone, for 7 years (vs. placebo) in 18,882 men 55 years of age or older who had a normal digital rectal examination and prostate-specific antigen (PSA) level. Finasteride reduced the 7-year prostate cancer prevalence by 24.8% and reduced high-grade prostatic IEN and benign prostatic hypertrophy (BPH), but it also increased the rates of sexual dysfunction and high-grade prostate cancer.[12] Secondary data from a trial of the dual (type I and II) 5α-reductase inhibitor dutasteride in BPH suggested that this relative of finasteride could also reduce the risk of prostate cancer (both are FDA approved for treating BPH and reducing the risk for urinary retention, but not for the prevention of prostate cancer). These and other data led to a prospective trial of dutasteride to prevent prostate cancer in men with an elevated PSA (between 2.5 and 10 ng/mL) and a negative 6- to 12-core prostate biopsy (REDUCE trial[139]).

In men who are at high risk for prostate cancer, the REDUCE trial demonstrated that men on the dutasteride arm had a 23% overall reduction of being diagnosed with biopsy-detected prostate cancer compared to placebo. This reduction was due to a decreased incidence of lower risk forms of prostate cancer (Gleason score of 6 or lower). However, analogous with the PCPT trial, dutasteride (0.5 mg/d for 4 years) was associated with increased risk of being diagnosed with a more serious form of prostate cancer (high-grade prostate cancer; Gleason score 8 to 10).[140] One interpretation of this result is that although treatment with dutasteride suppressed PSA production, this decrease in PSA levels is the result of shrinkage of benign prostatic tissue and may delay the diagnosis of high-grade prostate cancer until it may be difficult to cure.[141] Despite this increased risk of high-grade prostate cancer, the FDA still states that dutasteride remains safe and effective for their approved indications.

COX-2 and Prostacyclin Inhibitors

A small RCT of celecoxib in FAP patients showed that high-dose celecoxib (400 mg twice daily) for 6 months reduced the number of colorectal adenomas (polyps) compared with placebo (28 vs. 4.5%, $P = .003$[13]). Two secondary endpoints were a reduction in polyp burden and a modest (14%) reduction in difficult-to-resect duodenal polyps. This result led to FDA approval (via accelerated approval) of celecoxib as an adjunct to standard FAP therapy. The primary follow-up study (required by the FDA for drugs approved under the accelerated mechanism) is designed to prevent adenomas in young patients with genotypic familial adenomatous polyposis (Apc mutation carriers) but not yet expressing the phenotype. Three large placebo-controlled RCTs have found that COX-2 inhibitors significantly reduced sporadic adenomas. Rofecoxib (25 mg/day) produced a 25% reduction but also increased serious cardiovascular events, leading the manufacturer of rofecoxib to voluntarily withdraw it from the world market.[142] A large RCT of celecoxib at 200 mg twice daily (b.i.d.) and 400 mg b.i.d. versus placebo found adenoma rates of 61% (placebo), 42% (200 mg b.i.d.), and 37% (400 mg b.i.d.) at 3 years.[15] Another large RCT found that celecoxib at 400 mg/d reduced the 3-year cumulative rate of adenomas by 36% (vs. placebo). Both celecoxib RCTs found greater reductions in advanced than in less advanced adenomas and, unfortunately, increases in celecoxib-associated cardiovascular events.[15,143] On June 8, 2012, approval of the FAP indication for celecoxib was withdrawn by the FDA as requested by the manufacturer (Pfizer).[144] Yet, celecoxib continues to be marketed worldwide while being monitored carefully for cardiovascular safety.

In light of the adverse cardiovascular events, a recent study suggests that patients with a low baseline cardiovascular risk and low serum levels of high-sensitivity C-reactive protein (a circulating inflammatory marker) are at low risk for celecoxib-related SAEs in the treatment of colorectal cancer. These indices may be useful for selecting patients with a favorable risk-benefit profile for celecoxib chemoprevention for personalized therapy.[145]

Approximately 90% of lung cancer cases are attributable to tobacco smoking. Although smoking cessation does not remove the significant risk for lung cancer in former smokers, this risk decreases over time with continued abstinence. Nevertheless, effective chemopreventive agents are still needed. Two recent RCTs show encouraging results in lung cancer chemoprevention in former smokers. Six months of celecoxib regimen (400 mg b.i.d.) in a former-smoker cohort resulted in a decrease in bronchial Ki-67 labeling index (a cellular marker for proliferation).[146] Another RCT using the oral prostacyclin analog iloprost was the first to show statistically significant improvement in bronchial histology (i.e., regression of higher-grade lesions) in the airways of former but not current smokers, demonstrating the strength of the clinical signal provided by this observation and identifying iloprost as a promising chemopreventive agent in preventing lung cancer in former smokers.[147]

Vaccines

Vaccinating children against hepatitis B virus (HBV) has dramatically reduced the incidence and mortality of liver cancer in Taiwan.[148,149] Clinical trials have shown 85% to 95% efficacy in preventing chronic HBV infection, and this response rate can reduce the prevalence of chronic HBV infection to less than 1% in children living in HBV-endemic regions. Properly administered, the effectiveness of the HBV vaccine appears to extend into early adulthood.[150] Estimates from 2002 are that 84% of the world's countries now routinely provide the vaccine.

Infection by human papillomavirus (HPV) includes a spectrum of benign and malignant diseases and is a major worldwide public health concern. Genital HPV is the most common sexually transmitted infection in the United States, and although the majority of infections manifest with no clinical symptoms and are self-limiting, persistent infection with oncogenic types can cause cervical cancer in women. A subset of HPV types (HPV-16 and -18) is the main cause of virtually all cervical cancers as well as other noncervical cancers such as anal, vulvar, and oropharyngeal. The rate of cervical cancer has decreased in the United States because of the widespread use of the Pap smear, yet in certain countries where screening is not routine, the incidence of cervical cancer in women is on the rise.[151] In 2006, the FDA approved the quadrivalent HPV (types 6, 11, 16, and 18) recombinant vaccine (Gardasil) for the vaccination of females 9 to 26 years old for the prevention of cervical cancer, cervical adenocarcinoma in situ, and high-grade cervical, vulvar, and vaginal IEN. The efficacy of the vaccine was studied in four RCTs enrolling 20,541 females (as reviewed in Reference 152). The vaccine was 100% effective for preventing HPV-16– or -18–related cervical, vulvar, and vaginal IEN. This vaccine may reduce the incidence of cervical cancer and the 300,000 deaths it causes worldwide each year, not to mention the other HPV-related diseases such as oropharyngeal cancers.

A distinct form of oropharyngeal squamous cell carcinoma (OPC) is principally caused by HPV and is increasing in incidence among men in the United States. From 1988 to 2004, the population-level incidence of HPV-positive OPC increased by 225% and is expected to exceed the yearly number of cervical cancers by the year 2020. However, vaccine efficacy against oral HPV infections is not known, and therefore vaccination cannot be recommended as a first-line prevention of OPC.[153,154] Interestingly, the incidence of and mortality from this disease are higher in blacks than in whites. HPV-positive OPC patients have significantly better outcomes (vs. HPV-negative) with disease-free survival significantly greater in whites than in blacks. An analysis of overall survival in a retrospective and prospective cohort treated curatively for this disease revealed a racial survival disparity owing to the low prevalence of HPV infection in black OPC patients.[155] However, this outcome disparity data based on race for patients with locally advanced OPC requires confirmation in future analysis.

Vaccines targeting *Helicobacter pylori* are also under development. The public health implications of this work are substantial in view of the fact that *H. pylori* is the major cause of gastric cancer, the fourth most common cancer and second most common cause of cancer death in the world. An estimated 50% of the world's population harbor *H. pylori*, and more than 335,000 deaths resulted from *H. pylori*–caused gastric cancer in 2000.

The burden of *H. pylori*–associated diseases is high in Latin American countries, where resources are low and populations are diverse. In a different approach to address population-based interventions, an RCT of a Latin American population compared the effectiveness of four-drug regimens given concomitantly or sequentially with that of a standard 14-day regimen of triple therapy. In contrast to data from European and some Asian regions where resources are more plentiful and accessible, this study in *H. pylori*–positive patients showed that the probability of *H. pylori* eradication was higher for 14-day standard triple therapy. It was more effective than the 5-day concomitant or 10-day sequential four-drug regimen and shows that eradication of this

infection slows or reverses the progression of premalignant histological lesions.[156] That infections (viral, bacterial, and parasitic) have been recognized as a major cause of cancer worldwide underscores the need for prevention and treatment that can be practically implemented in developing countries where the prevalence of infection-related cancer remains high.[157]

Tumor-antigen–specific vaccines are promising immunopreventive approaches.[158-160] Stimulating an immune response to a specific neoplasia may last a long time and avoid the need for the extended frequent dosing required with cancer treatment or prevention drugs. Animal model studies have stimulated great interest in testing these vaccines for treating or reducing the risk of IEN and thus preventing cancer. Immunodeficient mice develop spontaneous tumors and are more susceptible than are immunocompetent mice to carcinogen-induced tumors, revealing the importance of the host immune response for combating cancer development. Tumor-specific vaccines have demonstrated far greater activity in IEN than cancer in animals, and these vaccines are relatively inactive against advanced cancer clinically. Human host immunosurveillance for IEN is receiving strong support from recent studies in patients showing immune response against the premalignancy monoclonal gammopathy of unknown significance (a clonal expansion of transformed plasma cells that is a precursor of multiple myeloma). These data support the hypothesis that we can boost normal host immune response in IEN with vaccines, and there is intense interest in using vaccines to target IEN. HER2/neu in breast carcinogenesis and MUC1 (e.g., in pancreatic and colorectal IEN) are promising targets for convergent vaccines. Tumor-specific vaccine approaches also may be promising for treating early cancer.[161]

Conclusion

The major direction of chemoprevention is molecular-targeted drug development, which is moving forward with advances in the biology of neoplasia (IEN and cancer), drug effects on relevant targets and pathways, and cancer risk.[162,163] With apparently, in general, lesser toxicity than standard therapy drugs and greater therapeutic activity than many prevention drugs, these agents herald an era of convergent (prevention-therapy) drug development, especially in the area of advanced IEN and early cancer[164,165] (Table 58-3).

Table 58-3 Targeted Agents with Established Cancer Risk-Reducing Effect

Intervention (Year)	Cancer Prevented
Hepatitis B vaccine (1997)	Liver cancer
Tamoxifen (1998) Raloxifene (2007)	Breast cancer Breast cancer
Human papillomavirus vaccine (2006)	Cervical cancer
Finasteride, dutasteride (2004)	Benign prostatic hyperplasia Prostate cancer (Gleason score ≤6)
Celecoxib, rofecoxib (1999)	Precancerous familial adenomatous polyps

Clinical oncology is expanding to the management of cancer risk (tamoxifen, raloxifene, and aromatase inhibitors for breast cancer risk) and IEN (celecoxib for familial adenomatous polyps and tamoxifen for ductal carcinoma in situ). The future also promises to bring a substantial acceleration in the drug development process from discovery to approval, which now takes 10 to 15 years for either a preventive or therapy drug. Merging the silo of new prevention drugs with that of new therapy drugs will potentially cut overall development time in half. The loss of drugs with prevention potential because they fail in therapy testing would cease in the setting of convergent, simultaneous prevention-therapy development. Because many molecular targets or pathways altered in neoplasia also are altered in other aging-related diseases such as atherogenesis, osteoporosis, arthritis, and neurodegenerative diseases, an important new direction of molecular-targeted chemoprevention is the development of agents targeting these shared (as well as distinct) alterations in carcinogenesis and other chronic disease processes.[1,164]

Cancer risk assessment and prevention are without doubt linked by their goal to definitively predict progression to cancer and intervene to reduce risk of cancer incidence and mortality. Extraordinary advances in cancer genomics and epigenomics have the potential to target personalized interventions aimed at the highest risk patients most in need of prevention. Accurate cancer risk biomarker discovery can also preclude unnecessary interventions for low-risk patients, offering them reassurance. These advances are paralleled by an increased understanding of the mechanisms of premalignant conditions and acquired therapeutic resistance that will undoubtedly improve and personalize strategies for cancer management and control—strategies that promise dramatic reductions in cancer mortality.[166]

59 Molecular Pathology

One of the primary challenges in the clinical management of cancer patients is to establish the correct diagnosis. For over a century, the primary means of diagnosis has been tumor microscopy, an approach that can readily distinguish benign from malignant conditions, but falls short on providing the additional detail needed to guide modern therapies. As a result, a number of technologies have been developed and are now routinely employed to molecularly subtype cancers. These include the application of antibodies to detect specific proteins and other moieties within a tumor, the use of fluorescently labeled probes to identify chromosomal changes within the nucleus, and the analysis of DNA and RNA extracted from the lesion. This chapter provides an overview of these technologies, which are increasingly important in the clinical setting. Used together, they provide far more information about a cancer than the traditional microscope, providing insight into the inherent aggressiveness of the tumor and the likelihood of its response to specific therapies.

Processing Cancer Specimens for Microscopic Evaluation

Samples of cancer tissue, whether from a biopsy or a complete surgical resection, are processed to generate microscopic sections in one of two ways. The first approach is to freeze the tissue in a semiliquid mounting medium that hardens at −20° C, allowing sections to be cut inside a refrigerated cabinet (a cryostat). The tissue in the resulting sections remains unfixed and can be used for a number of types of studies. In clinical pathology laboratories, such sections are routinely used as a rapid approach (5 to 10 minutes) for assessing the presence or absence of tumor within a given sample, or to evaluate the margins of a resected malignancy. This allows the pathologist to give immediate feedback to the surgeon in the operating room.

The second approach to creating microscopic sections of tumor tissue is to "fix" it in a preservative and then embed it in paraffin for sectioning at room temperature. First developed in the 19th century, the combination of fixation and paraffin embedding yields superior morphologic detail under the microscope as compared with cryosectioning. Organic fixatives such as acetone, methanol, or ethanol leave nucleic acids largely intact, but they are not used in clinical labs because the morphology is not as good as with for maldehyde. Nearly all clinical laboratories use formaldehyde because of this advantage, even though this fixative leads to extensive crosslinking of nucleic acids as well as spontaneous deamidation of cytosines. As a result, nucleic acids recovered from formaldehyde-fixed tissue are often highly degraded. The process of paraffin embedding adds additional insult to the quality of the tissue, as it requires dehydration through organic solvents such as alcohol and xylenes, followed by exposure to molten paraffin. Lipids are completely lost, and proteins and nucleic acids are greatly altered. Nevertheless, the vast majority of cancer specimens available from clinical archives are formalin-fixed, paraffin-embedded (FFPE) tissues.

The one advantage to FFPE tissue is that it is quite stable and can be used for studies over many years to decades. Indeed, FFPE tissue samples from autopsies performed during the influenza pandemic of 1918 were used 80 years later to help molecularly subtype the virus.[1] However, proteins and nucleic acids in FFPE tissues are greatly altered, and this has a significant impact on the types of assays that can be performed on them. For example, genomic DNA from FFPE tissue is highly fragmented, with an average size ranging from 250 to 500 bp, depending on the length of fixation. Likewise, RNA is very degraded and limited to the range of 100 to 200 bp in length.

Special Stains for Evaluating Cancer Tissues

The standard histological stain for examining tissue sections on a microscope is a combination of hematoxylin, which binds nucleic acids and yields a blue color, and eosin, which

stains protein-rich materials pink to red. This "H&E" stain is routinely performed on all specimens processed in clinical pathology laboratories and can be readily interpreted by anyone trained in histopathology. Other special histochemical stains can be used to highlight fibrous tissue or deposits such as iron, copper, or amyloid. However, the most useful special stains for classifying cancer specimens are based on immunodetection of specific molecules using antibodies.

Immunohistochemistry

First developed in the late 1960s, immunohistochemistry has become a standard tool for evaluating samples of cancer tissue.[2] This approach takes advantage of the exquisite specificity of antibodies to detect particular proteins or protein modifications (phosphates, sulfates, carbohydrates, and other moieties) in tissues (Figure 59-1). Visualization of a bound antibody is through a secondary enzymatic reaction that leaves a brown, red, or black deposit visible through the microscope. In most clinical laboratories, the process is fully automated and performed in about 2 hours, making this a rapid, cost-effective tool for defining the basic molecular features of cancer samples.

Thousands of antibodies have been developed for use in immunohistochemistry, and they serve to define key characteristics of tumor cells. For example, determining whether a high-grade malignancy represents a carcinoma, melanoma, sarcoma, or lymphoma can be very challenging based on microscopic morphology, but the diagnosis is readily settled with just a few stains. Other antibodies serve as highly specific lineage markers (see Figure 59-1). For example, thyroid transcription factor 1 (TTF1) is expressed only in carcinomas originating in the thyroid and lung, CDX2 is expressed in adenocarcinomas of intestinal origin, HMB45 is a marker of melanomas, and OCT4 is specific for some types of germ cell tumors.[3-6] These types of antibodies are routinely used in combination to help confirm or exclude a suspected site

Figure 59-1 Immunohistochemistry (A) (*1*) An antibody specific for a particular protein, phosphate, sulfate, carbohydrate, or other moiety is allowed to bind to the tissue section. (*2*) A secondary "anti-antibody" is added, bearing numerous biotin tags. (*3*) A complex of avidin and horseradish peroxidase (HRP) is added. Avidin binds tightly to the biotin on the secondary antibody, while HRP reacts with a chromogen in the presence of H_2O_2, producing a visible precipitate on the tissue. **(B)** Microscopic images of a gastrointestinal stromal tumor. The brown staining in the right image represents immunohistochemical detection of the KIT tyrosine kinase (CD117) in the tumor.

of origin for a cancer in a patient with metastatic disease. Finally, antibodies have been developed to detect specific protein variants, such as EGFR variant III (deletion of exons 2 through 7) in gliomas, or BRAF harboring the V600E mutation, which is an important treatment target in melanoma and other cancers.[7,8]

Although immunohistochemistry is a mainstay in modern pathology, it does have limitations. Not all antibodies are perfectly specific; background issues and cross reactivity can affect interpretation. Further, the technique is at best only semiquantitative and can be influenced by the length of formaldehyde fixation and many other parameters. Some of these limitations can be mitigated by automation of the staining, but tumor necrosis, intraoperative ischemia, and variation in specimen processing are all factors that can complicate the reading of immunohistochemical stains.

Immunofluorescence

Because formaldehyde fixation greatly distorts or even destroys many epitopes in tissue samples, there are numerous antibodies that will not work on FFPE sections. Such antibodies may still be useful, however, on cryostat sections, which can be prepared if fresh-frozen tissue is available. In these circumstances, fluorescence rather than histochemistry is the preferred method of detection, as it has greater sensitivity and allows for several antibodies to be stained at once (using different fluorophores).[9] Immunofluorescence is routinely used in evaluating medical diseases of the kidney and skin, but is rarely employed in cancer diagnosis.

In Situ Hybridization

Expression of particular mRNAs in tumor tissue can be measured by in situ hybridization (ISH).[10] In this approach, complementary oligonucleotide probes (either DNA or RNA) bearing a chemical tag such as digoxigenin are allowed to hybridize to their target mRNA. Once hybridized, the tag is detected with a secondary antibody (e.g., anti-digoxigenin), which is linked to an enzyme that produces a visible chemical deposit on the cells. Horseradish peroxidase and alkaline phosphatase of the two most commonly used enzymes in this powerful approach, which is widely employed in cancer research. However, ISH is technically challenging and works best on mRNAs that are expressed in high abundance. For these reasons, the use of ISH in clinical laboratories is generally restricted to the assessment of kappa and lambda light-chain expression in cases of suspected myeloma, or to detect the presence of Epstein-Barr virus in cases of lymphoproliferative disease driven by this infection.

Fluorescence in Situ Hybridization (FISH)

Nucleic acid probes are used not only to detect mRNA, but to assess interphase chromosomes in tumor cells. The probes may consist of either DNA or RNA, and they vary in length from short oligonucleotides to multigenic chromosomal segments cloned into bacteria (so-called bacterial artificial chromosomes, or BACs). When directly labeled with a fluorophore, they can be detected using a microscope equipped for immunofluorescence. This approach is routinely used in clinical cytogenetic laboratories to assess gene copy number as well as gene translocations. For example, FISH is commonly used to evaluate breast carcinomas for amplification of the ERBB2 (HER2) locus and to screen for increased copies of NMYC in neuroblastoma and MET in non–small-cell lung carcinoma. Loss of tumor suppressors such as PTEN, CDKN2A, and TP53 can also be assessed by this approach.

There is a long and growing list of gene translocation events that are linked to cancer. Whether the result of intra- or interchromosomal exchanges, these translocations commonly involve genes encoding a kinase or a transcription factor. The resulting fusion genes are often the principal drivers of tumorigenesis and therefore serve as diagnostic markers and/or targets for specific therapies (e.g., kinase inhibitors). Fusion mRNAs from translocation events can be detected by highly sensitive methodologies based on polymerase chain reaction (PCR); however, these approaches can be frustrated by the fact that a particular target gene may be fused to any of more than a dozen different partner genes, requiring numerous primers to cover all possible fusion events. In contrast, FISH can detect a translocation-related break in a target gene irrespective of which partner gene has been fused to it. This is done by labeling two pools of probes with different fluorophores; for example, one pool may be labeled red and hybridizes to the 5′ end of the gene, while the other is labeled green and hybridizes to the 3′ end of the gene. If the gene is intact, the red and green signals are close together and merge into yellow, but if the gene has been split apart by a translocation event, the red and green signals become well separated (Figure 59-2). A further advantage of FISH is that only a few tumor cells are required to make a diagnosis, which is helpful in biopsies containing low tumor content.

Preparing Nucleic Acids from Cancer Specimens

Many of the assays that are used to molecularly subtype cancers require the extraction of either RNA or DNA from the tumor tissue. Two important issues are often overlooked in this regard. The first is that the nature of the tissue dictates the quality of

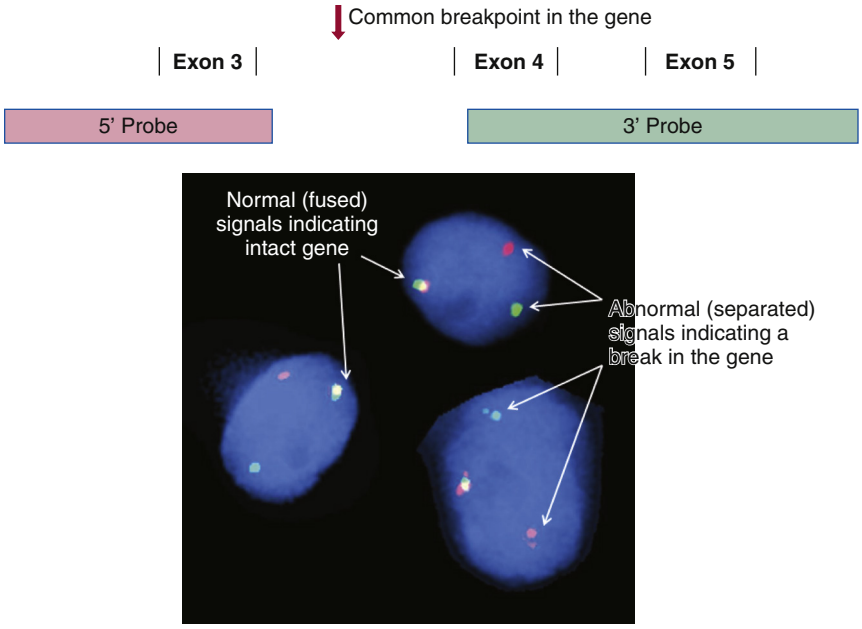

Figure 59-2 Fluorescence in situ hybridization (FISH) for identifying gene translocation events This approach is commonly used to look for evidence of gene translocations in interphase nuclei. Two probes are designed to hybridize to the 5′ and 3′ ends of a gene, flanking the region that is commonly "broken" during translocation. The probes are labeled with fluorescent tags of differing color, often creating a third color when they bind subjacently (e.g., green and red fusing into yellow). Wide separation of the probes indicates a break in the gene consistent with a translocation event. Note that this approach does not identify the partner gene in the translocation.

the available nucleic acid. Whereas fresh-frozen tissue will yield RNA or DNA that is largely intact, the nucleic acids derived from FFPE tissue are highly degraded. Thus, assays meant for use on FFPE-derived RNA or DNA must take into account the short, fragmented nature of these derivatives.

The second important issue is that tumor content and quality are highly variable from one specimen to the next, and even among different parts of the same specimen. For example, one paraffin block from a cancer resection specimen may consist of 90% tumor cells, while an adjacent block is dominated by stromal and inflammatory cells, with only 10% tumor cells being present. A third block from the same specimen may contain only necrotic tumor, as geographic necrosis is common at the center of large, high-grade malignancies. Thus, it is critical that all tumor material being considered for nucleic acid extraction first be evaluated by a qualified pathologist, who can assess whether the tumor sample is suitable for the proposed testing.

Tumor Enrichment by Macrodissection

The sensitivity of molecular diagnostic assays for mutations and other alterations in tumor DNA is dependent in part on the ratio of tumor DNA to normal cellular DNA present within a specimen. If 90% of the cells within a tissue sample are cancerous, mutation detection is straightforward, but if only 10% of the cells represent the tumor, DNA from the normal cells will effectively dilute out the mutation and make it harder to detect. For this reason, it has become standard practice to dissect out the tumor-rich areas of a specimen. This can be performed under a dissection microscope, but is more commonly done by simply scraping the tumor from unstained paraffin sections using a scalpel blade, or by taking a small core directly out of the paraffin block. Comparison with an H&E-stained section serves to guide the dissection.

Tumor Enrichment by Laser Capture Microdissection

Some tumor samples have too little tumor to allow macrodissection. In these cases, a microscope equipped with a laser can be used to isolate small clusters of tumor cells, or even single cells, from adjacent normal tissue elements. Although this is labor intensive and yields relatively little material for further testing, it can be used to salvage cases when no other tumor material from a patient is available.

Assays for Single Genes or Single Mutations

Over the past two decades, a long and growing list of genes that play a significant role in cancer has been identified. For mutations in those genes that are of particular prognostic importance or serve as important predictors of therapeutic response, a variety of assays have been developed for use in clinical laboratories. Most of these assays are focused on a single mutation or a set of mutations occurring in a single gene exon. Important factors in the design of such an assay include the amount of input DNA or RNA needed, the ease and rapidity with which the assay can be completed, and its

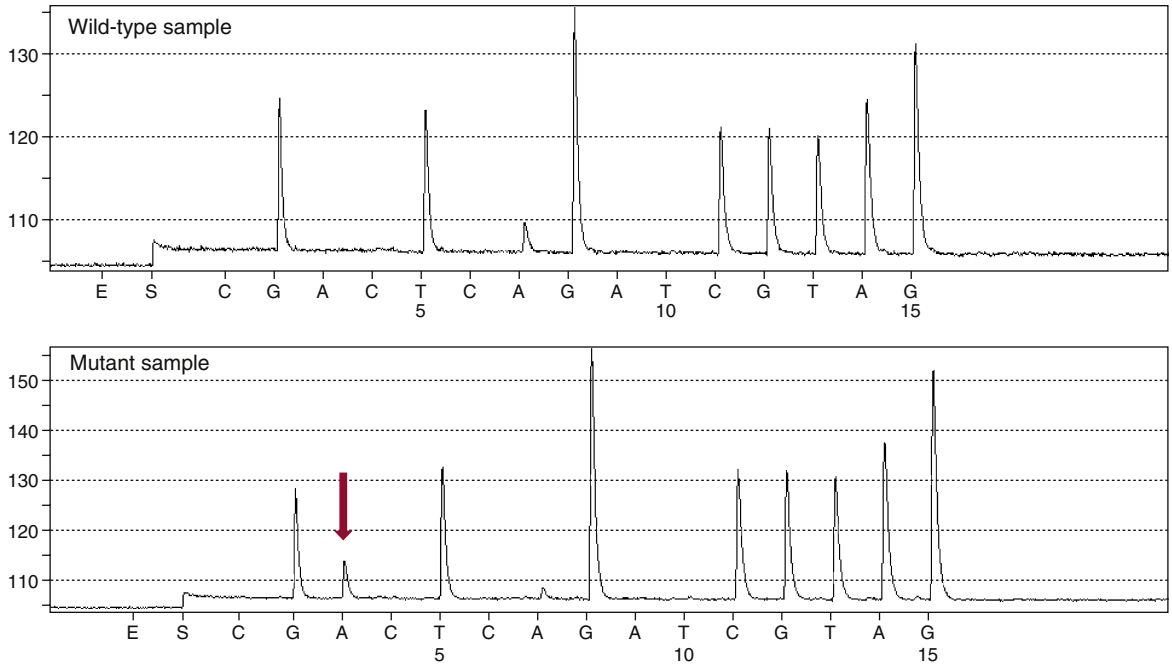

Figure 59-3 Pyrosequencing Two pyrograms are shown from tumor samples subjected to pyrosequencing for common mutations in the KRAS gene. The presence of an extra A peak in the lower panel is evidence for the presence of a mutation; the preceding G peak has a correspondingly lower signal, indicating a G→A substitution.

sensitivity and specificity. Of course, assay cost is another important factor. There are many different platforms used to support these types of assays, and each represents a significant investment for the laboratory.

Sanger Sequencing

The single most common approach to screening mutations in cancer genes is Sanger sequencing. First described by Fred Sanger and colleagues in 1976, this method mixes nonextendable, fluorescently labeled dideoxy nucleotides together with standard nucleotides to generate a set of fragments of varying length as the original template DNA is copied.[11] When separated by capillary electrophoresis, the sequence of the DNA can be interpreted from the color of the last incorporated (dideoxy) nucleotide on each successive fragment. Highly reliable and reproducible, Sanger sequencing was used to generate the first complete sequence of the human genome.[12] Nevertheless, it has several significant drawbacks. First, it can only detect mutations that are present in at least 15% to 20% of the input DNA molecules. Second, it takes approximately 24 hours to perform and is relatively labor intensive. Third, it can only cover mutations across approximately 200 bp of FFPE DNA. This means that many genes require multiple, overlapping sequencing reactions in order to ensure that a mutation can be identified, adding to the overall cost. For this reason, many laboratories rely on other approaches for screening common cancer-related mutations.

Pyrosequencing

Developed as a rapid and sensitive approach to sequencing very short regions of DNA (up to approximately 30 bp), pyrosequencing is used by many laboratories to screen for common mutations in tumor oncogenes such as KRAS, EGFR, and BRAF.[13] This technology differs from Sanger sequencing in that it does not require the synthesis and electrophoretic separation of DNA fragments. Instead, the incorporation of nucleotides during DNA synthesis is measured through a secondary reaction: each pyrophosphate released during nucleotide incorporation results in the generation of a light signal by the enzyme luciferase. As dATP, dCTP, dGTP, and dTTP are sequentially added, their incorporation is detected by the luciferase reaction, allowing the DNA sequence to be interpreted (Figure 59-3). The principal advantages of pyrosequencing are speed (sequencing can be completed in 2 hours) and sensitivity (as low as 5% mutant allele). A modification of the method is commonly used to assess DNA methylation.

High-Resolution Melting Curve Analysis

First developed in the late 1990s by Wittwer and colleagues, high-resolution melting curve analysis is now the backbone of a variety of assays designed to quickly and cost-effectively identify the presence of a mutation.[14] After the DNA of interest is amplified by standard PCR, the melting analysis

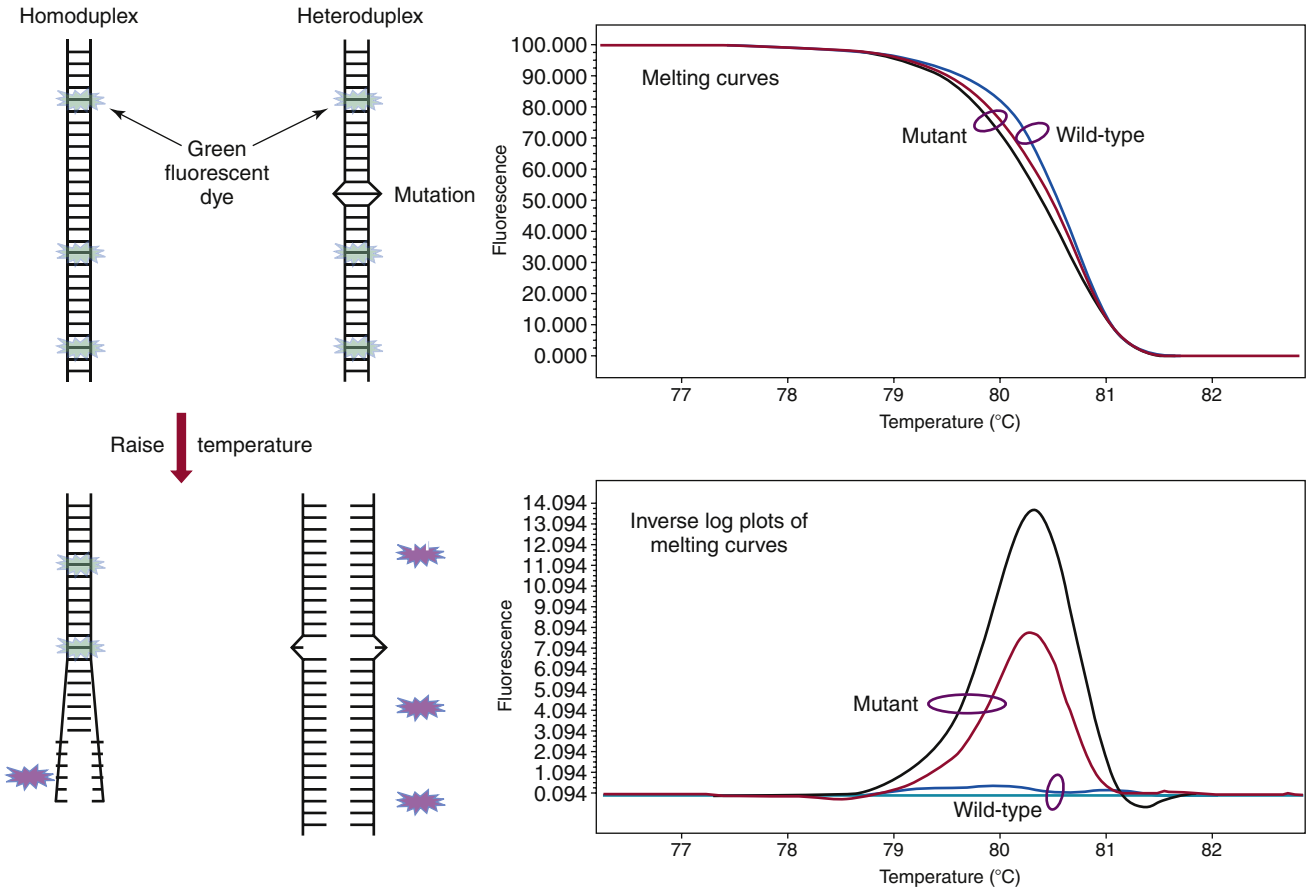

Figure 59-4 High-resolution melting curve analysis This method takes advantage of the fact that DNA heteroduplexes formed when a mutation is present have a lower melting temperature than do homoduplexes. The resulting shift in the melting curve can be detected by loss of fluorescent signal as a dye intercalated into the double-stranded DNA is released. Plotting the inverse log of the slope of the melting curve highlights the differences between samples that are wild-type and those containing a mutation. The approach can be used to detect point mutations, insertions, and deletions within amplicons of up to several hundred base pairs.

can be performed in approximately 20 minutes without the need to add reagents or switch to a different instrument. The analysis begins by melting apart the DNA strands of the final DNA product at 95° C and then allowing them to re-anneal as they cool. When a mixture of wild-type and mutant DNA is present in the sample, heteroduplexes are formed, and these can be detected by slowly ramping the temperature back up to 95° C in the presence of a fluorescent dye that binds preferentially to double-stranded DNA. As the temperature increases, the heteroduplexes unravel at a slightly lower temperature than the homoduplexes of wild-type/wild-type or mutant/mutant DNA (Figure 59-4). Thus, the presence of a mutation shifts the melting point of the overall population, and this shift is readily detected by a decrease in fluorescence as the DNA strands separate.

A number of variations of this assay type have been developed. Some will allow exact identification of a specific mutation, whereas others are optimized to detect intragenic deletions or insertions, the sequence of which requires confirmatory Sanger sequencing. In general, the sensitivity of these assays is approximately 10% mutant allele.

Allele-Specific PCR

A number of approaches have been developed that promote selective PCR amplification of a mutant allele over a wild-type allele.[15] Each depends on a primer that selectively binds to a site of mutation, the specificity being determined by the degree to which the mutant allele is favored over the wild type. Modifications to the primer, such as inclusion of peptide nucleic acids or locked nucleic acids, are generally necessary to achieve the selectivity that is optimal for clinical use.[16] The best assays have detection levels below 1%, with virtually no background contributed by false priming of the wild-type allele.

Multiplexed Approaches to Cancer Genotyping

The past decade has witnessed an explosion in the number of genes identified as playing a causal role in tumor

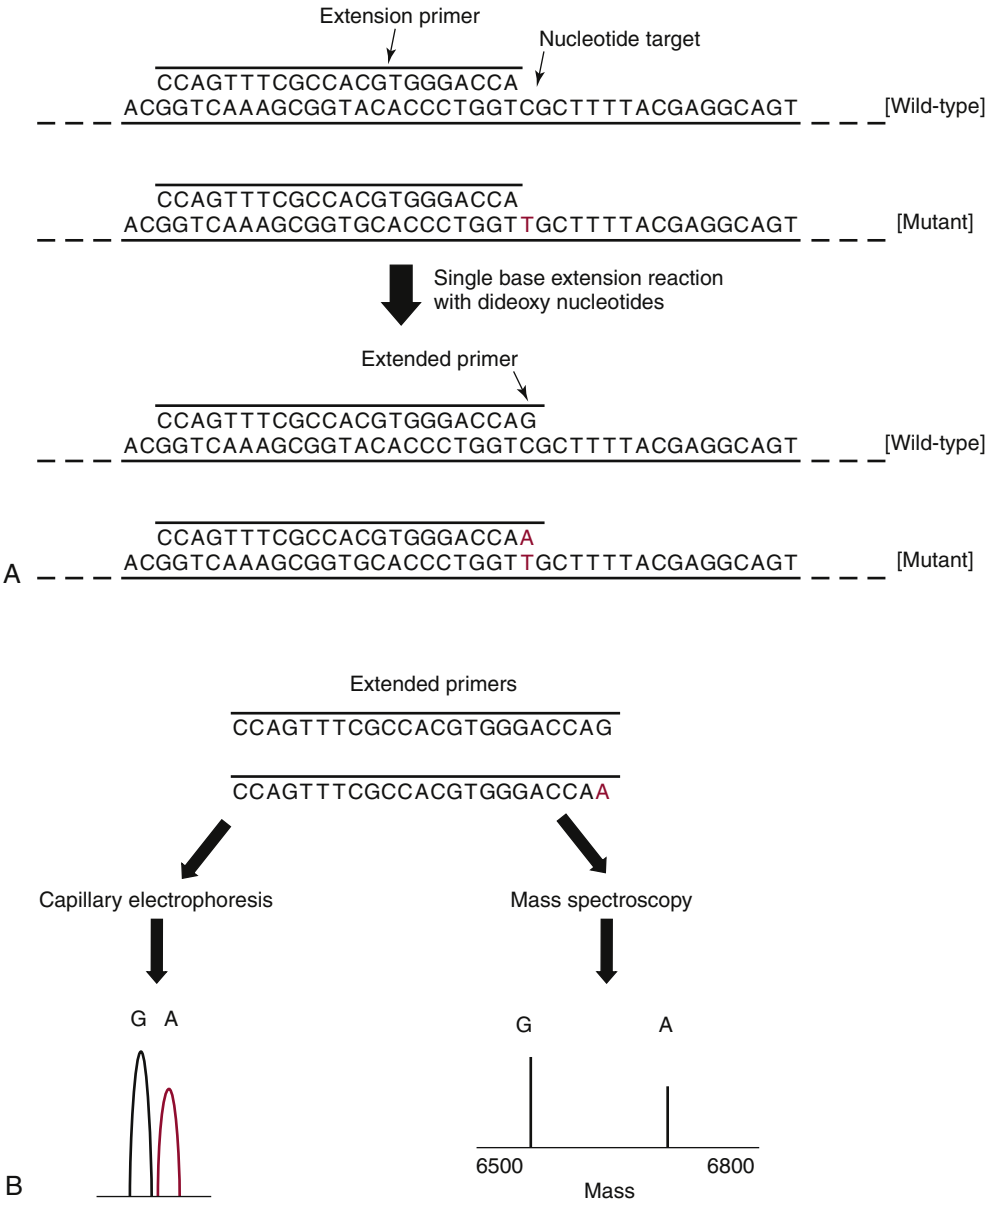

Figure 59-5 Primer extension assays These assays are used to interrogate specific "hotspot" sites of mutation occurring in oncogenes. **(A)** After an initial PCR amplification of the target sequence, an extension primer is added that sits immediately adjacent to the nucleotide of interest. **(B)** A single base extension reaction is then performed, and the products are analyzed either by capillary electrophoresis or mass spectroscopy. Both readouts are quantitative and have similar levels of sensitivity (5% to 10% mutant allele). *PCR*, Polymerase chain reaction.

development. This growing list of genes presents a challenge to clinical laboratories, which have traditionally used single-gene or single-exon approaches to genotyping. An alternative is to screen multiple genes/exons simultaneously using a multiplexed method, thereby saving on the labor and cost of performing multiple Sanger sequencing reactions. Two platforms have been developed to rapidly and cost-effectively screen for up to several hundred cancer gene mutations simultaneously. Both of these platforms—SnaPshot assays and mass spectroscopy–based assays—are based on so-called primer extension reactions.[17] In brief, each gene/exon of interest is amplified by standard PCR and then allowed to anneal to an oligonucleotide primer that sits immediately adjacent to a potential site of mutation. Dideoxy nucleotides are then added, and the primer is extended by a single base (essentially a single-base sequencing reaction), following which the product is interrogated to determine whether the added base represents wild-type DNA, a mutation, or both (Figure 59-5). The power of this approach is that the analysis can be performed in a multiplex manner, allowing many mutation sites to be screened at the same time.

SNaPshot Assays

Iafrate and colleagues were among the first to adapt this technology for screening oncogenic mutations in FFPE tumor DNA.[17] The initial PCR and subsequent primer extension reactions are multiplexed to the level of 5 to 10 reactions per tube; extended primers are then separated by capillary

electrophoresis and visualized via fluorescent tags present on the incorporated dideoxy nucleotides. Primers interrogating approximately 10 different mutation sites can be analyzed simultaneously on a single capillary. By running several multiplexes, more than 100 mutations can be screened across one or two dozen genes in approximately 24 hours. SNaPshot assays have excellent sensitivity (5% mutant allele) and are cost effective, making them popular in clinical diagnostic laboratories.

Mass Spectroscopy–Based Assays

These assays follow the same approach as SNaPshot assays, multiplexing PCR and primer extension reactions to the level of 10 to 30 per tube, but the readout on the extended primers is performed by mass spectroscopy instead of capillary electrophoresis. Although the sensitivity of the mass spectrometer is a bit lower (10% mutant allele), the throughput is significantly greater, as the instrument can read out 384 multiplexes (more than 4000 mutation sites) in 90 minutes.[18,19]

Next-Generation DNA Sequencing

The development of so-called next-generation sequencing has transformed the study of cancer by making it possible, and affordable, to generate large amounts of sequencing data in a reasonably short period of time. There are a number of different "next-gen" platforms in use, but they all share a common approach, which is to generate sequence from single molecules of genomic DNA or cDNA in a massively parallel fashion—hence the alternative name *massively parallel sequencing* (MPSS). This differs from traditional Sanger sequencing, which generates data from a population of DNA molecules that are all co-amplified during the initial PCR step.

How do MPSS systems determine the sequence of single fragments of DNA? A number of approaches are being used, and more are in development. For example, a platform developed by Pacific Biosciences is capable of visualizing individual incorporation events as nucleotides are added to a single molecule of template DNA. This extraordinary feat allows the sequencing of very long stretches of DNA (up to 10,000 bp) but is subject to relatively high error rates. Other companies are developing nanopores that will allow a single DNA molecule to pass through under an electric field. Sequence is then interpreted as the DNA molecule (either intact or as serially degraded single nucleotides) moves through the narrow channel or pore. These technologies hold the promise of extremely high throughput, but they are still in early development.

Most next-gen sequencing is currently being performed on platforms that determine the sequence from clones rather than single molecules of DNA. Clones generate more signal during the actual sequencing reaction and are therefore easier to work with. There are two common methods for generating libraries of clones from original DNA molecules. One is to seed the single DNA molecules across the surface of a glass slide and then PCR-amplify each in its place, creating microcolonies of identical DNAs.[20] These colonies, or clones, provide the substrate for subsequent sequencing reactions. The other approach is to mix a single DNA molecule together with a small sphere, or particle, within a tiny droplet of water suspended in oil (an emulsion).[21] Also included in the droplet are DNA polymerase and dNTPs, leading to amplification of the DNA across the surface of the sphere as the emulsion is subjected to PCR thermocycling. Both approaches generate a library consisting of thousands to millions of clonal DNA fragments, which are then sequenced all at the same time in a parallel fashion.

Depending on how the library of clones is generated, there may be anywhere from a few dozen to several thousand clones that represent copies of a particular segment of the original DNA. The resulting sequence from each clone is called a *read*. The sensitivity of MPSS for sequence alterations is directly determined by the number of reads that is generated for each segment of the original DNA. When sequencing the whole genome, 30 reads (or 30-fold coverage) is considered a minimum amount of data. For studies focused on the coding regions of the genome (the *exome*, representing approximately 1.8% of the total genome), read depths are generally greater than 100, whereas assays that are limited to a few hundred genes or less will often have read depths greater than 500, supporting mutation sensitivities below 5% mutant allele.[22]

An important consideration when evaluating MPSS data is the quality of the sequence reads. This can be influenced by many factors, including the source of the DNA or RNA/cDNA (e.g., FFPE versus fresh-frozen), the length of the reads, and whether the sequencing was performed in just one or both directions on the same piece of DNA. Another factor is the level of noise in MPSS datasets. Random errors occur during the initial clonal amplifications, as well as during the subsequent sequencing steps, creating variations in the sequence that must be distinguished from real changes. Finally, when MPSS is used to search for possible mutations in tumor DNA, it is best to compare the results with the sequence of germline DNA from the same individual, thereby defining which alterations are somatic. Without this comparison to the germline, it can be difficult to distinguish mutations from natural polymorphisms, which are abundant in all genomes.

Next-Generation Sequencing Based on Fluorescence Detection

There are several next-generation sequencing platforms that are based on the detection of fluorescence events during sequencing. The 454 system (Roche) is based on combination of emulsion PCR and pyrosequencing, using the same chemistry as described under single-gene assays.[23,24] The SOLiD system (Life Technologies) performs sequencing on glass slides by measuring the binding and ligation of short, fluorescently tagged oligonucleotides as they match up to the template DNA.[20] The most widely used systems, from Illumina Corp., also perform sequencing on glass slides, but measure the incorporation of individual fluorescently labeled nucleotides, similar to those used in Sanger sequencing.[25] The throughput on the Illumina systems has been expanded to the point where several whole-genome sequences can be generated simultaneously, while the cost per sample has decreased dramatically.

Next-Generation Sequencing Based on Semiconductors

One drawback to the fluorescence-based next-generation sequencing platforms is that they generate large numbers of very high-resolution image files, requiring terabytes of storage and considerable computing power to analyze. An alternative to the use of fluorescence for sequencing has been developed by Ion Torrent (Life Technologies). Their platform looks for the pH change generated as a nucleotide is incorporated into a nascent strand of DNA (a hydrogen ion is released).[26] Sequencing is performed on modified semiconductor chips containing between 1.2 million and 1.1 billion nanowells, each serving as a micro pH meter (Figure 59-6). Nanospheres that have been clonally loaded with DNA by emulsion PCR are seeded into the nanowells on the chip, and sequencing commences as nucleotides are serially flowed across the chip surface. Because pH changes are converted directly into electrical signals, this approach is very

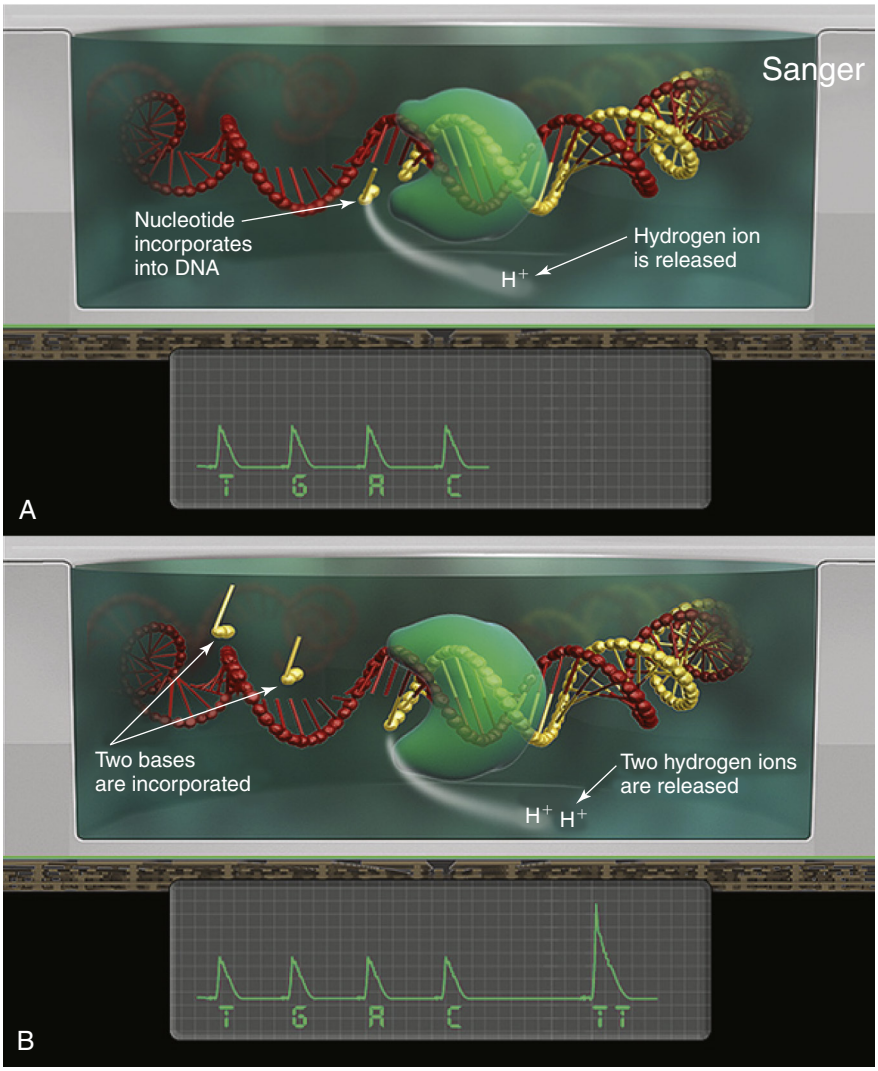

Figure 59-6 Semiconductor-based sequencing This method sequences DNA that has been clonally amplified onto nanospheres (0.5 to 3 μm) by measuring a drop in pH when hydrogen ions are released during nucleotide incorporation. **(A)** The nanospheres are distributed across a series of microwells, numbering from 1 to 660 million on a chip, each serving as an individual micro-pH meter. **(B)** As nucleotides are serially diffused across the chip surface, they are incorporated onto the nanosphere template DNA, and the resulting pH changes are interpreted to derive the template sequence.

fast and generates sequence files that are smaller than those from fluorescence-based platforms.

Future Directions

The diagnosis of cancer has been, and will continue to be, a process that depends heavily on microscopic examination of the tissue. Identifying areas of neoplasia, determining their relationship with surrounding normal tissue elements, and assessing the extent of the disease are all key elements in defining the characteristics of a malignancy. However, the field of pathology is quickly moving from routine histological assessments to increasingly sophisticated assays for molecular markers that have prognostic and/or predictive importance. The introduction of next-generation sequencing is serving to uncover the true diversity of cancers as well as to define recurring mutations that can be targeted with new therapies. Such genomic-level analyses will continue to have an impact for many years. Some have even predicted that sequencing will make microscopy moot; however, this view ignores the growing importance of assessing the relationship of cancer cells to surrounding stromal cells and to immune cells—whose influence is critical to cancer cell survival. Thus, imaging will also play a critical role in coming years, as new in situ approaches to measuring molecular events are developed and used to help further the field.
