analytical challenges due to their complexity in terms of the number of proteins that they carry, as well as the dynamic range of those proteins' concentrations.[110] Specifically, out of thousands of proteins likely present in plasma/serum, fewer than 20 account for more than 95% of the protein mass. Despite the currently achievable mid-attomole level of peptide detection, the dynamic range of plasma proteins, exceeding 10 orders of magnitude, is yet to be matched by the analytical capabilities of the most advanced mass spectrometers. Hence, strategies involving the depletion of the most abundant sample components have been widely adopted, mainly based on immunoaffinity approaches using IgG and IgY antibodies.[111-116] Although such a strategy enables much deeper interrogation of the proteome than would be otherwise feasible, it comes with a price. Namely, potential biomarkers that strongly bind to proteins targeted for removal will also be depleted and hence lost forever from further analyses.[113,117] The full extent of this potential problem is not presently known, but efforts toward evaluating the "omics" of a depleted fraction, currently focused mainly on proteins/peptides bound to albumin—the albuminome—are being pursued.[118-120] Of note, these studies could turn a problem into a solution: Abundant proteins targeted for depletion could be used as affinity reagents for enriching a specific subset of interacting proteins. In this regard, the "depletome" is a relatively untapped source of putative biomarkers.[121]

The very different approach of using intermolecular interactions to access the low-abundance end of the proteome is based on the concept of "equalizing" protein concentrations within the sample.[122,123] Rather than removing abundant species, each protein, regardless of its relative concentration, is given a statistically even chance of encountering a suitable epitope to which it would bind with high affinity. Importantly, all possible epitopes are delivered at equimolar concentrations that are significantly lower than the concentrations of high- and medium-abundance proteins. In this scenario, it is the number of high-affinity epitopes that are available rather than the overall amount of a protein in the original sample that would drive final composition of the extracted protein mixture. This approach was commercialized as ProteoMiner technology by BioRad and uses a library of hexapeptides attached to magnetic beads. Although the concept of dynamic range compression offered by equalizer beads is very appealing, it is yet to be optimized. The bulky physical format might be one of the limiting factors; a large volume of beads is required to achieve a comprehensive representation of all potential epitopes, thus necessitating the use of matching volumes of a sample. Nevertheless, the method was successfully applied to profile more than 1500 low-abundance proteins in erythrocyte lysates, a sample presenting great challenges because hemoglobin (Hb) comprises 98% of the cells' proteome. However, to achieve this feat, 5 g of total protein was used to isolate 8 mg of material—an estimated recovery of about 8% of the non-Hb fraction.[124] In plasma, antibody depletion and peptide ligand library enrichment methods performed similarly.[125] In addition, the utility of the latter capture method as applied to the analysis of conditioned medium, which contained serum, was recently shown.[126] A number of studies have been published that used the peptide ligand library approach in the context of cancer biomarker discovery.[127-129] Translation of this tool into a "nano" format might greatly enhance its utility.

Techniques for Relative Protein Quantification at the Discovery Stage of Biomarker Analysis

Biomarker discovery assays are designed to assess differences between the disease and control samples in a quantitative manner.[130-132] In contrast to MRM assays, discovery assays measure relative abundances rather than absolute concentrations. Hence, comparing the levels of the same protein across samples is more reliable than comparing abundances of different proteins in the same sample. Label-free approaches and methods based on the concept of isotopic dilution are commonly used. Label-free methods are attractive because they do not require any specialized sample processing, but they analyze one sample at a time.[133-135] As to the latter approach, a category of isobaric reagents has gained popularity because such reagents offer the opportunity of multiplexing samples for LC MS analysis—thus significantly minimizing analysis time, an important consideration for large proteomics studies. When using isobaric reagents, samples are processed independently up to the stage of labeling proteolytic peptides with stable isotope reagents and then combined for further fractionation and MS.[136,137] An attractive stable isotope–based approach of stable isotope labeling with amino acids in culture (SILAC) was originally introduced for studies on cell cultures where it is possible to incorporate stable isotope–labeled amino acids in vivo as natural precursors of protein synthesis.[138] SILAC allows samples to be combined at much earlier stages of sample preparation, thus minimizing artifacts related to sample processing.[139] Although clinical specimens themselves are not amenable to stable-isotope labeling, generation of labeled reference proteins in cell cultures extended the use of Super-SILAC[140-142] to nonculturable systems.

Specialized Approaches Tailored to Analysis of Protein Glycosylation

Aberrant glycosylation has long been recognized as a hallmark of malignant transformation of mammalian cells,[143,144] and hence changes in protein glycosylation can serve as

sentinels of cancer detection.[145-160] Many of the oldest and most widely used clinical cancer biomarker tests detect glycoproteins, including carcinoembryonic antigen (CEA), used as a marker of colorectal cancer[161,162]; cancer antigen 125 (CA125), frequently used to diagnose ovarian cancer[163,164]; prostate-specific antigen (PSA)[165-167]; and serum CA 19-9, commonly used for the diagnosis of pancreatic cancer.[168,169] However, because of the complexity of carbohydrate structures and related technical challenges, progress in glycoprotein analysis has been slow. Tellingly, the structures of CA125 glycans have not been fully characterized despite more than 30 years of intense investigation.[170] Nevertheless, the past decade saw significant progress in glycomics technologies,[134,167,171-182] including MS methods for direct analysis of glycopeptides[183-186] and development of bioinformatics tools for data analysis.[187-189]

When interrogating the glycoproteome for biomarkers, the proverbial "needle-in-a-haystack" challenge is exacerbated by the great heterogeneity of glycoprotein structures. Different classes of oligosaccharide structures are attached to proteins via Ser/Thr (*O*-linked) and Asn (*N*-linked) residues. Although a consensus sequence for *N*-linked glycosylation is known (NXT/S, where X is any residue except proline), the specific amino acid sequences that make up *O*-glycosylation sites are not well understood. Thus, use of these potential glycosylation sites varies widely for reasons that remain obscure. In addition, there is substantial heterogeneity in the *N*- and *O*-linked glycan motifs across different sites as well as occupancy of individual sites. Analysis of *N*-glycosylation is facilitated by the availability of a specific asparagine deamidase enzyme that releases *N*-linked structures. Peptide *N*-glycosidase F (PNGase F) hydrolyzes the amide bond of the asparagine residue to which the glycan is attached.[190] This process results in a 1-Da increase in the molecular mass of the deglycosylated peptide, thus marking the original *N*-glycosylation site with a mass tag easily identifiable by MS. When performed in the presence of ^{18}O-labeled water,[191] a 3-Da increase in peptide molecular mass provides greater distinction. On the other hand, the development of equivalent enzymes for the release of *O*-linked structures, and identification of their sites of attachment, has yet to be achieved. In this regard, engineering a proteinase that would hydrolyze the GalNAc-Ser/Thr linkage would greatly facilitate studies of *O*-linked structures and the glycoproteins that carry them. Importantly, the HUPO Human Disease Glycomics/Proteome Initiative coordinated a multi-institutional study aimed at evaluating methods for profiling *O*-glycosylation that demonstrated the preeminent performance of MS for *O*-glycopeptide and *O*-glycan analysis.[192] Reliable protocols for characterization of *O*-deglycosylated proteins using chemical[193] or partial enzymatic deglycosylation methods[186] were recently published.

Current approaches to the analysis of glycoproteins as potential biomarkers typically involve one or more enrichment steps, proteolytic digestion, and LC MS analyses. Enrichment of carbohydrate-containing species is performed at either the glycoprotein or glycopeptide level. Although both approaches offer distinct benefits, glycopeptide-based capture provides the advantage of identifying exact protein regions and, often, a specific site of glycosylation. On the other hand, in the workflows based on affinity selection at the glycoprotein level, protein identification is facilitated by the analysis of multiple peptides[194]—although with an increased risk of detecting off-target species, that is, those that either bind to a matrix in a nonspecific manner or interact with glycoprotein targets. The latter phenomenon might prove useful in detecting alterations in protein-protein interactions triggered by cancer-related changes in glycosylation.

Given that affinity selection of glycan-containing molecules is an important component of the glycoproteomics workflow, it is possible to analyze unfractionated samples. However, when analyzing plasma or serum that are overwhelmed by a small number of highly abundant proteins, their immunoaffinity depletion is often done before glycopeptides/protein enrichment, thus enabling deeper coverage of the remaining lower-abundance proteome where biomarkers typically reside. The most commonly used enrichment approaches take advantage of lectins, proteins that specifically bind to various *N*- and *O*-linked carbohydrate motifs.[195,196] In addition, chemical methods that exploit elements of glycan structures have also been introduced.[197]

A variety of protocols have been developed for lectin capture of glycoproteins and glycopeptides, based either on a single lectin[194,198-200] or on a combination of lectins with different selectivities, either in a serial[201] or a mixed-bed multi-lectin affinity capture manner[202-205] and using different analytical formats (e.g., gravity column chromatography, magnetic beads, or high-performance liquid chromatography [HPLC], the last providing the highest degree of reproducibility and speed).[13,14,200,206,207] Elution of captured glycoproteins/glycopeptides is accomplished using either mono- or disaccharides presenting lectin-specific epitopes[200,202,208] or nonspecific disruptors of lectin-glycan binding, such as acidic or high-salt reagents.[194,207,209,210] Additional fractionation of the captured species using various forms of HPLC is often performed before MS analysis. Judicious selection of lectins is vital for the success of a biomarker discovery experiment. An elegant study that explored the performance of lectins of varying specificities highlighted the potential utility of a polylactosamine-directed *Lycopersicon esculentum* lectin (LEL) of narrow specificity in differential analysis of the glycoproteome of breast cancer patients, as compared to control individuals.[194] In a study that focused on *Aleuria aurantia* lectin (AAL) enrichment of highly

fucosylated glycoproteins, approximately 50% of the glycoproteins correlated with a hepatocellular carcinoma diagnosis, with fucosylated hemopexin emerging as a potential biomarker of cancer with a high degree of specificity and selectivity of 92% for both.[199]

As to chemical methods of enrichment, two similar approaches, involving hydrazide[211] or boronic acid chemistry, capitalize on the *cis* diols present in monosaccharide structures. Bound glycoproteins are trypsin-digested in situ, and nonglycosylated/unbound peptides are removed by washing. Then covalently coupled *N*-linked glycopeptides are released by PNGase F treatment and analyzed by LC-MS/MS.[211] In an alternative approach, glycopeptides rather than intact glycoproteins were captured by hydrazide beads,[212] which resulted in a marked increase in the number of recovered glycopeptides. A complementary approach employed boronic acid–functionalized beads to covalently capture glycoproteins, which were then eluted with acid.[213] Building on data derived from these methods, Aebersold's group[214] developed a searchable online catalog for depositing data regarding *N*-linked glycosylation sites and glycopeptide sequences (www.UniPep.org). This repository is an important companion to sequence-based algorithms that predict *N*-linked glycosylation sites and, as such, is a valuable resource for plasma- and serum-based studies.

Studies focused on specific glycan structures rather than on their protein scaffolds are also being aggressively pursued, and a number of glycan-based cancer biomarkers have been proposed.[149,151,158,215-224] Here, glycans are released either by enzymatic (for *N*-linked) or chemical (for *O*-linked) methods, fractionated by chromatography, and analyzed by MS for compositional and structural profiling. The latter approach offers high sensitivity in differentiating between normal and disease-related structures, which are often more elaborate. Recently developed methods use isomer-sensitive stationary phases, such as porous graphitized carbon[220,225] or hydrophilic interaction chromatography,[222,226] for nanoLC separation of complex glycan mixtures. Importantly, high chromatographic resolution and reproducibility of the method allow isomeric structures to be assigned without the need for oligosaccharide derivatization. Recent high-throughput application of this technology to serum samples from ovarian cancer patients (n = 46) and controls (n = 48) revealed approximately 250 *N*-linked glycan features with more than 100 distinct compositions, and provided discrimination between healthy control and cancer samples.[227] Although these results require further validation, they nevertheless speak to the robustness of the platform and its potential utility in a screening format. Ongoing efforts aimed at complete annotation of the "normal" human serum glycome in terms of glycan composition, MS/MS spectra, and LC retention times will greatly facilitate use of platforms and workflows for interrogating the glycoproteome and the glycome spaces, which remain relatively unexplored.[225] Glycan tagging using hydrazide-based chemistry to enhance oligosaccharide ionizability and MS detectability has recently been reviewed.[228] Finally, engineering bioorthogonal monosaccharides bearing biologically inert functional tags that are accepted as natural substrates and incorporated into glycoconjugates is an attractive complementary approach for exploring structures of specific classes of cell surface glycans.[229,230]

Example: Biomarker Development Using a Mouse Model of Human Breast Cancer

A recently published account of credentialing a consolidated set of biomarker candidates in an animal model of breast cancer provides an excellent illustration of the complexity of the process of selecting high-value markers out of the large number of potential contenders.[231] The major focus of this work was verification, which built on the discovery data generated by the authors and other investigators using the results of 13 independent microarray and untargeted shotgun proteomics experiments performed in plasma and tissues. In the course of a multistep verification process, an initial set of 1908 putative biomarkers assembled according to preestablished criteria was reduced to a set of 36 proteins that were verified, using a high-stringency assay, as elevated in the plasma of tumor-bearing mice. From the standpoint of technology, this carefully designed study provides a unique perspective on capabilities of current methods under ideal conditions because the variability related to biological and environmental factors was minimized by using an animal model.

This work used a well-characterized doxycycline-inducible, bitransgenic MMTV-rtTA/TetO-NeuNT (Her2/Neu) mouse model of breast cancer. Healthy transgenic TetO-Neu animals were used as controls. The goal of the first triage step was to identify the candidate biomarkers that were detectable in plasma, as many originated from tissue-based studies. To this end, a targeted MS proteomics method, accurate inclusion mass screening (AIMS),[66] was used to screen pooled plasma from 20 tumor-bearing animals for the presence of peptides representing 1144 candidate proteins. Close to 17,000 proteotypic peptides[232-234]—those that are detectable under the experimental conditions and diagnostic for a given protein—were targeted, resulting in the detection of 43% of the candidate proteins. Not unexpectedly,

the highest confirmation rates were for candidates that originated from plasma analysis. However, 17% of the candidates that were originally discovered only in tissue were identified, including 2% that were derived exclusively from the mRNA analyses. In the second triage step, the authors used a semiquantitative format of SRM to further cull their list of candidate biomarkers. Of 383 candidates that were examined using plasma pools of tumor-bearing and control animals, relative concentrations of 43% and 10% proteins demonstrated differences estimated with high and medium levels of confidence, respectively. The third-stage triage employed quantitative targeted MS assays: SID SRM and SISCAPA. A total of 79 high- and medium-confidence candidates were evaluated in individual animals from two disease cohorts: animals with substantially advanced tumors (cohort 1) or mice in an early phase of the disease process (cohort 2). For cohort 1, 36 proteins (46%) were significantly elevated as compared to disease-free control mice. In contrast, only two proteins circulated at significantly higher levels in the mice from cohort 2 versus controls, which exemplifies the considerable challenge of verifying biomarkers of early-stage tumors. Final verification, which employed wild-type mice with confounding conditions, suggested that most of the identified biomarkers were likely to be specific for breast cancer.

In summary, in addition to its primary value of proposing potential breast cancer biomarkers, the study benchmarks the currently available technologies in a tightly controlled in vivo model. Significantly, of the 369 candidates selected solely on the basis of significant differences in mRNA expression in tissue, only about 2% were confirmed by AIMS, and none were subsequently verified. Likewise, none of the 35 candidates revealed by the label-free proteomics discovery assays in plasma alone were verified. These results clearly demonstrate that biomarker discovery focused solely on plasma is very unlikely to be effective without including concomitant analyses of affected tissues (or proximal fluids) at the protein level.

Conclusions

Currently, many more biomarker candidates have been proposed by MS proteomics discovery studies than have been validated with the rigor required for their use in the clinic. At the same time, only a small portion of the proteome has been interrogated, and hence only a fraction of potential biomarkers have been brought to light. In view of limited resources, this situation poses a dilemma as to what should be prioritized in the near future: verification of the plethora of candidate biomarkers or discovery of new ones. From the perspective of furthering understanding of cancer and helping patients, this is a false choice. Nevertheless, it is bound to affect funding decisions and consequently the directions that the field will take. A clear distinction is required in terms of addressing the needs of the validation versus discovery arms of the biomarker development pipeline. First, a robust strategy for traversing the precarious middle point in candidate biomarker evaluation is required. At the stage of biomarker qualification, the least likely targets need to be weeded out using relatively inexpensive semiquantitative approaches before investing in rigorous and costly assays for the most valuable contenders.[22] Validation requires the analysis of large number of samples from various well-defined cohorts using well-established, well-controlled, uniform, and standardized protocols. From this perspective, large research consortia, with guaranteed access to proper specimens and all the advantages that economy of scale brings in terms of infrastructure, stand the best chance of streamlining the process and producing reliable results in a timely fashion. In addition, major efforts are being made in the biotechnology and biopharmaceutical sectors. Further investments in the field of biomarker discovery should also promote novel protocols and strategies aimed at increasing the breadth and depth of coverage. As history teaches, these types of cutting-edge scientific endeavors tend to be most successful when left to small independent groups of highly creative researchers.

To summarize, we are far from the ability to detect, identify, and quantify every protein in all of its isoforms in biological specimens. When designing experiments, our decisions are based not only on scientific factors, but also on constraints of economy and logistics. Therefore we need to be pragmatic and strive for maximum efficiency while accepting the need for imperfect solutions. This approach goes against the grain of analytical chemistry, creating a healthy tension. In this context, it is more important for biomarker discovery methods to be as comprehensive as possible rather than reproducible, which comes into play at later stages. On the other hand, it is vital for validation methods to be rock solid, artifact free, and reproducible, preferably across analytical platforms and laboratories, to enable generation of the necessarily large volumes of data in a reasonable time frame. In an ideal world, it would be preferable to invest in methods that deliver biomarkers that provide insights into the disease process. However, given the pressing needs of cancer patients and people with other diseases, we are forced to accept less informative solutions that deliver clinically useful biomarkers, in terms of diagnosis and therapeutic responses, regardless of our current understanding of their functional relevance.

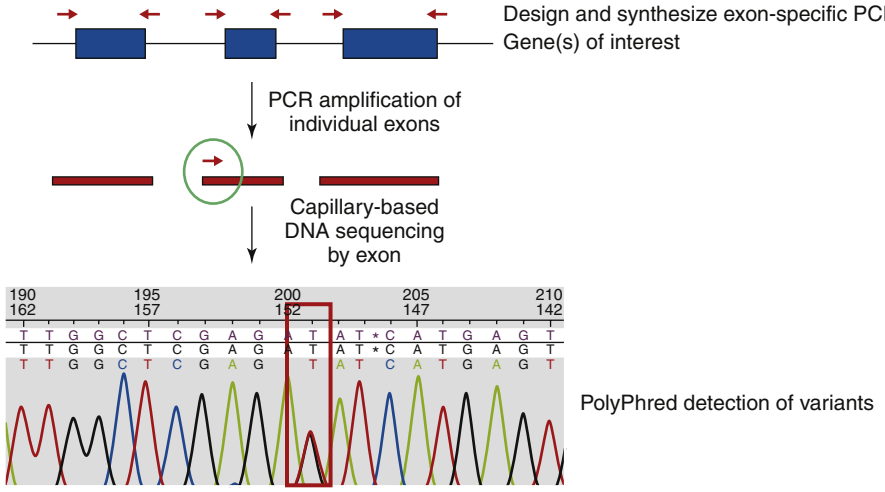
The Technology of Analyzing Nucleic Acids in Cancer

Introduction to Next-Generation Sequencing

Current DNA sequencing methods differ dramatically from a mere 7 years ago, when next-generation sequencing (NGS) instrumentation was first introduced.[1] Indeed, the science of DNA sequencing is only 35 years old, and its companion discipline known as *genomics* has been revolutionized by the advent of NGS instrumentation and its application to myriad biological questions. Whereas conventional DNA cloning and sequencing approaches, largely based on the initial descriptions by Fred Sanger and colleagues,[2-5] provided key reference genome sequences for model organisms (*Caenorhabditis elegans*, *Escherichia coli*, *Arabidopsis thaliana*, *Saccharomyces cerevisiae*, *Mus musculus*) and for humans,[6] next-generation instruments and associated analytical efforts have truly revolutionized the nature of biological inquiry. This fact is nowhere more evident than in the study of cancer, first proposed by Bovery as a disease whose origins lay in profound alterations of the nuclear DNA, remarkably before DNA was found to be the hereditary material and instruction set for the organism. His hypothesis about cancer as a disease of the genome was first supported by microscopic observations of reoccurring chromosomal translocations in leukemic cells.[7-10] Later, the fusion proteins resulting from these translocations were proven necessary and sufficient to induce the developmental arrest and proliferation of leukemic cells. Hence, genomic alterations were a precursor to cancer's development.[11-14]

Having the reference human genome in hand, the combination of polymerase chain reaction (PCR) and Sanger sequencing by fluorescent capillary methods provided the first nucleotide-level evidence that point mutations in tyrosine kinase genes also were associated with carcinogenesis.[15,16] Thus, DNA sequencing was shown to provide a higher resolution "microscope" with which to catalog specific genes that were commonly mutated in cancerous cell genomes. These efforts also established the rationale that genes found recurrently mutated in different cancer samples and ultimately across different types of tumors were likely drivers of oncogenesis. Although increasing the scale of this approach was attainable, there were known limitations to PCR- and Sanger-based approaches (Figure 23-1). On a practical level, PCR had many sources of failure, including the inability to design primers that bind with fidelity in repetitive sequences or exclude pseudogenes or distinguish specific genes in gene families, as well as amplification failure when primer annealing failed due either to DNA polymorphisms or to structural alterations that changed or removed one or both binding sites or to poor amplicon yield from high G+C content (common in the first exons of genes). Furthermore, data generation for large numbers of genes required a significant amount of DNA to be obtained from each tumor. In addition, although large-scale automation could be employed to provide throughput and reproducibility, scaling successfully to address all human genes in large numbers of samples was cost prohibitive. Beyond practical considerations, the approach provided no information about DNA rearrangements or copy number alterations and overall no appreciation of reoccurring events outside the genes.

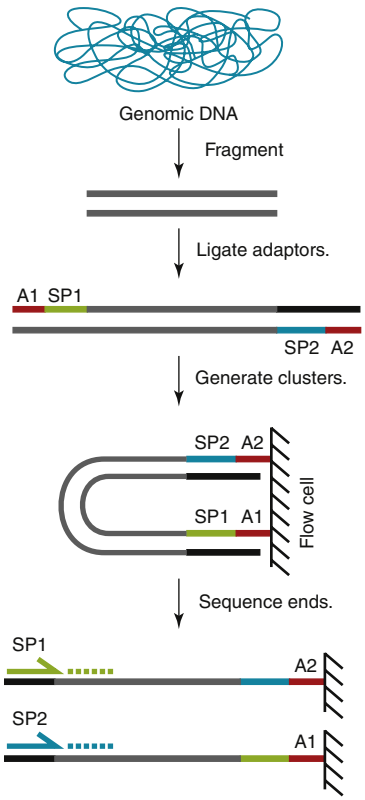
The advent of NGS instruments addressed many of these limitations by providing several advantages in terms of throughput and cost.[1] Although the technical nuances of the various NGS instruments differ, they generally share the same principles (Figure 23-2). These include (1) a simplicity of library construction that requires comparatively little DNA versus PCR-based methods, (2) an enzymatic amplification of each library fragment to produce sufficient signal during the sequencing reaction, and (3) a stepwise sequencing reaction that detects the signal from each nucleotide incorporation reaction of each amplified fragment population before moving to the next reaction. This en masse sequencing approach is why NGS is often referred to as "massively parallel." Indeed, dramatic increases in scale and speed, and decreases in cost, of



Pros:
Low computational overhead for data analysis
Scalable to medium throughput

Cons:
Primer design failures
Amplification failures
DNA consuming
Expensive
No structural variation or copy number information

Figure 23-1 PCR and capillary sequencing of exons A generalized workflow is shown for the PCR-based amplification of specific exons in the human genome, their sequencing, and separation of the nucleotide sequence by a fluorescent capillary sequencing approach. Nucleotide changes can be identified by the appropriate software, such as PolyPhred, which was widely used for analysis of capillary data. A single base substitution mutation is shown in the trace data example. Pros and cons of the approach are listed and described in the text.



Pros:
Rapid inexpensive data generation of whole genome data
Comprehensive analysis possible for nearly all somatic events
Low input DNA amounts possible
Scalable

Cons:
Large data volumes are computationally challenging
Short read lengths

Figure 23-2 Next-generation sequencing (NGS) of whole genomes A generalized workflow for the production of whole-genome sequencing data by next-generation or massively parallel sequencing is shown. Several pros and cons of this approach are listed and described in the text. Computational identification of the genome-wide differences between tumor and normal genomes requires highly specialized pipelines for each variant type (point mutation, copy number alteration, insertion/deletion variant, structural variant).

data generation by NGS have occurred in a very short time. The size of NGS datasets, especially from whole-genome sequencing (discussed later), coupled with relatively short read lengths compared to Sanger sequencing, have required substantial investments in the development of computer algorithms, computing/IT infrastructure, and computational biology expertise to successfully interpret the data.[17] These computational efforts have been further taxed by continued improvements in NGS data quality (error rates), increasing read lengths, and the ability to generate sequencing data from both ends of each library fragment (typically referred to as "paired end" sequencing) because of the need for new algorithm and data analysis pipeline development as well as refinements to existing computational pipelines. The bottom line is

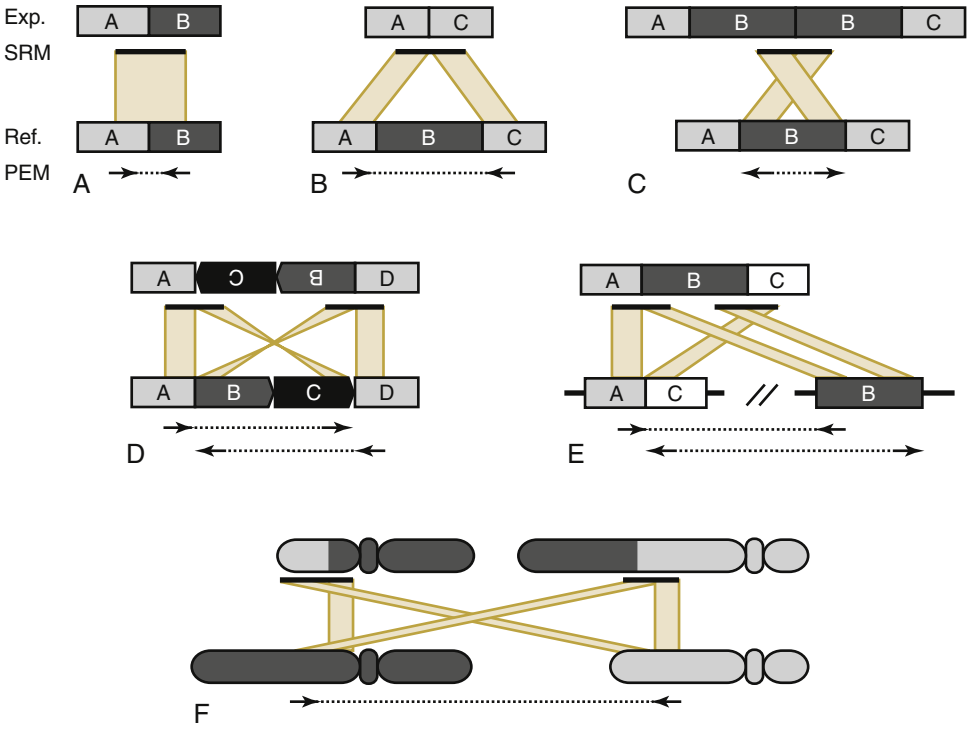


Figure 23-3 Read placement distance and orientation is indicative of structural variation of various types In each figure, the paired end mapping (PEM) orientation and distance on the reference genome (Ref) of the NGS data is shown relative to the short read mapping (SRM) of the experimental data (Exp). **(A)** The anticipated read mapping distance and orientation are shown. **(B)** A deletion in the experimental genome. **(C)** An insertion. **(D)** An inversion. **(E)** A complex rearrangement. **(F)** A translocation. *With permission from Quinlan AR, Hall IM. Characterizing complex structural variation in germline and somatic genomes.* Trends Genet. *2012;28:43-53.*

that the first step in interpreting short read data is computational alignment to a reference genome such as the Human Reference Genome.[18,19] Alignment maps each read or read pair to its origin in the genome and then assigns a quality score to the mapping position that can be interpreted for its certainty of correct placement. Subsequent analytical approaches further interpret the total read alignment (also called "coverage") in a variety of ways to identify single-nucleotide variants (SNVs), small insertion or deletion events that involve one or a few bases ("indels"), and structural variants (large insertion or deletion events, chromosomal inversions, or translocations–see Figure 23-3). Although read length and data quality improvements have overall expanded the utility of NGS for biological experimentation and decreased the cost of data generation by a trajectory that exceeds Moore's law, the computational requirements of NGS analysis have remained largely unchanged.[20] Many unique aspects, discussed later, further complicate sequencing and analysis from cancer samples. In spite of the obstacles, our understanding of the genomic landscape of cancer has changed remarkably in just a few short years.

Challenges to NGS Analysis of Cancer Nucleic Acids

The search for somatic variation in cancer DNA and RNA has a distinct advantage over other complex diseases: The exact comparison of tumor to normal nucleic acids within an individual patient distinctly identifies those alterations that are tumor unique. Furthermore, there are increasing amounts of data from various projects that have begun using NGS methods to catalog large numbers of cancer cases across different tumor types (ICGC [icgc.org], TCGA [cancergenome.nih.gov], PCGP [www.pediatriccancergenomeproject.org][21] that can be used to inform individual analyses about previously described alterations. In spite of these decided advantages, there are several significant challenges that confound experimental design and analytical approaches in cancer genomics studies. Several examples of these challenges are described next, along with the ways researchers attempt to overcome them, where applicable.

Tumor Cellularity

Cancerous cells in solid tumors do not exist in isolation in the body. Rather, they are always in close proximity to normal cells of various types, including stromal cells, immune cells, and components known as the *extracellular matrix* (ECM). The proportion of tumor cells can be estimated by an experienced pathologist examining the tumor section under hematoxylin and eosin staining, and this estimate is expressed as a "percent tumor nuclei" or "percent tumor cellularity" value. As a result of the association of tumor and normal cells, an isolate of DNA or RNA derived from a solid cancer sample will contain both tumor and normal cells unless a specific procedure such as flow cytometry or laser capture microdissection

(LCM) is used first to significantly enrich the percentage of tumor cells in the isolate. Also, certain tumor types, such as those from prostate or pancreas, are more prone to low tumor cellularity. Based on the pathology estimate, decisions in sequencing must be made in the context of tumor cellularity percentages. Namely, if the tumor cellularity is below 60%, the decision must be made either to enrich the tumor by flow cytometry (more common for blood cancers such as lymphoma or leukemia) or by LCM (used for solid tumors), or to try oversampling the tumor NGS library (increased sequencing coverage) by an amount commensurate with the tumor cellularity estimate. Although sorting or LCM seems the most obvious choice, one limitation of either approach is that significantly reduced yields of DNA or RNA will be obtained. Unless specialized procedures are in hand, the low yield may limit the ability to derive high-quality data from such samples. By contrast, oversampling may be effective for DNA sequencing but will be more expensive to generate and will require adjustment of variant calling parameters, or use of a more sensitive variant caller, to effectively identify somatic variants. Oversampling for RNA-seq from a sample with low tumor cellularity is generally not advised, as the tumor transcripts will be too difficult to discern from those of the normal cells unless LCM or sorting is first used to separate the tumor cells from the adjacent normal/nonmalignant cells.

Heterogeneity (Regional versus Genotypic)

Heterogeneity is a fundamental aspect of cancer cells found within the same tumor of which there are two types, regional and genotypic. Regional heterogeneity reflects the differences that emerge in solid tumors as they grow and progress. It refers to the different regions present in a tumor mass, such as areas of necrosis or areas of invasion (of surrounding normal tissue). Genotypic heterogeneity reflects the fact that cancer cells evolve during the process of tumor progression, so that not all tumor cells share the same somatic genotype. In genotypic heterogeneity, the use of NGS has demonstrated that by comparing the genomes from progression samples (a de novo leukemia compared to its relapse) using high-depth sequencing of somatic mutations, an initiating or "founder" clone can be identified that contains the core mutational load that initiates tumor growth as well as more advanced clones that combine newer mutations with those in the founder clone.[22] One shared aspect of regional and genotypic heterogeneity is that as a tumor mass increases in size, both are more likely to occur in that areas of regional heterogeneity are likely to have genotypic heterogeneity. There are so far only two studies to examine this at the DNA level; one study of two advanced-stage renal cell carcinomas that exhibited extreme genotypic heterogeneity[23] and one study of five early-stage (2/3) breast cancers that showed little to no genotypic heterogeneity[24] when sampled and studied at multiple sites.

Ploidy and Copy Number Alterations in DNA

Altered numbers of chromosomes (more or fewer than 2) have been widely observed in cancer cells, likely reflecting errors in chromosomal segregation that occur during rapid division and growth cycles. Observing ploidy alterations requires cytogenetic examination of the tumor cells in metaphase, which may or may not be part of the pathology-based diagnosis for the patient sample. Alternatively, ploidy alterations and large chromosomal arm or subarm amplifications and deletions (somatic copy number alterations or SCNAs) can be inferred from signal strength–based analysis of genotyping array data.[25,26] Ploidy increases and arm or subarm amplifications are important in DNA sequencing of the tumor because these regions will contribute more DNA to the library, and hence more reads will result than for the diploid (or haploid) regions of the genome. Thus increased coverage must be obtained for the tumor library to compensate for amplified regions or ploidy-altered chromosomes so the coverage of diploid genomic regions is sufficient for variant detection. Careful analysis of aligned reads in copy number–altered regions can provide exquisite resolution of the genes involved and of the relative timing of somatic mutation and copy number alteration when both occur in the same locus.[27]

FFPE Preservation and Nucleic Acid Integrity

Most pathology assays used in cancer diagnosis and characterization require stability of proteins and cellular structure. Hence, fixation in formalin and embedding in paraffin have been the standard pathology preparation methods for more than 100 years. As this practice is unlikely to change in the near future, and because so many clinically valuable specimens already have been preserved by this method, the study of formalin-fixed, paraffin-embedded (FFPE)-preserved nucleic acid isolates by NGS methods is increasing. The chemical reaction between formaldehyde, proteins, and nucleic acids leads to crosslinking proteins and nucleic acids, and ultimately the DNA/RNA backbone breaks because of the presence of abasic lesions.[28] This is a random interaction, and DNA/RNA fragmentation increases with longer exposure of nucleic acids to formalin and over time of storage. Therefore, the older a tumor FFPE block, the more likely to be advanced the degradation of the nucleic acid components. Nonetheless, careful examination of the nucleic acid integrity will identify those samples suitable for library construction for DNA or RNA, based on the average size

and distribution of degraded nucleic acid isolated from the sample. In DNA isolates, the average fragment size should be 300 bp or greater or a suitable NGS library is unlikely to result. In RNA, the 28S and 18S rRNA peaks should be visible by gel electrophoresis, with an RNA integrity number (RIN) of at least 5.

Applications of NGS to Study and Analyze Nucleic Acids

The genomic DNA isolated from cancer cell nuclei can be studied in a variety of ways, several of which are profiled here. Because cancer develops from alterations of the nuclear genome that are distinct from the germline genome, an inherent and powerful comparison can be obtained by studying the paired tumor and normal genomic DNA from individual cancer patients. In discovery efforts, large numbers of such cases can be studied to add information about the frequency of different types of somatic alterations and the genes whose protein products will be altered as a result. Higher level analyses of the pathways affected by somatic alterations in DNA can further inform the resulting tumor biology. Studies of RNA by NGS methods have deepened our understanding of the numerous types of RNAs, their membership, and how they are altered in the course of carcinogenesis, although not all alterations are comprehensible in the biological context. The latter reflects our ignorance of the many roles these molecules play in cellular biology, emphasizing the need for functional studies as a follow-on to NGS-mediated discovery efforts.

Whole-Genome Sequencing

The most comprehensive approach to identifying the somatic alterations present in cancer genomics is obtained by whole-genome sequencing (WGS) of the tumor and normal DNAs. In this approach (see Figure 23-2), the isolated high-molecular-weight genomic DNA from each tissue is fragmented by the application of high-frequency sound waves or other physical shearing methods and then enzymatically treated to blunt the fragment ends that result. Finally, short synthetic adapters are added to make a whole-genome library. After limited PCR amplification by primers that correspond to the forward and reverse adapters, a gel-based sizing allows specific size fractions to be isolated (two to four insert sizes are typical to enhance library diversity and genome representation). The more precise the size fraction, the more precisely structural variants can be identified by virtue of their relative position once mapped to the reference genome (see Figure 23-3). Libraries are then quantitated, diluted to the appropriate concentration, and amplified in situ to produce collections of fragments, each of which originated from a single library fragment. Thus the data generated from WGS are "digital" in nature and can be interpreted later in this context, to provide highly precise information about chromosomal amplification and deletion events genome-wide, and the relative frequency of mutations in the tumor cell genomes sampled by DNA isolation.[22] Read pair data are then generated from tumor and normal libraries to a minimum depth of 30-fold, allowing for a mapping rate of around 85% of read pairs; this equates roughly to 120 Gbp of data per genome. Following data generation, the signals obtained from the stepwise sequencing process are interpreted by instrument-specific software, culled for low-quality sequences, paired, and provided to the mapping algorithm for alignment to the Human Reference Genome as outlined earlier. Alignment is done for tumor-specific reads and for normal-specific reads separately. Variants are identified and then compared to one another.[29] There are many specialized algorithms that have been specifically developed to evaluate the somatic variants that are carried by the cancer cell genomes decoded by whole genome sequencing data. Depending upon the algorithm type, one can identify somatic single nucleotide variants (SNVs), focused insertion and deletion events of one to several nucleotides (in/dels), and larger, structural events such as translocations, inversions, deletions, and amplifications. Loss of heterozygosity (LOH) is a common somatic genome event, and there also are algorithms to identify stretches of LOH along chromosomes. Each algorithm has an associated false positive rate, so secondary validation of putative somatic variants is the best practice. The identification of structural variants is particularly prone to a high false positive rate due to the difficulty of identifying these regions, as illustrated in Figure 23-3. Here, the distance and orientation of read pair mapping to the Human Genome Reference for multiple unique read pairs is required to identify a structural event, as indicated in the figure. By using the read pairs that identify the event, and a short read assembly algorithm, one can reassemble the structural variant event to nucleotide resolution. Finally, one makes "sense" of the variants identified genome-wide by annotation, effectively overlaying our current understanding of genes, regulatory regions, and other identified features that help define the tumor-unique profile of genomic alterations.

As sequencing costs have dropped and instrument throughput has increased, the amount of read data and hence the coverage of the tumor genome has increased. This increase has occurred for several reasons: notably, the confidence of detecting somatic variations typically increases with increasing coverage. Furthermore, the heterogeneous nature of cancer cell genomes means that increased coverage

provides enhanced characterization of the mutational spectrum within the cells. Tumor progression is at its essence an evolutionary process in which new mutations arise from the fundamental tumor genome (often referred to as the "founder clone") and expand into new subpopulations of cells.[22,30] Thus, the higher the tumor genome coverage, the more likely it is that subpopulations can be identified.

Exome Sequencing

Although WGS data are straightforward to produce and provide comprehensive genome-wide information about somatic alterations, their production remains expensive, and they are difficult to accurately interpret. Much like the early PCR-directed methods used to characterize cancer somatic mutations, technology development efforts in NGS have resulted in an application typically referred to as "hybrid capture" to selectively isolate regions of the genome followed by NGS.[31-33] Sequence-based comparison of the isolated regions between tumor and normal generate specific information about somatic and germline SNVs and indels. Hybrid capture protocols combine the whole-genome library fragments from tumor and normal with a collection of specific probe sequences designed to capture, by hybridization, those fragments in the population that contain the same loci the probes represent. Because capture probes carry covalently attached biotin moieties, the probe:library fragment hybrids can be selectively removed from solution by association with streptavidin-coated magnetic particles and the application of a magnet. Unhybridized fragments are removed with the supernatant, and a secondary wash eliminates many (but not all) spurious hybridization events (typically referred to as "off-target effects"). The resulting captured fragments are eluted from the beads by denaturation, quantitated, and sequenced to about 100-fold average depth. In one commonly used version of hybrid capture, probes representing nearly all of the annotated exons in the human genome (the "exome") permit selective capture of these exons so they can be sequenced, compared, and annotated with respect to the somatic alterations identified. Exome capture reagents are available from commercial manufacturers, and the associated methods can be automated readily to provide a very high throughput of exome capture reactions, suitable for large-scale cancer discovery. As an alternative, custom capture probe sets can be designed and manufactured by one of several commercial suppliers to selectively isolate genes/loci of interest and characterize their mutational status in a large number of cancer cases or as a diagnostic reagent to assess specific mutational hotspots. This approach also can be used to select loci from a whole-genome library that carry putative variants, as a means of validation that mutations indeed exist.[22] Hybrid capture becomes of limited utility when the target loci (also referred to as "regions of interest" or ROIs) to be isolated fall below a combined length of approximately 500 kbp, mainly because the amount of off-target hybridization increases as the target space decreases. Because off-target captured fragments contribute to the overall fragment pool that is recovered for sequencing, the amount of sequence data actually mapping to the loci of interest decreases steadily to the point that data generation becomes too expensive to obtain the necessary coverage in desired targets. Below an ROI of about 500 kbp, either PCR and amplicon pooling or multiplex PCR are typically used.

DNA Methylation

One predominant mechanism of transcriptional control in cells is the covalent modification of the cytosine bases in DNA by methyl groups and their derivatives. Understanding the ways that methylation status changes in tumor cells can provide insights into changes in gene expression patterns, as well as new prognostic markers if sufficient clinical data and samples exist. This type of analysis requires comparator normal methylation data, ideally obtained from adjacent nonmalignant tissue genomic DNA isolates. Correlative analyses then can link DNA methylation changes to gene expression changes, providing insights into tumor biology that cannot be obtained by directly sequencing genomic DNA. Several approaches to identifying methylated cytosines in genomic DNA use chemical modification, antibody-based recognition of methylC, or comparative restriction enzyme digestion patterns from exposure to a methylation-sensitive versus non–methylation-sensitive isoschizomer. However, the most widely used approach is bisulfite modification.[34,35] In bisulfite modification, native genomic DNA is treated with sodium bisulfite to convert unmethylated cytosines to uracils (see Figure 23-4). When copied by a restriction enzyme, each unmethylated C will represent as a C to T transition, whereas methylated C residues are untouched and incorporate a G during copying. In the pre-NGS era, regions upstream of genes of interest that were activated or silenced by methylation changes were evaluated by comparing bisulfite treatment plus PCR to PCR alone between tumor and adjacent non-malignant (normal) DNA. In the era of NGS, whole genomic DNA of tumor and adjacent normal tissues are treated with bisulfite after library construction (the adapters are methylated to prevent their conversion) and then processed and sequenced as described earlier.[36] The resulting bisulfite converted reads are aligned in silico to a "bisulfite converted" genome in order to identify unmethylated (and by inference, methylated) C residues (Figure 23-4).

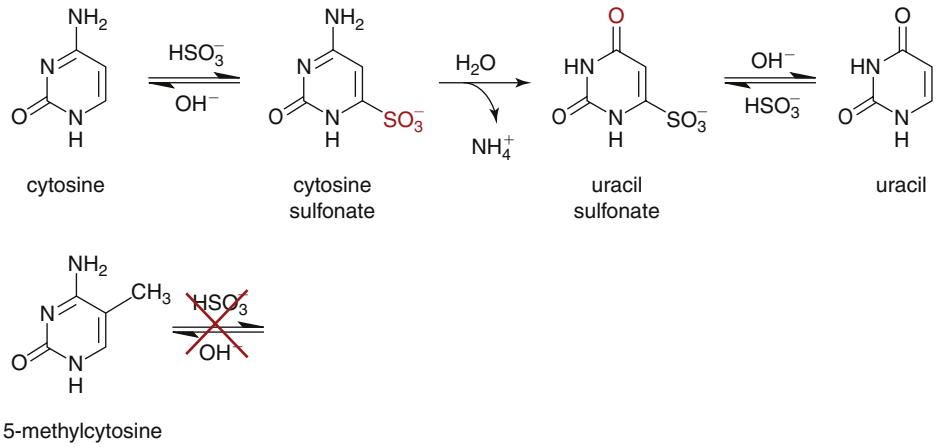

FIGURE 23-4 CHEMICAL CONVERSION OF UNMETHYLATED CYTOSINE RESIDUES BY BISULFITE The upper panel indicates the series of reactions that occur between unmethylated cytosine residues and the bisulfite reagent to sulfonate cytosine, eliminate ammonia to generate uracil sulfonate, and then eliminate bisulfite to generate uracil. In the lower panel, methylated cytosines do not participate in the reaction with bisulfite.

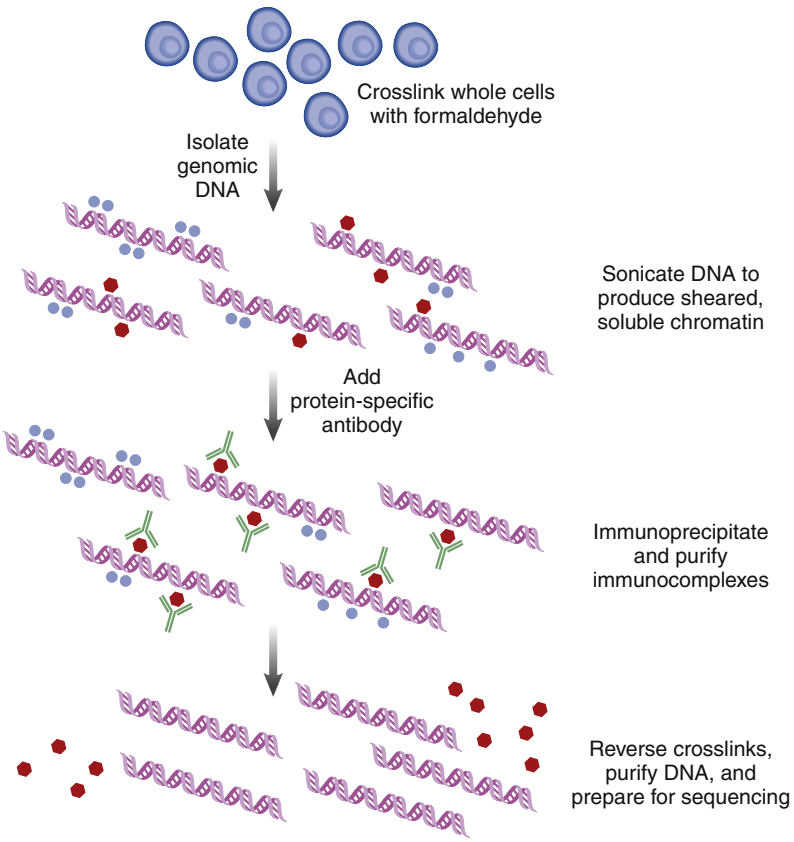

FIGURE 23-5 BASIC PRINCIPLES OF CHROMATIN IMMUNOPRECIPITATION (ChIP) After crosslinking DNA to proteins by treating live cells with formaldehyde, the DNA is isolated and then sheared to a uniform length distribution. By mixing the sheared DNA with a specific antibody to the protein of interest, crosslinked fragments can be bound and then isolated by immunoprecipitation. Following this step, reversing the crosslinking allows the DNA fragments to be reclaimed. The resulting low yield of DNA is converted to a next-generation sequencing (NGS) library and sequenced. Alignment to the reference genome and peak finding can identify those regions of the genome that are bound by the protein of interest.

Chromatin Immunoprecipitation

Genomic DNA contains myriad regulatory sites that provide the binding sequences recognized by the cell's transcriptional regulation machinery. In addition, complexing of the genomic DNA with histones provides a fundamental mechanism for permitting access to regions of the DNA so transcription can occur. Changes to binding sites due either to mutation or amplification/deletion can destroy protein binding and effectively silence the gene. Similarly, rearrangements of bound histones can make available or eliminate genes from transcriptional copying. One approach to evaluate these changes is broadly termed *chromatin immunoprecipitation*, or ChIP (see Figure 23-5). ChIP is based on two fundamental approaches: (1) DNA and protein in close physical proximity can be bound reversibly by the introduction of formalin to growing cell cultures, and (2) the DNA:protein complexes can be precipitated from solution by an antibody-mediated immunoprecipitation step. Before NGS methods, the genomic

region of interest was assayed from these immunoprecipitated DNA fragment populations by quantitative polymerase chain reaction (qPCR), allowing a selective look at protein binding status. In the NGS era, however, sequencing of the collective ChIP fraction can identify protein-bound regions.[37,38] These are challenging libraries to produce because of the low yield of DNA from the immunoprecipitation step. Once sequencing data are obtained, the reads are analyzed by first mapping onto the reference genome and then detecting the peaks that indicate factor- or histone-bound loci, as appropriate. The accuracy and sensitivity of these methods largely depend on the quality of the antibody used to effect immunoprecipitation, and on attaining enough coverage that peaks can be distinguished from noise.

Sequencing Messenger RNA (mRNA)

The pursuit to characterize RNA expression as a biomarker of prognosis, metastasis, therapeutic options, and other clinical metrics lies at the essence of cancer genomics. In particular, before sequencing was transformed by next-generation instrumentation, microarrays served as a mechanism to characterize tumor-specific gene expression in a reasonably comprehensive and measurable way. However, relative to microarrays, sequencing of coding RNAs (called "RNA-seq") provides data suitable for addressing a multitude of RNA-specific questions that one might use to characterize a tumor. For example, the digital nature of sequencing means that gene expression levels are quantifiable rather than relative, a concept first introduced by Wold and colleagues, who defined the metric known as FPKM (fragments per kilobase of transcript per million mapped reads) to express the normalized value of expression for each transcript detected.[39] Beyond gene expression levels, there are myriad levels of complexity that can be mined from RNA-seq datasets, including information about splice isoforms, allele-specific expression, chimeric or fusion transcripts, and RNA editing.[40,41] Much like ChIP-seq data, described earlier, these data are without context for an individual sample, unless a matched nonmalignant adjacent normal tissue is similarly prepared, sequenced, and evaluated. At present, there is a dearth of knowledge from RNA-seq analysis of normal human tissues to provide even a plausible baseline for these studies as an alternative to the adjacent nonmalignant tissue comparator. Integrating data from DNA and RNA sequencing can be incredibly powerful in the context of cancer genomics, such as DNA amplification leading to increased RNA expression levels for the genes lying in the amplified region (ERBB2 in breast cancer) or chromosomal translocation leading to a fusion gene transcript that drives oncogenesis (t15;17 and PML-RARα, t9:21 and BRC-ABL).

There are myriad approaches to producing RNA-seq data from tumor RNA isolates, depending on the yield obtained. Ideally, polyA selection is used for abundant total RNA samples (more than 2 μg) to reduce highly expressed rRNA transcripts, but these yields are not guaranteed with samples from clinical procedures such as fine-needle aspirates or LCM. In this regard, RNA-seq has benefitted from previous microarray studies because enzymatic RNA amplification is widely accepted to represent the RNA expression levels of the native sample. Amplification can be further refined by specialized approaches to RNA that accurately reflect the strandedness of the transcript or adjust for the fragmentation of RNA that is derived from FFPE preserved tissues. There are several methods that subsequently decrease the levels of abundant rRNA transcripts when polyA purification cannot be used, including selective amplification of polyA, use of abundance-based hybridization kinetics and selective double-strand hybrid depletion, or selective depletion using rRNA-targeted locked nucleic acids (LNAs).

Sequencing Noncoding RNAs

In addition to the transcripts from protein-coding genes, many classes of noncoding RNAs (ncRNAs) have been described and have been determined to be expressed at altered levels in cancer cells.[42,43] As for messenger RNAs (mRNAs), the digital nature of NGS can provide exquisite quantitation of expression levels while being comprehensive across a wide dynamic range of expression. Highly specialized library construction techniques for ncRNAs depend largely on a clever approach to selecting the ncRNAs from total RNA isolates and then performing a sizing step that isolates the specific population of interest. Obviously, the sequencing parameters of NGS instruments should be altered to specifically reflect the corresponding sizes of ncRNAs being studied and the types of analyses planned for the resulting data.

Conclusions

As illustrated by this overview, the impact of NGS and associated methods on our ability to characterize the nucleic acids involved in cancer, and hence to generate comprehensive hypotheses about tumor biology, has evolved rapidly. These methods and associated analyses continue to develop and are now coalescing toward diagnostic assays that provide an individualized focus for precise prognostic and therapeutic determinations. Over time, the cancer genomics revolution, fueled by NGS innovation, will profoundly affect the outcomes of cancer patients worldwide.

Understanding and Using Information about Cancer Genomes

High-resolution genome analysis techniques are now being used in international cancer genome analysis efforts to catalog aberrations driving the pathophysiology of nearly all major cancer types. The Cancer Genome Atlas (TCGA, http://cancergenome.nih.gov/) project and the International Cancer Genome Consortium (ICGC, http://www.icgc.org/)[1] represent the largest of these. The TCGA project is assessing aberrations in 500 to 1000 tumors from each of about 20 major human cancer types and together the TCGA and ICGC are currently committed to the analysis of ~47 separate tumor lineages. Results for glioblastoma,[2] serous ovarian cancer,[3] colon cancer,[4] squamous cell lung cancer,[5] and breast cancer[6] are already available from the TCGA project, and other technology centers around the world have contributed studies of cancers of the breast,[7-10] pancreas,[11] prostate,[12] lung,[13] and kidney[14] and of melanoma,[15] myeloma,[16] and AML.[17] The overall intent of these international genomics efforts is to provide a knowledge base of cancer genome landscapes that can be used to develop more effective cancer management strategies—for example, by enabling early detection of lethal or recurrent cancers, diagnosing patients with low malignancy potential tumors who may be spared from aggressive treatment, identifying novel therapeutic targets, and assigning therapies to the patients in which they are most likely to be effective. We summarize in this chapter general and specific aspects of human cancers that are emerging from international genomics efforts, describe computational and experimental efforts to identify aberrations that contribute to aspects of human cancer pathophysiology, and illustrate how genomic information is being used in aspects of cancer management.

The Emerging Cancer Genome Landscape

Genome aberrations found to be important in human cancers are illustrated in Figure 24-1[18] and include (1) somatic changes in copy number that increase or decrease the levels of important coding and noncoding RNA transcripts, (2) somatic mutations that alter gene expression, protein structure, or protein stability and/or change the way transcripts are spliced, (3) structural changes that affect transcript levels by altering gene-promoter associations or create new fusion genes, and (4) epigenomic events that alter transcription levels of diverse signaling pathways and that enable rapid emergence of therapeutically resistant subpopulations. Table 24-1 shows the number of gene aberrations catalogued in the Cancer Gene Census maintained by the Sanger Institute that have been implicated in one or more human cancer types (see http://www.sanger.ac.uk/genetics/CGP/Census). These aberrations have been implicated in deregulation of pathways that influence all aspects of cancer progression including invasion, immortalization, DNA replication and repair, proliferation, apoptosis, angiogenesis, motility, and adhesion. However, the 487 genes implicated in the Cancer Gene Census are likely to be only a small fraction of the aberrant genetic events that play important roles in the form and function of human cancers. These genes have been selected primarily because they were implicated in model system studies or because they occur frequently in one or more cancer subtypes. However, recent genomic studies demonstrate that hundreds to thousands of genes may be affected by somatic mutations and epigenomic modifications in an individual tumor. These comprise a mix of "driver" aberrations and a usually larger number of "passenger" aberrations. Driver aberrations are genomic or epigenomic events that are selected during tumor progression because they alter one or more aspects of cell and tissue physiology to allow cancer initiation, progression, and/or dissemination. Table 24-2, for example, illustrates several genes that might contribute to the deregulation of the cancer hallmarks designated by Weinberg and Hanahan.[19] Some of these aberrations have been targeted by therapeutics, and others have been shown to influence clinical behavior, including response to targeted and nontargeted therapies.[19] Passenger aberrations do not contribute to cancer pathophysiology but arise by chance

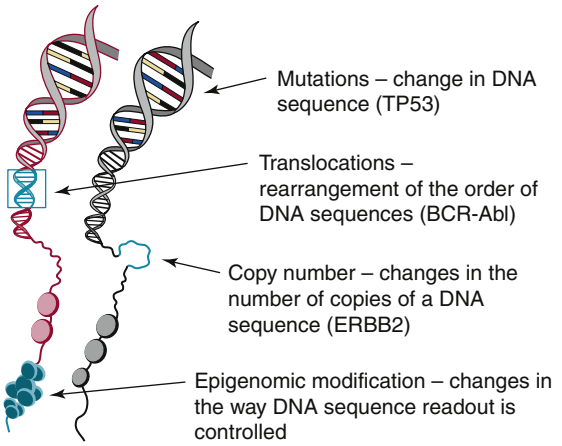

Figure 24-1 Schematic illustrations of the types of genome aberrations found in human cancers.[18]

Table 24-1 Cancer Gene Census Summary

Aberration Type	Number of Aberrations	Examples of Prominent Affected Genes
Amplification	16	ERBB2, EGFR, MYCN, MDM2, CCND1
Frameshift mutation	100	APC, RB1, ATM, MLH1, NF1
Germline mutation	76	BRCA1/2, TP53, ERCC2, RB1, VHL
Missense mutation	141	ARID1A, ATM, PIK3CA, IDH1, KRAS
Nonsense mutation	92	CDKN2A, FANCA, PTCH, PTEN
Other mutation	26	BRAF, PDGFRA, PIK3R1, SOCS1
Splicing mutation	63	GATA3, MEN1, MSH2, TSC1
Translocation	326	ABL1, ALK, BCL2, TMPRSS2, MYC

For more details see http://www.sanger.ac.uk/genetics/CGP/Census.

Table 24-2 Candidate Cancer Hallmark–Associated Aberrant Genes

Cancer Hallmark	Aberrant Gene
Resisting cell death	BCL2, BAX, FAS
Genome instability and mutation	TP53, BRCA1/2, MLH1
Inducing angiogenesis	CCK2R
Activating invasion and metastasis	ADAMTSL4, ADAMTS3
Tumor-promoting inflammation	IL32
Enabling replicative immortality	TERT
Avoiding immune destruction	HLA loci, TAP1/2, B2M
Evading growth suppressors	RB1, CCND1, CDKN2A
Sustaining proliferative signaling	KRAS, ERBB2, MYC
Deregulating cellular energetics	PIK3CA, PTEN

during progression in a genomically unstable tumor and are carried along because they exist in cells carrying driver aberrations. Driver aberrations are identified either because they occur frequently in tumor subpopulations or because they have been identified as contributing to aspects of cancer pathophysiology in laboratory models of cancer—for example, cultured cancer cells or genetically manipulated nonmalignant cells, or cancer cells grown as xenografts in animals—or have been demonstrated to influence aspects of cancer in genetically engineered living organisms. Several general cancer genomic observations from international cancer genomics projects are summarized in the following paragraphs.

One important observation from many genomic studies is the existence of recurrent molecular features that allow cancers that occur in specific anatomic regions to be organized into subtypes. The subtypes likely arise in distinct cell types within each tissue and are different diseases that differ in clinical outcome and/or response to therapy. Early genomic studies relied on expression patterns for cancer subtype definition, but current strategies use multiple data types (e.g., genome copy number, mutation, and expression) for subtype definition. Interestingly, epithelial and mesenchymal subtypes appear to be present in tumors that are of epithelial origin. The mesenchymal-like cancers tend to be more rapidly proliferating and motile and associated with reduced survival duration. Some tumor types show remarkably high transcriptional similarity, for example, in triple-negative breast cancer and high-grade serous ovarian cancers.[6] Many genomic aberrations also appear in multiple tumor subtypes. Some of the most common aberrations observed in multiple tumor types include amplifications of MYC and EGFR, deletion of CDKN2A and PTEN, and mutation of TP53 and PIK3CA. For a more comprehensive assessment, Kim and colleagues summarize recurrent genome copy number aberrations in 8000 cancers.[20] Efforts are now under way to combine data types (e.g., expression, genome copy number, and mutations) to increase the number of subtypes in order to increase the precision with which patients can be stratified according to outcome and/or therapeutic response.[21] Of course, this divides cancers into increasingly smaller subpopulations, so very large numbers of samples are needed to establish subtype differences in treatment response or overall outcome.

The number of aberrations that are present in an individual tumor can be remarkably high. The somatic mutation rate in human cancers varies between cancer types from about 0.1 to 10 mutations per megabase,[22,23] but individual tumors may carry as few as a hundred to more than a million somatic aberrations. High genomic instability occurs because of loss of telomere function during progression in the absence of telomerase,[24,25] diminished DNA repair capacity resulting from genomic and epigenomic deregulation of DNA repair pathways,[26] increased damage resulting from oncogene-induced

oxidative stress,[27] and toxic environmental exposures.[28,29] In some cases, the exact DNA sequence change in a mutation reflects the type of agent that causes the cancer—for example, mutations in sun-related cancers show CC to TT mutations caused by UV-induced cytosine dimers, whereas smoking-induced cancers in the lung are characterized by G→T transversions caused by the polycyclic aromatic hydrocarbons in tobacco smoke.[30,31] Ultimately, the functions and/or expression levels of hundreds to thousands of genes may be altered in an individual tumor. An unknown number of these will be drivers. Among these, some will have a strong, possibly dominant influence on an individual tumor, whereas others may have a more modest or near-negligible impact. So far, most attention in the field has focused on the strong drivers. However, it seems likely that the ensemble of aberrations will have to be taken into account in explaining the overall behavior of an individual tumor, which is addressed in a later section.

The same drivers of genome instability that enable tumor development also operate during tumor progression. As a result, individual tumors become increasingly heterogeneous as distinct clonal populations within the tumor evolve in diverse microenvironments, producing highly branched lineages. For example, events that enable metastasis may occur late during the genetic evolution,[32] whereas mutation of TP53, a key player in genome stability, can be an early event.[33] These instabilities and the resultant intratumor heterogeneity in an individual tumor are likely responsible for the rapid evolution of therapeutic resistance. This heterogeneity complicates clinical decision making because the importance of a low-frequency but actionable aberration remains unclear. One possible way forward is to focus treatment on aberrations that occur early during tumor development. The order in which aberrations occur can be inferred by examining a tissue at various stages of disease progression[34] by serial sampling of clinical tissue from individual patients,[18] by computational methods that examine mutation frequency,[35-37] or in some cases by analysis of the interactions between mutations and copy-number abnormalities.[33]

Functional Assessment of Cancer Genomes

Transforming cancer genomic data into interpretable knowledge consists of finding the parts and learning how they work together to enable aspects of cancer pathophysiology. Hypothesis-driven research has gone quite far in this process, but full understanding will require systematic analysis, both computational and experimental, of the aberrations that occur within a tumor genome.

Computational Approaches

Computational strategies to identify candidate driver aberrations begin with the cataloging of all aberrations and then move to the selection of high-priority candidate drivers.

Cataloging Approaches

Identification of genes that enable aspects of cancer pathophysiology (driver genes) is complicated by the high genomic heterogeneity within and between tumors. Nearly all cancer genomes analyzed to date appear to have at least one driving oncogenic point mutation, and the vast majority show copy number changes over both large chromosomal segments and smaller, more targeted regions of the genome. The evidence for structural rearrangements being a primary cause in most tumor types is less clear, but diseases including many leukemias, lymphomas, sarcomas, and prostate cancers all incontrovertibly show that rearrangements can be critical (http://atlasgeneticsoncology.org). Changes to chromatin state also are partly responsible for many cancers.[38-40] Over the past 20 years a number of technologies (predominantly microarray based) have been successfully used to catalog cancer genome aberrations, but nearly all efforts now depend on nucleic acid sequencing technology (Mardis, chapter on "The Technology of Analyzing Nucleic Acids").

Point mutations are identified by aligning DNA sequences obtained from cancer samples to normal genomes using tools such as BWA.[41] The requirement for the normal genome sequence is paramount because of private single-nucleotide polymorphisms (SNPs) that occur about once every 100,000 base pairs,[42] a rate that is about 10 times higher than the mutation rate in most epithelial tumors and 100 times higher than the rate of mutations in childhood cancers such as neuroblastoma.[3,6,22] Read depth and read quality are critical factors in determining how well mutations can be called within each patient's cancer genome. Read quality is the error rate per thousand base pairs of sequence. High quality is usually defined as having fewer than 1 error per 1000 bases of sequence. Read depth (the number of times a position in the genome has been sequenced) for high-quality bases then governs both the false-positive rate caused by sequencing errors and misidentifying private variants as mutations and false negatives caused by not generating sufficient data to observe mutations reliably. The greater the depth, the more confident mutation calls will be. Typically, 30× coverage of the normal genome and 40× to 80× coverage of the tumor produces high-quality results. Increasing read depth is needed for analysis of samples in which the tumor fraction is low because the presence of normal DNA reads dilutes the aberrant reads. Mutation detection is further complicated by intratumor heterogeneity that causes some aberrations to be present in only a

small fraction of the tumor cells. Many groups find value in exome sequencing—that is, targeting the small fraction of the genome that is coding, at even deeper levels (for example, 150×). Verifying the sensitivity of mutation calling remains difficult because there are no good true mutation standards.

Detection of insertions and deletions (indels) remains challenging. In principle, the same sequence coverage necessary to find point mutations can be used to identify indels. Unfortunately, the algorithmic methods for indel identification are much more computationally intense.[43] No good estimates exist on how well indel detection software works because of the lack of gold standards against which to measure algorithm performance. In general, indel detection is even more difficult than evaluating the substitution mutations.

Copy number and structural aberrations are identified using a combination of microarray and sequencing approaches. Microarrays and whole-genome shotgun sequencing are capable of identifying changes in DNA copy number that are as small as 1000 base pairs in length. This resolution is sufficiently good that nearly all gene-level aberrations can be detected. Microarray approaches look for differential signal gains from the hybridization, whereas DNA sequences detect changes in read depth. Direct sequencing of genomic DNA represents the most direct way to identify the breakpoints for structural rearrangements, but the methodology is challenging, requiring a high-coverage, high-quality DNA sequence. Often, structural rearrangements cannot be detected with the standard technologies because the sequencing approaches used cannot span the length of repetitive sequences in the human genome. Once a whole-genome shotgun sequence is generated, methods such as BreakDancer[44] and Delly[45] can be used to find the chromosome junctions. Other structural aberration detection technologies are emerging, so it is likely that we will be able to identify the majority of structural breakpoints in the near future.

Detection of promoter methylation is usually accomplished using microarray technologies. Microarrays that can measure methylation at more than 485,000 sites are now commonly used by groups such as TCGA.[7] In principle, DNA sequencing can be used for this purpose, but this is currently economically impractical, with costs 10 to 50 times greater than for microarray approaches. In addition, sequencing approaches currently require unreasonably large quantities of tumor DNA.

RNAseq is now the standard for measuring gene expression. RNA is depleted of ribosomal RNA (rRNA) by either polyA+ selection or any number of rRNA depletion steps and fragmented before complementary DNA (cDNA) production. Short cDNA fragments are sequenced and mapped to the human genome reference. Algorithms to estimate which transcripts are being produced and their relative abundances[46] are used to interpret the fragment data. One strength of RNAseq analysis is that it does not require that the transcriptome be known, and thus it has enabled the study of noncoding RNAs, including lincRNAs and, with adapted protocols, miRNAs.[47,48] RNAseq methods are still being refined, with improvements in molecular and algorithmic approaches regularly being developed.

Integrating Information

A central challenge in cancer genomics today is in distinguishing the causal components of disease from the effects of the disease, or even more importantly from the random aberrations that occur during progression and are carried along by chance association with driver mutations. Suites of tools have been developed to answer these key questions.

The major focus of efforts such as TCGA and ICGC has been to identify the recurrently mutated genes in specific cancer types. For example, in serous ovarian cancer 95% of all tumors have point mutations in *TP53*. Statistics are not needed for the average scientist to decide that *TP53* is a critical gene. In most cases, however, the process for deciding if a gene is recurrently mutated in a specific tumor type is much more complicated, even after one has identified the mutations. First, not all genes are of the same length; longer genes should have more mutations by chance if mutations are equally likely at each position. Failure to control for gene size often leads to the identification of genes encoding long proteins such as Titin, whose coding sequence is 100 times longer than that of the average human gene. Second, mutations within a tumor type are not evenly split among all possibilities. For example, tumors caused by UV light will show high rates of C→T mutations in general, especially at CC dinucleotides. Further, we now know that mutations are not randomly distributed over the genome. For example, regions of the genome near late replication forks can have mutation rates 10 times higher than the average rate. Without accounting for this, many genes will be identified as showing more mutations than expected by chance when in fact they do not.[49] Identifying driver genes based on patterns of recurrence is partly about understanding the mutagenic processes as a whole and performing appropriate statistical tests to incorporate them.[5,6]

Many genes have hotspots where mutations occur preferentially. For example, mutations in the *HRAS* gene have a bias to alter the 12th amino acid to valine from glycine. When these events occur repeatedly, similar statistics for overall mutation rate can be used, but instead constrained for a specific event. Thus, with far fewer examples, a specific gene mutation can be associated with cancer because of the increased power from decreasing the search space. Similarly, mutations that are clustered in a specific protein domain can be identified. Finally, if a variant has been found in one tumor type—for example, the canonical *KRAS* mutations found in

50% of melanomas—then when they occur in other tumor types, it is parsimonious to assume that they are oncogenic there as well even if they are rare.

At least a dozen methods have now been developed to identify genes (or sets of genes) that are selected by altering copy number changes. The principles for the detection of these genes are simple even if the implementations differ. First, copy number data are segmented to identify the locations of copy number change points using an algorithm such as CBS.[50] Once segmented, the data are normalized and germline copy number differences compared to the reference are removed. Finally, the data are analyzed to locate the genetic elements that are present in copy number aberrations more likely than expected by chance (e.g., STAC[51]). Copy number aberrations are thought to follow two distinct distributions: broad events that cover whole (or nearly whole) chromosome arms, and narrow events targeting much smaller regions (often fewer than 10 genes).[52] These software tools provide a list of the genes and chromosome arms that are frequently included in both broad and narrow events across many tumors. Although specific types of tumors have specific biases for (or against) specific genes/chromosome arms, many copy number aberrations are present in a diverse set of tumor types.[20] Methods to identify structural changes in the genome increasingly are based on the application of genome sequencing to both ends of genomic clones or fragments. The ends of each clone are then mapped onto a representation of the normal genome sequence. Structural aberrations are inferred when the paired ends of a clone map too close (signaling a deletion) or too far (signaling an insertion or translocation) along the genome. This approach was initially proposed for analysis of cloned sequences[53] but has become routine with the advent of massively parallel sequencing.[44] Once individual events are identified, standard statistical principles are then used to estimate the likelihood of seeing similar aberrations more frequently than expected by chance.

Organization into Pathways

A major challenge in cancer genomics is to understand how the ensemble of driver aberrations in an individual tumor influences its clinical and biological behavior. The remarkable genomic heterogeneity that exists in individual tumors can be managed to some extent by mapping aberrations onto pathways that influence the development of cancer hallmarks. The goal of these approaches is to reduce a dauntingly large number of functional genomic aberrations by mapping these onto a manageably small number of important pathways. Several approaches have been developed to organize omic information in ways that enable identification of pathways. We discuss gene-set enrichment approaches, pathway enrichment methods, and newer approaches that extend the repertoire of tools for pathway identification.

One of the most popular approaches is to use statistical tests on gene sets to implicate pathways that are deregulated by changes in the expression of that and related genes. A score is used to measure the degree to which each gene aberration is associated with the disease process, and then an enrichment analysis is performed using a large database of gene sets. For example, genes can be scored based on their length-normalized mutation frequency in a cohort, or assessed with more sophisticated analyses such as MutSig[54] or OncoDriveFM[55] to gauge how likely mutations in the gene provide a selective advantage to tumor cells. Once an appropriate score is applied to rank the genes, statistical tests can be used to identify enriched pathways. One approach is to threshold the list of genes to obtain those that are ranked toward the top of the list. These top-ranked genes then can be overlapped with each candidate pathway and a Fisher's exact or Hypergeometric test used to assess the statistical significance of the overlap to determine if it is higher than chance expectation. Overlap methods are implemented in web servers such as the DAVID[56] resource.

Gene Set Enrichment Analysis[57] (GSEA) compares the entire distribution of scores against a random background using a Kolmogorov-Smirnov–inspired test. Implicated pathways contain significantly more gene members with extreme (either high or low) scores. Gene set–based approaches are used frequently to test for enriched sets of genes, revealing important biological themes. However, the approach makes no use of known interactions between the tested genes. Thus, it is possible for a small but still significant subnetwork of genes to have significantly high scores and go undetected by these set-based approaches. In addition, all genes in a set are treated uniformly. However, some genes in the network may control many other genes while others are specialized effectors performing a specific cellular task in a limited set of conditions. Such genes may be weighted differently in the enrichment analysis to improve the sensitivity of the approach. Methods that incorporate notions of the local network organization of the scored genes can incorporate such intuitions and are discussed next.

"Master Regulator" algorithms attempt to identify genes residing at the logical "top" of predictive pathways whose manipulation would be expected to change the expression of downstream genes.[58] Signaling Pathway Impact Analysis (SPIA),[59] MARINa,[60] and GeneRank[61] are examples of algorithms in this class. The principle behind these algorithms can be likened to identifying authoritative pages on the Internet. A web page is considered authoritative if many other authoritative pages reference the page. The definition is necessarily recursive, forcing the algorithms to propagate information through the network to determine a solution. For master regulators, the links

in the network are reversed so that the methods home in on genes that control many other control genes, again in an iterative fashion. The approach has been used to propose master regulators for B-cell lymphoma.[60]

Another strategy is to search through large background networks for smaller subnetworks with a concentrated number of altered genes. Such subnetworks could represent pathways where disruptions in any of several gene members could interfere with the functioning of the pathway. These approaches make use of networks derived from high-throughput studies such as the collections of protein-protein interactions in BioGRID,[63] HPRD,[64] iREF,[65] and STRING[66] to identify novel pathways involved in tumorigenesis. These high-throughput sources can be used either alone or together with curated and directed signaling pathways found in resources like Reactome[67] and NCI's Protein Interaction Database.[68] Integrating somatic alterations and protein-protein interactions has the potential to provide a powerful means for cutting down false-positive rates present in either dataset because the sources of error are independent. Whether the subnetworks produced from these analyses are physiologically relevant is largely an open question but an area of intense activity.

HotNet[69] is a method for identifying enriched subnetworks, given a set of frequently altered mutations in a cohort. HotNet uses a heat-diffusion approach in which a mutated gene is considered to be a heat "source." The heat is allowed to dissipate on the background network for a short time interval so that genes neighboring the sources also heat up. Those residing close to multiple sources receive more heat than genes far away as an exponentially decaying function of the distance in the network. The algorithm then uses a hierarchical statistical test to identify significantly hot subnetworks. HotNet has been used to identify Notch-related pathways implicated in ovarian cystadenocarcinoma[3] and chromatin-remodeling pathways in clear-cell kidney carcinoma.[69a] These methods are especially well suited to the identification of subtype-specific subnetworks both within and across tumor types.

The Mutually Exclusive Modules (MEMo) algorithm[70] identifies novel networks from perturbation patterns observed across samples. This approach is based on the concept of mutual exclusivity—that is, mutation of a second gene in a cancer-related pathway provides no advantage in fitness beyond that provided by the first. The MEMo algorithm takes advantage of this mutual exclusivity property and builds an exhaustive graph of all approximate mutually exclusive gene pairs. Although the statistical significance of any two genes exhibiting such a mutually exclusive pattern is tenuous even in cohorts of hundreds of samples, the observation of a set of genes that all transitively share this property can be significant if the gene set is large enough (e.g., greater than three). MEMo leverages the significance of groups by exhaustively searching its network for subnetworks representing approximate cliques of sufficient size. Identified subnetworks are considered as candidate novel networks. New approaches in this vein, such as DENDRIX,[71] are also available that include additional statistical associations between genes beyond mutual exclusivity, such as the co-occurrence of mutational events.

The PARADIGM network analysis tool[72,73] uses information from multiple profiling measurements (copy number, mutations, transcription, etc.) to calculate inferred pathway activity levels (IPLs) for more than 1300 curated cell signaling pathways associated with specific recurrent aberrations, cancer types, or cancer subtypes. These data can be further combined into "superpathways" to identify subpathways therein whose activities differ between comparator populations (e.g., between transcriptional subtypes or between populations that differ in drug sensitivity). This approach has the advantage that it takes advantage of community knowledge of pathway architecture but has the disadvantage that the pathways may be inaccurate in some situations. PARADIGM has been used in several analyses,[3,4,6,73] demonstrating the power of inferred activities for identifying important tumor subtypes.

An extension of PARADIGM, PARADIGM-SHIFT[74] (PS), infers the impact of mutational events using network inference. Many mutations in advanced tumors are neutral passenger events resulting from the loss of genome integrity. In this background of a myriad spurious genomic perturbations, it is of interest to identify those that increase tumor fitness or that drive tumorigenesis forward. Several sequence-based methods are available to attack this important problem. However, an additional very important aspect, which has eluded computational analysis until very recently, is to predict whether the driving mutation causes a gain of function (GOF) or loss of function (LOF) to the protein. GOF mutations can lead to therapeutic manipulation because our biomedical tools often fare better at shutting down erroneously activated oncogenes than at introducing functional copies to rescue lost tumor suppressor activity. Pathway-based approaches offer promise in this area because the predicted activity of proteins in the pathway neighborhood can be inspected for signals of GOF and LOF. This is the approach taken by PS. PS predicts the impact of a mutation on the function of a protein by estimating the effects in the protein's pathway context. It uses two runs of the PARADIGM algorithm[72]—a "Targets-only" and "Regulators-only" run—to make this assessment. In the "Regulators-only" run, PS uses PARADIGM to infer the protein's activity after leaving connections only to the protein's upstream connections. In the "Targets-only" run, it estimates the activity of the protein with PARADIGM after leaving only the downstream connections intact. The difference, or "shift" between these two estimates provides an estimate of the loss or gain of function in the protein. PS has been successfully used to predict several known positive controls in

glioblastoma multiforme, lung squamous, and breast carcinomas.[74] One critical aspect for these network-based approaches is to select an informative local neighborhood around the protein, which can significantly influence overall accuracy. Thus machine-learning–based approaches such as the one described next could provide important synergies with these mutation-impact approaches.

Network-Induced Classification Kernels (NICK[75]) use networks to train support-vector machines to predict patient outcomes. Supervised machine learning is a well-established field that has contributed classification approaches for predicting discrete outcomes, and regression-based approaches for predicting continuous-valued outcomes. These methods face the "curse of dimensionality" problem when attempting to use the available large *feature spaces* (e.g., gene expression vectors) of high-throughput functional genomics to predict outcomes in a relatively small set (e.g., less than a thousand) of samples. Classifiers can suffer problems of robustness, reproducibility, and accuracy and can also misassess the importance of any single feature in the classification task. Only recently have approaches been developed to make use of a priori pathway knowledge for this task. NICK encodes the gene-gene interactions found in a network into the formulation of a support-vector machine classifier. The resulting method rewards selection of features that are adjacent in the network, thus resulting in solutions that are more robust, while maintaining classification accuracy. Methods such as NICK promise to stabilize solutions determined when the same task, such as predicting recurrence of disease, is applied to different datasets because the use of the same network should steer the solutions toward being comparable.

In summary, pathway- and network-based approaches represent a highly active area of current research in the analysis of cancer genomics datasets. New methods are still sorely needed to use the results of these approaches in a worthwhile effort to translate the findings to patient treatment. For example, the networks identified by these approaches could provide important insights into "Achilles' heel" attack points for cancer cells. We therefore need methods that can predict how a tumor might respond to a drug by simulating manipulations on such networks. An important antecedent to this, of course, is to prove that the networks capture enough of the salient features of a patient's tumor for it to be used as an "avatar" for in silico testing.

Experimental Approaches

The computational approaches just described attempt to predict functional genes based on their frequency, association with behavior, activation of pathways, and so forth. However, such approaches are limited by the number of samples available for computational assessment, the high heterogeneity within and between human tumors, and our imperfect understanding of the regulatory mechanisms that govern normal and malignant cell behavior. Thus, they serve to generate hypotheses that guide experimental validation in laboratory models.

Tumor Intrinsic Assessments

A wide range of in vitro and in vivo experimental systems are now available for functional assessment of the effects of genomic aberrations that occur in tumors and their impacts on therapeutic response. Given the extremely large number of aberrant genes and networks now being discovered, this summary focuses on methods that are sufficiently high throughput to allow "first pass" assessment of function. In general, these strategies assess the impact of manipulating cancer genes or networks on aspects of growth or immortalization and less frequently other aspects of cancer biology such as differentiation, angiogenesis, senescence, motility, and DNA repair activity. Biological systems now in widespread use for this purpose include well-characterized collections of immortalized cancer cell lines grown in two- or three-dimensional cultures,[73,76,77] cell lines such as IL-3–dependent, Ba/F3 hematopoietic cells that proliferate and survive in the absence of IL-3 when transfected with a constitutively active oncogene,[78,79] tumor xenograft collections,[80,81] genetically engineered murine models of cancer,[82,83] and mice subjected to transposon-mediated gene alteration leading to tumor formation.[84]

One powerful strategy for the manipulation of gene function introduces inhibitory RNA (RNAi) oligonucleotides into model organisms[85-87] to downregulate candidate genes or activated cancer regulatory networks. These RNAi precursors include short hairpin RNA (shRNA) oligonucleotides that are delivered through viral or bacterial vectors[87,88] and double-stranded RNA molecules, 20 to 25 base pairs in length, called *small interfering RNAs* (siRNAs)[85,89] that are transfected directly into target cells. Two general strategies are now commonly used to test the impact of RNAis in model organisms. One is to introduce libraries of RNAis that have been individually "barcoded" with unique nucleic acid sequences that can be identified by hybridization to oligonucleotide microarrays[89,90] or by massively parallel DNA sequencing.[91] The loss (selected against) or gain (selected for) of specific RNAis during growth is taken as evidence of the importance of the selected RNAis during growth. This approach has the advantage of enabling genome-wide screens at low cost but has the disadvantage of assessing only aspects of gene manipulation that affect aspects of cell growth. Another approach is to test the impact of siRNAs that

target individual genes in cells grown in microwells[92] or on cell spot microarrays.[93] The biological responses can be assessed by measuring changes in cancer-related properties relative to a control using assays that estimate cell number, or by using high-content imaging of cancer phenotypes such as DNA repair activity, differentiation, senescence, and motility after immunofluorescent staining for molecular surrogates for these phenotypes[94-96] and dynamic responses measured using time-lapse imaging.[97] These approaches have been useful in assessing the activity of specific pathways,[89] identifying genomic vulnerabilities that might be attacked therapeutically with single agents,[92] and developing strategies to combine therapeutic agents.[98,99]

Manipulation of gene function by transfection of cDNA libraries into nonmalignant cells also has been used to identify genes that enable the development of malignant phenotypes such as immortalization or colony-forming potential.[100] Another approach to cancer gene identification takes advantage of the tumorigenic integration of transposons into specific genes in murine model systems. The genomic locations in which transposons integrate are mapped by DNA sequencing approaches. Recurrent sites of integration identify genes that may contribute to tumor formation when activated or inactivated.[84,101]

Information about gene network function also can be inferred from measurements of responses of well-characterized cancer models to treatment with therapeutic agents that target specific genes or networks. Treatment with compounds in large collections of well-characterized cancer cell lines, for example, enables links to be established between specific aberrant genes or networks and biological responses using machine learning or pathway-based correlative strategies. The NCI's Discovery Therapeutic Program pioneered the use of cell lines to link omic features to response by measuring molecular features and responses to more than 100,000 compounds in a collection of about 60 cancer cell lines.[102] However, the NCI60 panel is of limited power in detecting subtype-specific responses because of the relatively sparse representation of specific cancer subtypes in the collection. This has led to the development of large collections of cell lines that represent the diversity within individual tumor types.[73,76] The Cancer Cell Line Encyclopedia (CCLE) and Sanger Cancer Cell Line (SCCL) projects have taken this approach to a higher level by assessing associations between responses to compounds in collections of approximately 800 cancer cell lines.[77,103] Several studies support the utility of in vitro testing in cell line panels. For example, in vitro model systems accurately show that (1) lung cancers with EGFR mutations respond to gefitinib,[104] (2) breast cancers with HER2/ERBB2 amplification respond to trastuzumab and/or lapatinib,[76,105] and (3) tumors with mutated or amplified BCR-ABL respond to imatinib mesylate.[106] Panels of xenografts also are now being developed for this purpose.[107]

Interaction with the Microenvironment

Much of cancer genomics research focuses on the tumor-intrinsic effects generated by aberrations in the tumors as discussed earlier. However, it is now apparent that the cancer-inducing functions of these aberrations are modified by signals from the microenvironments in which the cancer cells reside. Early research by Bissell and colleagues demonstrated that some extracellular microenvironments can counter the cancer-associated phenotypes generated by genomic aberrations[108]; Folkman and colleagues demonstrated the key role that angiogenesis plays in cancer progression.[109] Since then an explosion of research has illuminated many ways in which the microenvironment can affect aspects of cancer progression. These studies of the tumor-microenvironment interaction have been reviewed recently by Coussens and Hanahan.[110] They suggest that three general classes of cells from the microenvironment modulate cancer behavior in important ways: angiogenic vascular cells (AVCs), infiltrating immune cells (IICs), and cancer-associated fibroblastic cells (CAFs) as illustrated in Figure 24-2. They further suggest that the effects of these microenvironments influence aspects of cancer cell behavior including proliferation, growth, cell death, replicative immortality, inducing angiogenesis, energy metabolism, invasion, and metastasis. It is also apparent that the microenvironment influences responses to therapeutic agents—for example, by rendering cancer cells dormant so that they do not respond to cell-cycle active agents or by activating signaling therapy pathways. A challenge for the future will be to determine how diverse microenvironments experienced by metastatic cells influence the biological behavior of these cells—especially their responses to therapeutic interventions. Several model systems are now being developed to facilitate the study of the microenvironment on cancers. These include three-dimensional matrigel cultures,[111,112] two-dimensional systems engineered to carry many different proteins and growth factors from diverse microenvironments,[113,114] xenografts engineered to mirror important aspects of the human stroma,[115] and genetically engineered mice that model specific tumor intrinsic and extrinsic properties.[116]

Clinical Applications

Diagnosis and Detection

The manner in which normal tissue changes to malignant at the omic level is now being documented for a variety of

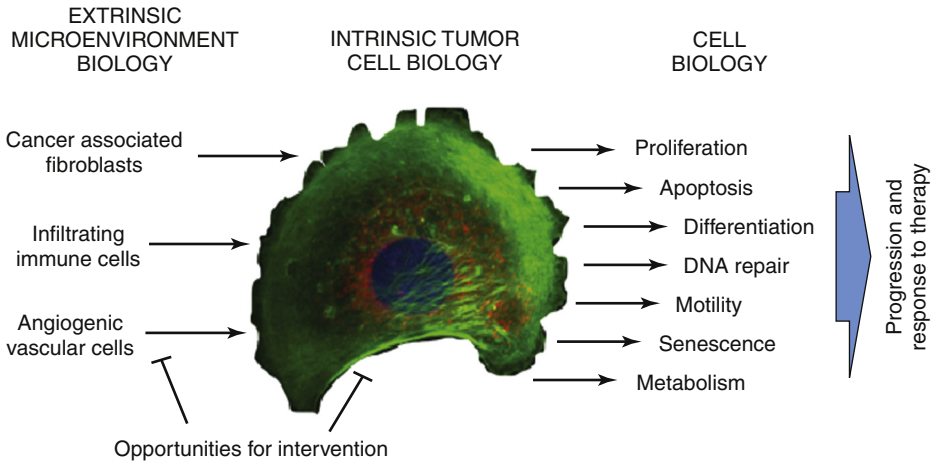

Figure 24-2 Interactions between tumor intrinsic and extrinsic features that influence cancer cell behavior and clinical outcome. *Cell image provided by Juha Rantala.*

cancers by international efforts. These efforts will provide the basis for improved precision in cancer diagnosis and will show that most tumor types can be divided into subtypes that vary in outcome and often in response to therapy. For example, breast cancer tumors have been treated according to estrogen receptor status and according to whether HER2 is amplified for more than a decade. The advent of transcriptional profiling enabled breast cancers to be divided into six major transcriptional groups,[117,118] and adding information about genome copy number allows the definition of 10 subtypes.[119] Adding information about recurrent mutations or functional mutations will further subdivide these groups. Some of the associations with outcome are so strong that changes in cancer management practices have resulted. For example, several commercial assays that measure expression levels of multiple genes are now marketed that predict therapeutic benefit in breast cancer patients.[120-122] Since then, potentially useful diagnostic signatures have been developed for many cancer types including leukemia[123,124] and colorectal,[125] pancreatic,[126] and lung cancer.[127] More recently, expression levels of noncoding RNAs have been proven prognostic in cancers of the colon,[128] lung,[129] and bladder.[130] In some cases, these signatures are cancer type specific and as a result can be used to classify cancers of unknown origin.[131,132] Although most of these diagnostic signatures focus on molecular events that arise in the cancer, some reflect molecular features of the environments in which the tumors reside—for example, molecular signatures that originate in invading immune cells that influence tumor outcome.[133,134]

The identification of molecular features that are unique to cancers and associated with poor outcome also provides the basis for the development of assays that may identify cancers at high risk of progressing to metastatic disease at a time before they have metastasized so that they can still be treated successfully. Development of such assays would improve outcomes in patients afflicted with cancers of high metastatic potential and would reduce overtreatment of patients with low propensity for recurrence. These assays likely will be composed of a tiered combination of blood-based, anatomic, or histopathological assays with increasing sensitivity, specificity, and cost as illustrated in Figure 24-3.

Blood-based assays to date have focused on the detection of cancer-specific proteins and are low cost but also relatively low in sensitivity and specificity. Assays of prostate-specific antigen (PSA) for prostate cancer and CA-125 for ovarian cancer are prototypical, but omic analyses are now revealing a wide range of cancer-specific changes in gene expression and/or splicing that might increase the specificity of these tests. For example, powerful mass spectrometry techniques and computational analyses of genomic changes

are revealing increasing numbers of cancer-specific proteins that may be detected in blood.[135,136] In addition, it is now apparent that the ongoing process of tumor cell death leads to the appearance of tumor DNA fragments or microRNAs in peripheral blood or urine. Some of these tumor-derived DNA fragments carry aberrations such as mutations, translocations, and changes in methylation that are unique or very specific to the tumor. As a consequence, sensitive blood-based assays are now being developed to detect the presence of these sequences as an indication of the presence of cancer. Recent examples include an epigenetic marker panel for detecting lung cancer using cell-free serum DNA,[137] analysis of mutations in DNA isolated from plasma and stool of cancer patients,[138,139] detection of translocations as an indication of cancers of the prostate[140] or ovary,[141] and detection of genome copy-number changes as an indication of the presence of metastatic breast cancer.[139]

Anatomic cancer detection strategies based on the detection of specific molecular species using positron emission tomography (PET) and magnetic resonance imaging (MRI) are now being developed to enable the detection of cancer-specific genomic features. This requires the development of contrast reagents that make tumors and the aberrant microenvironments they produce visible when the tumors are still small and locally contained.[142] Genome profiling studies are revealing molecular features that are unique to early cancers. A variety of contrast reagents that target these are now being developed. These include reagents for the detection of estrogen receptor[143] and PSA[144]; a range of nanoparticles carrying affinity molecules that detect cancer-associated proteins[145-147]; and molecular features associated with cancer-associated stroma.[148]

Histological assessment of tissue samples taken from cancerous lesions has long been the gold standard for cancer detection and diagnosis. However, routine analyses of tissue sections stained with hematoxylin and eosin (H&E) currently do not provide sufficient information to distinguish between lesions of high and low malignant potential. Genome studies such as those described earlier are increasingly able to define molecular features associated with the most aggressive malignant lesions. This information is fueling the development of multiplex immunohistochemical assays and/or histologically targeted genomic assays that are better able to identify lesions at high risk of progressing.[149,150] These same assays also offer the potential of detecting isolated cancer cells that might be otherwise missed during an assessment of H&E-stained sections.

Therapeutic Targets and Predictive Markers

Discovery of strong driver aberrations that can be attacked with therapeutic benefit was an early motivating factor in the development of international genomics efforts.[151] Early discoveries showed that chronic myelogenous leukemias driven by the BCR-Abl tyrosine kinase could be effectively targeted by imatinib mesylate[152] and breast tumors driven by amplification of *HER2* could be effectively treated with trastuzumab.[153] Table 24-3[154] summarizes more recent driver genomic aberrations, the cancers in which they occur, and the successful therapeutic agents that attack them. This list will expand continuously as additional therapeutic agents for recurrent genomic aberrations are tested. Additional genes harboring genomic aberrations for which therapies are now being tested include *AKT1, PIK3CA, PTEN, MYC, VHL,* and *HRAS*.[151]

These studies are stimulating the development of a wealth of new therapeutic agents. Almost 900 small-molecule inhibitors and biological therapeutics are now under development for the treatment of human malignancies.[155] These agents target molecular features ranging from

Table 24-3 Genomic Aberrations, Therapeutic Agents, and Relevant Cancers[154]

Aberration	Therapeutic Compound	Cancer Type
BCR-Abl translocation	Imatinib mesylate	CML
ERBB2 amplification	Trastuzumab, lapatinib, pertuzumab	Breast cancer
KIT mutation	Imatinib mesylate	GIST
	Sunitinib	Dermatofibrosarcoma protuberans
PDGFRA mutation	Nilotinib	Hypereosinophilic syndrome
	Dasatinib	Melanoma
EGFR mutation	Gefitinib, erlotinib	Lung cancer
	Cetuximab	Bowel cancer
FLT2 mutation	PKC412, SU11248, CMT53518	AML, ALL
BRCA1/2 mutation	Olaparib, veliparib, iniparib	Breast/ovarian cancer
BRAF mutation	Vemurafenib	Melanoma, lung cancer
ALK translocation	Crizotinib	Lung cancer
ROS1 translocation	Crizotinib	Lung cancer
RET translocation	Vandetanib	Thyroid cancer
MET amplification	Crizotinib	Esophagogastric adenocarcinoma
KRAS	Cetuximab, panitumumab	Colorectal cancer
ER expression	Tamoxifen, aromatase inhibitors	Breast cancer

broad-specificity conventional therapeutics to inhibitors that selectively target specific molecular aberrations and deregulated pathways. The general trend in drug development today is moving toward agents that are targeted toward pathways.[156]

The traditional path to the clinic for new cancer drugs is to test them in phased trials in the metastatic setting, followed by testing in randomized Phase III registration trials in the adjuvant setting. This approach requires a substantial investment in time, number of patients, and money. The U.S. Food and Drug Administration (FDA) has published draft guidance for using pathological complete response in neoadjuvant treatment for accelerated approval in high-risk breast cancer, which would dramatically accelerate the approval process.[157] Although a step forward, this approach has the weakness that drugs that are effective only in a small population of patients may be discarded because of lack of apparent efficacy. Biomarkers that predict response to therapy would enable identification of these small subpopulations so that they can be targeted early in the clinical trials. As described earlier, this can be accomplished by developing initial insights about subpopulation specificity using preclinical models of aspects of tumor-intrinsic and tumor-extrinsic heterogeneity that influence responses.

It is also becoming clear that specific regulatory pathways can differ among cancer subtypes so that these subtypes respond differently to targeted and nontargeted therapies. It has long been recognized, for example, that estrogen-receptor–positive (ER^+) breast cancers will respond well to selective estrogen response modifiers[158] and that a subset of prostate cancers is responsive to inhibitors of androgen receptors.[159] However, it now appears that most anticancer agents will be preferentially active in cancer subtypes defined according to their genomic characteristics.[73] The explanation for this seems to be that the use of molecular pathways that regulate cell behavior (and response to therapy) differs among subtypes. Efforts in the TCGA project and other international genomics efforts are defining subtypes in most anatomically defined cancers that can be considered for stratification of therapeutic response. Full use of this information will require the development of approved molecular assays that can stratify patients according to subtype.

Summary

International efforts are now defining the genomic and epigenomic landscapes of most major tumor types. The first set of cross-tumor (a.k.a. "Pan-Cancer") studies are now emerging to help delineate core and lineage-specific contributors of the disease.[160] These studies are revealing a few strong driver aberrations in each cancer type and many—sometimes thousands—of aberrations of unknown consequence. Much work remains to determine which of these contribute to the pathophysiology of each cancer type, but it is already clear that these analyses will have a profound effect on the way most cancers are managed. Aspects of cancer management that will benefit include early detection of the most lethal cancers, identification of recurrently aberrant genes and networks for high-priority therapeutic attack, and development of molecular markers that predict response to gene- or network-targeted therapies.

High-Content Analysis with Cellular and Tissue Systems Biology: A Bridge between Cancer Cell Biology and Tissue-Based Diagnostics

High-Content Analysis (HCA)

Background on Fluorescence Imaging in Cancer Biology, Drug Discovery, and Diagnostics

Cancer displays significant genetic and nongenetic heterogeneity.[1-4] Tumors are integrated tissue systems of interacting malignant cells, stem cells, and stromal components, including immune cells, fibroblasts, endothelial cells, and nerve cells (Figure 25-1).[5-9] Immune cells and other stromal components play cooperative roles in tumor development and metastasis and influence responses to therapies. The stromal phenotype and functions are strongly associated with disease progression and clinical outcome in cancer. Leukocytes are attracted into tumors by chemokines and can both protect the tumor from antitumor immunity and promote tumor progression via stimulating angiogenesis and tumor cell migration.[10-12] Tumors can render infiltrating immune cells anergic/nonresponsive[13,14] or drive such cells into apoptosis.[15] Tumor cell heterogeneity, the complexity of the tumor system, and the vital interactions of tumor cells with multiple components of the stroma highlight the need for a "tissue systems biology" approach to cancer diagnostics, which combines multiplexed biomarker measurements in the context of the tissue architecture and tumor cell function (Table 25-1)* with informatics tools to classify individual patients according to disease subtype, recurrence, and responses to therapies.[16]

Fluorescence-based imaging technologies have been applied to models of cancer and patient samples for many years. The applications have spanned the range from in vitro studies in single cells,[17,18] populations of cells,[18-24] mixed cell populations,[25-27] three-dimensional (3D) tumor models,[28,29] and pathology of patient tumor samples,[16,30] as well as imaging cells within mouse tumor models,[31-33] including antitumor immune responses,[31,34] dynamics of cancer growth and invasion,[31,35] tumor angiogenesis and regression,[31,36] and tumor cell movements.[37,38] Furthermore, applications in drug discovery have been performed in cells[39,40] and in small experimental organisms[41] including yeast,[42-45] *Caenorhabditis elegans*,[46-48] *Drosophila*,[49-52] and zebrafish,[53-56] as well as monitoring tumors in rodent models[33,57-59] with whole-body imaging of small mammals.[57,60]

The present chapter focuses on the application of high-content analysis (HCA) to populations of cells, more complex tumor models, and in vitro and patient samples where large image datasets can be created and explored with computational and systems biology tools to create a bridge between cancer cell biology and tissue-based diagnostics. The investigation and integration of the continuum of single cells, cell populations, 3D tumor models, and patient samples is needed to define the molecular basis of cancer.

HCA, originally termed high-content screening (HCS), is a platform technology created in the 1990s to automatically image, analyze, store, and mine large image datasets based primarily on fluorescence imaging microscopy, although transmitted light is an option.[61,62] HCA harnesses advances in automation of microscopy, image processing, image analysis, fluorescence-based reagents, automation of sample preparation, and relational databases (Figure 25-2).[61-64] There have been numerous books[65-67] and reviews on the applications of HCA in basic biomedical research, drug discovery/development, and diagnostics.[39,68-72] A broad range of fluorescence-based reagents for both live cell, kinetic studies and fixed-endpoint investigations have also been reviewed in detail.[63] The major types of reagents, readouts, and selected on-line databases are listed in

*Table 25-1 includes citations for References 214, 224, and 294 through 331.

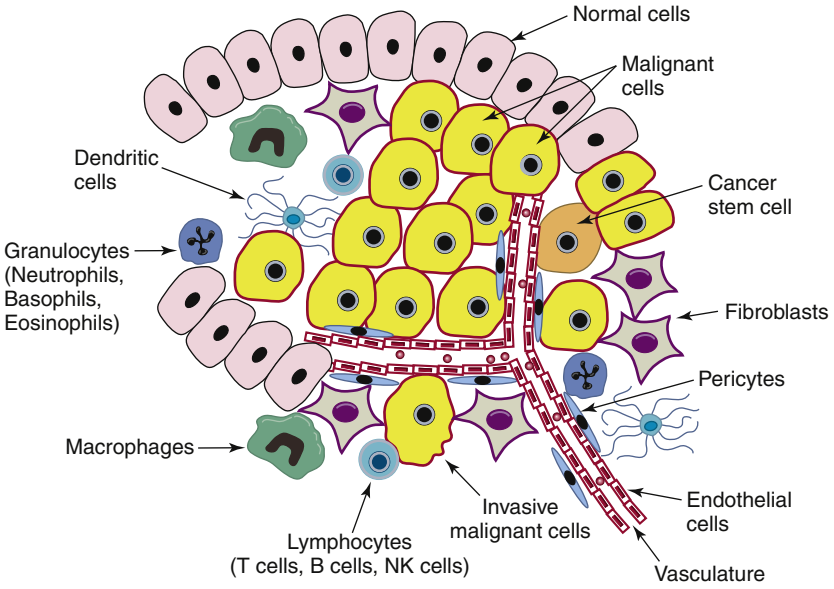

Figure 25-1 Solid tumors are systems within the human system The tumor system includes normal tissue/organ cells *(pink)*, tumor cells usually containing a range of genetic alterations *(yellow)*, and cancer stem cells *(orange)*, along with immune cells (e.g., dendritic cells, granulocytes, macrophages, lymphocytes) and other stromal cells, such as fibroblasts and vasculature, that all play a part in tumor development, progression, metastasis, and response to therapy, based in part on their spatial relationships.

Table 25-1 Key Tumor System Processes and Biomarkers

System Process	Example Biomarkers	References
Proliferation	Ki-67, Aurora A kinase	294, 295
Apoptosis	p53, Apo-1/Fas, FasL, TRAIL receptors, caspases, pAKT, Survivin, MCL-1, Bcl-2	296-303
Cell cycle control	p53, p21, p27, p16, cyclins D1, E	304-310
Adhesion	E-cadherin, beta-catenin, CD44, CD24, Claudin-1	311-315
Migration/motility	CXCR4, alpha6beta4 integrin, Net1, matrix metalloproteinases	316-318
Angiogenesis	VEGF, Flt-4, HIF-1alpha, pericyte markers	319-323
Immune responses	CD68, CD45RO, CD3zeta, CD4, CD8, PD-L1, FOXP3, CD1a, cytokines	224, 324-327
Inflammation	NF-kappaB, COX2, CSF-1R	214, 328, 329

Although the development of HCA has focused on the application of fluorescent probes, chromogenic probes continue to be used extensively for labeling tissue sections. Table 25-3** compares the advantages and disadvantages of fluorescent and chromogenic probes. Most HCA systems are optimized for the use of fluorescent probes, principally for their high sensitivity, high specificity, broad range of cellular functional readouts, broad range of wavelengths for multiplexing, and ability to engineer cells to express fluorescent proteins and biosensors. Because HCA makes use of automated imaging and quantitative image analysis, there is no need for direct viewing of the labeled specimen, and once the images are acquired, there is no further need for the specimen other than for institutional or clinical requirements. In traditional pathology, on the other hand, chromogenic probes have some advantages. The human brain is still the most sophisticated and reliable image processor for the interpretation of small numbers of images.[76] Readily available, low-cost chromogenic probes provide stable and dense labeling for visualization in a transmitted light microscope or by digital image pathology, while simultaneously viewing the contextual morphology of the cells. Although providing somewhat lower resolution and more limited multiplexing than fluorescent probes, chromogenic probes still provide a good labeling strategy where one to three biomarkers per slide can be useful.

Success in the Human Genome Project demanded tools to define the functions of the coding and noncoding portions of the genome, to define the dynamic interplay of cellular constituents within and between cells, and to characterize subpopulations, as well as to define the relationships between populations of cells in higher order biological systems. The field was named *cellomics*, and the platform technology was named *HCA*. HCA harnesses the ability to implement combinatorial treatments on large sample sizes by using microplates, patterned microarrays[77] and microfluidic devices[78] for cells, microplates for small organisms, and mounted sections/microarrays for tissues. These large sample sizes are required for statistical analyses and exploration by computational and systems biology.[16,21,63,79,80]

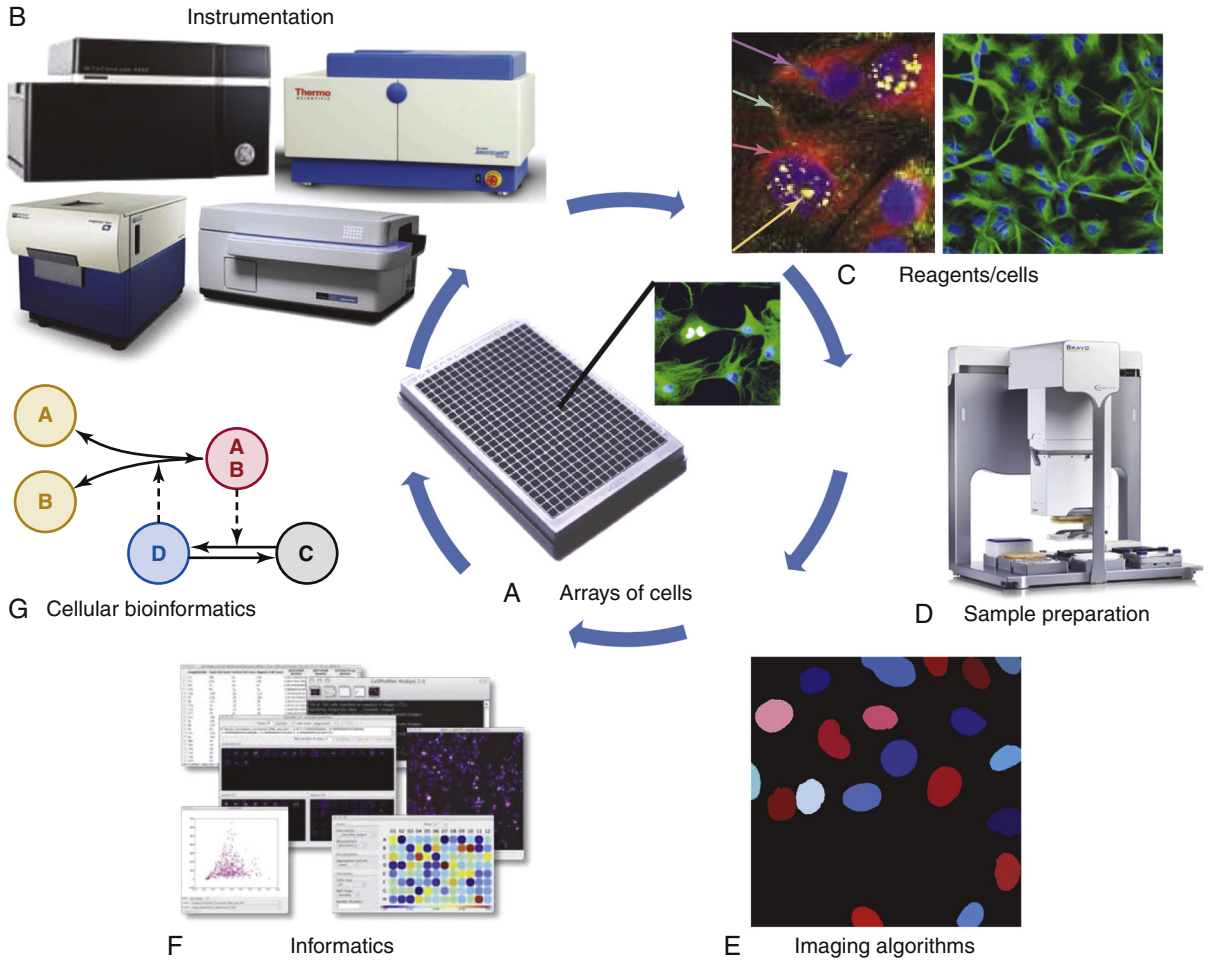

Figure 25-2 The components of high-content analysis (HCA) HCA is defined by the integration of **(A)** arrays of cells/tissues for high-throughput biology; **(B)** automated microscope systems available from multiple vendors; **(C)** a wide range of reagents and cell types; **(D)** automated sample preparation systems and protocols; **(E)** imaging algorithms typically designed to measure multiple features for each cell; **(F)** informatics to review and further process the data, for example, to fit dose-response curves; and **(G)** bioinformatics to relate multiparameter cellular features to biological functions.

Imaging Live Cells and Model Organisms with HCA

Imaging living cells and model organisms by HCA has the advantage of allowing the investigation of the dynamic, temporal-spatial interplay of cellular constituents that define normal and abnormal cell and tissue functions. Single time points and/or kinetic measurements can be generated and analyzed.[20,62] It is also possible to harness advanced, fluorescence-based probes and biosensors to measure physiological parameters not readily measured in fixed samples, such as cyclic protein translocations, pH, free Ca^{2+}, membrane potentials, and a growing number of physiological biosensors by fluorescence microscopy.[63,69] A disadvantage of investigating living systems by HCA is that biological processes can change from the time of imaging the first well in a microplate to the last well and this issue is multiplied when going from 96 to higher-density well plates. Depending on the time course for the specific biological process,[81] including cyclic changes[82] and the protocol for the addition of experimental treatments, large-scale, living samples usually have to be profiled in smaller batch sizes.

All HCA profiling or screening studies start with living systems that receive some combinatorial application of small molecules or biologics,[83-86] RNAi for knockdowns,[87-89] and/or nucleic acids for transfections or transductions. Although more demanding to perform, a recent investigation studied the kinetics of response of individual cells to drug treatments demonstrating the variability of cellular responses in a population.[19] Measuring kinetic responses should increase as even more biosensors are developed and the complex and dynamic aspects of signaling processes are investigated.

Imaging Fixed Cells and Model Organisms with HCA

The main advantage of using fixed samples is that large-scale sample preparation and robotic screening of many microplates or slides is possible without changes in the biology

Table 25-2 Classes of Fluorescence-Based Reagents, Readouts, and Online Resources for HCA

Resource	Type	Application	References
Fluorescent probe classes	Chemical fluorophores	Wide spectral range, easily attached to targeting molecules, some are environmentally sensitive, many useful properties	61, 63, 74, 75
	Nanocrystals	Stable, bright, single excitation, narrow emission, best for multiplexing in fixed cells or cell surface markers	75, 110, 332
	Fluorescent proteins (FPs)	Multiple wavelengths, transient or stable expression, linked to targets, some are environmentally sensitive, photoactivated (or switched), live or fixed cell assays	63, 69
Cellular labeling approaches	Antibodies	Target expression level and localization	63, 69, 75
	FISH probes	DNA copy number variants, RNA expression, including micro-RNA	197
	FPs	Target expression level, localization and dynamics, photobleaching or photoactivation for transport within or between compartments	63, 69
	Environment-sensitive probes	Ion concentrations, membrane potential, hydrophobic compartments	63, 69, 75
	Proximity probes	FRET, colocalization	63, 69, 75, 333, 334
	Enzyme activity	Fluorogenic substrates, cleavable linkers	63, 75
	Organelle specific	Nucleus (DNA), mitochondria, lysosomes, neutral fat, endoplasmic reticulum, etc.	63, 75
	Fluorescent biosensors	FPs or combinations of FPs engineered to report on activation of biomarkers or pathways	63, 69
HCA readouts	Intensity	Relative concentration of target	63, 69
	Distribution	Distribution and dynamics of molecular targets in cells	63, 69
	Colocalization	Similarity or difference in the distribution of two or more labels	63, 69
	FRET	Very sensitive determination of close proximity of two labels	63, 69
	Morphology	Texture, size, or shape of cells or organelles, aggregation	16, 68
	Lifetime	Local chemical environment	63, 69
	Polarization	Molecular interactions (bound vs. free)	63
	Cell tracking	Motility, metastasis	63
	Kinetics	Measure of any or all readouts over time	63, 69

FISH, Fluorescence in situ hybridization; *FRET*, fluorescence resonance energy transfer; *HCA*, high-content analysis.

Table 25-3 Comparison of Fluorescent and Chromogenic Readouts[177,341-344]

Reporter Type	Advantages	Disadvantages
Fluorescent	Present standard in cell analysis High sensitivity and specificity Quantitative readout Multiplex targets that are colocalized and/or in close proximity Broad spectrum of wavelengths Higher resolution with confocal imaging	Reagents are less stable for long-term storage More expensive fluorescence, more expensive imaging systems More expensive reagents
Chromogenic	Present standard in tissue analysis Long-term stability of labeling Brightfield microscopes Greater amplification	Variable sensitivity and specificity Multiplexed targets must be spatially separated Precipitates cause fuzziness around target

during the readout. Therefore, many combinatorial treatments can be prepared at one time and the microplates/slides stacked in a robotic system for screening/profiling. There are many fluorescence-based reagents including antibodies, fluorescence in situ hybridization (FISH) probes, and fluorescent proteins that can be used to define single time-point localizations, relative concentrations, and activities.[63] In order to optimally interpret fixed samples, either the half-time of a process under investigation must be determined in live sample profiles, or multiple time points must be generated in distinct wells or plates.

HCA has been extensively applied as a phenotypic approach to cancer drug discovery over the past few years, in both primary and secondary screens, either using live-cell[90-93] or fixed-cell[21,39,69,94] screening. Although specific molecular targets guide many of these screens, pathway modulations and phenotypic profiling are central to the approach.[39,71,95,96] Examples of cancer biologies explored include energy metabolism,[97] viral induction,[98] apoptosis,[99] cell cycle,[25,45,91] autophagy,[84] tumor invasion and metastasis,[50] pathway modulations,[47,100] a panel of biologies,[101] and phenotypic changes compared to mutants.[44,102] In many cases, HCA is also used in structure-activity relationship (SAR) to optimize lead compounds.[103,104] However, it is still important to ultimately identify the mechanism(s) of action of lead compounds. The role of HCA in cancer drug discovery and development has been further advanced with the application of more quantitative analyses of profiles using computational biology and systems biology approaches,[105-107] as explored in detail next.

Multiplexed to Hyperplexed Fluorescence-Based HCA

It has been the goal of imaging cytometry to increase the number of specific molecular parameters that can be measured in the same sample, so that complex interplays of components, pathway mapping, and heterogeneity of biological processes can be analyzed in increasing detail. We have defined multiplexed fluorescence in imaging applications as the combination in a sample of up to seven fluorescent probes that can be discriminated by spectral selection. Multiplexing has been accomplished in both live and fixed samples using a range of fluorescent probes.[63,108] Multiplexing by flow cytometry has reached the level of 15 to 18 distinct fluorescent probes,[109] but flow cytometry does not permit analyses of the temporal-spatial dynamics within or between cells. Hence, imaging technologies are being advanced to produce more parameters, especially in fixed samples. There have been a number of technical developments to increase the number of fluorescently labeled antibodies and FISH probes per sample, including new types of probes such as quantum dots,[110] new algorithms such as spectral unmixing,[111] and new protocols such as sequentially labeling, imaging, and quenching the fluorescence, and then repeating the process.[112-115] Recently, the GE Global Research Center has demonstrated that more than 60 fluorescence-based biomarkers can be applied to a single tissue sample using a sequential labeling approach.[111,116] This novel platform technology should have a great impact on basic cancer research, drug discovery, and diagnostics/prognostics. Generating the multiplexed to hyperplexed datasets creates a powerful platform that will enable the application of advanced computational methods to directly define pathways and modifications due to perturbations, as well as to characterize and understand heterogeneity. It is also possible to harness fluorescence lifetime imaging to gain some parameters,[117] as well as the application of mass spectroscopy[118] applied to single cells and tissues, but these latter approaches are not covered here.

In addition, other imaging modalities have been applied to cancer model systems and patients.[33,119,120] The data from these investigations must be integrated into the systems biology models developed in cells, small experimental organisms, and patient tissue sections.

Cellular Systems Biology in Cancer Research and Drug Discovery

Cell Lines, Primary Cells, and Tumor Microenvironments in HCA Studies

The biological interpretation of cancer genomic and proteomic data remains a major challenge.[121] The presence of both genetic and nongenetic heterogeneity among cancer cells complicates population-level data interpretation and implies the need for more detailed analysis at the cellular level.[122-125] Furthermore, the development of diagnostics and therapies requires consideration of the functions and responses in all cancer cells, not just the "average" cancer cell, as well as the role of the microenvironment. There has now been a shift in focus on screening for cancer drugs from relying exclusively on tumor cytotoxicity to understanding the signaling context within which the particular molecular target operates.[126] Multiplexed or hyperplexed cell analysis, when combined with computational modeling, can serve to directly assess multiple functions at the cellular level. Cell-by-cell analysis also allows detailed determinations of heterogeneity in cell populations. Rather than viewing heterogeneity as an interference in the development of diagnostics and therapies, researchers can use computational models of heterogeneity to gain a deeper understanding of the functioning of the underlying pathways and networks, as discussed later.[127] Furthermore, HCA can accelerate mechanism-of-action studies for

oncology research,[128] provided relevant models are used in the analysis. Two important aspects of cancer model development are the choice of cells and the design of the model.

There are now a large number of cancer cell lines available; however, the relevance of those cell lines has long been debated.[129-132] Cancer cell lines are attractive models as they provide an unlimited source of homogeneous, self-replicating material, free of contaminating stromal cells, and the majority are easy to culture in standard media. Although cancer cell lines may have diverged to some extent during culture, the genomics and even pharmacological profiles of large numbers of these cell lines are available and provide a basis for interpreting cellomics profiles in the context of pathways derived from genomics. For example, the recently published *Cancer Cell Line Encyclopedia* (CCLE), a compilation of gene expression, chromosomal copy number, and massively parallel sequencing data from 947 human cancer cell lines, coupled with pharmacological profiles for 24 anticancer drugs across 479 of the cell lines,[133] extends existing data characterizing cancer cell lines.[134-137] Furthermore, results from studying cancer cell lines in two dimensions (2D) serve as the simplest model for comparison with results from more complex 3D models involving tumor microenvironments, as well as results from patient samples, such as those available from *The Cancer Genome Atlas*.[138]

Cell-line fidelity with primary tumors varies depending on the tumor type. For example, the fidelity of breast cancer cell lines with primary tumors, assessed by comparison of genetic heterogeneity and copy number abnormalities, has been shown to be high.[134] Conversely, cell lines derived from glioblastomas have lower fidelity with primary tumors and mostly lack the amplification and mutation of epidermal growth factor receptor (EGFR) that is found in approximately 50% of glioblastomas.[139] Although it is clear that cell lines cannot model the hundreds to thousands of genetic aberrations found in primary tumors, HCA enables sufficient assessment of the many potential aberrations to identify those that are functional.

As a group, breast cancer cell lines faithfully reproduce the heterogeneity in human breast tumors as described earlier, though individually they exhibit profiles that fall short of truly representing the intratumoral heterogeneity of individual breast tumors. Studies suggest that collections of cell lines representing multiple cell types can be used to model the cellular heterogeneity in tissues.[140] Individual cell lines can also be useful models for specific functions. For example, the most commonly used breast cancer cell line, MCF-7, established in 1973 at the Michigan Cancer Foundation, exhibits exquisite hormone sensitivity through expression of estrogen receptor, making it an ideal model to study the hormone response.[141] It is important then to understand how well and which cell lines best model the diversity and which best model specific pathways. Microarray studies have identified molecular subtypes—luminal A, luminal B, ERBB2-associated, basal-like, and normal-like—with characteristic gene expression patterns and underlying DNA copy number alterations (CNAs). Genomic profiling of a collection of breast cancer cell lines found that they retained expression patterns with relevance to the luminal-basal subtype distinctions. That compendium of molecular profiles defines cell lines suitable for investigations of subtype-specific pathobiology, cancer stem cell biology, biomarkers, and therapies and provides a resource for discovery of new breast cancer genes.[142] The choice of cancer cell lines, primary cells, or stem cells to construct models for HCA should be made based on the basis of the abundant genomics, proteomics, and pharmacological profiles of the cell model; the goals of the study; and the analysis methods to be employed.

Whereas 2D cultures of cell lines provide simple models for HCA, pathway and network modeling (see later discussion), and drug discovery,[20,128,143] more sophisticated 3D microenvironment models are required to better recapitulate the tumor environment. 3D cell cultures are rapidly becoming the method of choice for the physiologically relevant modeling of many aspects of nonmalignant and malignant cell behavior ex vivo. 3D models include relatively simple tumor spheroid models[144,145]; more complex extracellular matrix models[146-149]; models that mimic the architecture of specific cancers[150]; cells grown on artificial scaffolds such as engineered organ models[151-154]; and tissue explants.[155,156] In addition, the development of microfluidic devices capable of maintaining a controlled, physiological environment will allow the construction of even more relevant tissue microenvironment models.[157]

In general, the simpler 2D models allow the greatest flexibility in terms of the range of markers and measurements that can be made cell by cell in the monolayer, using multiplexed HCA. Although confocal HCA systems can optically slice through thick specimens, the fact that the cells are not all in the same plane complicates the cell-by-cell quantitation of features. The approaches to the analysis of confocal sections are similar to the analysis of tissue sections, which is discussed in more detail later. The spheroid model is arguably the simplest 3D model for studying tumor cell biology, therapy resistance, cell-cell interactions, invasion, drug penetration, modeling, nutrient gradients, and tumor cell metabolism.[144,145] The self-organization and generation of distinct tumor microenvironments makes it an attractive model for high-throughput imaging.[158] The well-defined geometry of the spheroid simplifies the identification of microenvironments in the model.

There are a wide range of 3D tissue models that can be used with HCA analysis. Extracellular matrix models of

various compositions attempt to reconstruct the in vivo environment for studies of tumor cell biology, cell-cell interactions, cell migration, and invasion. Layers of cells are cultured on top of porous membranes for drug transport and binding, therapy resistance, and invasion assays. Engineered models such as micropatterned surfaces and 3D organizations,[147,150] as well as cells cultured within a network of perfused artificial capillaries for studying tumor cell metabolism, therapy resistance, and artificial organs, are the future. Each of these models, combined with a carefully chosen cell type and analysis approach, can provide insights into many functional components of cancer.[159] A deeper systems biology understanding of cancer will come from integrating data across these studies through the construction of computational models, based on combining pathways based on genomics, with functional data from HCA studies, as discussed later.

Heterogeneity as a Challenge in Cancer Biology and Drug Discovery

Cell-to-cell differences are always present to some degree in any cell population, and therefore the ensemble behavior of a population may not represent the behaviors of any individual cell.[160] Broadly speaking, cellular heterogeneity can be classified as either *genetic* or *nongenetic* in nature.[125] Genetic heterogeneity has been identified as an important factor in cancer progression and is thought by some to result from pressure for cells to adapt to new environments during metastasis or to evade immune responses.[161] Single-cell PCR gene-expression analysis, genomic profiling, immunohistochemistry, and other methods show that cancer tissues contain distinct cell populations and that the different gene expression programs linked to multilineage differentiation are strongly associated with patient survival.[162] Although genetic heterogeneity across cancer lines can be used as a predictor of drug efficacy,[137] intratumor genetic heterogeneity can also impede the development of personalized medicine. Phylogenetic differences, both intratumor and between primary tumors and their metastases, indicate that the sequence of a single sample does not reveal the full complexity of tumor genetics.[2]

Nongenetic heterogeneity is thought to originate from natural biochemical variations between clonal cells, such as differences in concentrations of biological compounds or slight discrepancies in the timing of cellular events. It plays an important role in cancer progression, as subpopulations of cells with significant stable variations in biochemistry exist within primary and metastatic tumor cell populations.[163] Transient drug-resistant phenotypes have been observed to emerge in cancer, conferring drug resistance in the absence of genetic mutation,[164] and drug treatment has even been observed to induce novel phenotypes.[124] The nongenetic heterogeneity in cancer further complicates therapeutic development, as it implies that genetic information by itself may be insufficient to explain the response of a particular tumor to treatment, even if distal regions of the tumor are sequenced. An emerging course of action is to address cancer at the level of pathway, simultaneously targeting multiple pathways to minimize potential drug resistance. In addition, defining the immune status and stromal cell content in tumors is critical to understanding individual responses to therapeutics.

Analyzing single cells within a population is a new frontier in platform technologies that has the potential to transform systems biology through new discoveries derived from cellular heterogeneity.[127] A great amount of information about the biochemical and environmental conditions of genetically homogeneous cellular populations can be uncovered by exploiting the differences between individual cells within the population. Patterns of heterogeneity in basal populations have been used to predict drug sensitivity in clonal populations of the NCI-60 panel of cancer cell lines,[165] and phenotype profiling has been applied to uncover compound mechanisms of action.[166-168]

The general approach to extracting biochemical information from inherent heterogeneity commences with the identification of well-defined phenotypes, through either expert opinion or automated clustering algorithms.[106] In the case of the former, supervised machine learning techniques are used to teach a computer how to correctly recognize phenotypes and classify cells. It has been shown that a computer trained by an experienced biologist to recognize 14 distinct morphological phenotypes can accurately classify human cancer cells at a rate of 70,000 per second.[169] Alternatively, unsupervised learning methods can be employed to allow computational identification of phenotypes based on clustering in feature space, without prior human interpretation. As an example, cellular phenotypes that were automatically identified using a support vector machine have been used to extract information about drug activity in HeLa cells.[105] In either case, it is necessary to use a set of features that is capable of distinguishing between phenotypes.[170] Once phenotypes are established and recognizable by computer, entire cell populations can be described in terms of the relative abundances of their constituent phenotypes.[79,171] *Statistical* or *mechanistic* techniques are used for analysis of the patterns of heterogeneity. Statistical analysis techniques involve comparing phenotype distributions that result from novel treatments to those that are associated with treatments of known action. Standard statistical measures, such as the KS statistic[172] or KL divergence,[173] are used to compare population distributions, and predictions for novel treatments

are based on which known treatments they most closely resemble. In mechanistic analysis, one or more cellular pathways of interest are modeled in silico, and their predictions are compared to the patterns of heterogeneity in the population. Predictions of concentrations of biomolecules within cells from pathway models can be compared directly to measurements from HCA experiments, and multiple pathway models can be combined to computationally represent a heterogeneous population of cells.[127]

Figure 25-3, *A*, illustrates the automated clustering of Cal33 head and neck cancer cells based on the relative activation of STAT1 and STAT3 in response to treatment with IFNγ and IL6 as measured by phosphorylation or translocation to the nucleus. In many cancers, abnormal activation of STAT3 functions to promote tumor growth, whereas STAT1, despite a greater than 50% sequence homology, is mostly antagonistic to STAT3 activity.[174] A better understanding of the differences in regulation and activation of STAT1 versus STAT3, on a cell-by-cell basis, will be important for therapeutic development. The cells were clustered on the STAT1 and STAT3 activation state using a Gaussian mixture model. The fraction of cells in each cluster varies over time, with a rapid but transient activation of STAT3 followed by a slower but more sustained activation of STAT1 (see Figure 25-3, *B*). The extent of each cluster indicates a highly heterogeneous level of activation, and the inclusion of a fraction near the origin indicates cells that appear to be unresponsive. Whether this is a kinetic effect or the result of the cells being in an activation-resistant state is still under investigation.

Tissue Systems Biology in Cancer Diagnostics/Prognostics

From H&E Staining to Multiplexed and Hyperplexed Fluorescence

For decades pathologists have used hematoxylin and eosin (H&E) and immunohistochemistry (IHC) with manual analysis by microscopy to assess tissue morphology and protein expression and distributions for diagnostic purposes. Although these methods are very valuable and are still used in the majority of cancer diagnoses, they are limited by subjectivity and intra- and interobserver variability, and they are only semiquantitative (see Table 25-3). There is a growing trend to digitize pathology to improve objectivity, standardization, and productivity, as has been done in radiology. Brightfield and fluorescence digital slide scanners from companies such as Aperio Technologies,[175] BioImagene (now Ventana Medical Systems),[176] Perkin Elmer, Omnyx, and 3DHistech[177] are increasingly being adopted in medical laboratories. Slide scanners produce whole-slide digital images for viewing and sharing by telepathology and to enable more reproducible analysis of morphology and biomarkers by image analysis software. Digital image analysis has been applied to IHC-labeled biomarker analysis in multiple types of cancers to improve reproducibility and standardize scoring methods.[178-181] Even with digital slide analysis, the accuracy of chromogenic IHC is limited by the inherent staining variability associated with the nonlinear signal amplification and is mostly limited to a few biomarkers

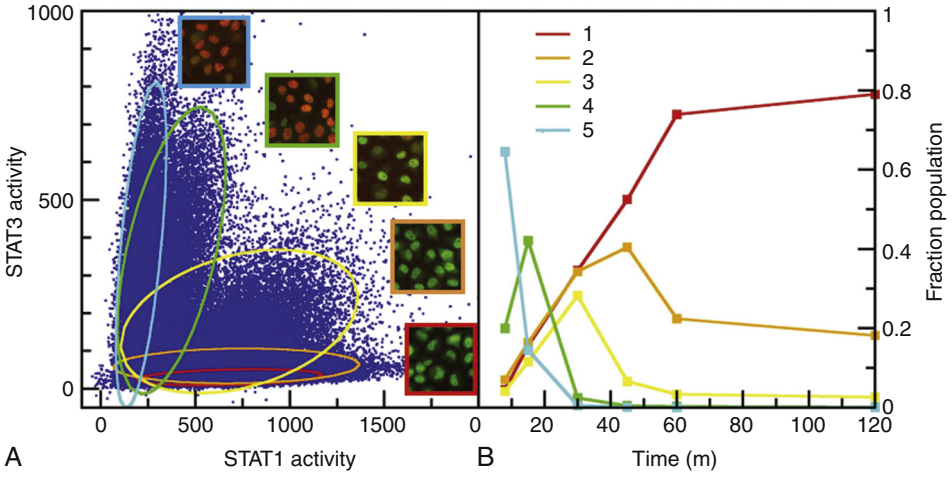

Figure 25-3 Automated identification and quantitation of subpopulations of cells **(A)** The scatterplot illustrates the relationship between STAT3 and STAT1 activity for ~72,000 Cal33 head and neck cancer cells stimulated with 50 ng/mL of IL-6 and 50 ng/mL of IFNγ for 8-120 min. STAT3 activity measured as fluorescence intensity of an antibody to phospho-STAT3-Y705, and STAT1 activity measured as the nuclear-cytoplasmic difference in fluorescence of an antibody to STAT1. Five subpopulations (*blue*, *green*, *yellow*, *orange*, and *red ellipses*) were automatically identified by a Gaussian mixture model algorithm. Pseudocolor images *(inset)*, STAT1 (*green* channel), and STAT3 (*red* channel) show the variation in labeling seen among the five clusters. **(B)** The distribution of the cells between subpopulations changes over time (*colored lines* correspond to clusters). At the earliest time point, 8 min, over 60% of the cells are in cluster 5 *(blue)*, principally STAT1(–) and STAT3(+). At 15 min, the largest fraction has shifted to cluster 4 *(green)* showing a slight activation of STAT1 and already a decrease in the STAT3 maximum. At 30 min, the cells are about equally distributed among clusters 3 *(yellow)*, 2 *(orange)*, and 1 *(red)*. By 1 hour, clusters 1 and 2 account for >95% of all the cells.

per slide (see Table 25-3).[182,183] Multiplexed IHC can be performed,[184] yet multichromagen images are more difficult to interpret visually and to deconvolve with image analysis software, particularly for biomarkers expressed in the same subcellular compartment (see Table 25-3). However, there is now some promise in applying unsupervised learning methods to chromagen-labeled samples.

Quantitative, multiplexed digital imaging methods can improve reproducibility and also measure the multitude of molecular changes in cancer that are associated with disease subtype, tumor progression, and response to therapies. Because these molecular changes precede morphological changes in the development and progression of cancer, molecular profiling can improve the sensitivity of diagnostic and prognostic testing in conjunction with histopathology.[185] Cancer progression and responses to therapies depend on multiple components of many signaling pathways within malignant cells and stromal processes. It has become clear that there are no "single bullet" biomarkers and that multiple biomarkers are required to accurately diagnose, predict risk of recurrence, and/or predict response to therapies for all patients with a particular type of cancer. Multiplexed fluorescence biomarker labeling with digital imaging represents a significant improvement over traditional histologic methods for tissue biomarker analysis, including the ability to quantify multiple antigens per tissue section, the ability to quantify antigens that are colocalized to the same subcellular compartment, and more consistent, linear, higher resolution labeling with greater dynamic range of biomarker measurements. Multiplexed biomarker analysis in the context of tissue morphology builds on cellular HCA, described earlier, and allows objective, reproducible extraction of quantitative biomarker data and morphology data by image analysis software.[186-189] Quantitative multiplexed fluorescence analysis of biomarkers in digital tissue images has been used to measure diagnostic, prognostic, and predictive cancer biomarkers in multiple cancer types.[102,186,190,191] These methods of protein biomarker measurement correlate with Western blot analysis,[192] match or exceed the accuracy of manual IHC scoring,[193-195] and can improve standardization of tissue biomarker measurements.[196] Labeling and imaging of nucleic acids in tissues can also add power to cancer testing. Locus-specific amplifications and losses and also microRNAs can be measured by FISH in intact tissues to enable interpretation within the context of tissue architecture.[197]

Multispectral imaging enables separation of overlapping dyes in both brightfield and fluorescence tissue images to increase the potential level of multiplexing.[177] Nanoparticles such as quantum dots and composite organic-inorganic nanoparticles (COINs) have emission spectra that are narrower and more symmetrical than traditional fluorophores, which results in minimal crosstalk between fluorescence channels and offers the potential for higher levels of multiplexing in tissues.[110,198] Hyperplexed fluorescence methods, defined earlier, can overcome the spectral limitations of fluorescence-based detection of biomarkers and offer the potential to assess dozens of protein and nucleic acid parameters per tissue section for protein network topology, spatial mapping of protein clusters, microRNAs, and CNVs in tissues.[114-116,199] Infrared spectroscopic imaging and Raman scattering imaging of unlabeled tissue sections enables the collection of thousands of spectra representing biochemistry in the context of the tissue architecture.[200,201] This type of high-content tissue imaging can be used to classify cancer types and distinguish cancer stages[202-204]; however, the mechanisms underlying the classifications are difficult to interpret because the specific molecules responsible for the hyperspectral signatures are not known.

Heterogeneity and Complexity of Tumors: Breast Cancer as an Example

Tumor heterogeneity and complexity highlight the need for a "tissue systems biology" approach to cancer diagnostics, as described in the first section and as exemplified by breast cancer. The current standard diagnostic and predictive tests for breast cancer are IHC-based measurements of estrogen receptor (ER), progesterone receptor (PR), and HER2/neu.[205] These biomarkers are usually measured one at a time in serial sections with manual scoring by a pathologist. HER2/neu status is confirmed by FISH in a subset of patients who are candidates for HER2/neu-directed therapies. Multiplexed fluorescence immunohistochemistry has been applied to these standard breast cancer biomarkers to improve standardization.[206,207] This limited set of biomarkers is insufficient to address breast cancer heterogeneity and cannot accurately stratify patients according to breast cancer subtype, predict risk for recurrence, or predict benefit from therapies. Gene expression profiling has identified molecular portraits of the main breast cancer subtypes and characterized the genetic and epigenetic abnormalities associated with each subtype.[1,3] RT-PCR– and DNA microarray–based multigene tests have been developed for prognostic and predictive testing in breast cancer. Oncotype Dx (Genomic Health, Inc., CA, USA) and Mammaprint (Agendia, BV, Netherlands) are two such tests that have achieved clinical adoption.[208-212] These approaches are valuable and have had a positive impact on patient care; however, the various multigene tests for cancer can be limited by bias introduced by interpatient variations in percentages of malignant, immune, and stromal cells. Furthermore, these methods require tissues to be digested, and the tissue architecture and spatial information, which are important for accurate biomarker

Table 25-4 Examples of Cancer Biomarkers Exhibiting Subcellular Relocation Based on Pathway Activity

Biomarker	Subcellular Relocation Based on Pathway Activity	References
NFκB	Restricted to cytoplasm in resting state, translocates to the nucleus on activation, and induces transcription of genes involved in inflammation, proliferation, and apoptosis in malignant cells and stromal cells.	345, 346
Beta-catenin	Activation of Wnt signaling leads to nuclear translocation of beta-catenin, which drives epithelial-mesenchymal transition and metastasis.	347-349
STAT1, STAT3, STAT5	Activation of STATs requires phosphorylation and nuclear translocation, which are associated with cancer prognosis.	215, 350, 351
p21	Nuclear localization is correlated with the inhibitory effect of p21 on cancer cell growth, whereas cytoplasmic localization is associated with protection from apoptosis.	352-354
HIF1-alpha	Master regulator of oxygen homeostasis that is cytoplasmic under normoxic conditions, translocated to the nucleus in response to hypoxia. Associated with clinical outcome in multiple cancer types.	355, 356
FOXO3a	Tumor suppressor that is active when localized to the nucleus and inactive when in the cytoplasm. Nuclear localization is associated with good prognosis and cytoplasmic localization is associated with poor prognosis in breast cancer.	357

measurement and interpretation, are lost. Stromal signatures including immune response and angiogenesis-related genes have been shown not only to add prognostic information but to have improved prognostic significance over standard breast cancer biomarkers and whole-tumor signatures in breast cancer.[213] The rationale for profiling biomarkers by digital imaging in intact tissue sections is based on extensive literature describing the importance of protein level, activation status, subcellular localization, tissue localization, spatial relationships, and distributions for the accurate measurement and interpretation of cancer biomarkers. Biomarker function is often more relevant to clinical variables than overall expression. For example, transcription factors such as nuclear factor-κB (NFκB) and signal transducers and activators of transcription (STATs) are ubiquitously expressed but are frequently activated in breast cancer.[214-216] Their activation is measured by translocation to the nucleus and/or by phosphorylation. Examples of cancer biomarkers exhibiting subcellular relocation based on pathway activity are provided in Table 25-4,* and tissue images showing nuclear translocation of transcription factors are shown in Figure 25-4.

Spatial relationships and microenvironments within the tumor system are also important in breast cancer. A three-part arrangement of an invasive breast cancer cell, a macrophage, and an endothelial cell in breast cancer has been described as a microenvironment conducive to distant metastasis.[217] The combined density and spatial distribution of mature dendritic cells and activated T cells has also been shown to have prognostic significance in breast cancer.[218,219] Macrophages infiltrate only the stroma in subsets of breast

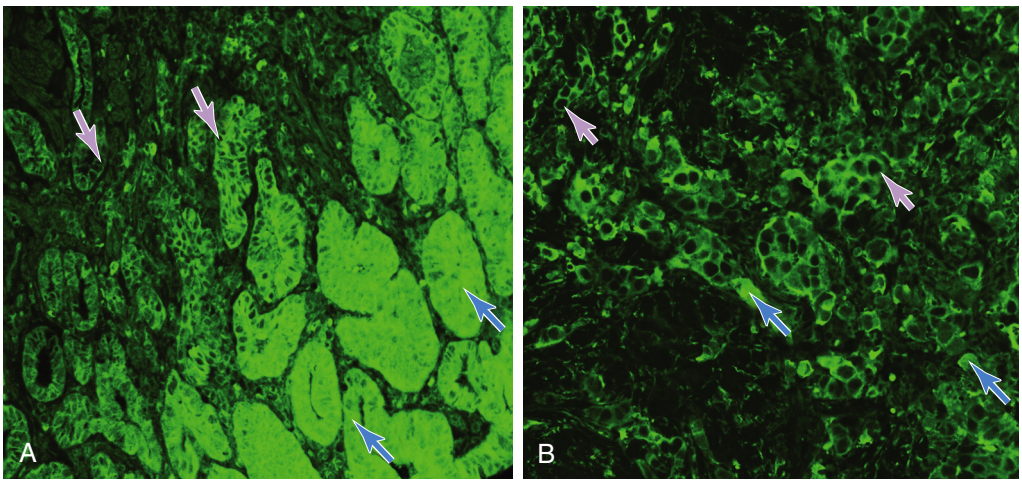

Figure 25-4 Multiplexed immunofluorescence labeling and digital imaging of functional biomarkers in tissues Sections of esophageal tissue with intestinal metaplasia **(A)** and breast cancer tissue **(B)** were labeled with a primary antibody specific to NFκB p65, fluorescently labeled secondary antibody, and Hoechst 33342 (nuclear stain). Slides were imaged using a fluorescence digital slide scanner (Aperio FL, Aperio Technologies, Inc., Vista, CA) at 20× magnification. Examples of cells exhibiting resting state NFκB in the cytoplasm are highlighted with *purple arrows* and cells with activated nuclear NFκB with *blue arrows* (**A** and **B**).

cancer patients and infiltrate the tumor nests in other patients (Figure 25-5, G, *H*), which has been correlated with survival in breast cancer patients.[220] This valuable spatial information is lost in molecular profiling approaches that digest tissues to extract DNA, RNA, or proteins, but is preserved and can be quantified by digital imaging approaches. Digital imaging of intact tissues also enables measurement of nuclear morphometric features and the amount of DNA in tumor cells, which have diagnostic and prognostic significance in breast cancer.[221] Multiplexed-to-hyperplexed biomarker imaging is also important for the measurement of specific cell types and phenotypes such as cancer stem cells[222,223] and immune cell subsets[224] that require multiple biomarkers for accurate classification. A major goal of hyperplexing will be to identify the optimal combination of protein, DNA, and RNA biomarkers that can stratify the disease subpopulations. Subsequently, a multiplexed subset of the biomarkers will be used in the development of diagnostic/prognostic tests. Figure 25-5 illustrates multiplexed immunofluorescence imaging of serial sections of a breast cancer tissue microarray, scatterplot analysis of the relationships between single cell features derived from the images, and examples of immune cell subsets infiltrating the cancer stroma and tumor cell nests.

Integration of Digital Imaging with Other Datasets

Multiregion spatial DNA sequencing has revealed significant intratumoral genetic heterogeneity that is underestimated by sequencing single tumor biopsies.[2] Quantitative pathology with digital imaging of intact tissues can be coupled to other platform technologies to allow HCA of various macromolecules and whole-genome sequencing in specific tumor microenvironments and cell populations to fully assess intratumoral heterogeneity. Tumor microenvironments and cell populations can be identified by digital imaging and captured by laser capture microscopy (LCM) or by coring of tumor samples for further genomic and proteomic analysis.[225-227] Sequencing of specific regions or the whole genome can be performed on the purified cell populations.[225] Proteomic profiling by mass spectrometry has been applied to highly enriched captured cell populations to characterize breast tumor microenvironments and to elucidate specific regulatory pathways involved in breast tumorigenesis.[226,228] Profiling of mutations in captured cell populations has been used to characterize genetic heterogeneity and to aid cancer diagnostic testing.[227,229] Gene expression profiling has also been applied to LCM-enriched epithelial cell populations to identify signaling pathways associated with specific subtypes of breast cancer[230,231] and to elucidate signatures associated with epithelial and stromal compartments that have diagnostic and prognostic significance.[213,232] DNA methylation analysis in purified cell populations from tumors has revealed changes in methylation of genes in specific cell types within the tumor system.[233,234]

The integration of the foregoing data sources with digital imaging technology and machine learning can be accomplished by employing a cellular/tissue systems biology approach like that illustrated in Figure 25-6. Genomics and proteomics have inferred pathway maps associated with normal tissue and alterations of those pathways associated with diseased tissue. Pathway maps provide insights into the composition and topology of the signaling network. However, they cannot be used to determine activation states of key proteins in a pathway, they do not provide quantitative information on relationships between pathways, and they do not provide information about cell-to-cell variability.[235] Multiparameter imaging of tissues and dynamics of cellular models, along with other platform data, combined with machine learning enables the identification and characterization of the dynamics and heterogeneity in signaling pathways, and the construction of computational models that provide a deeper understanding of the normal and abnormal functioning of those pathways.

Tools to Address Heterogeneity in Tissue Systems

Digital imaging of multiplexed biomarkers in tissues enables assessment of both genetic and nongenetic heterogeneity in tumor tissue systems. Quantitative multivariate data can be extracted from digital tissue images of protein, DNA, and RNA biomarkers at single-cell, subcellular, and tissue compartment levels, and spatial relationships can be measured. The digital imaging challenge is to separate neighboring and overlapping nuclei to enable single-cell and subcellular analyses. Approaches such as the watershed algorithm use grayscale information to separate nuclei by finding valleys of low intensity between the high intensities of nuclei centers. A priori knowledge about the shape, size, and intensity distribution of fluorescently labeled nuclei can also be used with pattern recognition algorithms, to guide image analysis algorithms and improve nuclear segmentation.[236-238] Once nuclei are segmented, the cytoplasm and plasma membranes of each cell can either be estimated based on the nuclear masks or specifically masked using cytoplasmic- and plasma membrane–restricted biomarkers. There are many commercially available image analysis software packages from companies such as Definiens, AG (Munich, Germany),[239] HistoRx (Branford, Conn, USA),[196] and Hamamatsu Photonics, K.K. (Hamamatsu City, Japan)[186] that can segment nuclei and enable

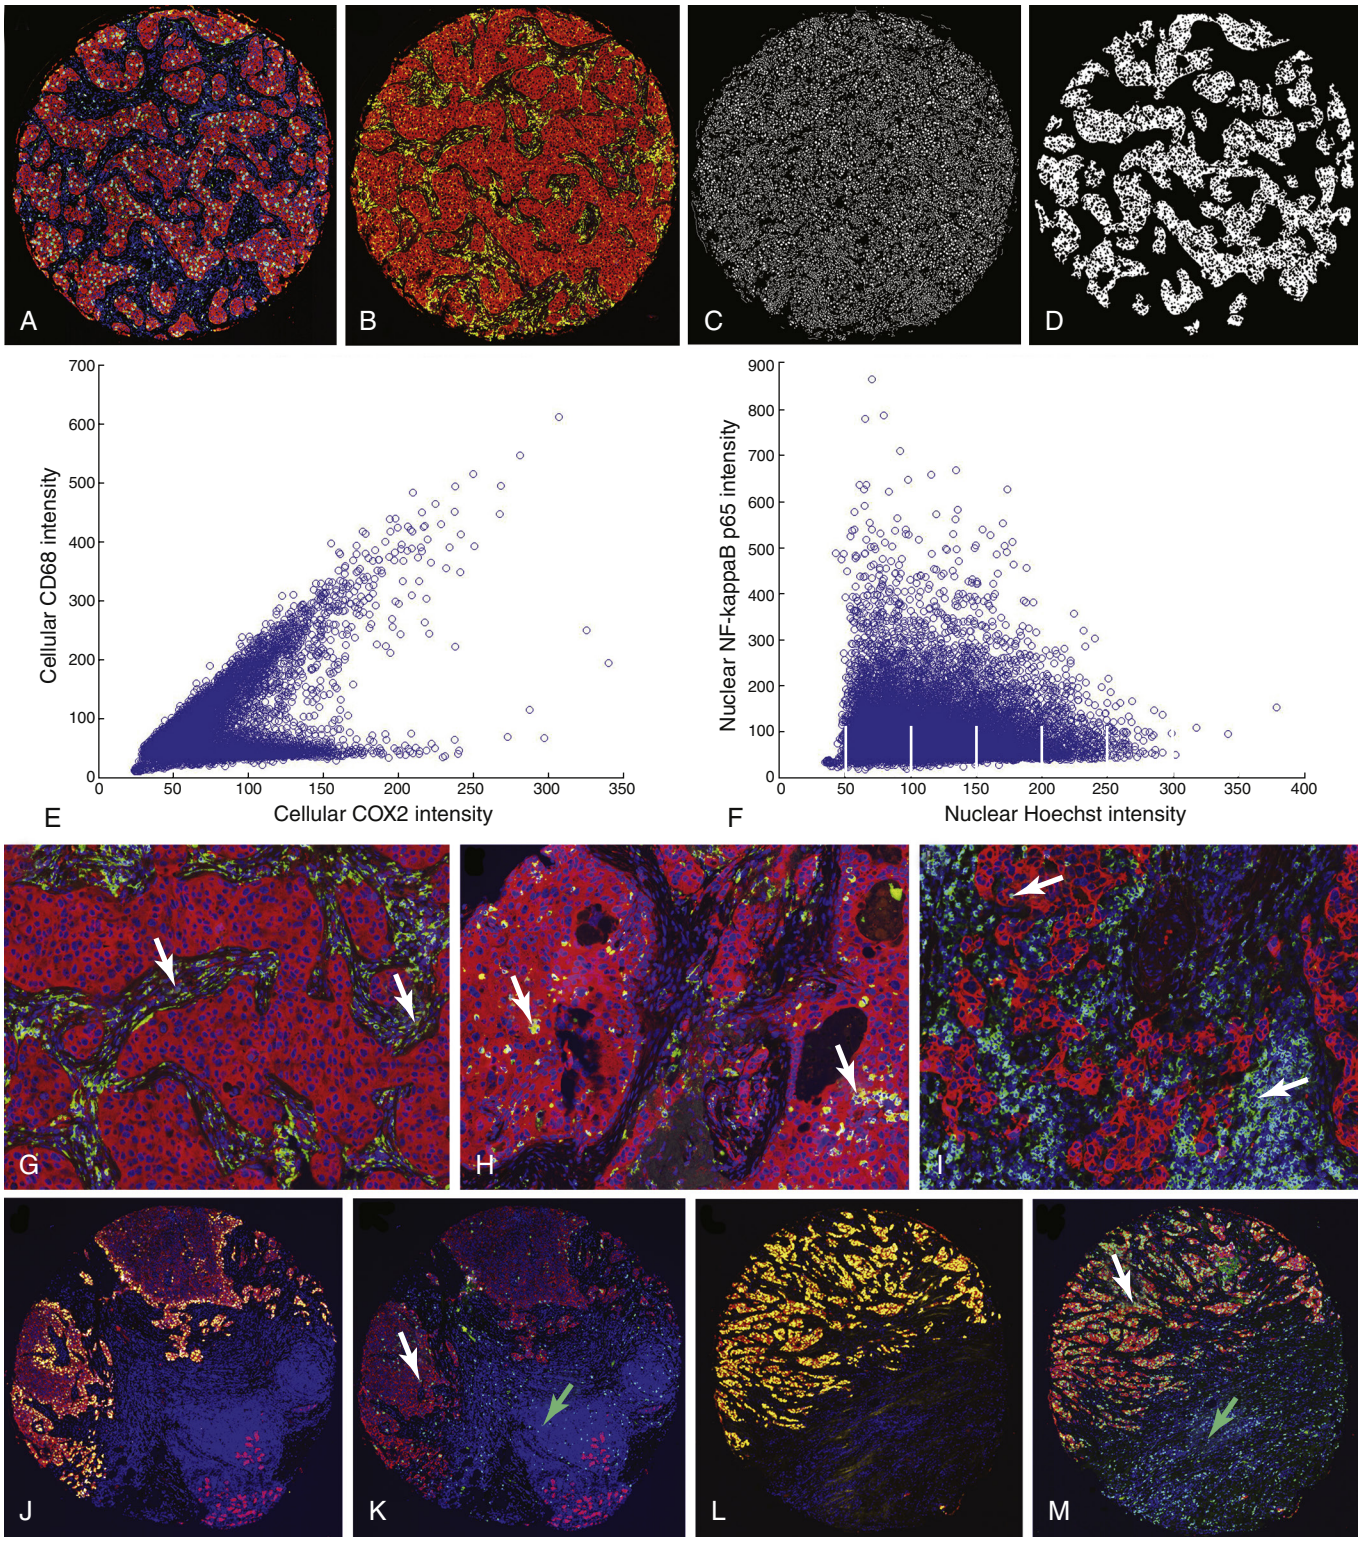

Figure 25-5 Multiplexed immunofluorescence and quantitative digital image analysis of tumor microenvironment biomarkers in breast cancer Serial sections of a breast cancer tissue microarray were labeled with primary antibodies specific for Ki-67, pan-cytokeratin, CD68, COX-2, NFκB p65, PD-1, and CD45RO, fluorescently labeled secondary antibodies specific to each primary antibody, and Hoechst 33342 (nuclear stain). Slides were imaged using a fluorescence digital slide scanner (Aperio FL, Aperio Technologies, Inc., Vista, CA) at 20× magnification. The digital images were analyzed using TissueCipher software (Cernostics, Inc., Pittsburgh, Pa) to segment nuclei, cells, and tumor cell nests as individual objects in which quantitative biomarker intensity measurements were made. **(A)** Ki-67 (*green* nuclear signal in both stroma and tumor nests), pan-cytokeratin (*red* plasma membrane signal in tumor nests) and DNA (*blue* nuclear signal) in breast cancer tissue core. **(B)** CD68 (*green* plasma membrane signal in stroma), NFκB p65 (*red* cytoplasmic and nuclear signal throughout tissue), COX-2 (*yellow* plasma membrane and cytoplasmic signal throughout tissue), and DNA (*blue* nuclear signal). **(C)** Nuclear image analysis mask. **(D)** Tumor nest image analysis mask. **(E)** Single cell measurements of cellular CD68 and COX-2 in the breast cancer tissue shown in image **B**. The bivariate data show that the tissue is composed of COX-2–positive, CD68-negative malignant cells and CD68-positive cells, i.e., macrophages, with a subpopulation expressing high levels of COX-2, which are known to promote tumor angiogenesis. **(F)** Single cell measurements of nuclear NFκB p65 and DNA in the breast cancer tissue shown in **B**, which shows a subpopulation of cells with nuclear localization of NFκB p65, promotes breast cancer cell migration and metastasis. **(G,H)** CD68 (*green* as in **A**), NFκB p65 (*red* as in **B**), and DNA *(blue)* showing stroma-restricted infiltration of $CD68^+$ macrophages **(G)** and macrophages infiltrating tumor nests **(H)** (examples indicated by *arrows*). **(I)** PD-1–expressing tumor cells (*red* plasma membrane signal) surrounded by $CD45RO^+$ memory lymphocytes (*green* plasma membrane signal) in the stroma and tumor nests (examples indicated by *arrows*); **(J-M)** p53 (*yellow* nuclear signal), Ki-67 (*green* nuclear signal), pan-cytokeratin (*red* plasma membrane signal) showing heterogeneity in p53 overexpression within tumor nests **(J)** and proliferating tumor cells and stromal immune cells, indicated by *white* and *green arrows*, respectively.

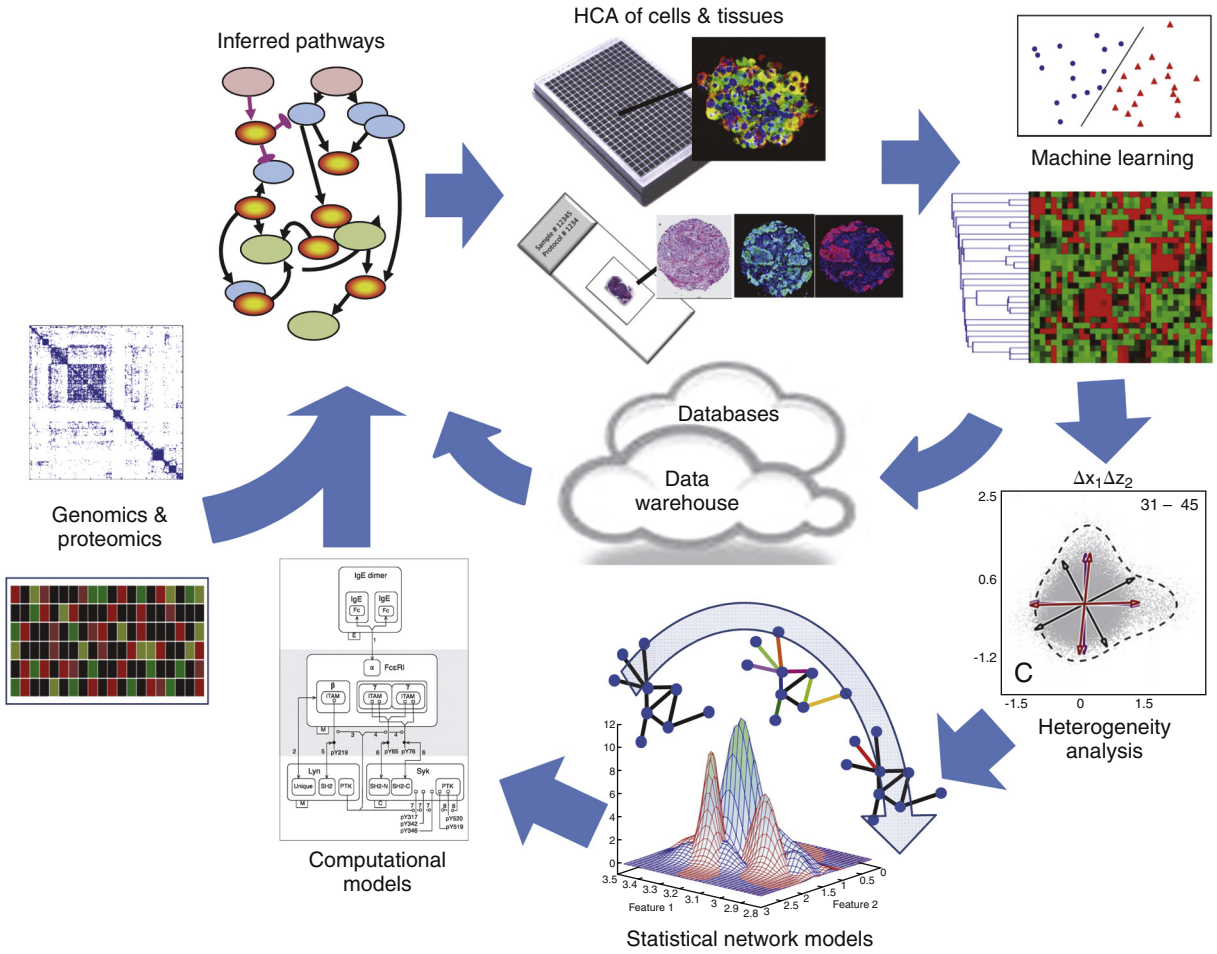

Figure 25-6 Application of cellular/tissue systems biology Cellular signaling pathway maps inferred from gene and protein expression data are used to select multiple biomarkers for interrogation in cells and tissues. The multiparameter data are used to identify correlations, construct classifiers that predict physiological conditions, and analyze cellular heterogeneity. Heterogeneity can be modeled as a statistical combination of networks that are used to refine computational models, to update the pathway models, and to select additional biomarkers for HCA.

quantitative measurements of biomarkers in subcellular compartments and measure tissue morphometric features.

Variation in tumor microenvironment is thought to be an important driver of tumor cell heterogeneity, as well as an impediment to treatment.[240] In order to understand the relationship between cellular heterogeneity and microenvironment, it is necessary to characterize the local environment of each cell in addition to the biomarker activities. Figure 25-7 illustrates an algorithm designed to identify and classify tissue regions with similar microenvironments. The image is divided into a series of small patches (see Figure 25-7, *A*). A feature set that characterizes biomarker intensity distributions within and between cells is measured for each patch. The similarity matrix (see Figure 25-7, *B*) indicates the degree of similarity between patches. The similarity matrix is converted to a network (see Figure 25-7, *C*) that is used to cluster the patches into groups with distinct microenvironments.[241-243] The correlation of biomarker activity with microenvironment class will be useful for the identification of biomarkers that are more commonly affected by the local environment and aid in the interpretation of the heterogeneity exhibited by those biomarkers.

Although computational imaging provides quantitative information on the structure and function of cells and subcellular structures, there are several key challenges in addressing tissue heterogeneity in digital tissue images. Robust, scalable image analysis tools are required that can operate in extremely low signal-to-noise ratio regimes and handle the data-intensive challenges presented by multiplexed and hyperplexed tissue biomarkers. Computational approaches must carefully analyze the long-tail behavior of biomarker intensity and feature distributions in order to characterize heterogeneous subpopulations of cells. Furthermore, the reasoning strategies of pathologists need to be incorporated into analysis approaches to flag diagnostically relevant areas of tissue images for cancer detection and analysis. These challenges can be addressed by machine learning approaches, which enable expert domain knowledge and rule-based decision making to be incorporated to guide tissue image analysis.

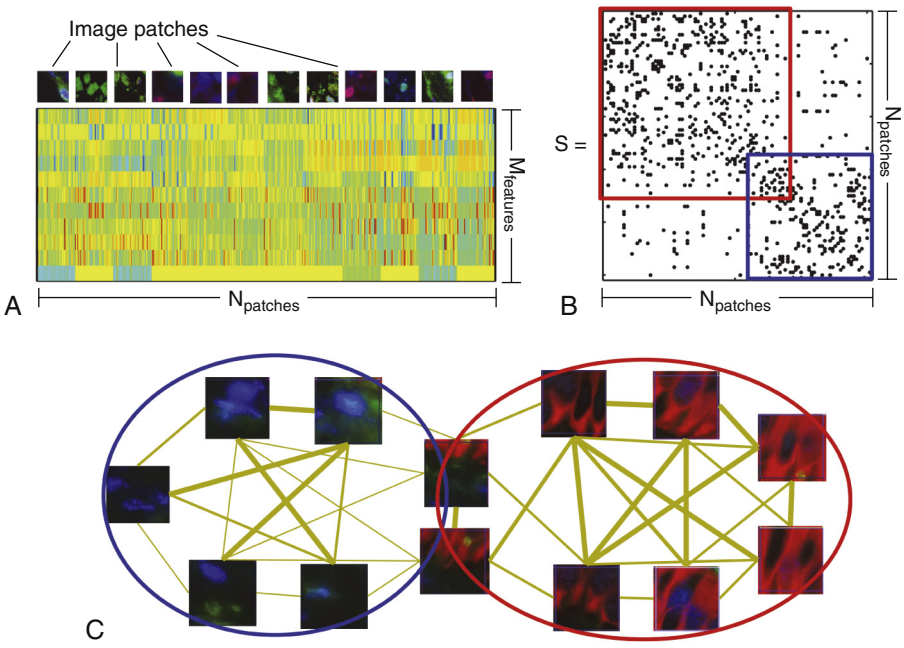

Figure 25-7 Automated identification of cancer cell microenvironments
(A) A fluorescent image is broken into small homogeneous texture regions ("patches") and a feature vector is measured for each image patch (e.g., distributions of biomarker intensities on nuclei, cells, and cytoplasm). **(B)** Matrix S indicates the degree of similarity between each texture patch. Nonzero elements of matrix S are indicated by black dots. **(C)** The similarity matrix can be converted into a network, so that each image patch is a node in the network, and values in S describe weights on edges between image patches (shown by the thickness of the connecting edge). By performing a random walk on the network, identifying bottlenecks, and removing them, a clustering of the nodes into groups of homogeneous image patches emerges naturally—each cluster containing a distinct microenvironment (shown in *colored ovals* in **C**).

Computational and Systems Biology Methods in Cancer Research and Diagnostics

Machine Learning and Other Computational Methods in Cancer Research, Drug Discovery, and Diagnostics

In parallel to the dramatic expansion of automated instrumentation for collecting biomedical research data over the past 30 years, machine learning has arisen as a powerful approach to the analysis and interpretation of this and many other kinds of data.[244] The field of machine learning has already led to many revolutionary technologies, from autonomous vehicles to voice commands to question-answering systems such as Watson, and promises much more. There are two distinct paradigms for posing questions using machine learning, with many intermediate approaches that combine them. These are *supervised learning*, or learning by example, and *unsupervised learning*, or learning models from data. In both approaches, a large set of objects/observations are provided that are described by various *features*. Objects can include individual cells or patients and features are measures such as cell size or blood antigen levels.

Within supervised learning there are two types of challenges: (1) *classification*, i.e., recognition of specific object classes, and (2) *regression* to estimate the value of output variables. In both supervised problems, the class names or output variable values for some of the objects form a *training set*, and the task is to learn a rule or rules that allow the class/value to be predicted/estimated from the feature values for new objects. Accuracy of the system is measured using a *test set*, or the training set can be divided into portions and some portions used for training and others for testing.

There are many frameworks for supervised learning, ranging from simple linear approaches (linear discriminants, nearest neighbor classifiers), to piecewise linear (decision trees), to highly nonlinear (artificial neural networks, support vector machines with nonlinear kernels). All have been increasingly used in biomedical research, particularly in analyzing results from microarray experiments. For example, gene expression profiles have been used to distinguish tumor samples from normal tissue.[245,246] Similar approaches have been used to correlate serum protein profiles measured by mass spectrometry with the presence of particular cancer types in patients.[247] Classification of gene expression data can also provide information for determining treatment or prognosis. This approach has been used to distinguish the tissue site of tumor origin[248] and to distinguish metastatic from nonmetastatic tumors.[249]

Similar approaches can be used to analyze biomedical images, in which the most challenging task is to decide on, and calculate, the features that describe a particular image or region of an image. Magnetic resonance imaging (MRI) is widely used for detection and staging of tumors, and performance on these tasks can be improved using machine learning.[250] Supervised learning methods have also been applied to analysis of traditional histopathology and have achieved similar, and often superior, results to manual scoring by pathologists.[251] These approaches use intrinsic tissue structural information; however, additional information can be gained by analyzing molecular changes in cancer tissues, such as gene expression levels or subcellular localizations of proteins.[252-254]

In unsupervised learning, only feature values are provided. Analogous to classification and regression in supervised learning, the challenge is either to discover classes or clusters that are present, or to build a model that allows estimation of some of the features from the others. The principle behind cluster analysis is to group observations based on similarity in feature values as measured by a distance function. Cluster analysis has been widely used to find clusters of genes with similar changes in expression level in response to some stimulus.[255] A variation on this theme is to perform cluster analysis and then validate the clusters by finding other distinguishing characteristics. For example, patients have been grouped into clusters based on DNA microarray data, and those clusters were shown to differ in clinical phenotypes.[256] In HCA, cluster analysis can be used to discover patterns that are present in a collection of images, whether for learning protein localization patterns[257] or for grouping compounds by their effects on cells.[21,106] In addition to characterizing average phenotypes across a population of cells, heterogeneity of responses can be determined automatically by finding clusters of cells that differ in their multivariate phenotype.[258] This approach has been demonstrated to be useful for predicting the response of various tumor cell lines to chemotherapeutic agents.[165]

Although most machine learning applications use the basic paradigms of supervised and unsupervised learning, there are many intermediate approaches termed *semisupervised learning* that use a degree of supervision to accomplish unsupervised learning goals. For example, unlabeled data can be used to learn probability distributions for features, and this knowledge can improve classifier training. Alternatively, labeled data can be used to learn a distance function that is then used for unsupervised learning. Human intervention can also be used to tune distance functions or classifiers; this is termed *interactive supervision*. An initial clustering can be done using all of the data without labels, and the distance function parameters can be optimized based on user feedback. Alternatively, examples of two or more classes can be given with classes assigned for unlabeled data, and then corrections can be made or new classes defined.

Interactive semisupervised learning can be a form of what is termed *active* machine learning. A semisupervised learning system would be termed active if the system chooses which points the human should focus on rather than displaying all points and allowing the human to choose points. Most machine learning methods assume that all of the data, i.e., features and/or labels, for a problem have already been obtained. Active learning deals with situations in which the data are incomplete but where it is possible to acquire more. Active learning begins by building a predictive model from currently available data using one or more of the methods described earlier. Various methods are then used to decide which missing data to acquire, with the goal of maximally improving the model. Active learning approaches are likely to be highly relevant to HCA as part of drug development.[80] Selection of drug candidates must be guided both by the desired effect on a given target and by lack of effects on other cellular targets that may lead to side effects. Given that the number of potential targets is over 10,000, and that the number of potential drugs is at least 1 million, screening all combinations would be prohibitively expensive. An alternative is to assay a representative subset of targets thought to reflect major cellular pathways.[259] This is clearly an improvement over current practice, but the complexity and interconnection of those pathways present significant challenges.

Two algorithmic approaches, namely *robust statistics*[260] and *spectral graph-theory*,[261] from the fields of computer vision and machine learning have the potential to address emerging challenges in digital tissue biomarker analysis. Robust statistics provide a suite of algorithms[262] to (1) fit parametric models to noisy data, e.g., to model a membrane wall with a parametric shape and extract the parameters of the shape model from noisy images of a membrane wall; (2) instantiate multiple occurrences of a model whose number and type must be determined from the data; and (3) account for structured outliers, i.e., discount certain observations in the data so that they do not affect the estimation of the model parameters. Algorithms from robust statistics and spectral clustering have significantly advanced the state of the art in the fields of computer vision and machine learning. These approaches are expected to be highly relevant to and widely applicable to the computational tasks of analyzing digital pathology datasets.[263-265]

Computational Modeling of Cellular Systems

The heterogeneity and complexity of cancer also pose major challenges for computational modeling. Cancer has signatures and mechanisms that operate at multiple scales. Two fundamental scales that are bridged by 2D and 3D cellomic data are the intracellular molecular network scale and the cellular scale at which cell-cell interactions take place. Just as experimental models must go beyond the uniformity of a single cell line, computational models at the molecular level must consider far more than single networks in isolation if they are to provide a realistic description. At the same time, models of processes at the cell population level must incorporate molecular details if they are to reveal underlying mechanisms through which cancer mutations and other disease-associated changes exert their effects. Bridging between the molecular and cell population levels is a major challenge for computational modeling going forward. Achievement of this integration will lead to improved mechanistic understanding of cancer and holds promise for the development of new therapies.

In a mechanistic model, cellular activity is represented as a directed network of chemical interactions. Each node of the network represents a type of molecule in or around the cell, and each network edge represents a chemical interaction. The system's behavior is determined by the network topology, molecular concentrations, and reaction constants, as illustrated in Figure 25-8.

The first major task in computational modeling is to identify a model or set of models that is compatible with both prior knowledge about underlying molecular and cellular mechanisms and the available data. In the discussion below we focus on the specific requirements for developing models based on HCA data, but the procedures for developing models are quite general. Figure 25-9 illustrates the

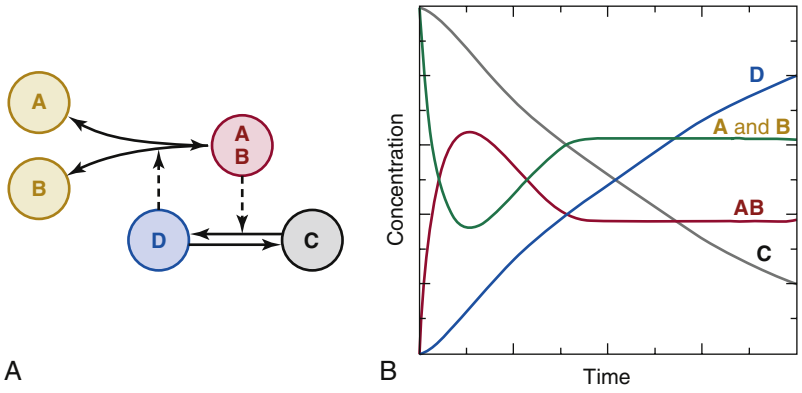

Figure 25-8 A simple reaction network and its output as an example of mechanistic pathway modeling **(A)** Reactants A and B *(green)* reversibly combine in equal amounts to form the homodimer AB *(red)*, which catalyzes the conversion of C to D *(blue)*. D in turn catalyzes the dissociation of AB into A and B. The system of equations represented by this network can be solved to find how the concentrations evolve in time. **(B)** The time evolution of molecular concentrations if A, B, and C are initially present in equal amounts and AB and D are initially absent. The shapes of the curves depend on the rates of the chemical reactions.

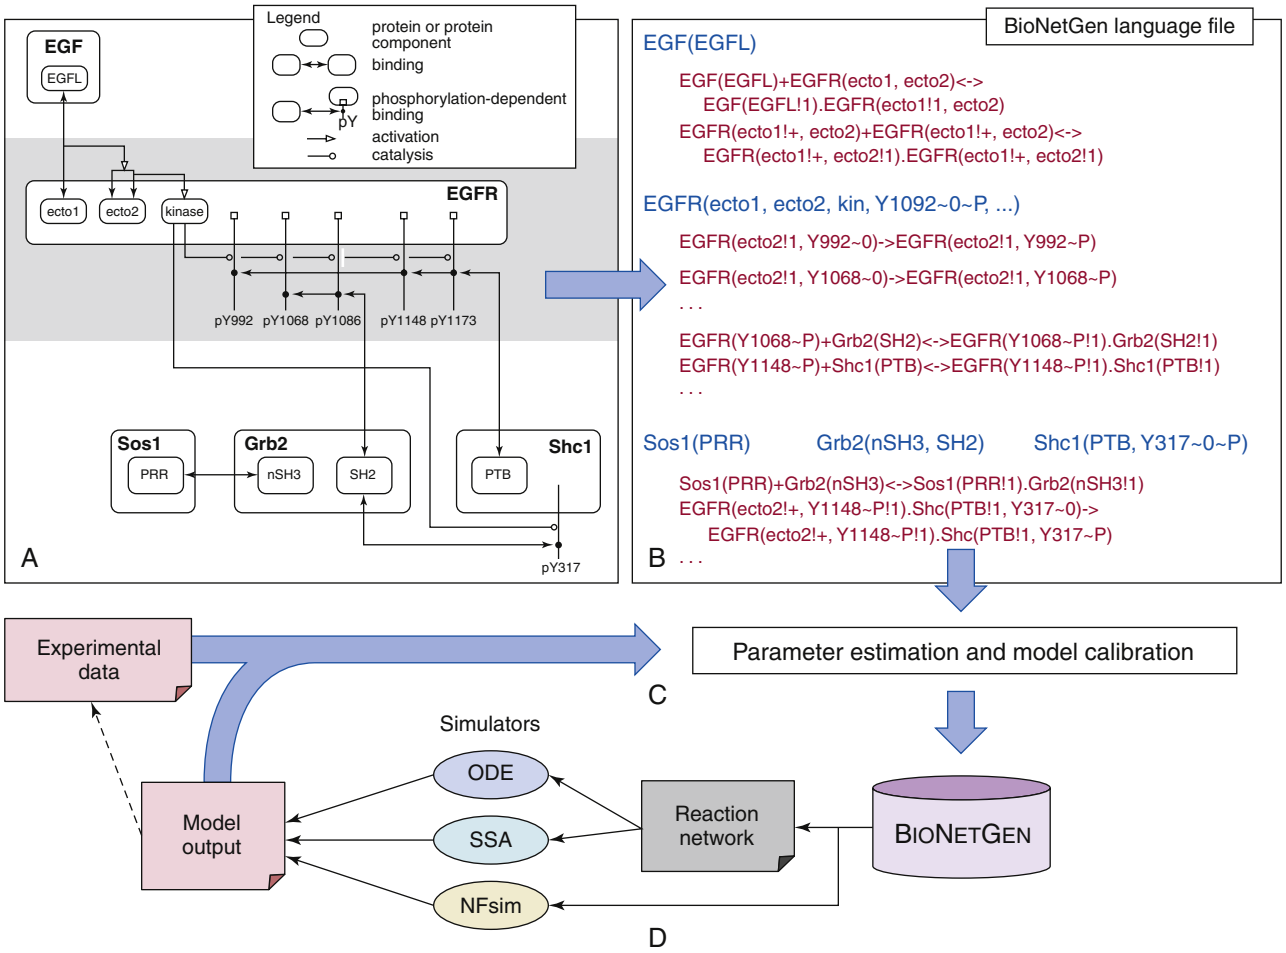

Figure 25-9 Steps in rule-based modeling of intracellular signaling Building a pathway model, such as the epidermal growth factor receptor (EGFR) pathway involves the following steps: **(A)** Create a map of pathway components and interactions; **(B)** translate elements of the map into molecules *(blue)* and rules *(red)* using, for example, the syntax of the BioNetGen[266] modeling language; **(C)** estimate the parameters, such as initial concentrations of proteins and rate constants, and calibrate model; and **(D)** run simulations using one of several methods such as ordinary differential equations (ODE), stochastic simulation algorithms (SSA), or network-free simulation (NFsim). Steps **C** and **D** are frequently iterated as model predictions are used to drive experimental studies, and the resulting data are used to refine and recalibrate the model.

procedure for constructing a rule-based model, using the EGFR pathway as an example. Rule-based modeling languages like BioNetGen[266] bridge the gap between the design of the model and the mathematical definition of its computation. Mechanistic modeling is distinct from machine learning approaches in that the underlying models are biophysical and biochemical in origin rather than purely descriptive of the data.[267,268] The two approaches share a common problem, which is the identification of model parameters that are consistent with a given set of data.[269] This step is necessary to generate predictions from the model and to estimate the confidence or uncertainty in those predictions,[270] but is currently a major bottleneck in the development of all forms of mechanistic models. This problem is particularly acute for large-scale models that have potentially tens to hundreds of unknown parameters.[271,272]

Here we identify four main challenges for developing computational models that integrate HCS data: network complexity, cell-to-cell variability, spatial complexity, and multicellularity, which we consider in the following paragraphs.

Network Complexity

Mechanistic models of cell signaling are usually based on standard chemical kinetics descriptions that arise from treating the cell as a well-stirred chemical reactor. Such reaction network models of cellular processes can be simulated by numerical integration of differential equations (if the cellular concentrations are large enough to be approximated as continuous) or through kinetic Monte Carlo simulations (most commonly, the Gillespie algorithm[273]), if the noise arising from small molecular concentrations is important. This approach is typically used to model systems ranging in size from a few species to as many as a few hundred, although parameter estimation becomes problematic for models of such complexity. More coarse-grained simulation approaches, such as Boolean network[274] or fuzzy-logic approaches,[235] which may reduce the problem of parameter estimation, have also been used as a basis for automated methods of learning model structure, i.e., the rules that govern interactions among the model components. Recently, statistical methods for model selection have also been applied to reaction network models to determine model architectures most compatible with experimental data.[275]

A major problem in cancer modeling is to predict the effect of observed mutations on the network response. Because mutations tend to effect specific molecular interactions, achieving this predictive capability drives the development of increasingly complex models. Unfortunately, the reaction network approach suffers from the problem of combinatorial complexity, which results in an explosion of network size—the numbers of species and reactions that must be considered in the model—as the complexity of molecules and number of interactions grows. This problem makes manual specification of reaction networks, the standard approach, time consuming and ultimately prohibitive. The cost of simulations also grows rapidly with network size and can become prohibitive even for relatively small systems.[276] The recent development of rule-based modeling[277,278] largely eliminates the effects of combinatorial complexity in the specification and simulation of models, although the general issue of calibrating the parameters of large-scale biological models remains open.

Cell-to-Cell Variability

In principle the effects of cell-to-cell variability in protein expression and other basic parameters such as volume or surface area can be modeled using reaction network models. For example, the distribution of responses to a fixed stimulation of a cell population could be modeled if the distributions of the key signaling components affecting the response were known. Recently, protein expression levels have been measured on a genome scale in single cells and shown to largely follow simple distributions characterized by only a few moments, e.g., mean, variance, and skewness.[279] If the necessary antibodies are available, HCA data can also be used to parameterize expression level distributions for a cell population, and these parameters can be fed into a model to predict the distribution of responses. An important additional issue, which has not often been addressed, is how correlations in protein expression affect variability. In one study of T-cell signaling, positive correlation between expression levels of activating and inhibitory components of a signaling pathway was shown to reduce the effect of cell-to-cell variations in those proteins.[280] A number of studies have shown that variability in protein expression can lead to dramatic variation in cellular responses, leading to bimodal distributions of activity or outcome.[280-282] Such effects typically arise from nonlinear effects, such as positive feedback, but can have other origins. Cell populations may use such variability as a form of bet-hedging to avoid making costly decisions, such as whether to grow or undergo apoptosis, in response to possibly spurious signals.[283] In the context of cancer, the effect of such variability complicates the development of effective treatments.

Spatial Complexity

Imaging provides a wealth of information about the spatial localization of molecules within cells. This localization is critical to many signaling processes. The movement of molecules between cell compartments is a major component of information flow and signal processing, e.g., endocytosis and transport of complexes through nuclear pore complexes. A range of modeling and computational approaches have been developed to describe such effects.[284] At the simplest level, compartments can be introduced to reaction network

models to prevent interactions between components in different compartments.[285] Models based on partial differential equations (VCell[286]) or Brownian dynamics (MCell[287]; Smoldyn[288]; GFRD[289]) handle spatial effects at a much higher level of detail. Depending on the level of resolution that is chosen, inclusion of spatial effects increases the simulation cost and the difficulty of fitting model parameters. Currently these costs preclude the possibility of model selection in most cases. At the same time, software for spatial simulation is advancing rapidly and can be expected to play a more important role as the amount of HCA data increases.

Multicellularity

The most daunting challenge for modeling HCA data comes in handling cell-cell interactions and coupling those to the molecular scale. Cell behaviors are coupled through the secretion and uptake of ligands, competition for resources, and direct cell-cell contacts. Modeling these effects requires multilevel models that couple intracellular regulatory networks to mechanisms for cell-cell communication. Cells are typically modeled as agents in such models. In order to develop multilevel models, standard methods for modeling cells as discrete agents in a population must be combined with reaction network modeling methods. Currently there are relatively few software tools available for the construction of such models,[290] and most of the models that have been developed use special-purpose code. Use of multilevel modeling has grown in the past few years and has been accompanied by the development of several new frameworks for developing multilevel models, such as ML-rules[291] and chaste.[292] The major issues going forward will be the computational expense of simulating such models and the accompanying issues of model parameterization and model selection.

Recently, the first truly comprehensive model of cellular processes and their regulation was developed for *Mycoplasma genitalium*, one of the simplest known organisms.[293] The model demonstrates that a wide range of cell processes can be modeled and integrated into a single computational model, but the effort required to construct and simulate the current model, which describes the behavior of only a single cell under controlled conditions, demonstrates the magnitude of the challenges that lie ahead.

Conclusion and Outlook

The integration of all imaging modalities with genomics and proteomics will have an important impact on our understanding of the molecular basis of cancer. In particular, HCA coupled to computational biology will yield the necessary statistical analyses to define and understand the impact of heterogeneity in both diagnostics and therapeutics. Although challenging, the development and application of systems biology tools should make it feasible to begin modeling the complexities of cancer.

Molecular Genetics of Acute Lymphoblastic Leukemia

Introduction

Acute lymphoblastic leukemia (ALL) is a sharply contrasting disease in the pediatric and adult populations. In children, it is both the most common leukemia and the most common malignancy. Childhood ALL has been emblematic of medical progress, with steady improvement over the past 50 years and a current 5-year event-free survival (EFS) rate of over 85%[1] (Figure 26-1). In contrast, in adults, ALL constitutes a minority of the leukemias and a tiny fraction of all malignancies. In addition, the long-term disease-free survival for adults with ALL is poor, in the range of 30% to 40%.[2] An understanding of molecular genetics is playing an increasingly important role in optimizing therapy in pediatric ALL, defining distinct prognostic subgroups for which therapy can be tailored so that low-risk patients are spared unnecessary toxicity, while high-risk patients receive the intensive therapy most likely to effect a cure. Furthermore, some of the discrepancy between cure rates in childhood and adult ALL can be explained by noting that positive prognostic genetic lesions tend to be more common in children, whereas genetic lesions that are associated with more resistant disease tend to be more prevalent in older patients. New insights into the molecular biology of ALL may both increase the ability to more accurately risk stratify patients and identify targets for novel therapeutics that could increase survival and decrease toxicity in all patients with ALL.

Prognostic Factors

The cornerstone of ALL therapy is stratification of patients into different risk groups based on a combination of clinical, laboratory, and molecular features, so that the type and intensity of therapy may be tailored appropriately.[1] For example, in children, three major factors are used to assign risk-based therapy at diagnosis. First is the Rome-National Cancer Institute (NCI) risk status, which defines high-risk ALL as those with an age less than 1 year or more than 9.99 years, and/or initial white blood cell (WBC) count greater than 50,000/μL. In adults, older age and higher WBC are associated with increasing risk. Second is early response to treatment. Third, and increasingly important, is molecular genetic alterations of the tumor cells.

Overview of Molecular Genetics of ALL

Cytogenetic analysis using karyotypic characterization and fluorescence in situ hybridization (FISH) is a crucial element in diagnostic evaluation. Translocations are relatively common in ALL and generally cause two types of events: a proto-oncogene may be brought into the proximity of a T-cell receptor or immunoglobulin locus, causing its overexpression; or the genes at the breakpoints of the rearranged chromosomes, often transcription factors, may fuse to form a new, chimeric protein that is oncogenic because of altered properties and/or expression patterns.[3]

Although ALL has traditionally been defined by recurrent karyotypic changes, about one quarter of patients lack characteristic chromosomal rearrangements. In addition, none of the known rearrangements has been shown to be both necessary and sufficient for leukemogenic transformation. Recent technological advances in high-resolution genomic sequencing coupled with active large-scale support by initiatives such as the NCI TARGET (Therapeutically Applicable Research to Generate Effective Treatments; www.target.gov) project have led to large sample surveys identifying more than 30 validated recurring tumor-specific somatic subchromosomal mutations in a majority of patients with ALL. Among these, most occur in key signaling pathways such as B-cell development/differentiation, the TP53/RB

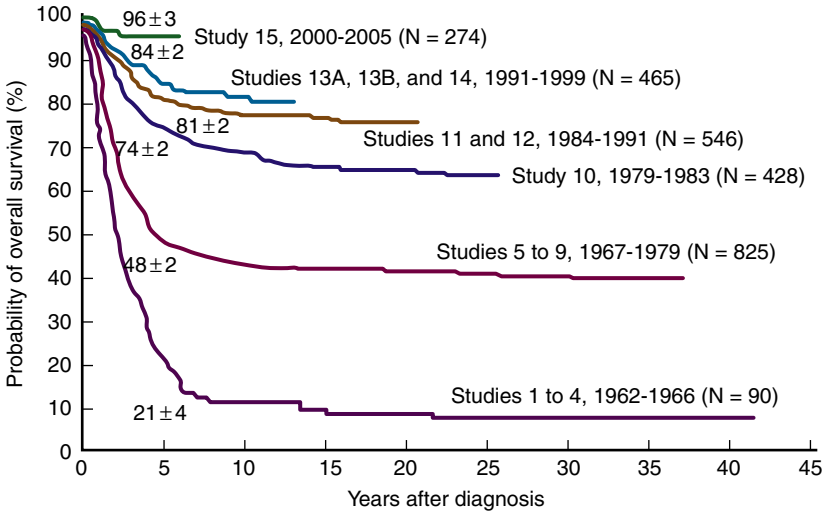

Figure 26-1 Kaplan-Meier analysis of overall survival in 2628 children with newly diagnosed acute lymphocytic leukemia (ALL). The patients participated in 15 consecutive studies conducted at St. Jude Children's Research Hospital from 1962 to 2005. The 5-year overall survival estimates (± SE) are shown, except for Study 15, for which preliminary results at 4 years are provided. *(From Pui CH, Evans WE. Treatment of acute lymphoblastic leukemia.* N Engl J Med. *2006;354:166-178, with permission.)*

tumor suppressor pathway, and Ras and Janus kinase signaling.[4] These advances, along with microarray-based analyses of gene expression and epigenetic profiles, have elucidated important basic science aspects of leukemogenesis (Table 26-1). In addition, some of these findings have already translated into several promising novel therapies.

Abnormalities of Chromosome Number (Ploidy)

Ploidy can be assessed either by chromosome number or by flow cytometry using the DNA index (DI), the ratio of fluorescence in leukemic blasts compared to normal cells. Normal diploid cells have 46 chromosomes and a DI of 1.0, hyperdiploid cells have higher values, and hypodiploid cells lower. Hyperdiploidy is further classified as "low" and "high" (greater than 50 chromosomes).

Hypodiploid cases constitute approximately 6% of pediatric and 2% to 8% of adult ALL.[5] Those with fewer than 45 chromosomes have significantly worse outcome, with the worst outcome occurring in near-haploid cases (24 to 28 chromosomes).[5] The adverse prognostic impact in adults is somewhat weaker. "Pseudodiploid" cases, with normal chromosome number but structural abnormalities, also do relatively poorly. Rare cases with near triploidy or near tetraploidy (more than 80 chromosomes) have traditionally been associated with poor outcome. However, more recent reports analyzed from studies using modern therapies refute this claim, showing that these lesions should be classified prognostically as neutral[6] or even favorable.[7]

Hyperdiploidy occurs in about 35% of pediatric and 25% of adult ALL cases.[8] In children, ALL with more than 50 chromosomes, or simply the simultaneous trisomies of 4 and 10 (and less importantly 17), is an independent positive prognostic indicator. In adults, the prognostic implications are less clear. Although the biologic basis of hyperdiploidy is poorly defined, it often co-occurs with other favorable risk factors as well as *Ras* and *FLT3* mutations and *FHIT* hypermethylation.

Genetic Abnormalities in ALL

B-ALL

Abnormalities of Chromosome Structure

(*ETV6-RUNX1*), t(12;21)(p13;q22)

The *ETV6-RUNX1* (*TEL-AML1*) fusion protein formed by the t(12;21)(p13;q22) translocation is the most frequent abnormality in children (25%), whereas it is much rarer in adults (2%). *ETV6* (ETS variant gene 6) is also known as *TEL* (translocation-ETS-leukemia). *RUNX1* (runt-related transcription factor 1) is also known as *AML1* or *CBFA2* (core binding factor A2). In nearly all cases the translocation is cryptic, involving a region too small to be detected by karyotype.

ETV6 encodes a widely expressed nuclear protein belonging to the Ets family of transcription factors, which are involved in diverse developmental processes including the establishment of embryonic and adult hematopoiesis. A helix-loop-helix (HLH) region known as the ETS domain allows DNA binding for transcriptional regulation, and an HLH region known as the pointed domain appears to facilitate self-association (Figure 26-2, *A*). *RUNX1* is a transcription factor with highly restricted expression in hematopoietic cells and developing ganglions but that is required for transcription of several hematopoietic-specific

Table 26-1 Selected Genetic Abnormalities Associated with ALL

Chromosomal Abnormality	Genes Involved	Pediatric (%)	Adult (%)	Mechanism of Transformation	Prognostic Impact
Pre-B ALL					
t(12;21)(p13;q22)	*ETV6-RUNX1*	25	2	Represses AML1 function as transcriptional activator	Favorable
t(1;19)(q23;p13)	*E2A-PBX1*	6	3	Promotes PBX1 function as transcriptional activator	Formerly poor; negated by intensive therapy
t(17;19)(q23;p13)	*E2A-HLF*	<1	<1	Repression of E2A and antiapoptotic effects (?)	Poor
t(9;22)(q34;q11)	*BCR-ABL*	3	25	Increased tyrosine kinase activity	Poor; partially ameliorated by imatinib (Gleevec)
t(4;11)(q21;q23)	*MLL-AF4*	8	10	Disruption of Hox expression patterns	Poor
iAMP21	*RUNX1*, mir-802, and DSCR	2		Initiates development of secondary lesions (in, e.g., *IKZF1*, *ETV6*, *RB1*)	Poor
PAX5 mutation	*PAX5*	30	12	Disrupts normal B-cell maturation process	No known significance
EBF1 mutation	*EBF1*	4	1.5	Disrupts normal B-cell development/decreases PAX5 expression	No known significance
IKZF1 mutation	Ikaros	80 (Ph^+) 7 (Ph^-)	63 (Ph^+) 19 (Ph^-)	Activation of JAK/STAT and increased expression of Bcl-xL	Poor
CRLF2 overexpression	*CRLF2*	8 (15% in high risk and 50% of DS-ALL)	10-15	Upregulation of JAK/STAT and PI3K/mTOR pathways	No significance in DS; controversial in SR, poor in HR
JAK mutation	*JAK1*, *JAK2*, *JAK3*	10 in B cell (mostly JAK2)	17 in T cell (mostly JAK1)	Constitutive activation of the JAK tyrosine kinase	Poor
CREBBP mutation (relapsed ALL)	*CREBBP*	19	N/A	Impaired transcriptional regulation of CREBBP targets	No significance
T ALL					
NOTCH mutation	*NOTCH1*	>50	>50	Constitutively activated NOTCH1 causing activation of downstream targets (e.g., c-Myc, cyclin D, and NFκB)	Improved
t(1;14)(p34;q11)	*TAL1*, *TCRα/δ*	7	12	Repression of E2A transcriptional activity	Poor vs. no prognostic significance
t(11;14)(p15;q11)	*LMO1*, *TCRα/δ*	<1	<1	LMO1 activation; repression of E2A transcriptional activity	Unknown
t(11;14)(p13;q11)	*LMO2*, *TCRα/δ*	1	<1	LMO2 activation; repression of E2A transcriptional activity	Unknown
t(10;14)(q24;q11); t(7;10)(q35;q24)	*HOX11*, *TCRδ*, or *TCRβ*	0.7	8	Dysregulated expression of intact HOX11	Favorable if intensive therapy
t(5;14)(q35;q32); t(5;14)(q35;q11)	*HOX11L2*, *BCL11B*, or *TCRδ*	2.5	1	HOX11L2 activation	Poor vs. no prognostic significance
t(8;14)(q24;q11)	*MYC*, *TCR*	<1	<1	MYC overexpression	Unknown
t(7;19)(q35;p13)	*LYL1*, *TCRβ*	1.5	2.5		Unknown
Mature B ALL					
t(8;14)(q24;q32)	*MYC*, *IgH*	2	4	MYC overexpression	
t(8;22)(q24;q11)	*MYC*, *Igλ*	<1	<1		
t(2;8)(p12;q24)	*Igκ*, *MYC*	<1	<1		

DS, Down syndrome; HR, high risk; SR, standard risk.

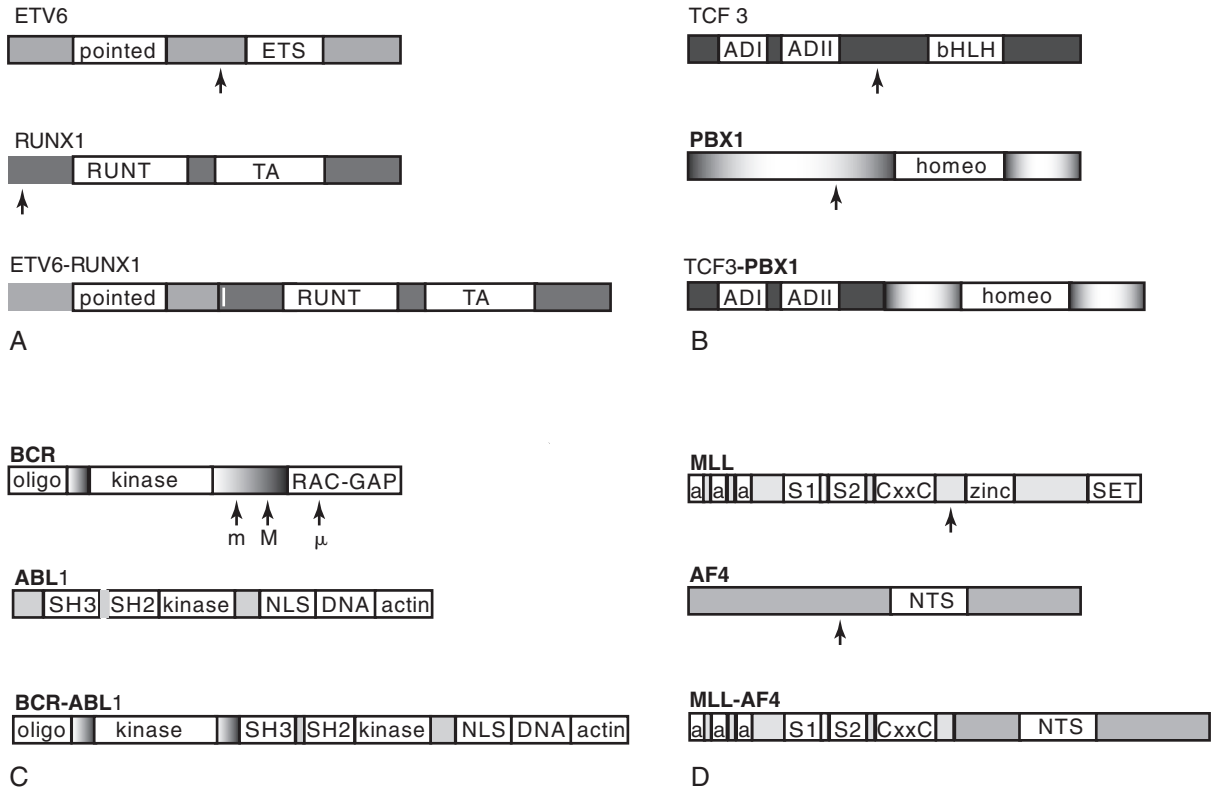

Figure 26-2 Schematic of key domains of the genes involved in several principal translocations in acute lymphocytic leukemia (ALL) and the translocation products. *Arrows* indicate common breakpoints. Note that loss of the domain conferring sequence specificity to transcription factor binding occurs in ETV6-RUNX1 (ETS domain of TEL) and TCF3-PBX1 (bHLH domain of E2A). Gene regions are not drawn to scale. **(A)** ETV6-RUNX1. *TA,* Transactivation domain. **(B)** TCF3-PBX1. *ADI* and *ADII,* Activation domains I and II; *bHLH,* basic helix-loop-helix, sequence-specific DNA-binding domain; *homeo,* homeobox domain. **(C)** BCR-ABL. All three breakpoint regions are indicated (*M,* major, for p210 protein; *m,* minor, for P190 protein; μ, associated with P230 protein). Only the P190 fusion product is illustrated. *oligo,* Oligomerization domain; *kinase,* serine-threonine kinase domain; *RAC-GAP,* RAS-like GTPase; *SH3, SH2,* and *kinase,* SRC homology domains; *kinase,* tyrosine kinase domain; *NLS,* nuclear localization domains; *DNA,* DNA-binding site; *actin,* G and F actin binding site. **(D)** Mixed lineage leukemia. *a,* AT-hook; *CxxC,* cysteine-rich motif homologous to DNA methyltransferase; *S1* and *S2,* subnuclear localization domains; *NTS,* nuclear targeting sequence; *zinc,* zinc fingers.

genes, and may organize the factor complex necessary for lineage-specific transcription.

The *ETV6-RUNX1* fusion protein is widely expressed because of the *ETV6* promoter and converts *RUNX1* from a transcriptional activator to a repressor. The exact mechanism of repression is unclear, as is the manner in which this mediates leukemogenesis. *ETV6-RUNX1* overexpression causes leukemia in only a minority of mouse models, with low penetrance and prolonged latency, suggesting that additional events are crucial for full transformation. A frequent secondary event in *ETV6-RUNX1*+ ALL is loss of heterozygosity (LOH), deletion, or otherwise downregulated expression of the remaining normal copy of *ETV6*, suggesting a potential role for *ETV6* as a tumor suppressor.

ETV6-RUNX1 positivity tends to occur in children 1 to 10 years of age, and nearly exclusively in $CD10^+$ B-precursor ALL. In the past, cases characterized by *ETV6-RUNX1*$^+$ ALL had a hallmark tendency to relapse late, with excellent chemosensitivity and salvage rate. On modern treatment regimens *ETV6-RUNX1* relapsed disease is extremely rare and, although survival for all subtypes of ALL in children with contemporary chemotherapy strategies has improved, *ETV6-RUNX1* has retained positive prognostic significance.[9] When relapse does occur, evidence suggests that it may represent evolution of a new leukemic clone from the preleukemic *ETV6-RUNX1*$^+$ cell of origin.

TCF3-PBX1, t(1;19)(q23;p13)

The *TCF3-PBX1* fusion protein, associated with the t(1;19)(q23;p13) translocation, is the second most common translocation in pediatric ALL, occurring in approximately 6% of all pre-B ALL.[10] It is a rare (3%) and adverse feature in adults. The fusion protein combines the two activation domains of the basic helix-loop-helix (bHLH) transcription factor *TCF3* (previously *E2A*) on chromosome 19 with the homeobox (*HOX*) gene *PBX1* (for pre-B cell homeobox 1) on chromosome 1, resulting in a strong transcriptional activator effect on PBX1 (see Figure 26-2, *B*). *TCF3* is a transcriptional activator critical in lymphocyte development, as well as widely expressed and influential in diverse cellular

processes. *PBX1* belongs to the TALE (three amino acid loop extension) class of atypical homeodomain proteins. The homeodomain mediates both DNA-binding and *HOX* gene interaction.

The *TCF3-PBX1* chimeric transcription factor strongly activates a subset of *HOX* genes normally regulated by *PBX1*. The basis for its transforming ability may be reduction of wild-type *TCF3* levels; aberrant activation of *PBX1* targets in pre-B cells; or activation of targets not normally regulated by *PBX1* that are affected by the *TCF3-PBX1* fusion protein.[11] Fusion protein overexpression in mouse models causes a variety of leukemias, although not B-lineage ALL, suggesting potent non–lineage-specific transforming activity. Unlike other ALL translocations, t(1;19)$^+$ ALL does not show evidence of in utero origin.

TCF3-PBX1 positivity often coincides with other high-risk factors. Early studies indicated an independent adverse prognostic impact, but on modern intensive pediatric regimens, survival is equivalent.[10] The t(1;19) occurs most often as an unbalanced translocation. Cases with a balanced translocation do more poorly in some studies but not others.

TCF3-HLF, t(17;19)(q23;p13)

The t(17;19) translocation is a much rarer event, occurring in approximately 1% of pediatric ALL and rarely in adults.[12] The *HLF* (for hepatic leukemia factor) fusion partner is a transcription factor not normally expressed in hematopoietic cells. Potential oncogenic effects of the fusion protein include repression of normal *TCF3* function, altered transcriptional activity of *HLF*, and promotion of lymphoblast survival, possibly as the result of antiapoptotic effects. *TCF3-HLF* ALL tends to occur in adolescents and is frequently associated with hypercalcemia, disseminated intravascular coagulopathy (DIC), a cIgM-negative, low CD10 positivity pro-B cell immunophenotype, and a poor prognosis despite intensive chemotherapy.

BCR-ABL1, t(9;22)(q34;q11)

The t(9;22) translocation was the first recurrent chromosomal abnormality identified in human cancer, in association with chronic myelocytic leukemia (CML). This translocation, known as the Philadelphia chromosome (Ph), is necessary and sufficient in transformation to the preleukemic, myeloproliferative neoplasm CML. *BCR-ABL1* is also the most common translocation noted in adult ALL, with a prevalence of 25%, where it is known to be leukemogenic but not in itself sufficient to cause disease. The occurrence of the Ph in ALL increases with age and is therefore seen only in about 3% of childhood ALL cases.[13] Philadelphia-positive ALL is primarily a CD10$^+$ precursor B ALL with frequent coexpression of myeloid markers. Patients with Ph$^+$ ALL tend to be older, present with higher leukocyte and peripheral blast counts, have central nervous system (CNS) involvement, and historically have exhibited lower induction remission rates, shorter remission durations, and very poor overall survival (OS). Monosomy 7 and/or loss of 9p are secondary aberrations that may be associated with worse outcomes.

The Philadelphia chromosome is formed by in-frame fusion of the 5′ portion of *BCR* (for breakpoint cluster region) on chromosome 22 to the 3′ portion of the tyrosine kinase *C-ABL1* on chromosome 9, a proto-oncogene that is part of the *RAS* signaling pathway (see Figure 26-2, *C*). The fusion protein upregulates *ABL1* tyrosine kinase activity. Two main fusion proteins occur, which differ in *BCR* breakpoint. Breaks within the 5.8-kb major breakpoint cluster region (M-BCR), occurring in CML and 25% of adult Ph$^+$ ALL, form a 210-kDa protein known as p210. In the remainder of adult ALL and the majority of pediatric ALL, the breakpoint occurs further upstream, in the minor breakpoint cluster region (m-BCR), forming a 185- to 190-kDa protein usually known as p190. An additional breakpoint generates a 230-kDa protein associated with a rare CML variant with neutrophilia and occasionally with classic CML. All three transcripts can be detected at very low levels using sensitive PCR techniques. It has been suggested that the p190 protein arises de novo, whereas the p210 protein may represent the blast crisis of a previously unrecognized CML. Other features that may distinguish cases that originated as CML include basophilia, marked splenomegaly, and persistence of the *BCR-ABL1* fusion protein in hematopoietic precursor cells of all lineages following remission.

Treatment of CML and Ph$^+$ ALL was revolutionized by the development of imatinib mesylate, also known as STI-571 or Gleevec, introduced in 2001.[14] Imatinib, a selective tyrosine kinase inhibitor, was the first molecularly targeted therapy to attain large-scale clinical success, fulfilling the goals of antitumor selectivity and low systemic toxicity. Despite its success, however, it has not been effective as a single agent because of the rapid development of resistance. Nevertheless, in ALL, when combined with standard cytotoxic chemotherapy, imatinib has dramatically improved patient outcomes. In adults, imatinib plus chemotherapy alone or as a bridge to transplant has improved 4-year OS from roughly 15% to between 38% and 54%.[15] In children, outcomes with the addition of imatinib have been even more striking. Children's Oncology Group (COG) study AALL0031 demonstrated that addition of imatinib to high-intensity chemotherapy improved 3-year EFS to 80% compared to historical controls of 35%.[13] Outcomes in patients treated with chemotherapy plus imatinib were similar to those in patients receiving sibling donor bone marrow transplant (BMT), suggesting that BMT in first remission may no longer be the treatment of choice for Ph$^+$ ALL

in children.[13] New developments in the treatment of Ph+ ALL include more potent second-generation tyrosine kinase inhibitors; dual SRC and *BCR-ABL1* kinase inhibitors; and combination therapy with a farnesyl transferase or a PI3 kinase inhibitor.

MLL, 11q23 Rearrangements

MLL gene rearrangements (*MLL*-r) occur in 8% of pediatric ALL and 10% of adult ALL and constitute the most frequent abnormality in infant ALL, occurring in 60% to 70% of cases.[16] *MLL*-r is also associated with AML, particularly secondary malignancies following anthracyclines and epipodophyllotoxins. *MLL*-r leukemias are unusual in two respects: the N terminus of *MLL* forms a fusion protein with the C termini of more than 70 different partners, including itself;[17] and *MLL*-r are found in both ALL and AML, whereas most other translocations are lineage specific. Indeed, *MLL* takes its name, "mixed lineage leukemia," from this distinguishing feature (it is also known as *HRX* or *HTRX* for homology to *trithorax* in *Drosophila*, and *ALL1* for involvement in ALL). *MLL*-r ALL has a unique gene expression pattern suggestive of arrest at an earlier hematopoietic progenitor stage. The *MLL-AF4* fusion protein formed by t(4;11) is the most common *MLL* translocation in ALL, making up 70% of cases. The *MLL-ENL* fusion formed by t(11;19) comprises another 13%.

Infant ALL with *MLL*-r tends to be associated with age less than 6 months, massive tumor burden, organomegaly, frequent CNS involvement, coexpression of myeloid antigens, and CD10-negative pro-B immunophenotype. *MLL*-r is a very poor prognostic feature in infant ALL, and a poor prognostic feature in children more than 1 year of age. One surprising exception is *MLL-ENL*, associated with good prognosis in both T ALL and patients age 1 to 9 years.[18]

MLL is a large protein consisting of multiple motifs, including AT-hook DNA-binding domains, transcriptional activation and repression zinc finger domains, and a highly conserved SET domain that regulates homeotic (*Hox*) promoters. Several motifs are homologous to the *Drosophila* trithorax protein, which maintains appropriate expression of the *Hox* genes controlling segment determination. In normal hematopoiesis, MLL is required to generate stem-cell progenitors and to establish both lymphoid and myeloid lineages. In general, the many *MLL* fusion partners fall in the broad categories of signaling molecules and nuclear transcription factors.

Because *Hox* genes can induce leukemia, it is thought that the MLL-r protein mediates leukemogenesis through disruption of normal *Hox* expression patterns. The contributions of *MLL*'s many fusion partners to leukemic transformation remain unclear, as they do not all share structural or functional similarities (see Figure 26-2, *D*). One common function may be converting MLL to a constitutive transcriptional effector. In addition, there is a growing body of evidence that *MLL*-r leukemias are driven primarily by epigenetic dysregulation, including aberrations in DNA and histone methylation and histone acetylation.[19]

Both infant and treatment-related leukemias show nonrandom clustering of *MLL* breakpoints within exons distinct from the breakpoints in de novo *MLL*-r leukemias, suggesting a shared mechanism of leukemogenesis. One hypothesis is that infant ALL arises from in utero exposure to topoisomerase II inhibitors, analogous to the initiating insult in therapy-related *MLL*-r leukemias. Epidemiologic studies of the association between infant leukemia and in utero exposure to topoisomerase II inhibitors have identified a modest association between dietary intake and *MLL*-r AML, and a stronger association between certain medications and insecticides and *MLL*-r ALL.[20]

Event-free survival in infant ALL is generally poor, ranging from 20% to 40%, with t(4;11) having a particularly dismal prognosis. Induction rates are generally comparable to other types of ALL, but early relapse is frequent, usually within a year of diagnosis. *MLL*-r ALL shows relative resistance in vitro to glucocorticoids and L-asparaginase, and sensitivity to cladribine and Ara-C. High-dose Ara-C has been incorporated into infant ALL regimens with modest success. The receptor tyrosine kinase FLT3 is highly expressed in *MLL*-r ALL[21] and the use of *FLT3* inhibitors and other novel molecularly targeted therapies is under investigation.

Intrachromosomal Amplification of Chromosome 21 (iAMP21)

Recently, a novel recurrent chromosomal abnormality, the intrachromosomal amplification of chromosome 21 (iAMP21), has been identified in a rare (1.5% to 2% of ALL) and very poor prognostic subgroup of patients with ALL. In childhood ALL, iAMP21 patients tend to be older, with lower initial white blood cell and platelet counts. Clinical outcomes are poor, with relapse rates ranging from 38% to 61% depending on the treatment regimen.[22] Most known abnormalities take place in a 5.1-Mb common region of amplification (CRA) on the long arm of chromosome 21 that includes *RUNX1*, miR-802, and genes mapping to the Down syndrome critical region (DSCR). ALL with iAMP21 consistently has multiple copies of *RUNX1* identified in array-based comparative genomic hybridization and FISH assays (Figure 26-3, *A*). However, gene expression assays fail to show either overexpression of *RUNX1* RNA or a unique iAMP21 signature as compared to other ALL samples. Although the basis for the increased risk of relapse in this subgroup remains unclear, iAMP21 is now used to stratify patients to receive intensified chemotherapy on several current ALL treatment protocols.[23]

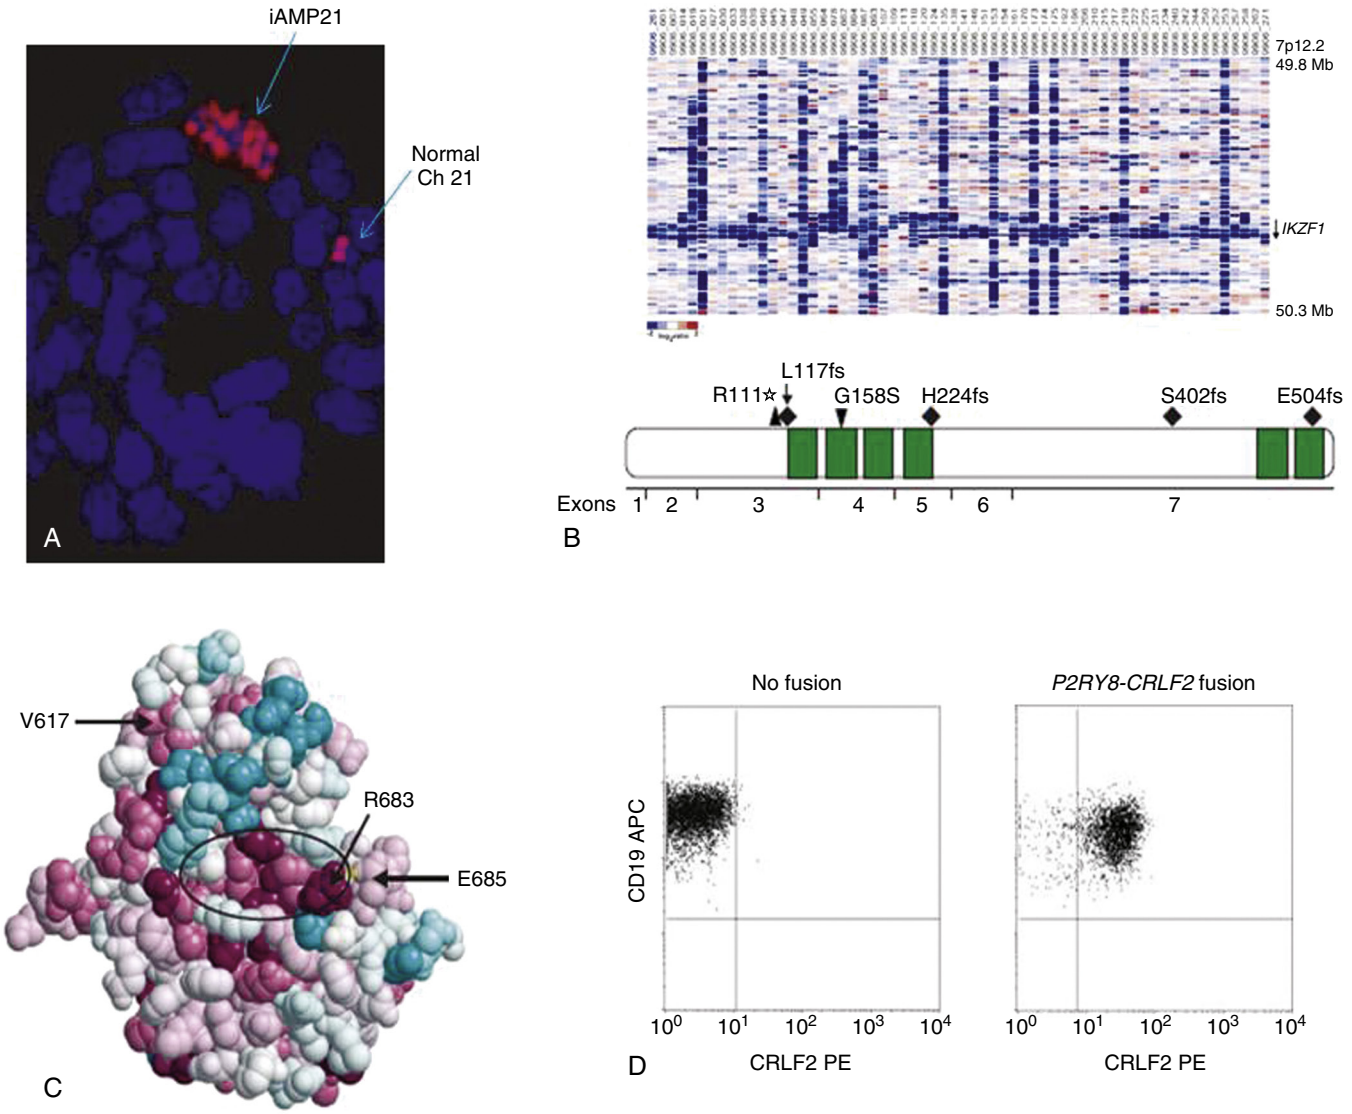

Figure 26-3 Recently identified chromosomal aberrations in ALL **(A)** iAMP21: Metaphase FISH demonstrates multiple RUNX1 signals (*red*) on the chromosome 21 with the iAMP21 aberration (*top*), whereas a single signal is noted on each normal chromosome 21 *(right)*. *(Modified from Harrison CJ. Cytogenetics of pediatric and adolescent acute lymphoblastic leukemia.* Br J Haematol. *2009;144:147-156, with permission.)* **(B)** IKZF1 deletions and mutations: DNA copy number heatmap *(top)* demonstrating deletions *(blue)* at the IKZF1 locus in a cohort of ALL cases, and primary protein structure of IKAROS *(bottom)* showing the location of the six zinc fingers *(green)* and missense *(downward-pointing arrowhead)*, frameshift *(diamonds)*, and nonsense *(upward-pointing arrowhead)* mutations observed in six ALL cases. *(From Mullighan C, et al. Deletion of IKZF1 and prognosis in acute lymphoblastic leukemia.* N Engl J Med. *2009;360:470-480, with permission.)* **(C)** JAK2 mutations: Amino acid structural model showing that R683, the amino acid most frequently affected by point mutations in ALL, is situated on a rim of highly conserved *(red)*, exposed amino acids that make up an apparent binding pocket (encircled by *ellipse*) that is distinct from the V617 amino acid commonly mutated in myeloproliferative neoplasms. *(From Bercovich D, et al. Mutations of JAK2 in acute lymphoblastic leukemias associated with Down's syndrome.* Lancet. *2008;372:1484-1492, with permission.)* **(D)** CRLF2 overexpression: Flow cytometric analysis of cell surface expression of CRLF2 demonstrates CRLF2 overexpression in ALL cases with the *P2RY8-CRLF2* fusion and not in fusion-negative cases; CD19 co-staining was performed to demonstrate selectivity for the leukemic cell population. *(Modified from Mullighan C, et al. Rearrangement of CRLF2 in B-progenitor and Down syndrome associated acute lymphoblastic leukemia.* Nat Genet. *2009;41:1243-1246, with permission.)*

Submicroscopic Abnormalities

PAX5 and *EBF1*

In a landmark study, Mullighan and colleagues performed genome-wide analysis of 242 pediatric ALL patient samples using high-resolution single-nucleotide polymorphism arrays and genomic DNA sequencing. They discovered that precursor B-cell ALL samples on average carried 6.63 copy number alterations, indicating relative genomic stability, but confirming the presence of additional subchromosomal cooperating lesions in ALL cases with known leukemogenic karyotypic abnormalities. Notably, about 40% of cases carried aberrations in genes that regulate B lymphocyte development, including *EBF1* and *PAX5*.[24] *EBF1* (early B-cell factor) is known to be a master regulator for B-cell development, as *Ebf1*-deficient mice produce only B-biased progenitor cells but not mature B cells. In addition, *EBF1*, by remodeling chromatin at the *PAX5* locus, is required for

PAX5 expression; in turn, *PAX5* controls the commitment of the common lymphoid progenitor to the B-cell pathway by repressing genes inappropriate for the B lineage and by activating genes required for B-cell maturation[25]. All known *PAX5* aberrations were shown to reduce the transcriptional activity of *PAX5* and its downstream targets. However, neither *EBF1* nor *PAX5* lesions demonstrate prognostic significance.[26]

IKZF1, CRLF2, JAK, IL7R, and the "*BCR-ABL1*-like" Signature

Recurrent deletions and inactivating mutations in the B-cell development gene *IKZF1* were also identified by Mullighan and associates.[24,26] *IKZF1* encodes the zinc finger lymphoid transcription factor IKAROS (see Figure 26-3, *B*). Isoforms of *IKZF1*, which lack N-terminal zinc fingers but retain the ability to dimerize, act as dominant negative inhibitors of IKAROS function and have been shown in murine models to be leukemogenic. Although thought to exist in only 7% of pediatric and 19% of adult ALL patients, the incidence is higher in high-risk ALL populations (29%)—especially in those carrying the t(9;22) Philadelphia chromosome, where they are present in over 80% of pediatric and 63% of adult patients.[27] In addition, *IKZF1* deletions are observed at the progression of CML to lymphoid blast crisis (but not in CML chronic phase) and are therefore thought to be central in the pathogenesis of *BCR-ABL1* lymphoid leukemia. It was also noted that *IKZF1* mutations were highly correlated with (but not pathognomonic for) a "*BCR-ABL1*-like" gene expression signature even in *IKZF1* mutant ALL lacking the t(9;22).[26,28,29]

Several other recently identified mutations also give rise to a "*BCR-ABL1*-like" signature: *CRLF2* alterations, *JAK* mutations (see Figure 26-3, *C*), and *IL7R* mutations.[29] *CRLF2* forms part of a heterodimeric complex with the interleukin-7 receptor alpha (IL7RA) to serve as the type I cytokine receptor for thymic stromal lymphopoietin (TSLP), a ligand that mediates B-cell precursor proliferation and survival through its activation of downstream JAK/STAT and PI3K/mTOR pathways. Several alterations of *CRLF2* have been noted in ALL, all of which lead to *CRLF2* overexpression, including a focal interstitial deletion of the pseudoautosomal region of the sex chromosomes that creates the *P2RY8-CRLF2* fusion, a translocation of *CRLF2* to the immunoglobulin heavy-chain transcriptional enhancer (*IGH@-CRLF2*) and the *CRLF2* F232C point mutation (see Figure 26-3, *D*).[30-32] *CRLF2* alterations have been noted in 5% to 8% of pediatric[29] and 10% to 15% of adult ALL, and with a higher incidence in high-risk ALL, in patients of Hispanic/Latino ethnicity, and in patients with Down syndrome (DS). *IL7R* gain-of-function mutations are seen in 6% to 10% of ALL and are noted in both B and T phenotypes.[33] *CRLF2* aberrations generally occur in cases lacking classic cytogenetic abnormalities, demonstrate a "*BCR-ABL1*-like" gene expression signature, and tend to co-occur with *IKZF1* and/or *JAK* mutations.[27,34] *CRLF2* has been shown to be a negative prognostic indicator in patients with NCI high-risk disease but not in those with standard-risk disease or in those with DS.

JAK2 mutations were initially identified as occurring in approximately 20% of DS ALL,[35] and *JAK* (mostly, but not exclusively *JAK2*) mutations were subsequently identified in 10% of a high-risk non-DS cohort.[36] Most are point mutations at R683, a site distinct from the V617F mutations frequently observed in polycythemia vera and other myeloproliferative neoplasms, but also within the *JAK2* pseudokinase domain and resulting in constitutive kinase activity. Not surprisingly, 70% of the *JAK*-mutated cases contained concomitant *IKZF1* deletions, and all cases clustered with the *BCR-ABL1* gene expression signature and had a poor outcome.[36] Several studies have demonstrated in vitro sensitivity to *JAK* inhibitors in *JAK*-mutated ALL. This has served as the rationale for an ongoing Phase I study of the JAK1/2 inhibitor ruxolitinib.

Secondary to the complex interactions among *IKZF1*, *CRLF2*, *JAK*, the "*BCR-ABL1*-like" gene expression sig *Nature*, and NCI risk status, it has been difficult to determine which factors retain independent prognostic significance. However, in a recent multivariate analysis, NCI high-risk status, positive end-induction minimal residual disease (MRD), high *CRLF2* expression, and *IKZF1* lesions had an independent adverse impact on relapse-free survival, and subgroup analyses demonstrated that high *CRLF2* expression was associated with poorer relapse-free survival in NCI high-risk but not standard-risk disease.[37]

CREBBP and Relapsed ALL

CREBBP (CREB binding protein or CBP) encodes for a large ubiquitously expressed protein of the same name that performs multiple roles in transcriptional coactivation, including the acetylation of histone and nonhistone targets. Germline mutations in *CREBBP* are observed in Rubenstein-Taybi syndrome, a developmental disorder characterized by dysmorphology, intellectual impairment, and increased susceptibility to solid tumors, and somatic mutations have recently been noted in more than one third of diffuse large-cell non-Hodgkin lymphoma and follicular lymphoma at diagnosis. Aberrations of *CREBBP* are exceedingly rare in de novo ALL; however, 19% of relapsed samples harbor loss-of-function mutations. Functionally, mutations impair histone acetylation and transcriptional regulation of *CREBBP* targets, including glucocorticoid-responsive genes.[38] Contemporaneous work identified a relapse-specific epigenetic profile characterized by global CpG island hypermethylation,

upregulation of genes involved in regulation of the cell cycle, and apoptosis and downregulation of genes involved in sensitivity to thiopurines, alkylators, and glucocorticoids. Along with in vitro studies demonstrating a chemosensitizing effect of histone deacetylase inhibitors and DNA methyltransferase inhibitors on relapsed patient samples, these data have formed the rationale for a recently opened Phase I trial of vorinostat and decitabine added to an intensive chemotherapy backbone in patients with relapsed ALL.

T ALL

T ALL makes up 12% of pediatric and 25% of adult ALL. It occurs most often in adolescents and young adults, frequently presenting with an extremely high WBC, CNS involvement, a mediastinal mass, marked lymphadenopathy, and hepatosplenomegaly. Historically, survival was dismal compared to B-lineage ALL, but with intensified therapies it has improved to approximately 80% in pediatrics[1] and 50% in adults. However, traditional risk factors such as age and WBC used for stratification in B-lineage ALL appear not to be as prognostically informative in T ALL, highlighting the importance of identifying molecularly based prognostic differences instead.

Although genetic translocations have been identified in T ALL (e.g., *MLL-ENL*, *CALM-AF10*, *ETV6-JAK2*, *ETV6-ABL1*, *EML1-ABL1*, and *NUP214-ABL1*), the leukemogenic event typically involves overexpression of an unaltered proto-oncogene, rather than generation of a novel fusion protein, due to a translocation placing it under control of a T-cell receptor (TCR) promoter or enhancer, most often TCRβ or TCRα/δ. The breakpoints occur at junctions where RAG recombinase acts during normal V(D)J recombination, suggesting they are the consequence of physiologic gene rearrangement processes gone awry.[39]

Numerous transcription factors have been identified as aberrantly expressed through juxtaposition to TCR loci in T ALL. They include MYC and several homologous bHLH proteins: TAL1, TAL2, LYL1, and BHLHB1. In addition, homeobox genes and components of the TCR signaling pathway such as SRC-family tyrosine kinases, *LCK*, and *NRAS* appear to be important targets of dysregulation in T ALL.

Aberrant *TAL1* expression via a variety of mechanisms occurs in more than 60% of T ALL. The oncogenic activity of *TAL1* seems to occur through sequestration and inactivation of *E2A* within a binding complex. LMO1 and LMO2 are transcription factors that play important roles in hematopoiesis and vascular development, serving as an interface for binding of multiple transcription factors in a large complex. TAL1 forms a heterodimeric DNA-binding complex with either LMO1 or LMO2, which cooperate in leukemogenesis at least in part through their inhibition of *E2A*.

A disturbing confirmation of the oncogenicity of LMO2 occurred during a gene therapy trial for X-linked severe combined immunodeficiency (SCID) caused by γ-chain deficiency.[40,41] Patients underwent retrovirus-mediated γ-chain gene transfer into autologous bone marrow progenitor cells. Approximately 3 years later, 2 of the 10 patients developed T ALL. The apparent mechanism was retroviral insertional mutagenesis. In both cases, the retroviral particle integrated close to the LMO2 locus and presumably exerted enhancer activity on the *LMO2* promoter, causing its overexpression in lymphoblasts.

NOTCH

The heterogeneous molecular genetics of T ALL was partially unified in 2004 with the discovery of a single gene upregulated in more than 50% of cases in both children and adults.[42] The gene, *NOTCH1*, is a regulatory transmembrane receptor that plays a crucial developmental role in cell fate determination and pattern formation, and in hematopoietic stem-cell maintenance and T-cell fate specification in the mature organism. *NOTCH1* was first identified in the rare T ALL translocation t(7;9)(q34;q34.3), which juxtaposes it to the TCRβ locus, leading to overexpression of a constitutively activated, truncated protein.

Poor prognostic features in T ALL include CD10 positivity, pro-T immunophenotype, and possibly *TAL1* expression. *HOX11* is generally associated with a favorable outcome, at least with modern intensive therapy. *HOX11L2* was reported in some studies as a poor prognostic feature, but intensive therapy appears to eliminate this effect. Cases with the *NUP214-ABL1* fusion appear aggressive and may benefit from imatinib. MRD positivity is a significant adverse prognostic marker in T ALL, occurring more often and correlating more closely with relapse compared to B-lineage ALL. Data suggest that *NOTCH1* mutations may be associated with a very favorable prognosis.[43]

Compound 506U, also known as nelarabine, is a nucleoside analog preferentially accumulated in T ALL that is being incorporated in current clinical trials. Since mutated *NOTCH1* activity depends on γ-secretase activity, γ-secretase inhibitors are also being investigated for therapeutic use.

Early T-Cell Precursor Phenotype (ETP)

A minority of T-ALL cases has recently been noted to carry a gene expression profile reminiscent of normal T-cell precursors, a subset of cells early in the process of thymic maturation that retain multilineage differentiation potential.[44] Consistent with a leukemogenic block early in development, ETP leukemia is defined by the lack of T-cell markers CD1a

and CD8, dim or absent CD5 expression on flow cytometric analysis, and the retention of one of a number of myeloid and/or hematopoietic stem-cell markers. The incidence is estimated at 15% in pediatric and 23% in adult T-ALL cases. Prognosis for ETP leukemia is very poor on conventional therapy, with a 10-year overall survival of 19% to 35%.[44] ETP exhibits a high burden of DNA copy number alterations (a mean of 14.1 per case vs. 6.3 per case in non-ETP T-cell ALL and 6.4 per case for all ALL), indicating a high degree of relative genomic instability[44]. Although no unifying genetic lesion has been identified, the ETP gene expression signature shows significant positive enrichment for genetic abnormalities expressed in leukemic stem cells and in AML cases with a poor outcome, such as cytokine receptor, *RAS*, and epigenetic modification.[45] These observations have raised the possibility that ETP should be treated with therapies known to be effective in AML and/or therapies known to inhibit cytokine receptor signaling.

ERG

The v-ets erythroblastosis virus E26 oncogene homolog (*ERG*) gene, at band 21q22, is a member of the ETS family of transcription factors, which are downstream effectors of mitogenic signaling transduction pathways and are involved in key steps in the regulation of cell proliferation, apoptosis, and differentiation. *ERG* is frequently expressed at high levels in leukemia. In fact, it has recently been shown that forced expression of ERG in adult bone marrow cells alters differentiation and induces expansion of T and erythroid cells; furthermore, the expanded T cells develop T ALL after acquisition of *NOTCH1* gene mutations in experimental models.[46] *ERG* overexpression has been shown to have adverse prognostic impact in both AML and T ALL.

Other ALL Aberrations

c-MYC, t(8;14)(q24;q32)

One of the first links between a chromosomal translocation, oncogene overexpression, and development of a human cancer was the discovery of *c-MYC* dysregulation in Burkitt's lymphoma in the early 1980s. The t(8;14)(q24;q32) translocation places *c-MYC* on chromosome 8 under control of the immunoglobulin heavy-chain gene on chromosome 14, resulting in constitutive *c-MYC* overexpression. *MYC* dysregulation is also an essential feature of mature B-cell leukemia, also known as Burkitt's leukemia. In essence, Burkitt's lymphoma and mature B-cell leukemia are best viewed as two manifestations of a common disease, differing only in the extent of dissemination. The similarity of their symptomatology, prognosis, and treatment illustrates the importance of a common underlying genetic mechanism in defining disease biology.

More than 90% of mature B-cell ALL exhibits the t(8;14) translocation. In the remainder, t(2;8)(p12;q24) or t(8;22)(q24;q11) places *MYC* under the control of the κ or λ light chains, respectively. Another variant, t(8;14)(q24;q11), involves the TCRα locus and has been reported in association with T ALL. Outcome for mature B-cell ALL has improved substantially since the shift from standard ALL therapy to much shorter (roughly 8-month duration), more dose-intensive regimens containing not only traditional ALL chemotherapy such as prednisone, vincristine, doxorubicin, cyclophosphamide, and high-dose methotrexate but additional drugs such as Ara-C, etoposide, and most recently rituximab.

7p Deletions and Monosomy 7

Losses involving chromosome 7 are more common in AML, but they do occur in approximately 5% of adult and pediatric ALL.[47] In adult ALL, deletion or loss of chromosome 7 is often associated with Ph positivity and does not have independent prognostic significance. In pediatric ALL, chromosome 7 losses tend to occur in patients with other concomitant adverse risk factors, but retain some independent negative prognostic impact.

9p21 Deletion

Deletions in the 9p21-22 region occur in 10% to 30% of ALL and more than 50% of T ALL, with the incidence rising as cytogenetics laboratories adopt more sensitive detection methods.[48] The principal targets appear to be the *INK4A* and *INK4B* loci, which contain two cyclin D kinase inhibitors, p16 and p15, that prevent abnormal cells from passing through the G_1 cell cycle checkpoint and are mutated, deleted, or epigenetically silenced in many cancers. 9p21 deletion often coincides with other adverse factors; its independent significance is controversial.

Cooperating Pathways: *p53, FLT3, Ras, PTPN11*

p53 is a classic tumor suppressor gene that initiates cell cycle arrest or apoptosis in response to abnormal proliferation, hypoxia, or DNA damage and is mutated in many human cancers. Mutation of p53 itself is rare in ALL, but mutations of elements of the pathway such as p14(ARF) and p21(CIP1) are common and may be associated with an unfavorable prognosis. FLT3 (for FMS-like tyrosine kinase) is a membrane-bound receptor tyrosine kinase involved in hematopoietic proliferation, differentiation, and apoptosis. Mutations resulting in ligand-independent activation are oncogenic and occur in 15% to 35% of AML and 1% to 3% of ALL.[49] *FLT3* mutations and FLT3 overexpression in ALL are particularly associated with *MLL*-r and hyperdiploidy. Ras family members play crucial signaling roles in proliferation, antiapoptosis, and other processes. Mutations in *NRAS* and *KRAS* have been linked to parental

exposures to certain drugs and hydrocarbons. Activating mutations of *PTPN11*, which encodes the tyrosine phosphatase SHP-2, enhance Ras signaling. Forty-five percent of *ETV6-RUNX1*-negative cases of pre-B ALL have mutations in *PTPN11*, *NRAS*, and/or *KRAS2*.[50] *RAS* mutations do not appear prognostically significant, whereas the significance of *PTPN11* mutations remains unclear. Recently, mutations in p53 and in the Ras and Pi3K signaling pathways were identified in hypodiploid ALL, with approximately half of the p53 mutations being germline (i.e., a manifestation of Li-Fraumeni syndrome).

Clinical Implications of Genetic Lesions in ALL

At diagnosis, the main adverse features currently being used for treatment decisions in pediatric ALL are *BCR-ABL1*, *MLL*-r, iAMP21, hypodiploidy (fewer than 44 chromosomes), and *MYC* rearrangements. Favorable features are *ETV6-RUNX1* and high hyperdiploidy or the presence of the particular trisomies 4 and 10. In adults, *BCR-ABL1* and *MLL*-r may affect treatment choices, whereas the other abnormalities are too rare or uncertain in impact to be routinely assessed or acted on.

Detection of molecular abnormalities in ALL has important implications for initial risk assignment as well as for disease monitoring. The classical definition of remission is less than 5% lymphoblasts in the bone marrow assessed by morphologic examination. However, newer molecular definitions of remission based on MRD detection are far more sensitive in identifying patients at risk of ultimate morphologic relapse. MRD can be measured by flow cytometry or PCR and sensitivity ranges from 10^{-3} to 10^{-6}. Numerous pediatric studies have demonstrated that MRD positivity has poor prognostic impact independent of other risk factors, at time points ranging from early induction to 24 months into treatment. Conversely, rapid achievement of MRD negativity before the end of induction identifies a favorable risk group that might be spared the adverse effects of high-intensity regimens. Adults tend to have higher MRD levels and more frequent and prolonged duration of MRD positivity—not surprisingly, given the comparative drug resistance of their disease. Nevertheless, MRD does appear to have independent predictive value in the adult population as well.

Conclusions

Unraveling the molecular genetics of ALL has paved the way toward many advances in our understanding of leukemogenesis, including improving our ability to stratify patients by risk group at diagnosis, tracking disease status during treatment, and identifying novel therapeutic targets. On a practical level, however, the recent explosion in the quantity of molecular genetic information regarding ALL poses an increasing challenge to those attempting to determine which abnormalities can best be exploited in current and future clinical trials.

Molecular Biology of Childhood Neoplasms

Cancer is the most common cause of disease-related death in children beyond the newborn period. Although childhood cancers, as a group, account for only a small proportion of all human cancer,[1] their unique biologic features, cell of origin, and response to therapy make them intriguing models with which to study and understand the process of human carcinogenesis.

Although most childhood cancers occur sporadically and their etiology remains unclear, hereditary or familial factors are evident in 25% to 40% of cases.[2] Obvious environmental influences on cancer initiation are not generally apparent. Cancer predisposition syndromes manifesting in childhood in which nonmalignant phenotypic features are not observed include hereditary retinoblastoma (RB), Li-Fraumeni syndrome, and familial polyposis; others such as von Hippel–Lindau disease and Gorlin syndrome are associated with the coincident presentation of both benign and malignant neoplasms. Nonrandom molecular and cytogenetic alterations are frequently observed in most childhood cancers. These "markers" provide not only unique diagnostic identifiers but also frequently prognostic value with respect to disease outcome and anticipated response to therapy. Many of these genetic markers also recapitulate normal developmental processes and thus offer a window into the biologic mechanisms of carcinogenesis and normal embryologic growth and development (Table 27-1). Importantly, the introduction of routine predictive genetic testing together with the development and implementation of clinical surveillance protocols has led to early tumor detection and improved survival for both children and adults with hereditary forms of cancer. In this chapter, we address the diversity of molecular mechanisms in several prototypical childhood cancers and cancer predisposition syndromes.

Retinoblastoma

Clinical Description and Pathology

Retinoblastoma (RB) is a rare childhood tumor thought to arise in the embryonic retinal epithelium. Although the incidence of RB is only approximately 1 in 20,000 births, or some 200 new cases per year in North America,[3] this tumor has been a target of intense research interest. RB is the prototype cancer caused by mutations of a tumor suppressor gene. Tumors are often bilateral and multifocal. In approximately 40% of RB cases, the disease is inherited as an autosomal dominant trait, with a penetrance approaching 100%.[4] The remaining 60% of cases are sporadic (nonheritable). Fifteen percent of unilateral RB is heritable but by chance develops in only one eye. Survivors of heritable retinoblastoma have a 100-fold increased risk of developing mesenchymal tumors such as osteogenic sarcoma, fibrosarcoma, and melanoma later in life. RB is characterized by the rapid growth of undifferentiated neuroblastic precursors derived from various layers of retinal ganglion cells. The cells are small and round with a high nuclear:cytoplasmic ratio, exhibiting numerous mitoses that reflect their rapid proliferative rate. RB cells appear undifferentiated, with evidence of ganglionic differentiation, including the presence of Flexner-Wintersteiner rosettes.

Tumors that are limited to the globe are staged according to the schema of Reese and Ellsworth, which is based on the number and size of the tumors.[5] These classification systems predict the likelihood of obtaining local tumor control and preservation of vision. Each eye is staged individually. RB can spread beyond the orbit by direct invasion of adjacent tissue and hematogenous spread. The treatment of patients with RB depends on the size of the tumor and the extent of tumor invasion at the time of diagnosis. Surgery is the mainstay of treatment for children with unilateral RB. Large intraocular tumors as well those with bilateral multiple tumors are treated with adjuvant chemotherapy.

Genetics and Cell Biology

The *RB* gene maps to chromosome 13q14.[6] Biallelic disruption of the *RB* gene leads to disease—an observation consistent with Knudson's "two-hit" theory of carcinogenesis.[4,7] *RB* consists of 27 exons and encodes pRB, a 105-kDa nuclear phosphoprotein plays a central role in the control of cell cycle

Table 27-1 Acquired Molecular and Cytogenetic Abnormalities in Childhood Neoplasms

regulation, particularly in determining the transition from G_1 through S (DNA synthesis) phase in virtually all cell types.[8]

In the developing retina, inactivation of the *RB* gene is necessary and sufficient for tumor formation. It is now clear, however, that these tumors develop as a result of a more complex interplay of aberrant expression of other cell cycle control genes. In particular, a tumor surveillance pathway mediated by Arf, MDM2, MDMX, and p53 is activated after loss of pRB during development of the retina. In a small fraction of RB tumors, no *RB1* mutations are detected; in the majority of these, high-level amplification of the MYCN oncogene is observed, suggesting a novel mechanism of tumorigenesis in the presence of nonmutated *RB1* genes.[9] Not only do these observations provide a provocative biologic mechanism for tumor formation in retinoblastoma, but they also point to potential molecular targets for developing novel therapeutic approaches to this tumor. For example, the MDM2/MDMX antagonist, Nutlin-3a, efficiently targets the p53 pathway and is effective as an ocular formulation in treating RB in orthotopic xenografts.[10]

Wilms Tumor

Clinical Presentation and Pathology

Wilms tumor (WT), or nephroblastoma, is an embryonal malignancy that arises from remnants of immature kidney.[11] It affects approximately 1 in 7000 children, usually before the age of 6 years (median age at diagnosis, 3.5 years). Five percent to 10% of children present with synchronous or metachronous bilateral tumors. WT typically presents as an asymptomatic abdominal mass, although a small fraction of children have symptoms such as hematuria or hypertension. Approximately 20% of children present with metastatic disease.

The relationship between WT and aberrations of normal development is striking. In early development, the embryonal mesonephros emerges from a complex interaction between epithelial-derived ureteric bud tissue and mesenchymal-derived metanephric blastema through a series of differentiation events. Mature nephrons derived from the mesonephros are composed of nephroblasts, tubules, and stromal tissues that ultimately form the adult kidney. These different tissues together confer the distinctive "triphasic" histologic features of WT that arise in the intralobar area. Tumors that arise in the perilobar area tend to be biphasic or monomorphic, typically epithelial. This presentation suggests that these tumors arise from a cell that is more prevalent later in development, having a more limited potential to differentiate along multiple lineages.

A peculiar feature of WT is its association with nephrogenic rests, foci of primitive but nonmalignant cells whose persistence suggests a defect in kidney development. These precursor lesions are found within the normal kidney tissue of more than one third of children with WT. Nephrogenic rests may persist, regress spontaneously, or grow into large masses that simulate true WT and present a difficult diagnostic challenge.[11] Another intriguing feature of WT is its association with specific congenital abnormalities, including genitourinary anomalies, sporadic aniridia, mental retardation, and hemihypertrophy. A genetic predisposition to WT is observed in two distinct disease syndromes with urogenital system malformations—the WAGR (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation) syndrome[12] and the Denys-Drash syndrome (DDS[13])—and in Beckwith-Wiedemann syndrome (BWS[14]). WT was the first of the solid tumors of childhood recognized as being curable even in the setting of metastatic disease. Sequential clinical treatment protocols evaluated by the National Wilms Tumor Study have led to effective multimodality approaches that cure up to 90% of children with WT. The cornerstone of therapy is surgery; chemotherapy agents with or without radiotherapy are used to treat minimal residual or metastatic disease.

Genetics

The WAGR syndrome is associated with constitutional deletions of chromosome 11q13.[12] Whereas it is now known that the WAGR deletion encompasses a number of

contiguous genes, including the aniridia gene *Pax6*, cytogenetic observation in patients with WAGR was also important in the cloning of the *WT1* gene at chromosome 11p13. *WT1* spans approximately 50 kb of DNA and contains 10 exons that encode the WT1 protein transcription factor. DDS, the second syndrome closely associated with this locus, is a rare association of WT, intersex disorders, and progressive renal failure.[13] Virtually all patients with DDS carry germline *WT1* point mutations.

WT1 is altered in only 10% of Wilms tumors. This observation implies the existence of alternative loci in the etiology of this childhood renal malignancy. One such locus also resides on the short arm of chromosome 11, telomeric of *WT1*, at 11p15. This gene, designated *WT2*, is associated with BWS. Patients with BWS are at increased risk of developing Wilms tumor, as well as other embryonic malignancies, including rhabdomyosarcoma (RMS), neuroblastoma, and hepatoblastoma.[14] The putative *BWS* gene maps to chromosome 11p15.[15] Whether the BWS gene and *WT2* are one and the same or two distinct yet closely linked genes remains to be determined. Using long-oligonucleotide array comparative genomic hybridization (array CGH), a novel gene termed *WTX* was identified on chromosome Xq11.1. *WTX* is inactivated in one third of WTs, and tumors with *WTX* mutations lack *WT1* mutations.[16] Bilateral WT or a family history of WT occurs in 1% to 5% of patients. Although linkage studies have indicated that the gene for familial WT must be distinct from *WT1* and *WT2*, and from the gene that predisposes to BWS, this gene has been neither cytogenetically localized nor isolated.

Tumors of the Peripheral Nervous System: Neuroblastoma

Clinical Presentation and Pathology

Neuroblastoma (NB) is the most common tumor of the peripheral sympathetic nervous system in children. The embryonic neural crest gives rise to the peripheral nervous system including cranial and spinal sensory ganglia, autonomic ganglia, the adrenal medulla, and other para-endocrine cells distributed throughout the body.

NB most commonly arise in cells of the adrenal medulla and at other abdominal retroperitoneal sites of the known peripheral nervous system. Approximately 15% of cases occur in the paravertebral thoracic cavity in close association with the dorsal root ganglion. Most cases of NB (60% to 70%) present with metastatic disease, most commonly involving bone, bone marrow, and liver. NB is characterized histologically by the presence of small, round cells with hyperchromatic nuclei and stippled chromatin. At a cytogenetic level, homogeneously stained regions and double-minute chromosomes are typically observed (Figure 27-1). A hallmark of its light microscopic appearance is the presence of Homer-Wright rosettes characterized by tumor cell clusters around a central mesh of cell processes, termed *neuropile*.

The clinical stage and age of onset are highly significant independent prognostic variables. For example, a unique presentation of NB, stage IV-S (IV-special) is frequently associated with spontaneous remission.[17] This form of the disease typically presents in infants younger than 1 year of age with evidence of remote disease in the liver and bone marrow, though sparing bone. It is not known whether IV-S NB represents metastatic disease or a multifocal nonclonal disorder of neuroblast development. Stages I and II NB can generally be effectively managed with surgical resection alone, although those rare patients with low-stage disease and adverse biologic markers often require adjuvant chemotherapy. Multimodality therapy, including high-dose chemotherapy, hematopoietic stem cell harvest and rescue, radiation therapy, ^{123}I-MIBG therapy, and Ch14.18 immunotherapy are required to achieve remissions in stage IV (and to a lesser

extent stage III) NB, although remission is maintained in less than 40% of patients.

Genetics and Cell Biology

Nonrandom cytogenetic abnormalities are observed in more than 75% of neuroblastomas. The most common of these is deletion or rearrangement of the short arm of chromosome 1, although loss, gain, and rearrangements of chromosomes 10, 11, 14, 17, and 19 have also been reported. Two other unique cytogenetic rearrangements are highly characteristic of neuroblastoma: homogeneous staining regions and double-minute chromosomes (see Figure 27-1). These contain regions of amplification of the *N-myc* gene, an oncogene with considerable homology to the cellular proto-oncogene c-myc. *N-myc* amplification is associated with rapid tumor progression, and virtually all neuroblastoma tumor cell lines demonstrate amplified and highly expressed *N-myc*.[18] Decreased *N-myc* expression is observed in association with the in vitro differentiation of neuroblastoma cell lines.[19] This observation formed the basis for therapeutic trials demonstrating a survival advantage to patients treated with *cis*-retinoic acid.[20]

Neuroblastoma cells that express the high-affinity nerve growth factor receptor trkA can be terminally differentiated by nerve growth factor and demonstrate morphologic changes typical of ganglionic differentiation. Tumors showing ganglionic differentiation and *trkA* gene activation have a favorable prognosis. Expression of trkB receptor is associated with poor prognosis tumors and appears to mediate resistance to chemotherapy.

In addition to chromosomal loss on chromosome 1p36, unbalanced loss of heterozygosity at 11q23 is independently associated with decreased event-free survival. Alterations at 11q23 occur in almost one third of neuroblastomas, being most commonly associated with stage IV disease and age at diagnosis greater than 2.5 years. Telomerase expression and telomere length are yet other valuable markers of clinical significance.[21] In particular, short telomere length is predictive of favorable prognosis, regardless of disease stage, whereas long or unchanged telomeres are predictive of poor outcome. Both in vitro and in vivo studies suggest that telomerase inhibition may represent a unique mechanism for novel biological treatment of NB.[22] A small subset of neuroblastomas is inherited in an autosomal dominant fashion. Until recently, the only gene definitively associated with neuroblastoma risk was *PHOX2B*, also linked to central apnea.[23] Utilizing high-resolution microarray and next-generation sequencing approaches, de novo or inherited missense mutations in the tyrosine kinase domain of the ALK (anaplastic lymphoma kinase) gene on chromosome 2p23 have been observed in many hereditary neuroblastoma families, as well as in sporadic cases,[24] although no clear correlation with stage of disease has been observed. Current Phase I/II clinical trials with ALK inhibitors substantiate the value of such target identification for novel therapies. However, combination whole-exome, genome, and transcriptome sequencing of neuroblastoma identifies few recurrently mutated genes (*ALK*, *PTPN11*, *ATRX*, *MYCN*, and *NRAS*) or pathogenic germline variants (*ALK*, *CHEK2*, *PINK1*, and *BARD1*).[25]

Tumors of the Peripheral Nervous System: Ewing Sarcoma and Primitive Neuroectodermal Tumors

Clinical Description and Pathology

The Ewing sarcoma family of tumors (ESFT) make up the second most common bone malignancy after osteosarcoma in children and young adults with a peak incidence at age 15. Rarely, these tumors can arise in the soft tissues. ESFT includes Ewing sarcoma, peripheral primitive neuroectodermal (PPNET), and Askin tumors, among others. These tumors share indistinguishable genetic alterations, immunohistochemical profiles, and lineage-specific marker expression patterns. As in the case of neuroblastoma, therapy for patients with localized PPNET or ES is highly effective, whereas the prognosis for patients with metastatic disease is extremely poor even in the setting of multimodal therapy. Surgery and radiation are used for primary local control with multi agent chemotherapy used to treat systemic disease.

Genetics and Cell Biology

PPNET and ES typically carry a t(11;22)(q24;q12) chromosomal rearrangement, although variant translocations have been observed.[26] The translocation breakpoint has been molecularly cloned and characterized as an in-frame fusion between the 5′ half of the ES gene, *EWS*, on chromosome 22 and the 3′ half of the human homologue of an ETS transcription family member, *FLI1*, on chromosome 11. The resultant chimeric protein replaces the DNA-binding domain of EWS with the ETS-like binding domain of Fli-1, retaining the DNA-binding activity of Fli-1. Important transcriptional targets of the EWS-Fli1 transcription factor may include the IGF-I receptor,[27] which is thought to play a role in the pathogenesis of ES. Several studies have indicated the importance of the autocrine stimulation of the insulin-like growth factor I receptor (IGF-IR) for cell transformation and proliferation induced by EWS-Fli1.

Small-molecule inhibitors that block the EWS-Fli1 interaction with RNA helicase A showed promise in inhibiting Ewing sarcoma cell growth[28]; however, weak association of IGF-1R activity in ES cell lines and primary tumors indicate that it is not an ideal druggable target in this tumor.[29] Expression profiling analysis has also revealed that *TP53* is transcriptionally upregulated by the EWS-ETS fusion gene. *NKX2.2* has been found to be another target gene of EWS-Fli1 that is required for malignant transformation. Several variant translocations have also been identified, invariably fusing the *EWS* gene to an ETS family member. Interestingly, it has been suggested that the specific fusion protein expressed in ESFT has prognostic significance.[30] In particular, a rearrangement that joins exon 7 of *EWS* to exon 6 of *Fli1* may confer a more favorable outcome. As well, use of RNA sequencing (RNAseq) in EWS-FLI fusion negative ESFTs has identified at least one novel alteration that fuses *BCOR* (encoding the BCL6 co-repressor) on chromosome X 11p.14 with *CCNB3* (encoding the testis-specific cyclin B3) on chromosome X 11p.22, essentially identifying a novel sarcoma phenotype.[31]

Rhabdomyosarcoma

Clinical Description and Pathology

Sarcomas arise in supportive tissues that have their origin in embryonic mesenchyme. These tissues include fibrous tissue, muscle, cartilage, and bone. Each of the different sarcomas exhibits evidence of differentiation along one or more of these cellular lineages.

Rhabdomyosarcoma is the most common soft tissue sarcoma of childhood, with approximately 200 new cases annually in the United States, accounting for nearly 10% of all childhood solid tumors. The incidence of RMS is higher in males than in females (1.4:1), and most cases are diagnosed in children under the age of 6.[32] Rhabdomyosarcoma is believed to arise from primitive embryonic mesenchymal cells committed to the skeletal muscle lineage; however, RMS tumors have been found in tissues not usually containing striated muscle, such as the urinary bladder. Multiple histologic subtypes exist, including predominantly embryonal (ERMS; 63% of all tumors) and alveolar (ARMS; 19%) morphologies. ARMS tend to occur in the extremities and exhibit a more aggressive clinical behavior than ERMS, which tend to present in an axial distribution and with a somewhat more favorable prognosis. The management of RMS typically includes local control with both surgery and radiation treatment, with neo-adjuvant chemotherapy being used for management of known and micrometastatic disease. It is notoriously difficult to achieve a sustained remission, or cure, for children with metastatic RMS, particularly those with the alveolar variant. Although the overall survival for childhood RMS is approximately 75%, those with metastatic disease have a less than 20% chance of cure.

Genetics and Cell Biology

Characteristic genetic lesions have been found in both major subtypes of RMS. More than 75% of tumors of the alveolar subtype demonstrate one of two chromosomal translocations, t(2;13)(q35;q14) or t(1;13)(p36;q14),[33,34] which fuse the 5′ DNA-binding region of *PAX-3* on chromosome 2 or *PAX-7* on chromosome 1, respectively, which are implicated in neuromuscular development, to the 3′ transactivation domain region of the *FKHR (FOXO1A)* gene—a member of the forkhead family of transcription factors commonly associated with regulation of apoptosis (Figure 27-2). Tumors with the t(2;13) translocation have a much poorer prognosis than those with the rarer t(1;3) rearrangement. Interestingly, fusion-negative ARMS tumors are clinically and molecularly indistinguishable from embryonal RMS, and demonstrate outcomes more closely resembling ERMS than fusion-positive ARMS, thus making the presence of the PAX-FKHR fusion a diagnostic criterion for ARMS.[35] Additional epigenetic or genetic events seem required for RMS tumorigenesis. PAX-3-FKHR fusion is associated with increased expression of c-met. Met is the receptor tyrosine kinase for hepatocyte growth factor/scatter factor and is overexpressed in embryonal and alveolar RMS. Other frequently reported genetic alterations that may be common to embryonal and alveolar RMS include activated forms of *N-* and *K-RAS*, inactivating *TP53* mutations, and amplification and overexpression of *MDM2*, *CDK-4*, and *N-MYC*.

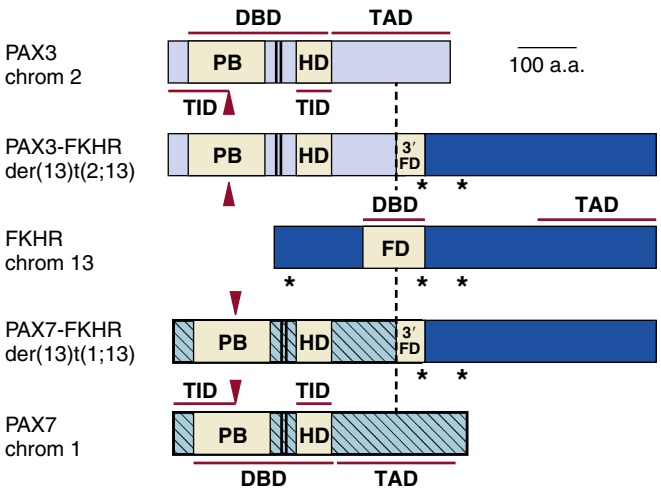

Figure 27-2 Translocation breakpoints in rhabdomyosarcoma.

At the molecular level, embryonal tumors are characterized by loss of heterozygosity (LOH) at the 11p15 locus, which is of particular interest because this region harbors the *IGF2* gene.[36] The LOH at 11p15 occurs by loss of maternal and duplication of paternal chromosomal material.[37] Although LOH is normally associated with loss of tumor suppressor gene activity, in this instance LOH with paternal duplication may result in activation of *IGF2*. This occurs because *IGF2* is now known to be normally imprinted—that is, this gene is normally transcriptionally silent at the maternal allele, with only the paternal allele being transcriptionally active. Thus, LOH with paternal duplication potentially leads to a twofold gene-dosage effect of the *IGF2* locus.

In addition to the somatic molecular changes associated with RMS, the tumor is also observed in hereditary cancer syndromes, including Li-Fraumeni syndrome (see following section), in which carriers harbor constitutional mutations of the *TP53* tumor suppressor gene. The possible importance of the patched gene, *PTCH*, in the development of RMS is suggested by the finding that mice lacking this gene develop RMS. *PTCH* is mutated in the germline of patients with Gorlin syndrome, a disorder that includes predisposition to tumor (medulloblastoma) development. Strikingly, *PTCH* is shown to regulate another gene, *GLI*, which is found to be amplified in RMS and Gorlin syndrome–associated tumors. Activation of the *HRAS* oncogene by heterozygous germline mutations predisposes to RMS in Costello syndrome,[38] further highlighting the multiple molecular pathways associated with rhabdomyosarcomagenesis.

Childhood Sarcomas: Osteosarcoma

Clinical Description and Pathology

Osteosarcoma (OS) occurs most frequently in adolescence during a period of rapid bone growth. It is the most common tumor in this age group other than those of hematopoietic tissues. OS most commonly occurs at metaphyseal growth plates of long bones, develops earlier in girls than in boys, and is more frequent in taller children. These observations suggest an important role for cellular proliferation in the oncogenic conversion of immature bone precursors from which these tumors are thought to arise. The histologic diagnosis of OS is made when tumor osteoid and disorganized bone can be identified within malignant stromal tissues. A wide range of histologic patterns is seen, although the natural history of these variants is not yet clinically distinguishable. Tumors are classified as osteoblastic, chondroblastic, or fibroblastic OS depending on whether the predominant differentiation is a long bone, cartilage, or stromal tissue pathway, respectively. Surgery is the primary therapeutic modality in the management of osteosarcoma. Neo-adjuvant chemotherapy is used to control micrometastases, which are present in 75% of patients. The response to chemotherapy, as measured by histologic grading of the degree of tumor necrosis, is a key prognostic factor. Biologic response modifiers, monoclonal antibodies, and targeted small-molecule kinase inhibitors have had no impact on the treatment of osteosarcoma.

Genetics and Cell Biology

OS is characterized by the presence of complex unbalanced karyotypes.[39] Combined inactivation of the RB1 and T*P53* tumor suppressor pathways are observed in most OS, indicating important roles for both these genes in OS pathogenesis. Further evidence for the role of p53 in OS pathogenesis includes the predisposition of patients with germline *TP53* mutations (Li-Fraumeni syndrome [LFS]) to develop OS. There is low prognostic significance of *TP53* mutations in sporadic OS, with no impact on distant recurrence. Furthermore, p53 status is concordant in paired samples of primary and distant metastases, suggesting that p53 pathway alterations may occur early in OS pathogenesis. Modifying effects of other expressed genes are being explored in OS. In particular, amplification of chromosome 12q13 region (containing *MDM2* and *CDK4*) or deletion of *INK4A* can disrupt both the p53 and RB pathways. Many recurrent, nonrandom chromosomal abnormalities are observed in OS. Common numerical abnormalities in OS include gain of chromosome 1; loss of chromosomes 9, 10, 13 (at the *RB1* locus), and/or 17 (at the *TPS3* locus); and partial or complete loss of the long arm of chromosome 6. Frequent structural abnormalities include rearrangements of chromosomes 11, 19, and 20. Genome-wide efforts to identify potential tumor suppressor genes associated with LOH in OS have identified at least one novel locus encompassing the *LSAMP* gene on chromosome 3p13.4.[40] Examination of 38 chromosomal arms from OS tumor samples for LOH has found that the mean frequency of LOH is 30.79% for any chromosome arm, an unusually high mean frequency for a childhood tumor. Moreover, several chromosome arms (3q, 13q, 17p, and 18q) underwent LOH with a frequency more than two standard deviations higher than the average ($p < 0.002$).[26] Further mitotic mapping has identified minimal regions thought to contain candidate tumor suppressor loci on chromosomal arms 3q26.2 and 18q21.33,[41] though specific gene identification has been elusive. Finally, an intriguing mechanism of chromosomal instability defined as "chromothripsis," in which chromosomal fragments undergo a catastrophic one-time rearrangement, has been observed in about 25% of osteosarcomas—far greater than the 2% to 3% observed in other human cancers.[42]

Abnormalities of bone growth and remodeling are thought to play an important role in the pathogenesis of OS. Normal bone repair involves proliferation of mesenchymally derived precursor cells mediated by platelet-derived growth factor (PDGF), epidermal growth factor (EGF), IGFs, interferon-α, and other mitogens. The PDGF receptor encodes a tyrosine kinase; when PDGF binds to its receptor, it induces expression of fos, myc, and a cascade of cellular genes important for initiating proliferation. EGF may also play a role in OS pathogenesis. Some OS cell lines express EGF receptor and proliferate in response to exposure to EGF. The mitogenic response to both EGF and PDGF may be blocked by TGF-β, which at low doses may stimulate the proliferation of cells.

Interest in other signaling pathways has implicated the Fas cell death pathway in determining chemosensitivity and metastatic behavior in OS.[43] Tumor cells expressing surface Fas will apoptose when Fas ligand (FasL) is present unless a mechanism of resistance is present. This has been suggested by studies in which metastasis-prone OS cell lines that have been transfected with Fas demonstrate reduced metastatic potential. In addition, overexpression of CyclinE1, which promotes oncogenic transformation of osteoblasts and confers resistance to cisplatin (a drug that forms the backbone of osteosarcoma therapy), offers new avenues for therapy.[44]

Cancer Predisposition Syndromes

Several hereditary cancer syndromes are associated with the occurrence of childhood as well as adult-onset neoplasms. Although it is beyond the scope of this chapter to describe them all, it is worthwhile to discuss a few to highlight the important molecular basis on which these disorders develop (Table 27-2).

Li-Fraumeni Syndrome

Li-Fraumeni familial cancer syndrome is the prototypical familial cancer predisposition syndrome. The definition of classical LFS requires a proband with a sarcoma diagnosed before 45 years of age, a first-degree relative diagnosed as having any cancer when younger than 45 years, and a first- or second degree relative with a diagnosis of cancer when younger than 45 years or a sarcoma at any age.[45] The classic spectrum of tumors that includes soft tissue sarcomas, osteosarcomas, breast cancer, brain tumors, leukemia, and adrenocortical carcinoma (ACC) has been overwhelmingly substantiated by numerous subsequent studies, although other cancers, usually of particularly early age of onset, are also observed. Similar patterns of cancer that do not meet the classic definition have been termed Li-Fraumeni–like syndrome (LFS-L). The sensitivity and specificity of the Chompret criteria are 82% and 58%, respectively, making it perhaps the most rigorous and relevant definition to justify *TP53* mutation analysis.[46]

Germline alterations of the *TP53* tumor suppressor gene are associated with LFS.[47,48] These are primarily missense mutations that yield a stabilized mutant protein. The spectrum of germline *TP53* mutations is similar to that of somatic mutations found in a wide variety of tumors. Carriers are heterozygous for the mutation, and in tumors derived from these individuals, the second (wild-type) allele is frequently deleted or mutated, leading to functional inactivation. Several comprehensive databases document all reported germline (and somatic) *TP53* mutations and are of particular value in evaluating novel mutations as well as phenotype-genotype correlations. Approximately 75% of "classic" LFS families have detectable *TP53* alterations. It is not clear whether the remainder are associated with the presence of modifier genes, promoter defects yielding abnormalities of p53 expression, or simply the result of weak phenotype-genotype correlations (i.e., the broad clinical definition encompasses families that are not actual members of LFS). The variability in type of cancer and age of onset within and between LFS families suggests that expression of modifier genes might influence the underlying mutant *TP53* genotype. Several of these have been described, including those that accelerate age of tumor onset in *TP53* mutation carriers such as a single-nucleotide polymorphism (SNP) in the promoter of the *MDM2* gene (SNP 309) that is involved in the p53 degradation pathway[49]; accelerated telomere attrition—perhaps inducing chromosomal chromothripsis in somatic cells[50]; and increased constitutional copy number variation (CNVs).[51] Others, such as a 16-bp duplication in *TP53* intron 3 (PIN3), delay tumor onset by up to 19 years.[52] Until recently, options for intervention in LFS were thought to be limited, but two studies have clearly demonstrated the value of total body imaging (with or without biochemical marker studies) in *TP53* mutation carriers (Table 27-3).[53,54] This has proven to be effective in early tumor detection, which leads to improved survival—offering hope for these patients that the combination of molecular testing with early clinical surveillance can interfere with the natural history of the disease.

Hereditary Paraganglioma Syndromes

Paragangliomas are benign non–catecholamine-secreting tumors that often occur in the head and neck region, along the parasympathetic chain. Catecholamine-secreting tumors can develop along the sympathetic chain, in the adrenal

Table 27-2 Hereditary Syndromes Associated with Childhood Neoplasms

Syndrome	OMIM Entry	Major Tumor Types	Mode of Inheritance	Genes
Hereditary Gastrointestinal Malignancies				
Adenomatous polyposis of the colon	175100	Colon, thyroid, stomach, intestine, hepatoblastoma	Dominant	*APC*
Juvenile polyposis	174900	Gastrointestinal	Dominant	*SMAD4/DPC4*
Peutz-Jeghers syndrome	175200	Intestinal, ovarian, pancreatic	Dominant	*STK11*
Genodermatoses with Cancer Predisposition				
Nevoid basal cell carcinoma syndrome	109400	Skin, medulloblastoma	Dominant	*PTCH*
Neurofibromatosis type 1	162200	Neurofibroma, optic pathway glioma, peripheral nerve sheath tumor	Dominant	*NF1*
Neurofibromatosis type 2	101000	Vestibular schwannoma	Dominant	*NF2*
Tuberous sclerosis	191100	Hamartoma, renal angiomyolipoma, renal cell carcinoma	Dominant	*TSC1/TSC2*
Xeroderma pigmentosum	278730, 278700, 278720, 278760, 278740, 278780, 278750, 133510	Skin, melanoma, leukemia	Recessive	*XPA, B, C, D, E, F, G, POLH*
Rothmund-Thomson syndrome	268400	Skin, bone	Recessive	*RECQL4*
Leukemia/Lymphoma Predisposition Syndromes				
Bloom syndrome	210900	Leukemia, lymphoma, skin	Recessive	*BLM*
Fanconi anemia	227650	Leukemia, squamous cell carcinoma, gynecological system	Recessive	*FANCA,B,C,D_2,E,F,G*
Schwachman-Diamond syndrome	260400	Leukemia/myelodysplasia	Recessive	*SBDS*
Nijemegen breakage syndrome	251260	Lymphoma, medulloblastoma, glioma	Recessive	*NBS_1*
Ataxia telangiectasia	208900	Leukemia, lymphoma	Recessive	*ATM*
Genitourinary Cancer Predisposition Syndromes				
Simpson-Golabi-Behmel syndrome	312870	Embryonal tumors, Wilms tumor	X-linked	*GPC3*
von Hippel–Lindau syndrome	193300	Retinal and central nervous hemangioblastoma, pheochromocytoma, renal cell carcinoma	Dominant	*VHL*
Beckwith-Wiedemann syndrome	130650	Wilms tumor, hepatoblastoma, adrenal carcinoma, rhabdomyosarcoma	Dominant	*CDKN1C/NSD1*
Wilms tumor syndrome	194070	Wilms tumor	Dominant	*WT1*
WAGR syndrome	194072	Wilms tumor, gonadoblastoma	Dominant	*WT1*
Costello syndrome	218040	Neuroblastoma, rhabdomyosarcoma, bladder carcinoma	Dominant	*H-Ras*
Central Nervous System Predisposition Syndromes				
Retinoblastoma	180200	Retinoblastoma, osteosarcoma	Dominant	*RB1*
Rhabdoid predisposition syndrome	601607	Rhabdoid tumor, medulloblastoma, choroid plexus tumor		*$SNF5/INI1$*
Medulloblastoma predisposition	607035	Medulloblastoma	Dominant	*SUFU*
Sarcoma/Bone Cancer Predisposition Syndromes				
Li-Fraumeni syndrome	151623	Soft tissue sarcoma, osteosarcoma, breast, adrenocortical carcinoma, leukemia, brain tumor	Dominant	*TP53*
Multiple exostosis	133700, 133701	Chondrosarcoma	Dominant	*EXT1/EXT2*
Werner syndrome	277700	Osteosarcoma, meningioma	Recessive	*WRN*

Table 27-3 Clinical Criteria for Classic Li-Fraumeni Syndrome, LFS-Like Criteria, and Chompret Criteria

Classic LFS Criteria
Proband diagnosed with sarcoma before age 45
A first-degree relative with cancer diagnosed before age 45
A first- or second-degree relative on the same parental lineage with cancer diagnosed before age 45 or a sarcoma at any age
LFS-like Criteria (Birch)
Proband with any childhood cancer or sarcoma, brain tumor, or adrenocortical cancer diagnosed before age 45
First- or second-degree relative with typical LFS cancer (sarcoma, breast cancer, brain tumor, leukemia, or adrenocortical cancer) diagnosed at any age, AND
A first- or second-degree relative on the same side of the family with any cancer diagnosed under age 60
LFS-like Criteria (Eeles)
Two first- or second-degree relatives with LFS-related malignancies at any age
Chompret Criteria for LFS
Proband diagnosed with a narrow-spectrum cancer (sarcoma, brain tumor, breast cancer, or adrenocortical carcinoma) before age 46 and at least one first- or second-degree relative with any cancer, except breast cancer if the proband has breast cancer
Proband with multiple primary tumors, two of which belong to the narrow spectrum and the first of which occurred before age 46, regardless of family history
Proband with adrenocortical cancer or choroid plexus carcinoma, regardless of age at diagnosis or family history

medulla (pheochromocytoma) alongside the aortopulmonary vasculature, in the organ of Zuckerkandl, or even in the bladder and vas deferens. Paragangliomas have an estimated population incidence of 1 in 30,000. However, in the presence of an underlying germline succinyl dehydrogenase (*SDHx*) mutation, the tumor rate is extraordinarily high, with disease penetrance approaching 80%.[55,56] Germline *SHDx* mutations are identified in nearly 30% of patients with nonmetastatic paragangliomas and pheochromocytomas and in 44% of adults and 81% of pediatric patients with metastatic disease.[57] Other tumors, including renal cell carcinoma, oncocytoma, papillary thyroid cancer, pituitary tumors, gastrointestinal stromal tumor (GIST), and even neuroblastoma, are observed in *SDHx* mutation carriers. Although patients with localized asymptomatic disease are frequently observed, those with metastatic disease are particularly difficult to treat, often requiring multiple surgical procedures. Systemic chemotherapy is generally not effective, although the introduction of multitargeted kinase inhibitors provides a new avenue of molecularly targeted therapy.[58]

Genetics

Succinate dehydrogenase (SDH) is part of respiratory complex II in the mitochondrion, and this enzyme complex is responsible for converting succinate to fumarate as part of the Krebs cycle. SDH is composed of four distinct proteins called SDHA, SDHB, SDHC, and SDHD.[59] A fifth gene called *SDHAF2*, or SDH Assembly Factor 2, is responsible for assembling all of the individual SDH proteins into a fully functioning enzyme complex.[60] Germline mutations in each of these *SDHx* genes may lead to development of paragangliomas or pheochromocytomas. Lack of a functioning SDH complex leads to increased succinate, with subsequent increases in HIF signaling and possible histone deregulation. Germline mutations in other genes such as *NF1*, *VHL*, *RET*, *TMEM127*, and *MAX* also have been associated with the development of paragangliomas and pheochromocytomas (Figure 27-3). Based on gene expression and pathway analysis, these tumors can be divided into two different clusters that correspond to their underlying gene mutations: Cluster 1 (Cluster 1A: *SDHx*, Cluster 1B: *VHL*) associated with pseudohypoxia and aberrant VEGF signaling, and Cluster 2 (*RET/NF1/TMEM127/MAX*) associated with aberrant kinase signaling pathways.

The phenotype associated with each *SDHx* gene mutation leads to a different disease phenotype and clinical presentation, as outlined in Table 27-4.[59] To facilitate genetic diagnosis, risk assessment and treatment options, it is now possible to test for all the *SDHx* genes simultaneously.

Regular surveillance can detect early tumors in patients with underlying germline *SDHx* mutations. As with

surveillance in *TP53* mutation carriers, this is important so that smaller, asymptomatic SDH-deficient tumors can be removed before they transform to malignant and metastatic disease. Although no formalized screening guidelines exist, many clinicians will perform annual physical examinations, blood pressure checks (for hypertension due to increased catecholamines), and blood work for serum metabolites. Previously, urine catecholamines were examined from 24-hour urine specimens, but many clinicians have eliminated urine screening in favor of serum testing. Fractionated plasma metanephrines are the most sensitive and specific serum test for detecting secreting paragangliomas and pheochromocytomas.[61] Increased methoxytyramine, a metabolite of dopamine, seems to be helpful for predicting the likelihood of metastatic disease and for distinguishing SDH-related tumors from VHL-related tumors. However, testing of methoxytyramine remains difficult to obtain on a clinical basis.

Regular imaging has been demonstrated by several groups to be very effective at identifying SDH-related tumors, especially in the setting of negative biochemical results.[62] Screening approaches using rapid-sequence whole-body magnetic resonance imaging (MRI) in conjunction with urinary and or fractionated plasma metanephrine levels are being used widely. Abnormal MRI results (or biochemical results) are followed with positron emission tomography (PET) imaging to refine the anatomical location of the tumor.

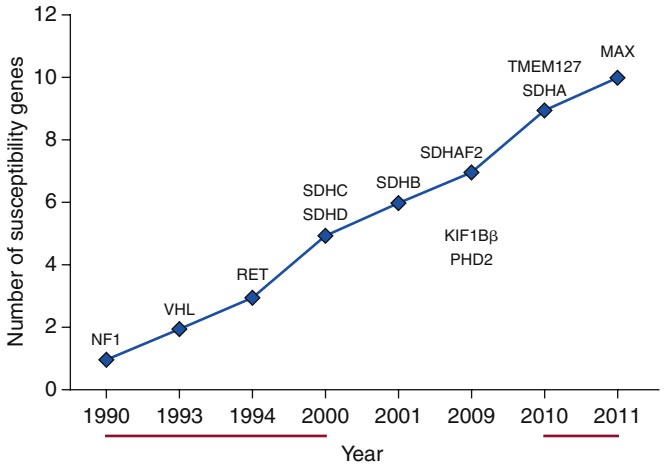

Figure 27-3 Accelerated discovery of genes associated with predisposition to hereditary pheochromocytoma/paraganglioma syndromes.

Beckwith-Wiedemann Syndrome

Beckwith-Wiedemann syndrome occurs with a frequency of 1 in 13,700 births. BWS is associated with a wide spectrum of phenotypic stigmata, including hemihypertrophy/hemihyperplasia, exomphalos, macroglossia, gigantism, and ear pits (posterior aspect of the pinna). Laboratory findings may include profound neonatal hypoglycemia, polycythemia, hypocalcemia, hypertriglyceridemia, hypercholesterolemia, and high serum α-fetoprotein (AFP) level. With increasing age, phenotypic and laboratory features of BWS become less pronounced. Although neurocognitive defects are not universal in BWS, early diagnosis of the condition is crucial to avoid deleterious neurologic effects of neonatal hypoglycemia and to initiate an appropriate screening protocol for tumor development. The increased risk for tumor formation

Associated with neuroblastoma	–	–	–	+	–

in BWS patients is estimated at 7.5% and is further increased to 10% if hemihyperplasia is present. Tumors occurring with the highest frequency include Wilms tumor, hepatoblastoma, neuroblastoma, rhabdomyosarcoma, and ACC.

The genetic basis of BWS is complex, and it does not appear that a single gene is responsible for the BWS phenotype. Various 11p15 chromosomal or molecular alterations have been associated with the BWS phenotype (Table 27-5) and its tumors.[63] Abnormalities in this region affect an imprinted domain, indicating that it is more likely that normal gene regulation in this part of chromosome 11p15 occurs in a regional manner and may depend on various interdependent factors or genes. These include the paternally expressed genes *IGF2* and *KCNQ10T1* and the maternally expressed genes *H19*, *CDKN1C*, and *KCNQ1*. Paternal uniparental disomy, in which two alleles are inherited from one parent (the father), has been reported in approximately 15% of sporadic BWS patients.[64] The insulin/IGF2 region is always represented in the uniparental disomy, although the extent of chromosomal involvement is highly variable. Alterations in allele-specific DNA methylation of *IGF2* and *H19* reflect this paternal imprinting phenomenon.[64] As with other cancer susceptibility syndromes, effective clinical surveillance protocols regularly identify tumors with demonstrable improved outcomes. Regular (every 3 months) AFP levels and abdominal/pelvic ultrasound are recommended until the affected child is about 9 years old and generally beyond the risk age for the associated tumors.

Gorlin Syndrome

Nevoid basal cell carcinoma syndrome, or Gorlin syndrome, is a rare autosomal dominant disorder characterized by multiple basal cell carcinomas, developmental defects including bifid ribs and other spine and rib abnormalities, palmar and plantar pits, odontogenic keratocysts, and generalized overgrowth.[65] The sonic hedgehog (SHH) signaling pathway directs embryonic development of a spectrum of organisms. Gorlin syndrome appears to be caused by germline mutations of the tumor suppressor gene *PTCH*, a *receptor* for SHH. Medulloblastoma develops in approximately 5% of patients with Gorlin syndrome. Furthermore, approximately 10% of patients diagnosed with medulloblastoma by the age of 2 years are found to have other phenotypic features consistent with Gorlin syndrome and harbor germline *PTCH* mutations.[66] Although Gorlin syndrome develops in individuals with germline mutations of *PTCH*, a subset of children with medulloblastoma harbor germline mutations of another gene, *SUFU*, in the SHH pathway, with accompanying LOH in the tumors.

Multiple Endocrine Neoplasia

The multiple endocrine neoplasia (MEN) disorders comprise at least three different diseases—MEN type 1, MEN type 2A, and MEN type 2B, which are all cancer predisposition syndromes that affect different endocrine organs. The most common features of MEN type 1 are parathyroid adenomas (about 90% of cases), pancreatic islet cell tumors (50% to 75% of cases), and pituitary adenomas (25% to 65% of cases).[67] MEN2A is associated with medullary thyroid carcinoma, parathyroid adenoma, and pheochromocytoma. MEN2B is a related disorder, but with onset of the tumors in early infancy, ganglioneuroma of the gastrointestinal tract, and skeletal abnormalities.

Although MEN1 is caused by mutation in the tumor-suppressor gene, MEN1, MEN2A, and MEN2B are caused by mutations in the proto-oncogene *RET*. Further studies

Table 27-5 Beckwith-Wiedemann Syndrome Genetic and Epigenetic Subgroups

	DNA	RNA	Karyotype	Frequency	Inheritance
A. Regional	Paternal 11p15 UPD		Normal lipis	10%-20%	Sporadic
	Disruption of *KCNQ10T1*		Duplication 11p15	1%	Sporadic
			Transl/Inver	1%	Sporadic
B. Domain 1	*H19* hypermethylation	*IGF2* LOI	Normal	2%	Sporadic
	Normal *H19* methylation	*IGF2* LOI	Normal	25%-50%	Sporadic
C. Domain 2	*CDKN1C* mutation	KNQ1OT1 LOI	Normal	5%-10%	Sporadic
	CDKN1C mutation		Normal	25%	AD
	KvDMR1 LOM		Normal	50%	Sporadic

	Unknown		Normal	10%-20%	Sporadic

AD, Autosomal dominant; *LOI*, loss of imprinting; *LOM*, loss of methylation; *UPD*, uniparental disomy.

confirmed constitutional mutations in the *RET* proto-oncogene in families with MEN2A and 2B. The pattern of mutations seen in MEN2 families does not follow the "two-hit hypothesis" for tumor suppressor genes: the RET proto-oncogene is not inactivated, and there is no loss of the second allele in the tumors. Thus the predisposition to cancer in families with MEN2 is based on the inheritance of an activating mutation in the *RET* proto-oncogene. Genetic testing is possible by direct mutation analysis of the 10 exons of the gene.

DICER1 Syndrome

DICER1 syndrome is a very recently characterized phenotypic association of distinctive dysontogenic hyperplastic or overtly malignant tumors. The most frequent of these is the rare childhood lung malignancy pleuropulmonary blastoma. A wide spectrum of other, primarily endocrine, manifestations are evident: ovarian Sertoli-Leydig cell tumors (SLCT), nodular thyroid hyperplasia, pituitary blastoma, papillary and follicular thyroid carcinoma, cervical rhabdomyosarcoma, cystic nephroma, and possibly Wilms tumor.[68] Germline mutations in DICER1 have been identified in children and young adults affected with one or several of these tumors, and somatic DICER1 mutations have been variously identified in sporadic component tumors of the disorder. DICER1 is an endoribonuclease that processes hairpin precursor microRNAs (mi RNAs) into short, functional miRNAs. Mature 5′ miRNAs as well as other components of the RNA-induced silencing complex (RISC) downregulate targeted mRNAs.[69] Unlike the classical "two-hit" mechanism associated with inactivation of tumor suppressor genes, the effect of DICER1 loss of function appears to primarily result from an initial inactivating mutation that reduces by half the amount of wild-type DICER1 protein, whereas the second hit specifically knocks out production of 5′ mature miRNAs. Furthermore, penetrance of the mutations is highly variable, and the explanation for the wide spectrum of both hyperplastic and malignant neoplasms is not clear. Although many of the lesions in *DICER1*-mutation carriers are relatively indolent or benign, the risk in childhood of some potentially lethal tumors such as pleuropulmonary blastoma and pineoblastoma indicates a need for clinical surveillance particularly targeting the lungs, abdomen, and brain.

Molecular and Clinical Surveillance for Cancer Predisposition in Children

As in tumors of adults, continued investigation of the molecular alterations that underlie tumor pathogenesis in children can be expected to provide insights that will lead to a highly specific molecular therapeutic target and that in turn should lead to more specific, more efficacious, and less toxic therapies. Because tumors associated with highly penetrant genetic predispositions often occur early in life, such insights into pathogenesis also provide novel opportunities for the diagnosis of cancer in children. The evidence to justify the use and continued refinement of molecular analysis for tumor diagnosis, prognosis, and development of novel therapeutic avenues for children with cancer is overwhelming. The use of molecular screening as a tool for identification of children at risk for the purpose of developing rational clinical surveillance guidelines is more controversial. Several issues are worth noting. Based on recommendations of the American Society of Clinical Oncology,[70] genetic testing should only be undertaken with fully informed consent, including elements of risk assessment, psychological implications of test results (both benefits and risks), risks of employer or insurance discrimination, confidentiality issues, and options and limitations of medical surveillance or prevention strategies. When children are not competent to give informed consent, the main consideration should be for the welfare of the child. Although screening for some mutations, such as *TP53*, *RET*, or *RB*, is associated with clearly defined beneficial medical management decisions that lead to improved outcomes, it has been argued that presymptomatic identification of other gene mutations, such as in DICER1 syndrome, are of less obvious clinical benefit. Regardless of the scenario, the complexity of the issues underlies the importance that referral of these patients and families is made to an experienced multidisciplinary team including oncologists, geneticists, psychologists, and genetic counselors to facilitate the most appropriate management.

Biology of Adult Myelocytic Leukemia and Myelodysplasia

Introduction

The genesis of human myeloid leukemia involves the deregulation of the differentiation and maturation programs of the hematopoietic myeloid lineage that originates from primitive stem cells with multilineage potential. Myeloid leukemias have been linked to the acquisition of chromosomal aberrations and/or somatic mutations that result in subversion of the proliferation, differentiation, and survival cellular programs. Historically, the different acute myeloid leukemia (AML) phenotypes have been classified into subtypes according to the specific myeloid lineage from which they morphologically appeared to arise. However, it is now widely recognized that the complexity of molecular genotypes largely exceeds the number of recognizable morphologic phenotypes. As more genetic alterations are being recognized in AML, most modern taxonomic efforts have dynamically integrated the wealth of available genetic and emerging molecular information with clinical correlates. Myelodysplastic syndromes (MDSs), on the other hand, are a collection of clonal malignancies arising in hematopoietic stem cells characterized by abnormalities in cellular differentiation, dysplastic changes, increased apoptosis, and a propensity to progress to AML. There is considerable overlapping regarding the types of cytogenetic abnormalities and gene mutations observed in AML and MDS. Most patients with AML or MDS still succumb to their malignancies, which underscores the need to develop novel therapeutic approaches.

Acute Myeloid Leukemia

Cytogenetic aberrations are detected in approximately 50% of patients with AML at the time of diagnosis and remain the strongest predictor of survival (Table 28-1). The remainder, however, will present with a normal karyotype. These patients, although traditionally classified as having intermediate-risk AML, exhibit very variable clinical outcomes, which suggests the involvement of other molecular events in the pathogenesis of this AML subtype. Patients whose pretreatment karyotype is abnormal frequently present with chromosomal losses and/or with balanced reciprocal translocations involving the fusion of a transcription factor important in normal hematopoiesis such as core binding factor (CBF), retinoic acid receptor alpha (RARa), or homeobox (HOX) family members. Patients with normal karyotypes frequently present with mutations in genes involved in survival, proliferation, and differentiation, such as the receptor tyrosine kinase receptors FMS-like tyrosine kinase 3 *(FLT3)* or nucleophosmin member 1 *(NPM1)*. The discovery of these mutations has remarkably improved current risk stratification algorithms in AML.

According to the structural chromosome aberrancies detected at diagnosis, patients can be classified in three risk categories, favorable, intermediate, and adverse. Patients with t(15;17)(q22;q12-21) have an excellent prognosis and those with t(8;21)(q22;q22) or inv(16)(p13q22)/t(16;16)(p13;q22), that is, those with CBF AML, have a relatively favorable prognosis. By contrast, patients with inv(3)(q21q26)/t(3;3)(q21;q26), –7 or a complex karyotype (i.e., at least three chromosome aberrations) have a poor clinical outcome. The presence of the poor-risk cytogenetic abnormalities –5, del(7q), –17/17p–, –18, or –20, are frequently associated with complex karyotypes. The frequency of the latter is higher in patients with secondary AML, and it increases with the patient's age. The value of the pretreatment cytogenetic analysis has been validated across different age groups. Multiple studies in recent years have highlighted the prognostic importance of a number of gene mutations in patients with CN-AML (e.g., *NPM1*, *FLT3*, and *DNMT3a* mutations).

Table 28-1 Frequent Chromosomal Aberrations in AML

	Genes	Morphological Association	Incidence*
Translocations/Inversions			
t(8;21)(q22;q22)	*RUNX1;RUNX1T1*	M2 with Auer rods	6%
inv(16)(p13q22)or t(16;16)(p13;q22)	*CBFB;MYH11*	M4Eo	7%

Molecular Pathogenesis of AML

The most frequently mutated genes in AML encode transcription factors, which are typically implicated in chromosomal translocations that result in their inappropriate activation in the hematopoietic compartment, resulting in impairment of maturation and differentiation of myeloid cells (e.g., CBF translocations and *RARα* and *MLL* gene rearrangements) (Figure 28-1). Frequent types of mutations are those that confer a proliferative and survival advantage to cells (i.e., activating mutations). An example of the latter include mutations in *KIT* or *FLT3* (Table 28-2). Mutations in AML are a concept in flux, both during the natural course of the disease and during the course of therapy (i.e., clonal evolution), as shown by whole-genome sequencing analyses performed in paired samples obtained at diagnosis and at relapse. Of note, in some cases, new mutations were found on relapse in the dominant clone in the primary leukemia sample, whereas in others, these newly acquired mutations occurred in small subclones of the founding clone, which resulted in expansion and clonal dominance in the relapse sample. Importantly, varying proportions of clonal cells from the founding clone persisted after chemotherapy in all cases.

Mutations Disrupting the Function of Transcription Factors in AML

Two different types of transcription factors play a major role in hematopoiesis and therefore in the pathogenesis of AML. The first group consists of master regulatory transcription factors, which, like AML1, are implicated in the development of all hematopoietic lineages. Impairment of the signaling stemming from these types of transcription factors results in complete hematopoietic failure. A second category of transcription factors is involved in the development of specific hematopoietic lineages. For instance, GATA-1 skews the development of hematopoietic progenitors toward the erythroid lineage, whereas C/EBPα promotes granulocytic differentiation.

PML-RARα Rearrangements

Translocations involving the *retinoic acid receptor (RAR)* locus on chromosome 17, such as t(15;17)(q22;q11), drive the pathogenesis of acute promyelocytic leukemia (APL), which comprises 10%-15% of all cases of adult AML. Such translocations produce the *PML-RARα* transcript that encodes a fusion protein containing most of the functional domains of RARα (including the *RAR* binding domain and the DNA binding domain) and the majority of the *PML* gene. The breakpoints within the *PML* gene cluster locate to three different regions referred to as *breakpoint cluster region* (bcr) 1, 2, and 3. In addition to t(15;17)(q22;q11), there are at least two other variant translocations involving *RARα* associated with the APL phenotype. These include t(11;17)(q23;q21) and t(5;17)(q35;q21), which lead to the fusion of the *RAR?* gene to the promyelocytic leukemia zinc finger *(PLZF)* and *NPM1* genes, respectively. Transgenic mice expressing *PML-RARα*, *NPM/RARα*, or *PLZF/RARα* under the control of a human *Cathepsin* G exhibit an APL phenotype after a variably long latency. Comparison of gene expression profiles set by *PML-RARα* and *PLZF-RARα* have demonstrated the inhibition of genes involved in DNA repair, repression of myeloid transcriptional regulators, and activation of the WNT/Catenin and Jagged/NOTCH pathways, which promote self-renewal of leukemic cells.

AML, Acute myeloid leukemia.
*≤70% of inv(16) leukemias have mutations in receptor tyrosine kinase or *RAS* genes.
†Prevalence based on a limited number of cases.

Patients with APL harboring *PLZF-RARα* fail to respond to *all-trans retinoic acid* (ATRA), although, paradoxically, both *PML-RARα* and *PLZF-RARα* contain identical *RAR* sequences and inhibit ATRA-induced gene transcription as well as cell differentiation.

The PML-RARα oncoprotein disrupts the interaction of retinoic acid and *RARα*, which converts the latter into a transcription activator, resulting in maturation arrest of hematopoietic progenitors at the promyelocyte stage. *PML-RARα* expression also disrupts PML localization, causing it to relocalize from discrete nuclear structures, the PML nuclear bodies, into microspeckled aberrant structures. PML-RARα acts as a dominant negative inhibitor of the PML protein, as well as the major heterodimeric partner of RARα, RXRα (retinoid X receptor). PML-RARα recruits several co-repressors, including the nuclear co-repressor (N-CoR). N-CoR inhibits transactivation from RARα target genes through the recruitment of the molecules sin3 and histone deacetylases, which in turn inhibit the binding of transcription factors and the binding of the transcriptional machinery to promoters, resulting in inhibition of gene expression for hematopoietic differentiation. Similarly, the PML moiety of the PML-RARα protein interacts with the DAXX co-repressor. Mutations preventing DAXX recruitment, although allowing PML-RARα dimerization,

abrogated the ability of PML-RARα to block hematopoietic differentiation and immortalize cells. ATRA is the mainstay of therapy in APL, inducing leukemic cell differentiation and remission in patients with t(15;17)/*PML-RARα* or t(5;17)/*NPM-RARα*. Similarly, arsenic trioxide (As_2O_3) has been demonstrated to be effective in the treatment of de novo as well as of ATRA-resistant t(15;17)/*PML-RARα* APL. Current evidence suggests that the combination of ATRA and As_2O_3 represents a valid alternative to chemotherapy-containing regimens for the treatment of APL.

Core Binding Factor AMLs

CBF is a heterodimeric transcription factor that consists of a DNA binding α-subunit, encoded by one of three members of the RUNX family (*RUNX1* or *AML1*, *RUNX2*, and *RUNX3*), and a β-subunit encoded by the *CBFβ* gene that increases DNA-binding affinity to the complex. Mutations involving CBF rearrangements occur in 15% of cases of AML and are associated with a favorable prognosis. CBF AML includes those carrying inv(16)/t(16;16), which gives rise to the fusion of *CBFβ* with the *smooth muscle myosin heavy-chain* gene (*MYH11* or *SMMHC*), and t(8;21), which is associated with the fusion transcript composed of the *AML1* and the *eight-twenty-one* (*ETO*) genes. Of note, in AML expressing the CBF translocation *AML1-ETO*, this fusion oncogene acts as a dominant negative inhibitor of native *AML1*. Similarly, the *CBFβ-MYH11* oncoprotein is a dominant negative inhibitor of CBF both in transactivation assays and during development. In knockin *CBFβ-MYH11* chimeric mice, *CBFβ-MYH11* expression alters adult multilineage hematopoietic differentiation. *CBFβ* also modulates the effect of *CBFβ-SMMHC* in adult hematopoiesis and leukemogenesis.

Rearrangements of the MLL and HOX Genes

Approximately 4% of patients with de novo AML have balanced translocations or insertions involving the *mixed-lineage leukemia* (MLL) gene. *MLL*-gene fusions are highly associated with previous therapy that includes topoisomerase-II inhibitors. The estimated incidence of this type of rearrangement in secondary treatment-related AML is 2% to 12%. *MLL* is the human homologue of *Drosophila TRX* and constitutes a maintenance factor for HOX proteins, which are central during development and hematopoiesis. The N terminus of *MLL*, which contains the AT-hook DNA-binding motif and a region homologous to DNA methyltransferase, is always retained in the fusion protein arising from chromosomal translocations, whereas the C terminus, which contains the activation and SET domains, is always replaced by the fusion partner. The *MLL* AT hooks bind to the minor groove of DNA, which facilitates the binding and recruitment of transcription factors to promoter elements.[1] *MLL* fusion genes can initiate both myeloid and lymphoid leukemogenic programs depending on the fusion partner, of which more than 65 have been thus far identified in AML. Differential activation of the Wnt/β-Catenin pathway is required for the maintenance of MLL leukemia stem cells, and MLL-AF9, one of the most frequent fusion transcripts, requires interacting with the Polycomb Group protein CBX8 to induce a leukemogenic transcriptional program. Approximately 5% to 10% of AML cases present with rearrangements of *MLL* consisting of an in-frame partial tandem duplication (*MLL*-PTD) of exons 11-5 or 12-5. *MLL*-PTD promotes increased histone H3/H4 acetylation and methylation of H3 Lys4 at *cis*-regulatory *HOXA* sequences. Mislocalized activity of the H3K79 histone methyltransferase DOT1L has been proposed as a driver of leukemogenesis in AML carrying MLL rearrangements. Pharmacological inhibition of DOT1L with the selective DOT1L inhibitor EPZ004777 selectively inhibits H3K79 methylation and blocks expression of leukemogenic genes with little effect on non–MLL-translocated cells, suggesting that DOT1L inhibition represents a potential therapeutic option for patients with MLL rearrangements.

HOX genes are frequently overexpressed in leukemia. Constitutive *HOX* gene activation is required for *MLL* fusion protein-mediated AML. Gene expression profiling analysis showed that the *HOXA4*, *HOXA9*, *HOXA10*, *PBX3*, and *MEIS1* homeobox genes are coexpressed across diverse cytogenetic groups but are undetectable in terminally differentiated hematopoietic cells. In AML, *HOX* genes are mainly disrupted via chromosomal translocation, such as the fusion of *NUP98*, *NUP214* (also known as *CAN*), or *MLL* to *HOXA9*, *HOXD13*, *DEK*, and *DDX10*. Overexpression of *HOXA6*, *HOXA7*, *HOXA9*, and the HOX cofactor *myeloid ecotropic viral integration site 1 (MEIS1)* has also been correlated with chromosome 11q23 abnormalities involving the MLL protein, which directly regulates the expression of *HOX* genes. The *caudal-type homeobox transcription factor 2 (CDX2)* is overexpressed in 90% of patients with AML in spite of its lack of expression in hematopoietic progenitors. *CDX2* overexpression in primary murine hematopoietic progenitors resulted in transplantable AML in vivo, which was associated with upregulation of *HOXB6* expression, a protein that is overexpressed in 40% of cases of CN-AML.[2] This suggests the possibility that *CDX2*-mediated deregulation of *HOX* genes is a major pathway to leukemogenesis.

Mutations in the C/EBPα and PU.1 Genes

The *C/EBPα* gene, which encodes the CCAAT/enhancer-binding-protein-alpha, is a member of the family of leucine-zipper (bZIP) transcription factors that couples lineage commitment to terminal differentiation and cell cycle arrest in the process of myeloid differentiation. *C/EBPα* initiates growth arrest through induction of *p21* and by disrupting

the E2F transcriptional complexes during the G1 phase of the cell cycle. Mutations in the *C/EBPα* gene occur in 15% to 19% of patients with AML and normal cytogenetics. *C/EBPα* mutations increase the capacity of bone marrow myeloid progenitors to proliferate and predispose mice to a granulocytic myeloproliferative disorder. In the absence of specific *C/EBPα* mutations, decreased expression may serve as an alternative mechanism that disrupts *C/EBPα* gene function. For example, *AML1-ETO* appears to indirectly suppress *C/EBPα* expression by inhibiting positive autoregulation of the *C/EBPα* promoter. Notably, *C/EBPα* mutations, when biallelic, are associated with a favorable prognosis in patients with cytogenetically normal (CN)-AML.

The transcription factor PU.1 is indispensable for myelomonocytic differentiation during normal hematopoiesis and for regulating the commitment of multipotent hematopoietic progenitors. The course of AML in mice after knockdown of *PU.1* includes a preleukemic stage during which immature myelomonocytic precursors accumulate in the bone marrow, followed by a leukemic phase with elevated leukemic blasts in peripheral blood. Also, PU.1-induced upregulation of *CSF1R* is crucial for leukemia stem cell potential induced by MOZ-TIF2. Despite its leukemogenic potential, *PU.1* mutations have been rarely found in human AML.

Mutations Altering Signal Transduction

Mutations at several oncogenes promoting cell growth have been shown to participate in the pathogenesis of AML. *FLT3* expression is restricted to $CD34^+$ cells and a subset of dendritic precursors, where it regulates proliferation, differentiation, and apoptosis.[3] Internal tandem duplication (ITD) within the *FLT3* juxtamembrane domain (exons 14 and 15) is among the most prevalent mutations in patients with CN-AML, being detected in about 30% of cases. Moreover, 7% of patients with AML harbor missense point mutations affecting the activation loop of the tyrosine kinase domain of FLT3 coded by exon 20, typically involving residue 835. There is evidence suggesting that *FLT3* mutations occur in leukemic stem cells. In fact, 84% of patients with AML carrying *FLT3-ITD* mutations exhibit the same mutation at relapse. *FLT3-ITD* mutations activate aberrant signaling, including STAT5, PI3K/AKT, and MAPK pathways, and repress *PU.1* and *C/EBPα*. *FLT3* gene mutations are associated with high relapse rates and poor prognosis. Small-molecule tyrosine kinase inhibitors directed against the constitutively activated FLT3 protein such as midostaurin, sorafenib, or quizartinib have shown encouraging results in clinical trials. Further development of these agents is being pursued in the context of chemotherapy or hypomethylation-based combinatorial approaches.

Activation of the KIT tyrosine kinase by somatic mutation has been documented in a variety of human malignancies, including core binding factor AML, clustering within exon 17 and exon 8. *KIT* mutations confer a higher risk of relapse in patients with CBF AML. Gain-of-function *KIT* mutations may serve as a target for tyrosine kinase inhibitors (e.g., dasatinib), and their activity warrants further investigation in CBF AML harboring such mutations.

RAS oncogenes encode a family of membrane-associated proteins that regulate proliferation, differentiation, and apoptosis. The RAS proteins oscillate between a guanosine triphosphate (GTP)- and a guanosine diphosphate (GDP)-bound state. GDP-bound RAS is incapable of activating signal transduction pathways. *NRAS* mutations can be detected in 10% of patients with AML. Mutated RAS proteins are constitutively activated, which is held in their GTP-bound status, and efficiently induce an AML-like disorder in a mouse bone marrow transplantation model. The prognostic impact of RAS mutations in AML remains controversial. MEK inhibitors are currently being tested in patients with AML carrying *RAS* mutations.

Other Genetic Events Implicated in the Pathogenesis of AML

Mutations of the Nucleophosmin Gene

The *NPM1* gene encodes a nucleus-cytoplasm shuttling protein implicated in preventing nucleolar protein aggregation, regulation of ribosomal protein assembly, initiation of centrosome duplication, and regulation of *p53*, *p19ARF*, and HDM2. *NPM1* is involved in the control of primitive hematopoiesis, and mice lacking *NPM1* alleles develop a syndrome reminiscent of human myelodysplasia. Translocations involving the *NPM* gene cause cytoplasmic dislocation of the NPM protein. *NPM1* mutations are found in approximately 35% to 40% of adult patients with primary AML and are associated with high sensitivity to cytarabine-based therapy and to higher complete remission rates. Most of the cases (60% to 80%) carrying mutant *NPM1* alleles correspond to patients with CN-AML. *NPM1* mutations are typically heterozygous and almost exclusively map to exon 12.[4-6] A duplication of a TCTG tetranucleotide at position 956 to 959 accounts for 75% to 80% of cases.[6,7] Notably, NPM1 mutations are associated with a very favorable prognosis in the presence of wild-type FLT3 alleles, particularly when associated with IDH1 mutations. The recent development of experimental mouse models lacking NPM1 alleles or carrying NMP1 mutations will aid in understanding the role of *NPM1* in

the pathogenesis of AML and in developing novel targeted agents.

Mutations in Genes Involved in Epigenetic Patterning and Chromatin Conformation

DNA methylation is a common mode of epigenetic regulation, typically involving cytosine residues that reside within GC-rich promoter regions called *CpG islands*. Another means of epigenetic regulation is via histone modifications. Histones, like DNA, can be methylated, but they are also acetylated, phosphorylated, sumoylated, and ubiquitinated. Histone modifications can result in either gene activation or repression. Mutations in a series of genes encoding proteins involved in epigenetic pathways are frequently found in patients with CN-AML, including *ASXL1* and *MLL*, which encode histone modifiers, and *DNMT3A*, *TET2*, and *IDH1/2*, which encode proteins that regulate cytosine modifications (Figure 28-2).

DNMT3A is an enzyme that catalyzes cytosine methylation, which is critical in DNA imprinting and modulation of gene expression. An analysis of 281 AML samples reported that 22% of cases carried mutations in *DNMT3A*, a frequency that increased to 34% among those with CN-AML. *DNMT3a* mutations were associated with a markedly shorter overall survival compared to that of patients carrying wild-type *DNMT3A* alleles (12.3 vs. 41.1 months).

Mutations in the *TET2* gene are found in 8% to 23% of patients with AML and have been associated with a poor prognosis (Figure 28-3). The role of TET2 mutations in the pathogenesis of AML is not well understood. TET proteins catalyze the conversion of 5-methylcytosine, which acts as a transcriptional repressor, to 5-hydroxymethylcytosine, thus potentially promoting transcription. The enzymatic activity of TET2 is inhibited by 2-hydroxyglutarate (2-HG), which is found at high levels in cells carrying mutant *IDH1/2* alleles. Mutations at the *IDH* alleles have been described at frequencies ranging from 15% to 20% overall and from 25% to 30% among those with CN-AML. The most frequent mutations in AML take place at the arginine 132 residue (R132) in *IDH1*, and the corresponding arginine 172 (R172) residue in *IDH2*, as well as at the arginine 140 (R140) residue in *IDH2*. Available data suggest that *IDH2* R140Q is associated with a favorable prognosis, whereas *IDH1* R132 confers a worse prognosis. *IDH2* R172 does not appear to affect the prognosis of patients with AML. Of note, *TET2* and

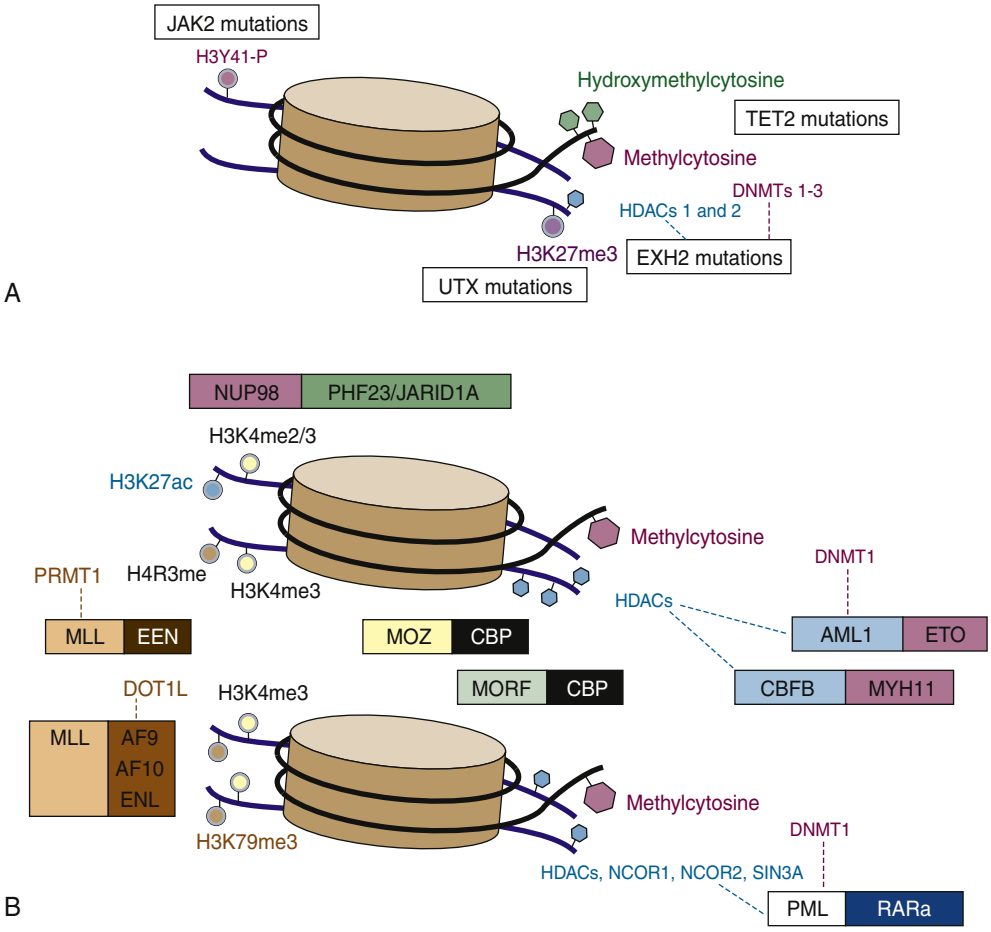

Figure 28-2 Simple mutations and chromosomal translocations in the epigenetic machinery in AML and MDS (A) Somatic mutations that affect the epigenetic machinery include gain-of-function mutations in JAK2 (which can phosphorylate histone 3 tyrosine 41) and loss-of-function mutations in UTX, EZH2, and TET2. **(B)** Epigenetic modifying genes can also be altered via chromosomal translocations such as those involving MLL fusions that lose H3K4 methyltransferase and gain H3K79 methyltransferase activity, JARID1A/PHF23 fusions that regulate H3K4 di/tri-methylation, and fusions such as PML-RARA or those involving core binding factors, which interact with histone deacetylases and modulate chromatin state. *From Abdel-Wahab O, Levine RL. EZH2 mutations: mutating the epigenetic machinery in myeloid malignancies.* Cancer Cell. *2010;18:105-107.*

IDH mutations are mutually exclusive. *IDH* proteins convert isocitrate to α-KG, and *IDH* mutations result in neomorphic alleles that encode proteins that produce 2-HG in excess, which in turn inhibit the activity of *TET2*. The end result of both *TET2* and *IDH* mutations is the inability of cells to metabolize 5-methylcytosine to 5-hydroxymethylcytosine, thus inducing a hypermethylation phenotype. This suggests that possibility of using hypomethylating agents for the treatment of *TET2*- or *IDH*-mutated AML, although so far small trials have not shown any significant benefit. In addition, small molecules are being developed to inhibit the activity of mutated *IDH1/2*.

Overexpression of Specific Genes in AML

Overexpression of *BAALC*, the brain and acute leukemia gene, mRNA in the cytoplasm of peripheral blood blasts portends an adverse clinical outcome in terms of both failure to achieve complete response and shorter overall survival. The *MN1* gene is occasionally overexpressed in AML and is associated with worse overall survival. A similar phenomenon

B

Figure 28-3 Somatic acquired *TET2* mutations Patients with **(A)** AML or **(B)** MDS acquire somatic missense, nonsense, and frameshift mutations in *TET2*. *From Cimmino L, Abdel-Wahab O, Levine RL, et al. TET family proteins and their role in stem cell differentiation and transformation.* Cell Stem Cell. *2011;9:193-204.*

has been demonstrated among patients whose AML cells overexpress the v-ets erythroblastosis virus E26 oncogene homologue (*ERG*) gene, particularly among patients with low *BAALC* expression, as well as among those overexpressing the ecotropic viral integration site 1 (*EVI1*) gene. Elevated FOXO expression is present in 40% of cases of AML and is necessary to maintain leukemia-initiating cells. Resistance to FOXO depletion is mediated by JNK/c-JUN signaling. Over the past few years, a number of studies have correlated certain gene mutations with different patterns of microRNA (miR) expression. For instance, *NPM1* mutations associate with upregulation of miR-10a and miR-196a, whereas *FLT3* mutations associate with upregulation of miR-155 and *C/EBPα* with upregulation of miR-181 in CN-AML. Also, miR-10a, miR10b, and miR-196a-1 correlate with expression of *HOX* genes in CN-AML.

Myelodysplastic Syndromes

MDS is a heterogeneous group of clonal disorders of the hematopoietic stem cell, characterized by excessive apoptosis, maturation abnormalities of hematopoietic precursors manifested as dysplastic changes, and ineffective hematopoiesis. Unlike other malignant hematologic disorders, the biologic hallmark of the stem cell in MDS is a limited ability for self-renewal and differentiation. Furthermore, MDS has a tendency to transform into AML. Indeed, approximately 30% to 40% of cases evolve to AML. The survival of patients with MDS is quite heterogeneous, ranging from weeks to years. In an attempt to incorporate clinical features associated with prognosis in MDS, the International Prognostic Scoring System (IPSS) was developed. This system identified the presence of specific cytogenetic aberrancies, the percentage of blasts in the bone marrow, and the number of cytopenias as the most important variables in disease outcome.[8] Patients with therapy-related MDS are usually refractory to standard chemotherapy-based therapies, and their prognosis is very poor.

Although it is established that MDs arises from primitive hematopoietic progenitors, our understanding of the pathobiology that drives these diseases is incomplete. Some of the difficulties in determining the critical defects responsible for MDS can be explained by the fact that several programs such as cellular differentiation, apoptosis, and/or proliferation contribute to the etiology of this disease. MDS, like other cancers, results from multiple genetic alterations, likely acquired in a stepwise fashion, which frequently result in transformation to AML (Figure 28-4). This is in consonance with other models of molecular progression described in solid tumors such as colon or pancreatic cancer.

Cytogenetic Abnormalities in MDS

The main prognostic factors in patients with MDS are chromosomal abnormalities. An abnormal karyotype is present in approximately 50% of patients at diagnosis. Although multiple chromosomal lesions have been associated with MDS, losses of chromosomes 5 and/or 7 are associated with a worse prognosis among patients with de novo MDS. The precise genomic regions and genes responsible for the phenotypes observed in patients with specific chromosomal abnormalities are being revealed. Two commonly deleted regions (CDRs) have been defined: 5q33.1, which is associated with the 5q– syndrome, and 5q31, which is associated with therapy-related MDS and progression to AML. *RPS14* has been shown to be critical for the erythroid phenotype observed in the 5q– syndrome; miR-145 and miR-146 have been associated with an elevated platelet count. Approximately 10% of patients will present

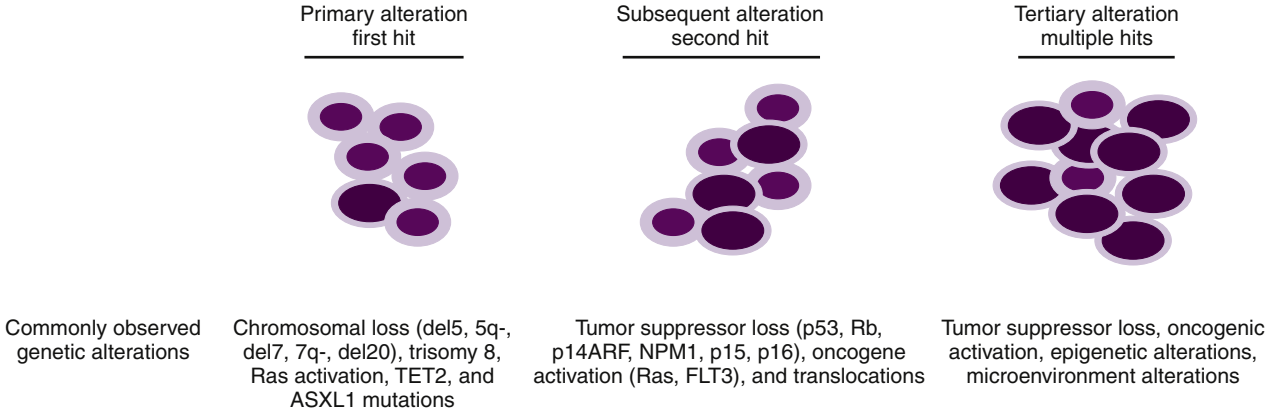

Figure 28-4 Progression of MDS to AML Primary somatic mutations in hematopoietic stem cells or myeloid progenitors result in dysplastic phenotypes. Subsequent genetic lesions that confer proliferation or anti-apoptotic advantages aid in the clonal evolution of the disease. Following numerous genetic anomalies, the dysplastic clone is rapidly amplified and becomes dominant.

with abnormalities of chromosome 7, where three CDRs have been identified. Importantly, EZH2, which acts as the catalytic component of the histone H3 lysine 27 methyltransferase polycomb repressive complex 2 (PRC2), maps to 7q36, which may explain why chromosome 7 losses are so frequent in MDS. Trisomy 8 occurs in 8% of patients and is also associated with poor prognosis in MDS. Other chromosomal abnormalities have been associated with a more favorable prognosis such as 20q− or −Y.

Loss of miRNAs 145/146

The miRNAs *miR-143*, *miR-145*, and *miR-146a* mapping at 5q33 are significantly reduced in bone marrow cells isolated from 5q− syndrome patients. *miR-145* and *miR-146a* regulate the toll-interleukin-1 receptor domain-containing adaptor protein *(TIRAP)* and tumor necrosis factor receptor–associated factor 6 *(TRAF6)*. TIRAP is a regulator of TRAF6, an E3 ubiquitin ligase, required for nuclear factor κB (NFκB) activation. Collectively, these proteins regulate innate immunity. Haploinsufficiency of *miR-145* and *miR-146a* resulted in increased *TIRAP* and *TRAF6* expression and activity in hematopoietic stem/progenitor cells. Transplantation of haploinsufficient *miRNA145/146a* cells or *TRAF6*-overexpressing cells into recipient mice resulted in several hallmark MDS/5q− syndrome phenotypes, such as thrombocytosis, neutropenia, dysplastic megakaryopoiesis, and propensity to transform to AML. These findings link innate immunity to MDS pathogenesis.

NUP98-HOX13 Translocation

NUP98 maps to 11p15.5 and can partner with multiple genes by chromosomal translocation in MDS. In t(2;11)(q31;p15), NUP98 fuses with HOXD11 or HOXD13.[9] Transgenic mice expressing NUP98-HOXD13 exhibit anemia, decreased neutrophil and lymphocyte counts, dysplastic changes, and increased bone marrow cellularity, thus recapitulating an MDS phenotype. Furthermore, a subset of *NUP98-HOX13* transgenic mice also transforms to AML after a latency of approximately 1 year, suggesting the need for secondary hits for transformation, which have been shown to consist of activating RAS mutations.

Gene Mutations in MDS

Mutations in the Spliceosome Machinery

Spliceosomes are complexes composed of small nuclear RNA (snRNA) that remove introns in protein-encoding genes. Several groups, by means of next-generation sequencing platforms, have unveiled the presence of somatic mutations in genes encoding proteins involved in the spliceosome machinery in 45% to 85% of patients with MDS or chronic myelomonocytic leukemia (CMML). Collectively, eight different splicing genes—SF3B1, SRSF2, U2AF35 (also known as U2AF1), ZRSR2, SF3A1, PRP40B, SF1, and U2AF65—can be found mutated in MDS, constituting, as a group, the most frequently detected mutations in MDS (Figure 28-5). These splicing factors are highly expressed in hematopoietic lineages and are involved in recognition of the canonical 3′ DNA splice elements. Similar gene mutations can also be found at low frequencies in chronic lymphocytic leukemia (9% to 15%) or myeloproliferative neoplasms (3% to 9%), and in rare instances of solid cancers (e.g., breast or renal cancer). In MDS, these mutations are always present in the heterozygous state and are almost mutually exclusive. Across studies, mutations in SF3B1 have been described in 20% to 45% of patients and in 65% to 85% of those with MDS with ringed sideroblasts. It is hypothesized that altered splicing of key cancer genes might result in oncogenic gain or loss of function. In addition, genes such as SF3B1 might have oncogenic nonsplicing mechanisms because they have been shown to be implicated in cell cycle control and Hox gene regulation. The impact of these genes has not been clearly delineated, but SF3B1 mutations appear to confer a more favorable prognosis, whereas U2AF1 mutations are associated with poor prognosis among patients with MDS.

Gene Mutations Altering Epigenetic Regulation in MDS: TET2, IDH1/2, and ASXL1

There is now growing evidence that in addition to genetic changes, epigenetic modifications play a critical role in the pathogenesis of MDS.[10,11] Loss-of-function mutations in *TET2*, a protein involved in global DNA demethylation, occurs in approximately 20% of patients with MDS.[12,13] However, TET2 mutations are not responsible for the dysplastic changes observed in the bone marrow of patients with MDS. The complete loss of *Tet2* resulted in myeloproliferation, increased repopulation of transplanted cells in recipient mice, and expansion of the hematopoietic progenitor pool. *Tet2*$^{-et}$ mice display phenotypes reminiscent of MDS with a short latency. The impact of *TET2* mutations on the outcome of patients with MDS remains controversial, with more recent reports indicating no impact on overall survival.

Much like in AML, *IDH1/2* mutations in MDS are heterozygous and appear to act as dominant negatives. However, IDH1/2 mutations are significantly less frequent in MDS than in AML, with frequencies ranging from 5% to 10%. A recent genetically engineered mouse model in which the *IDH1* R132H mutation was expressed in the hematopoietic system has been reported. Cells carrying the mutation exhibit high 2-HG levels, which are associated with an expansion of the stem cell pool and epigenetic changes frequently seen in MDS and AML (i.e., DNA and histone

hypermethylation). Recent studies suggest that *IDH1* mutations may portend an adverse prognosis in MDS, whereas *IDH2* mutations had no impact.

ASXL1 (additional sex-comb like-1) encodes a member of the polycomb family of chromatin-binding proteins that, depending on the cellular context, either activates or silences genes. *ASXL1* alleles are mutated at the C terminus of the protein, and mutations can be detected in approximately 10% to 20% of patients with MDS and in 17% of those with AML. Loss of ASXL1 function results in aberrant repression or activation of numerous genes. Deletion of *Asxl1* in the germline of mice resulted in an embryonic lethal phenotype in some animals. Those surviving exhibited disrupted expression of the Homeobox family of *Hox* genes and defects in differentiation of lymphoid and myeloid progenitor cells but not in multipotent progenitors. The lack of an informative phenotype in the $Asxl1^{-/-}$ mice could be due in part to compensatory activities of the *ASXL1* homologues, *ASXL2* and *ASXL3*. However, Asxl1 functions are most frequently disrupted by DNA mutations that result in frameshift mutations. These types of mutations often confer dominant negative activities, which result in phenotypic changes quite different from those resulting from allelic loss. Knockin mice harboring *ASXL1* mutations are warranted

to fully examine the role of these mutations in the pathogenesis of MDS. *ASXL1* frameshift mutations have been associated with a reduced time to progression to AML and shorter survival.

RUNX1 Mutations

RUNX1 (also known as *AML1*) is a transcription core binding factor and represents the third most frequently mutated gene in MDS, being detected in 7% to 15% of cases. *Runx1* knockout mice die at the embryonic stage with no evidence of definitive hematopoiesis. When *Runx1* is deleted in adult hematopoietic tissues, mice expand their myeloid compartment and exhibit inefficient platelet production. Mutations in the Runt domain of Runx1 in mice are associated with a dominant negative/gain-of-function phenotype characterized by increased blast burden and AML-like disease.

NPM1 Mutations

NPM1 maps to chromosome 5 and is mutated in 5% of cases of MDS. NPM1 regulates the p53 pathway via $p14^{ARF}$. Genetic deletion of both *NPM1* alleles in mice results in embryonic lethality due to severe anemia. However, $Npm1^{+/-}$ mice are viable and present with several hematopoietic anomalies consistent with MDS, including abnormal platelet counts and erythroid or megakaryocytic dysplasia. In addition, aged $Npm1^{+/-}$ mice had an increased rate of incidence of AML. This model clearly establishes *NPM1* as a true tumor suppressor in MDS. *Npm1* mutant mice harboring a humanized *Npm1* mutation driven by a hematopoietic promoter have also been developed. These mice also exhibit myeloid-specific phenotypes, but they are more reminiscent of a myeloproliferative neoplasm.

TP53 Mutations

TP53 maps to 17p and is found mutated in 5% to 15% of patients with de novo MDS. *TP53* mutations portend a very poor prognosis regardless of IPSS score, and they are associated with advanced disease and complex karyotypes. *TP53* mutations to chromothripsis and complex DNA rearrangements in myeloid malignancies. TP53 activation has been demonstrated to be critical for the erythroid phenotype induced by *RPS14* haploinsufficiency in 5q- syndrome patients.

Alterations in the Bone Marrow Microenvironment

Although genetic and epigenetic factors clearly play a role in the pathogenesis of MDS and its progression to AML, little is known about the impact of alterations in the bone marrow niche. The importance of such signals has been recently demonstrated in one study that used Osterix-mediated Cre expression to delete the *Dicer* gene in osteoprogenitor cells.[14] Mice harboring *Dicer* deletions in osteoprogenitor cells exhibited MDS features such as cytopenias and morphologic changes in hematopoietic cells, demonstrating that bone marrow alterations may play an important role in MDS pathogenesis.

Concluding Remarks

The increasing sophistication of genome-wide sequencing techniques as well as of genetically engineered murine models has provided important insights into the pathogenesis of myeloid malignancies. These advances have also opened new avenues for the development of targeted therapies directed against mutant proteins present in AML or MDS cells, such as FLT3, KIT, IDH1/2, or RAS. However, a better understanding of the various cellular functions and signaling pathways subverted by these mutant proteins is warranted to extend the concept of targeted therapy in AML beyond the isolated paradigm that constitutes the success of ATRA and arsenic trioxide therapy in PML expressing *PML-RARα*. The alterations in transcription factor expression observed in AML or MDS are truly "tumor specific" and, as such, provide novel targets for therapy. However, designing therapeutic modalities aimed at modulating transcription factors remains challenging.

29 Lymphoma

The lymphoid malignancies comprise one of the most diverse and heterogeneous sets of diseases that exist under a single type of malignancy. In 2012, the American Cancer Society estimated there were about 70,000 cases of non-Hodgkin lymphoma (NHL), and about 10,000 cases of Hodgkin lymphoma in the United States, collectively accounting for about 4% to 5% of all cancers. The estimated number of U.S. cancer deaths attributed to lymphoma is about 3% for both males and females, ranking it about 8th among all causes of cancer death. Hodgkin lymphoma typically carries a better prognosis, accounting for approximately 1000 deaths per year. Whereas the lifetime risk of developing any cancer is about 1 in 2 for males and 1 in 3 for females, the lifetime risk of developing non-Hodgkin lymphoma is about 1 in 43 and 1 in 51 for males and females, respectively (for the years between 2006 and 2008). Despite the relatively lower incidence compared to other types of cancers, the trend in 5-year survival between 1975 and 2007 has been progressively improving. The trend in 5-year survival for all sites of cancer has improved between the years 1975 and 1977 (49%), 1987 and 1989 (56%), and 2001 and 2007 (67%), whereas for lymphoma in particular, for the same time periods, the 5-year survival reported by SEER is 47%, 51%, and 70%, demonstrating marked improvements in outcome over the past several decades. Many of these improvements stem directly from an improved classification system that has allowed for better risk stratification of patients, as well as the development of novel drugs targeting the unique pathogenetic features of the disease.

The classification of non-Hodgkin lymphoma has evolved since the first attempts at classifying these diseases were published. These classification schemes largely evolved from systems focused on morphology (large versus small cells, diffuse versus follicular patterns of lymph node growth), to ones that rely on immunohistochemical techniques to delineate lineage-specific markers, like those proposed by Luke and Collins and Kiel. The NCI Working Formulation attempted to integrate morphologic features and clinical presentation into the definition of subtypes, describing low-grade, intermediate, and high-grade lymphomas, where the grade refers to the aggressiveness of the clinical behavior, not the histologic grade of the tumor. The more recent classification systems as proposed by REAL and WHO represent fully integrated classification systems that take into account morphologic, immunologic, genetic, and clinical criteria to classify these complex diseases (Table 29-1). Increasingly, the integration of cytogenetic features has begun to subclassify discrete entities of these diseases, as has been demonstrated for the ALK^+ and ALK^- variants of anaplastic large T-cell lymphoma. In this case, the presence of the ALK translocation (t[2;5]) confers a highly favorable prognosis, which has a standard of care treatment recommendation (that is, CHOP-based chemotherapy); in contrast, the ALK^- ALCL, which is thought of more like peripheral T-cell lymphoma (PTCL), carries a very poor prognosis.

The lymphoid malignancies include a broad spectrum of diseases, including non-Hodgkin lymphoma, Hodgkin lymphoma, plasma cell malignancies such as multiple myeloma, and two forms of leukemia, namely, chronic lymphocytic leukemia (CLL) and acute lymphoblastic B- and T-cell leukemia/lymphoma (ALL) (though virtually any lymphoid malignancy can have a leukemic form of the disease) (Figure 29-1). These entities range from some of the fastest growing diseases known to science (such as Burkitt's lymphoma and blastic NK-cell lymphoma), to some of the slowest (CLL, marginal zone lymphoma). All lymphoid malignancies are derived from B-, T-, or NK lymphocytes originating in the primary lymphoid organs, such as the thymus and bone marrow (Figure 29-2). These lymphocytes are derived from pluripotent hematopoietic stem cells resident in the adult and fetal bone marrow as well as the fetal liver. Lymphoid malignancies derived from these less differentiated lymphocytes, before their differentiation in the thymus (for T-cell) or germinal center (for B cells), are considered undifferentiated lymphoid malignancies and typically give rise to diseases such as T- or B-cell acute lymphoblastic leukemia/lymphoma. Once the lymphocytes leave the primary lymphoid organs, they migrate to secondary lymphoid organs including the lymph nodes, tonsils, Peyer patches, spleen, and skin, where they undergo a multistep

process leading to their differentiation. Further differentiation of specific lymphocyte subsets then becomes more lineage dependent.

B- and T-Lymphocyte Development

The ontogeny of B cells is complex and proceeds through a series of developmental and genetic steps, leading to the creation of unique B cells carrying unique B-cell receptors, capable of identifying unique antigen (Figure 29-3). These developmental and genetic steps are defined by changes in the genome at the antibody loci. B lymphocytes play a fundamental role in the humoral branch of the adaptive immune system and can be distinguished from other types of lymphocytes by the panoply of cell surface markers (CD19, CD20, CD22, CD23) and the presence of the B-cell receptor (BCR), which itself is a surface immunoglobulin. Undifferentiated and immature B cells are produced in the intramedullary compartment of the bone. The antibodies produced by individual B cells are composed of two identical light chains (κ or λ), composed of two segments called the *V and J segments*, and one heavy chain (M, D, A, G) composed of three segments called the *V, D, and J segments*, where V denotes the variable region that comprises the terminal Fab portion of the antibody.[1] At the genetic level, early lymphocytes in the bone marrow undergo a process referred to as *VDJ recombination* (see Figure 29-2), which is the mechanism by which B cells produce immunoglobulin diversity. Once B lymphocytes undergo VDJ recombination, they exit the bone marrow, where they then hone to secondary lymphoid organs such as the lymph node. There they undergo highly controlled mutagenesis, in a process referred to as *somatic hypermutation* (SMH). SMH plays a crucial role in the affinity maturation of the humoral response, by mediating the introduction of discrete random mutations in the loci of the genes encoding the variable (V) regions of the immunoglobulin.[2] Once engaged by antigen, the subsequent proliferation of the B cell undergoes an incredibly high rate of somatic mutation that is at least 100,000- to 1 millionfold higher than the normal rate of mutation across the genome. This highly regulated mutagenesis, mediated initially by activation-induced cytidine deaminase (AID), introduces single base substitutions predominantly at hotspots in the DNA called *hypervariable regions*.[2] Paradoxically, it is this directed hypermutation of the BCR variable regions that allows for the selection of B cells with an enhanced capability to identify and bind specific foreign antigens, which, when dysregulated or uncontrolled, creates an opportunity for aberrant somatic hypermutation, leading to lymphomagenesis. This potential for any error, or error-prone mutagenesis of B lymphocytes, can create the background for malignant transformation.

In contrast, T lymphocytes play a central role in cell-mediated immunity and can be distinguished from other lymphocytes by the expression of their own unique set of surface proteins (e.g., CD3, CD4, CD8) and the T-cell receptor (TCR). T lymphocytes typically mature in the thymus, in contrast to the germinal center for B lymphocytes. In the thymus, T lymphocytes expand through multiple series of cell division to produce a large population of more immature cells. Initially, these cells do not express CD4 or CD8 and are referred to as double-negative thymocytes.[3] As they differentiate into a specific subset of T lymphocytes, they eventually become positive for both CD4 and CD8 (that is, double positive). In their final step of thymic maturation they emerge as single positive T lymphocytes, including CD4-positive/CD8-negative T-helper cells or CD4-negative/CD8-positive cytotoxic T cells. The TCR recognizes antigen bound to major histocompatibility complex (MHC). Engagement of the TCR by antigen incites a number of downstream events important to the

Figure 29-1 **(A)** Relative incidence of select B- and T-cell lymphomas. **(B)** Relative incidence of select T-cell lymphomas. A survey of 1314 peripheral T-cell and natural killer/T-cell leukemia cases from 22 sites around the world evaluated the histopathology of previously untreated patients consecutively diagnosed between 1990 and 2002. PTCL-NOS was the most common subtype at 25.9%. Anaplastic large cell lymphoma (ALCL) ALK+/–, angioimmunoblastic lymphoma, adult T-cell leukemia/lymphoma, and natural killer/T-cell lymphoma were also common subtypes. **(C)** Classification of the mature T-cell lymphoma (WHO). PTCL refers to a heterogeneous group of aggressive T- and NK-cell lymphomas, characterized by the involvement of mature (thymic) T or NK cells. The term *peripheral* in PTCL does not refer to anatomic sites. T- and NK-cell lymphomas may be characterized as cutaneous, nodal, extranodal, or leukemic disseminated. *Data from Armitage JO et al.* Ann Oncol. *2004;15:1447-1449; Rodriguez J et al.* Crit Rev Oncol Hematol. *2008; Swerdlow SH et al.,* WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues*; 2008. Figure 29-2 Schematic representation of the ontogeny of B-lymphocytes and select lymphoma relative to their sites of origin.

lymphocytes role in mediating cellular immunity. The generation of the TCR is quite similar to that discussed earlier for the BCR. Composed of four chains and existing as a dimeric structure (alpha pairing with the beta chain or the gamma chain pairing with the delta chain), unique TCR is produced through VJ (the alpha and gamma chains) or VDJ (the beta and delta chains) recombination. Like the heavy and light chains comprising the BCR, it is the unique combination of these specific regions that accounts for the diversity of the TCR.[3]

Although complex, the ontogeny of B and T lymphocytes provides the basis for thinking about the diversity of different forms of non-Hodgkin and Hodgkin lymphoma, and in particular the cell of origin (see Figure 29-3). In the case of the lymphoid malignancies, identifying the cell of origin goes well beyond the identification of the lymphocyte and is ascribed to the discrete step in development at which the clonal expansion is thought to occur. Increasingly, the understanding of immunohistochemical staining and cytogenetics has allowed for a description of the natural ontogeny of lymphocytes and, by extension, the more accurate identification of the cell of origin, leading to a more biologically relevant classification of different subtypes of lymphomas (Table 29-2).

Pathogenesis of Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma (DLBCL) comprises a group of aggressive lymphomas with very heterogeneous clinicopathologic and molecular genetic features. The current 2008 World Health Organization (WHO) classification[4] defines DLBCL as a diffuse growth of neoplastic large B-lymphoid cells with a nuclear size equal to or exceeding normal macrophage nuclei or more than twice the size of a normal lymphocyte. DLBCL is the most common subtype of lymphoma and accounts for 30% to 40% of adult NHL.[5] The 2008 WHO classification recognizes a large number of DLBCL subgroups primarily based on their distinct morphologic, biologic, immunophenotypic, or clinical features. Despite revisions to the classification, a significant proportion of large-cell lymphomas remain biologically heterogeneous, not fitting into any specific DLBCL subgroup. These are typically defined as DLBCL, not otherwise specified (DLBCL-NOS). DLBCL-NOS is a diagnosis of exclusion, not corresponding to one of the specific subtypes. It is still the most common type of lymphoma, accounting for 25% to 30% of NHLs.[5]

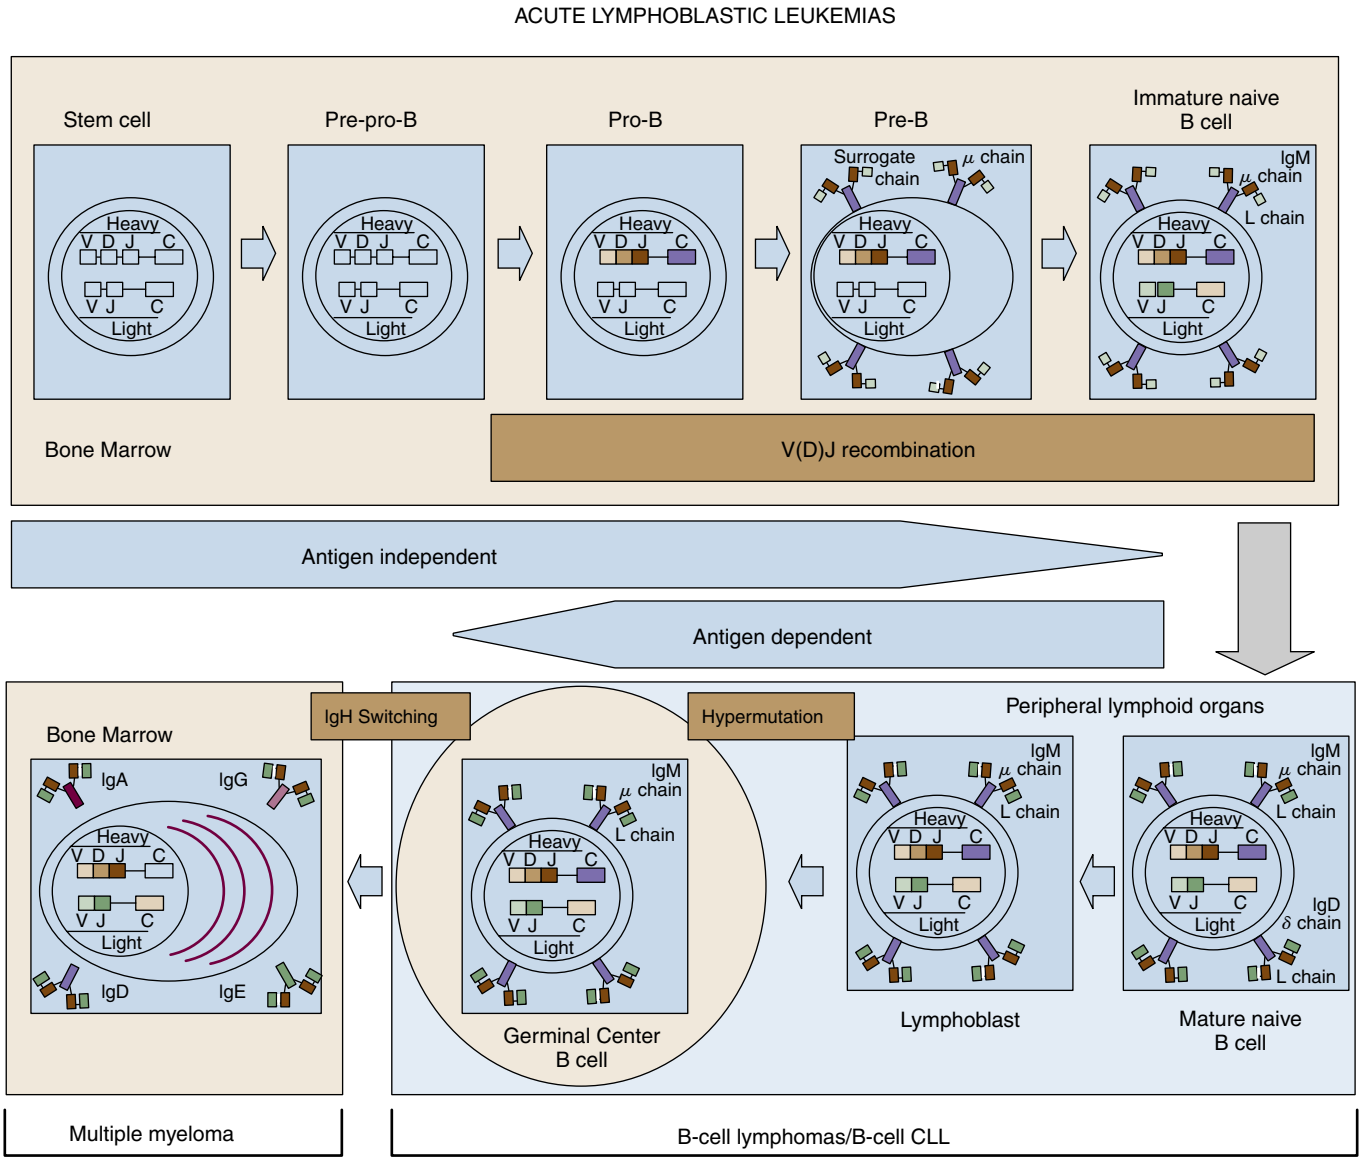

Figure 29-3 Stages of B-cell development and correlation with different lymphoid diseases. *CLL*, Chronic lymphocytic leukemia.

The focus in recent years has shifted toward the identification of molecular alterations and specific pathogenetic pathways leading to transformation in DLBCL. Gene expression profiling (GEP) of DLBCLs has identified at least two major molecular subtypes, which correlate with prognosis and may have relevance for treatment based on the dominant signaling pathways. DLBCL could be classified by GEP as resembling either germinal center B cells (GCBs) or activated B cells (ABCs), establishing a putative "cell of origin"[5] (Figure 29-4). Because GEP is technically difficult and therefore cannot be performed in every case for diagnostic purposes, various algorithms based on immunohistochemical profiles have been proposed as surrogates of the GEP.[5,6] Although the correspondence is not precise, similar prognostic correlations can be drawn with immunohistochemically defined subgroups. These immunohistochemical algorithms have facilitated risk stratification of DLBCL patients and DLBCL research using archival materials.[5]

The ABC and GCB DLBCL subtypes, originally formulated based on a cell-of-origin model, have more recently been shown to be characterized by the different pathways of cellular transformation and oncogenesis. Although substantial progress has been made toward molecular subclassification of DLBCLs, the translation to effective treatment strategies is only now beginning to be explored.[5] Next-generation sequencing (NGS) platforms have evolved to provide an accurate and comprehensive means for the detection of molecular mutations and will likely contribute to a more sophisticated understanding of DLBCL biology and, it can be hoped, more biologically relevant treatment.[7]

Table 29-2 Characteristic Immunophenotypic and Genetic Features of Selected Lymphoma Subtypes

Lymphoma Subtypes	Immunophenotypes	Frequent Translocations/ Aberrations	Genes Involved	SHM	Ongoing SHM	Putative Cell of Origin
GC B-cell–like DLBCL	CD20, CD22, CD79a, BCL-2 CD10	t(3q)(27) → t(14;18) → t(8;14) →	BCL6 (35%) BCL2 (15-30%) MYC (15%)	√ √	√ –	GC B cell GC B-cell subset or extra-GC mutated B cell
Activated B-cell–like DLBCL	MUM1	t(3q)(27) gain18q del6q gain3p del9p21 gain/amp19q	BCL6 (25%) BCL2, NFATC1 (40%) PRDM1 (BLIMP1) (25-30%) FoxP1 (25%) CDKN2A (30%) SPIB (25%)			
Follicular lymphoma (FL)	CD20, CD22, CD79a, CD10, BCL-2, BCL-6	t(14;18) →	BCL2 (90%)			GC B cell
MALT lymphoma	CD20, CD79a; negative for CD10 +/- CD 5 and CD23	t(11;18) → t(14;18) t(3;14) t(1;14) → +3/3q and/or +18 del6q	API2-MALT1 (30%) IGH-MALT (5%) IGH-FOXP1 (10%) BCL10 (1%) - (40%) TNFAIP3 (A20) (30%)	√	√	GC B cell or post-GC B cell
Mantle-cell lymphoma	CD20, CD79a, CD5; negative for CD10, CD23	t(11;14) →	Cyclin D1 (95%)	–	–	Pre-GC B cell
Burkitt's lymphoma	CD20, CD10, BCL-6	t(8;14) →	MYC (100%)	√	√	Pre-GC B cell
Classical Hodgkin lymphoma	CD30, CD15 (CD79a) PAX5; MUM1	Gain/amp2p t(16p)(13)	REL (54%) CIITA (15%)	√	–	GC or post-GC B cell
Nodular lymphocyte predominant Hodgkin lymphoma	CD20, CD79a, BCL-6, CD45, CD75, OCT2	t(3q)(27)	BCL6 (50%)	√	√	GC B cell

DLBCL, Diffuse large B-cell lymphoma; *GC*, germinal center; *MALT*, extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissues; *SHM*, somatic hypermutation.

Although increased understanding of DLBCL based on cell of origin is emerging, it is clear that the dysregulated pathways across this entity are often overlapping, providing redundancy to promote growth and prevent cell death signals. These signaling pathways are often necessary for the development and differentiation of normal memory B cells and plasma cells and are coopted during malignant transformation.

For example, in ABC-derived DLBCL, most of the deranged signaling pathways converge to aberrantly activate the NFκB pathway, leading to evasion of cell death and resistance to chemotherapy (see Figure 29-4, *B*). Activation of this molecular pathway translates into poor outcomes for patients with ABC-DLBCL compared to GC-DLBCL, with 5-year overall survival of 40% versus 60%, respectively. Constitutive activation of NFκB is complex, involving both "classical" and "alternative" pathways, and can be regulated by many different mechanisms. Derangements leading to activation of NFκB can be attributed to a number of different molecular lesions, including tonic signaling of the BCR. BCR signaling is essential to B-cell development, antigen selection, and humoral immunity. Aberrations in BCR signaling, including tonic signaling that occurs in the absence of antigenic stimulation, can lead to uncontrolled B-cell growth and survival.

BCR signaling, whether it be in a normal or malignant B-cells, leads to the formation of the CBM complex consisting of CARD11, *B*CL10, and *M*ALT1. This complex leads to activation of NFκB through direct activation of NFκB and inhibition of negative NFκB regulators. Gain-of-function somatic mutations of the coiled-coil domain of CARD11 are found in nearly 10% of ABC-DLCBL and 16% of primary CNS lymphoma (an ABC variant). This mutant CARD11 leads to initiation of the NFκB cascade via IKKβ signaling in cooperation with casein kinase 1α (CK1α) and MALT1. MALT1 can also augment NFκB signaling through cleavage of two negative NFκB regulators, namely, A20 and CYLD. *TNFAIP3*, the gene encoding A20, can also be inactivated through mutations, deletions, or epigenetic silencing in ABC-DLCBL. Mutations of other negative regulators of NFκB, such as *IKBKA* encoding the inhibitor IkBα, lead to uninhibited translocation of NFκB to the nucleus and increased transcription of NFκB-dependent genes. Interestingly, linkage of this intrinsic ABC biology to B-cell receptor signaling may offer an interesting opportunity to affect the adverse prognostic features of this DLBCL phenotype.

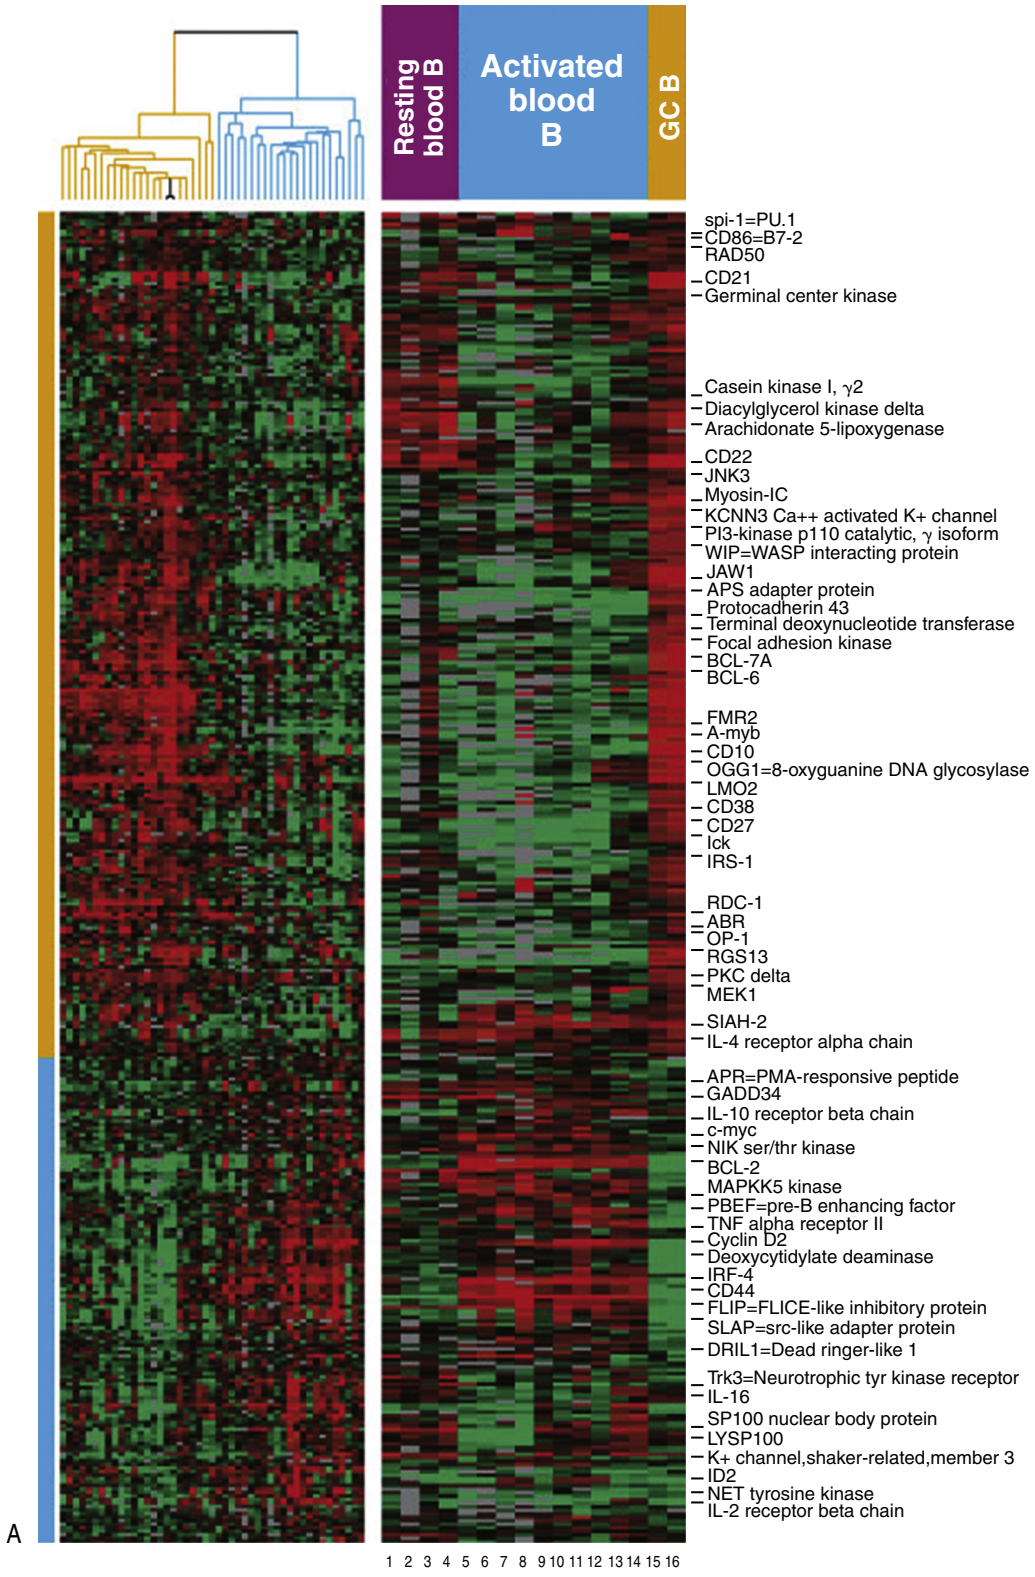

Figure 29-4 (A) Classification of diffuse large B-cell lymphoma based on cell of origin. The left panel represents hierarchical clustering of the genes selectively expressed in GC-derived DLBCL *(yellow)* and ABC-derived DLBCL *(blue)*. The right panel compares normal lymphocytes from blood and lymph nodes in various states of B-cell activation.

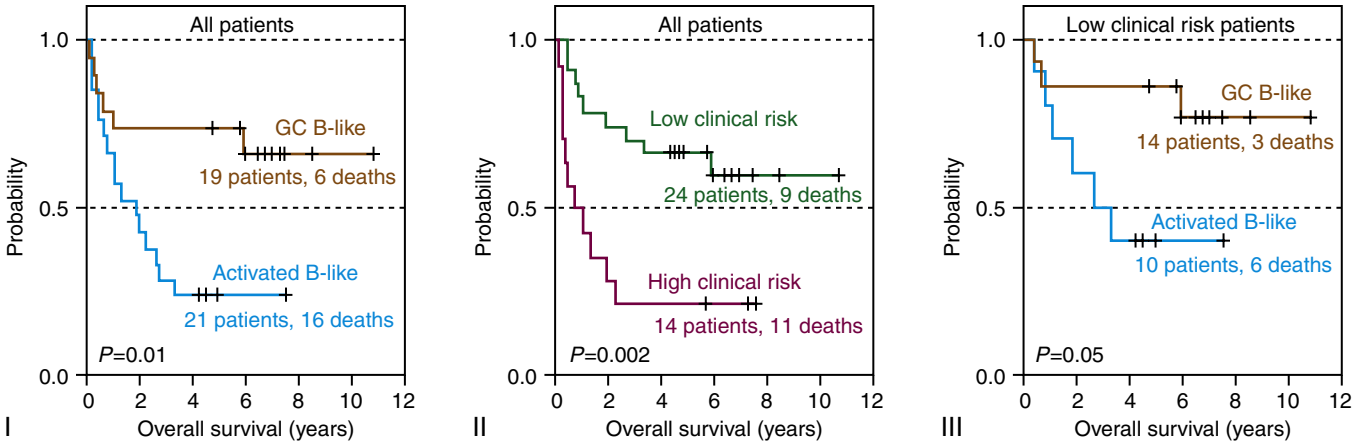
Continued



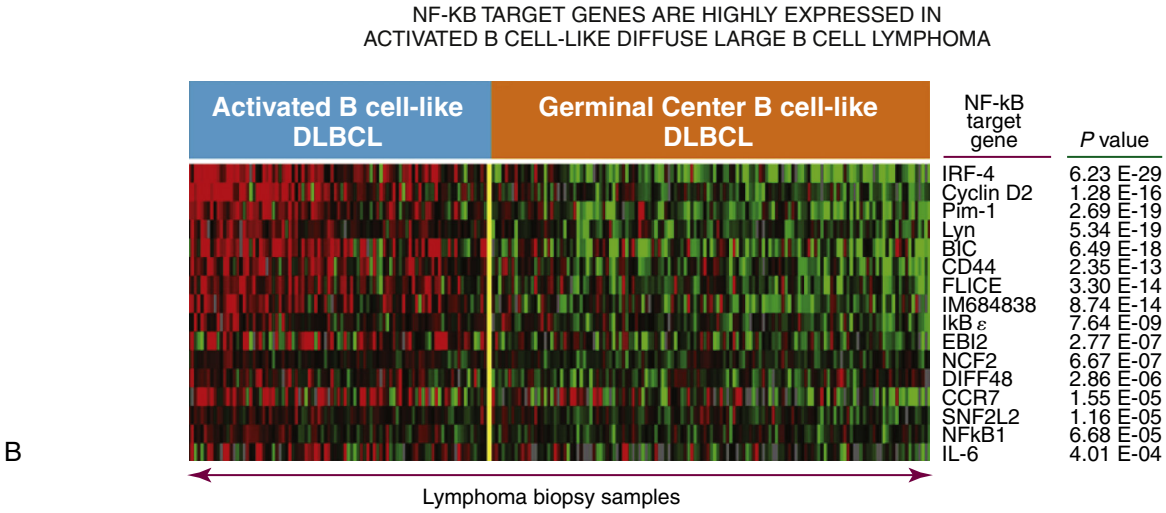


Figure 29-4, cont'd **(B)** Gene expression profile for the GC and ABC subtypes of DLBCL reveal that the ABC phenotype is enriched for NFκB-regulated genes, while the GC phenotype is enriched for Bcl-6-regulated genes. Gene expression profiling has revealed three subtypes of DLBCL, two of which include the germinal center subtype (GC) and the activated B-cell subtype (ABC). These molecular phenotypes override the prognostic impact of the International Prognostic Index (IPI). *Courtesy Wyndham Wilson. Data in* ***A*** *from Alizadeh et al.* Nature *2000;403:503-511.*

In addition to the BCR-CBM effects on NFκB regulation, the BCR can activate NFκB through a number of alternative mechanisms. On antigenic stimulation or tonic dysregulation, the BCR heavy chains are coupled to cell surface markers CD79a and CD79b. This leads to phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAM) by LYN, FYN, and BLK, which then recruit SYK, engaging the NFκB, PI3K, NFAT MAP kinase and RAS signaling pathways. Currently, an inhibitor of SYK is under investigation as a therapeutic target in those DLBCLs known to be addicted to BCR signaling. Substitutions and deletions of the CD79a and CD79b ITAMs are present in more than 20% of ABC-DLBCL and lead to a gain of function of the BCR signaling pathway. These mutants evade negative feedback by LYN and also allow for increased cell surface localization of the BCR.

Tonic BCR signaling also recruits Bruton's tyrosine kinase (BTK) via the PI3K pathway. This tends to occur in ABC-DLBCL that do not possess CARD11 mutations. BTK is required for the survival of wild-type CARD11 ABC-DLBCL and knockdown of its components or effectors SYK, BLNK, PLCγ2, PI3Kδ, PKCβ abrogates NFκB signaling. BTK is activated by LYN or SYK, and on activation initiates signaling of the classical NFκB pathway. In addition, BTK forms a complex with BLNK, which, through a series of events that activates CARD11, contributes further to activation of the NFκB pathway. BTK inhibitors have demonstrated promising activity in patients with ABC-DLBCL and other lymphomas with aberrant BCR signaling, such as CLL.

All known ABC-DLBCL cell lines and 30% of tissue samples from patients with ABC DLBCL harbor MYD88

gain-of-function mutations in the toll-interleukin receptor (TIR) domain. MYD88 is an adaptor protein that interacts with IRAK4 and IRAK1 to activate both the NFκB and interferon pathways through TRAF6. Mutant MYD88 promotes secretion of the cytokines IL6 and IL10 activating the JAK/STAT pathway. This potentiates NFκB through a positive feedback loop.

Many of the mutations just discussed are expressed in tandem and are restricted to the ABC-DLBCL variant over GCB-derived DLBCL. As testament to the redundancy in these signaling pathways, knockdown of parallel pathways in cell lines or mouse models has demonstrated synergistic cytotoxicity in ABC-DLBCL, compared to the knockdown of singular elements in a pathway. The clarification of this underlying biology has led to the identification of several new drugs potentially affecting these specific pathways, including inhibitors of Syk, BTK, and CD79a and b, and proteasome inhibitors that inhibit degradation of IkB, leading to inhibition of NFκB.

Although there is overlap in the pathogenesis of GC- and ABC-derived DLBCL, there are unique features of both that may create opportunities to affect the discrete natural history of these subtypes rationally. For example, transcription factors, oncogenes, and epigenetic alterations are often responsible for driving proliferation and survival in GC-DLBCL. *BCL6*, an oncogene, is a transcriptional repressor considered the hallmark of GC-DLBCL, and acts as a master regulator of the germinal center reaction. Although physiologically active in normal germinal center B cells promoting somatic hypermutation (SMH) and class switch recombination, this pathway is co-opted in malignant lymphomas to enforce the "damage phenotype" of GC-DLBCL. Dysregulation through point mutations and translocations of the 3q27 locus lead to constitutive activation of this transcription factor in over 50% of DLBCL lymphomas. Specifically, mutations in the BCL6 autoregulatory domains upstream from the promoter regions via somatic hypermutation and AID result in lost feedback loop inhibition from Bcl6, IRF4, and STAT5. This phenomenon leads to the GC-DLBCL subtype. In addition, the Bcl6 BTB domain recruits the co-repressors NCOR, BCOR, and SMRT, along with HDACs to repress genes involved in the DNA damage response such as ATR, p53, CHK1, p21, and p27. This repression leads to unchecked cell cycle progression in the face of inhibited apoptosis and permissive DNA damage. Furthermore, the Bcl6 RD2 domain recruits MTA3 to repress *PRDM1*, which encodes Blimp-1, the master regulator of plasma cell development, trapping centroblasts within the germinal center. Interestingly, Bcl6 inhibits both *MYC* and *BCL2*, but in double-hit lymphomas, where these two oncogenes are overexpressed by translocations, they overcome repression by Bcl6, leading to even more aggressive variants of DLBCL.

Another target gene of Bcl6 is IRF4, a transcription factor that facilitates exit from the germinal center, leading to plasmacytic differentiation. Bcl6 silencing of IRF4 further inhibits transcription of Blimp-1, which would retain cells in the germinal center. IRF4 may also be inhibited by translocations in GC-DLBCL (predominantly pediatric cases). In these cases, IRF4 may serve as an oncogene. Nonstructural aberrations not interfering with IRF4 function have been found to be required for survival of ABC-DLBCL. The effects of IRF4 in ABC and GC-DLBCL are clearly different, and this likely contributes to their classification by cell of origin. One mechanism proposed is that IRF4 works as a positive feedback loop involving CARD11.

Although Bcl6 translocations occur in GC-DLBCL (10%), translocations of the 3q27 locus involving the BCL6 gene that lead to arrest of cells in the plasmablastic stage of development can be seen in 30% of ABC-DLBCL. These translocations have promiscuous partners and ultimately lead to silencing of *PRDM1*. The tumor suppressor functions of *PRDM1* may be silenced by truncation, deletion, mutation, or epigenetic modifications as well.

Transcriptional control has also been influenced by mutations in epigenetic regulators. *CREBBP* and *EP300* encode histone acetyl-transferases (HATs) that have classically been known to modify chromatin condensation and, by extension, transcription. It is now known that these enzymes also influence the activity of key modulators of DLBCL such as p53, NFκB, and Bcl6. Acetylation can act either as an activating posttranslational modification (p53), or as an inhibitory posttranslational modification (Bcl6). Nonoverlapping mutations of *CREBBP* (40%) and *EP300* (10%) are found in GC-DLBCL. The inactivating mutations in these two genes lead to the activation of Bcl6 and inhibition of p53 by impaired acetylation. Reversal of this effect may be accomplished by therapeutic alteration of these posttranslational modifications pharmacologically with pan-Class1-2 histone deacetylase (HDAC) inhibitors.

GC-DLBCL has also been found to have mutations in the EZH2 component of the polycomb repression complex-2 (PRC2). This complex has histone methyltransferase activity and primarily trimethylates histone H3 on lysine 27 (i.e., H3K27me3), a mark of transcriptionally silent chromatin. In order to produce the pathologic effect, mutations are required to be heterozygous, allowing the wild-type allele to methylate H3K27, followed by the uncontrolled methylation mediated by the enzyme encoded by the mutant allele. This action leads to hypermethylated CpG islands, which in turn attracts methyl-CpG binding domain proteins (MBDP: MBD1, MBD2, MBD3, MeCP2 i Kaiso) to recruit HDACs, leading chromatin condensation and transcriptional silencing. Hypomethylating drugs have been shown in preclinical models to have therapeutic potential

and synergize with HDAC inhibitors to restore normal methylation and acetylation patterns on histones.

Although only recently described, the role of microRNAs in DLBCL lymphomagenesis has begun to emerge. MiRNAs can have both oncogenic and tumor suppressor properties. The miR-17-92 family, also known as oncomir-1, has been found to be amplified specifically in GC-DLBCL, which leads to increased expression of MYC and downregulation of BIM and p21. miR-17-92 also has an inverse relationship with p53, each inhibiting the other.

Molecular Pathogenesis of Follicular Lymphoma

Follicular lymphoma is a B-cell lymphoma derived from germinal center B cells with rearranged heavy- and light-chain genes. This derivation is depicted by the immunoarchitectural features of follicular lymphoma, particularly reflected in the expression of a germinal center immunohistochemical profile as well as a follicular growth pattern. Cytogenetically, about 90% of follicular lymphoma cases harbor the t(14;18) or variant B-cell CLL/lymphoma 2 *(BCL2)* rearrangements with immunoglobulin kappa or lambda on chromosome 2 and 22, respectively. Although centrocytes and centroblasts are regarded as the particular cell of origin, the lymphomatous counterpart demonstrates ongoing somatic hypermutations, which is of particular interest as it decreases the detection rate of follicular lymphoma by standard polymerase chain reaction (PCR) testing.

The most prominent cytogenetic abnormality in follicular lymphoma involves t(14;18) with rearrangement of *BCL2*. Normal BCL2 protein has an antiapoptotic effect by affecting mitochondrial permeability and release of cytochrome c. During the translocation of the IgH regulatory apparatus on chromosome 14 and the bcl-2 gene on chromosome 18, *BCL2* is juxtaposed to immunoglobulin heavy-chain gene (IgH) sequences, including enhancer sequences, which brings *BCL2* under the influence of the immunoglobulin promoter region. This leads to deregulated expression/overexpression of a functional protein, promoting increased cell survival and neoplastic transformation.

The rearrangement can occur in different breakpoint regions as noted:

- 65% to 70% occur in the major breakpoint region (MBR) located in an untranslated region of the last exon (exon 3).
- 20% occur at the 3′ end of the *BCL2* gene or 5′ to the minor cluster region (mcr).
- 10% occur in the mcr, which is about 30 kb outside of the *BCL2* gene.

Although additional breakpoints are being studied, efforts to associate these different breakpoints with different clinical characteristics or clinical outcome have been unrevealing.[8]

Testing for the *BCL2* rearrangement can be determined by conventional cytogenetic karyotyping, fluorescence in situ hybridization (FISH), or PCR. Although conventional cytogenetic karyotyping detects the majority of cases with *BCL2* rearrangement, independent of the partner gene, the limiting factor with this approach remains the availability of viable tissue. In comparison, FISH can be performed on paraffin-embedded tissue and detects the translocation in up to 90% of cases. Lower detection rates have been reported depending on the ethnic group studied—such as in Japanese patients, where the frequency of the t(14:18) has been shown less frequently compared to patients from Western countries.[9] Of interest, PCR testing has been proven to be less valuable, as most PCR assays contain primers targeting the MBR and mcr regions, which decreases the detection rate to 60%.[10] Although increased detection rates can be achieved by adding more primers to the 5′ mcr and 3′ MBR breakpoint regions, targeting incomplete DH-JH rearrangements or mutations of the primer-binding sites, false-negative PCR results are common and still occur with alternate breakpoints as mentioned earlier.[11] Therefore, up-to-date FISH analysis remains the preferred testing modality.[11]

The absence of *BCL2* translocation using the routinely available methods is described in a subset of follicular lymphomas, particularly primary cutaneous and pediatric follicular lymphoma. Further complicating the matter is the fact that multiple follicular lymphoma cases have been shown to increase their *BCL2* expression through alternate mechanisms, as shown in cases with an addition of 18q or trisomy 18.[12] Furthermore, the frequency of *BCL2* rearrangement is not only variable in different subsets of follicular lymphomas, but also differs as a function of the grade of the follicular lymphoma. More than 80% of low-grade follicular lymphoma cases possess the translocation, whereas higher grade follicular lymphoma cases harbor the translocation with a frequency of 70% and less than 15% in grades 3A and 3B, respectively.[13] However, a positive result for *BCL2* rearrangement demands additional studies, as the rearrangement is not specific and has been identified in other subtypes of lymphomas as well as in healthy individuals and in benign follicular hyperplasia.[14]

An additional random locus of genetic alteration in follicular lymphoma includes alterations of BCL6 at 3q27. Grade 3B follicular lymphomas frequently have rearrangements of this locus similar to diffuse large B-cell lymphoma.[13,15] The Bcl6 protein is a zinc-finger protein that acts as a repressor of IRF-4/MUM-1 transactivating ability, as well as influencing cell cycle control and proapoptotic

genes. The major breakpoint region of this translocation is within the 5′ first exon and a portion of the first intron of the Bcl-6 gene. In addition to translocation events, the coding region of the Bcl6 gene is also altered by somatic mutation.

Because t(14;18) can be identified in healthy individuals, the translocation is thought to be an early event in B-cell development, neither necessary nor sufficient for lymphomagenesis in B cells. The *BCL2* rearrangement is thought to enhance the life span of the neoplastic cell, which in return retains the capability to develop additional genetic defects. So far a myriad of additional abnormalities have been described, including gains of 1q, 2p, 7, 8q, 12q, 18q, and X and losses of 1p, 6q, 10q, 13q, and 17p.[16]

After detection of these additional abnormalities, prognostic factors have been identified, including gains of 1q, 12, and X, as well as losses of 1p, 17p, and 17q, all considered late events with a poor prognosis or associated with histologic transformation.[16] Transformation to diffuse large B-cell lymphoma is a relatively common event, occurring in 25% to 35% of follicular lymphoma cases.[16] To date, large-cell transformation has been linked to gains of 7, 12q, and X; losses of 4q, 13q, and 17p; *MYC* deregulation; and inactivation of *TP53* and *CDKN2A*. Although *MYC* deregulation has only been occasionally described in follicular lymphoma, it harbors a particularly poor diagnosis.[17] Newer diagnostic modalities such as comparative genomic hybridization (CGH) have firmly established that additional chromosomal abnormalities, such as gains in 12p and 18p in more than 10% of cases and deletions of 3q, 9p, and 11q in less than 10% of cases, are associated with particularly poor prognostic factors. Although these deletions involve the *CDKN2A* and *CDKN2B* loci as well as the LIM domain and have been partially associated with decreased survival, the overall significance of these findings has yet to be determined.[18]

Next-generation sequencing has been used to elucidate the mutational landscape of follicular lymphoma. With this modality it was discovered that 89% of cases harbored MLL2 mutations, 33% of cases showed CREBBP mutations, and 13% of cases depicted MEF2B mutations. E300 mutations were identified in 9% of cases, EZH2 mutations in 7% of cases, and the TBL1XR1/TP63 fusion gene was identified at a very low incidence. So far mainly the presence of EZH2 is of interest, as this particular mutation supports the hypothesis that the polycomb repressor complex-2 orchestrates the pathogenesis in a subset of germinal center–derived lymphomas, but in general the implications of these findings are still under investigation.[19]

Additional factors thought to be involved in the pathogenesis of follicular lymphoma include the nature of the microenvironment. In particular, the role of T cells and dendritic cells appears to be of substantial importance. GEP of the microenvironment has identified two distinct signatures. These signatures have been categorized as immune response 1 (IR1) and immune response 2 (IR2). Whereas immune response 1 (IR1) shows increased expression of T-cell genes and the macrophage genes *TNFSF13B* and *ACTN1*, immune response 2 (IR2) shows increased expression of follicular dendritic cell genes and different macrophage genes. Immune response 1 has been linked to a more favorable prognosis, but immune response 2 has been linked to an unfavorable prognosis.[16] To date, these genetic changes have not yet led to the tailoring of specific therapies for specific genetic subsets of the disease.

Molecular Pathogenesis of Marginal Zone Lymphoma and Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

Marginal zone lymphoma (MZL) arises from memory B cells that normally reside in the marginal zone of secondary lymphoid follicles. MZL is the third most common type of non-Hodgkin lymphoma, representing about 10% of all cases of NHL. At least three distinct entities of MZL have been included in the WHO classification, including extranodal MZL of mucosa-associated lymphatic tissue (MALT) lymphoma, which represents more than two thirds of all MZL cases; splenic MZL with circulating villous lymphocytes; and nodal MZL. Clinically, MZL typically presents as early-stage disease in most patients and exhibits an indolent course in most patients. However, MZL can become disseminated or transform into aggressive large-cell lymphoma. Over the past two decades we have witnessed unprecedented progress in our understanding of the biology of MZL at the molecular level, and some of that knowledge is being translated into the development of rational treatment paradigms.

Because MALT lymphoma develops in tissues that are not necessarily abundantly enriched with lymphocytes, the first step in the pathogenesis is the abnormal aggregation of lymphoid tissues in extranodal sites and organs. The etiologic factor in this process can be infectious and/or inflammatory. Gastric MALT lymphoma represents more than 50% of all MALT lymphoma and has been shown to be intricately associated with colonization of the stomach by the bacterium *Helicobacter pylori*.[20] Although aggregation of lymphocytes stimulated by *H. pylori* is a prerequisite for MALT lymphoma, *H. pylori* infection alone is not sufficient to cause the malignant transformation of lymphocytes into lymphoma cells. *H. pylori* is found in more than 90% of patients with MALT lymphoma, yet most patients with *H. pylori* infection do not develop lymphoma. *H. pylori* also produces inflammation and reactive oxygen species (ROS)

that further increase genomic instability, which is essential for lymphomagenesis. In support of the theory of genomic instability in gastric MALT lymphoma, a balanced translocation t(11;18)(q21;q21) was reported in up to 50% of all cases of the disease.[21] The translocation results in the production of fusion protein API/BIRC3-MALT1, which interacts with CARD11/CARMA1 to activate the critical pro-survival transcription factor NFκB.[22] The translocation t(11;18) has been found to be mutually exclusive of other cytogenetic abnormalities, further suggesting its role as an important, if not the singular, driver for the development of MALT lymphoma.[23] Importantly, the emergence of t(11;18) is associated with unfavorable clinical outcomes and resistance to antibiotics and chemotherapy in the treatment of gastric MALT lymphoma.[24]

In addition to its occurrence in the gastrointestinal tract, MALT lymphoma has been reported in the lung, ocular adnexa, salivary gland, and less commonly the skin and thyroid. MALT lymphoma in these sites often involves a different etiology. For example, *Chlamydophila psittaci* or *Borrelia burgdorferi* is thought to be responsible for MALT lymphoma of the ocular adnexa and skin, respectively, whereas inflammation caused by autoimmune disease is responsible for MALT lymphoma in the thyroid and salivary gland. Cytogenetic abnormalities are well described for MALT lymphoma in these sites and include t(14;18) and t(1;14), which involve MALT1 and BCL10, respectively. Other genetic abnormalities in MALT lymphoma include t(3;14) involving IGH-FOP1, +3/3q, +18/18q, and −6q23, many of which target TNFAIP3 (A20), a negative regulator of NFkB, which is also mutated and silenced by methylation in subsets of MZL.[25] The pathogenetic role of many of these genes and loci are poorly understood at present.

Splenic MZL is a less common entity of MZL and has been shown to be associated with hepatitis C infection (HCV) in some cases.[26] In these cases, HCV glycoprotein E2 interacts with CD81 on B cells and causes activation of the BCR and its downstream signals.[27,28] Similar to other etiologic factors in MZL, HCV is required for the initiation and maintenance of the malignant phenotype of MZL, but not sufficient to cause malignant transformation of memory B cells in the marginal zone. This is evident from the fact that most patients with HCV do not develop splenic MZL. Furthermore, the majority of patients with splenic MZL are not associated with HCV. Clearly, genetic and epigenetic alterations are required for the development of splenic MZL. Although t(11;18) is not associated with splenic MZL, cytogenetic abnormalities are very common in splenic MZL, including partial trisomy of 3q, gain of 12q, and deletion or translocation of 7q32.[21,29] Furthermore, recent studies have demonstrated that deregulation of the NFκB pathway is frequently observed in splenic MZL. For example, mutations and copy number abnormalities of NFκB genes have been shown to occur in 36 (36%) of 101 splenic MZLs in one series; in another series, inactivating mutations were found in the NFκB negative regulator A20 (6/46 = 13%), and activating mutations were found in MYD88 (6/46 = 13%) and CARD11 (3/34 = 8.8%). Interestingly, these mutations are largely mutually exclusive of each other, suggesting that they may play vital roles in the pathogenesis of splenic MZL. Mutations in NOTCH2, a gene required for marginal-zone B-cell development, is a recurrent genetic lesion in splenic MZL, accounting for approximately 20% to 25% of cases.[30] Importantly, NOTCH2 mutations are restricted to splenic MZL but not other indolent B-cell lymphoproliferative disorders such as MALT lymphoma.[31] These mutations are predicted to cause impaired degradation of the NOTCH2 protein or may result in a gain of function of the truncated NOTCH2 in splenic MZL. The 7q deletion mentioned earlier was investigated recently using a combination of high-resolution array comparative genomic hybridization and integrated transcriptomic analysis. No single gene from these analyses could be identified as a potential driving event for splenic MZL with del7q.[32] Rather, a number of genes and microRNA species were found to be downregulated, some attributed to promoter hypermethylation. Another study of the 7q deletion arrived at a similar conclusion and was able to find nucleotide changes in IRF5 in two of the patients, resulting in fourfold downregulation of the IRF5 gene in lymphomas with 7q32 deletion versus deleted tumors.[33] Importantly, ectopic expression of IRF5 in marginal-zone lymphoma cells decreased proliferation and increased apoptosis in vitro, and impaired lymphoma development in vivo, suggesting that IRF5 may be a haploinsufficient tumor suppressor in this lymphoma entity.

Another layer of complexity in the pathogenesis of splenic MZL was revealed by the discovery of frequent microRNA dysregulation.[34] When compared to reactive lymphoid hyperplasia and other lymphoproliferative diseases, splenic MZL is found to have distinct expression of miRNAs, including highly overexpressed miR-155 and miR-34a, and repressed expression of miR-377 and miR-145, which are candidate diagnostic tools for splenic MZL.

Nodal MZL is a rare entity of MZL and is also associated with HCV infection, though probably to a lesser degree than splenic MZL. No characteristic translocations or chromosome imbalances, such as the t(11;18) in MALT lymphoma and del7q in splenic MZL, have been described in nodal MZL. Only a few cytogenetic alterations of NMZL have been reported, including trisomy 3 in 50% to 70% of cases, none with a clearly established role in either the diagnosis or pathogenesis of nodal MZL. Recent studies by Arribas and colleagues demonstrated that nodal MZL is characterized by upregulation of the IL6 and IL2 cytokine pathways and CD40 signaling, which are involved in B-cell

survival.[35] Some of the highly expressed genes include SYK, which is involved in BCR signaling, and TAC1, which is involved in activating NFκB. In the molecular signature of nodal MZL, a large number of overexpressed genes were associated with the NFκB signaling pathway, such as CD74, CD81, CD82, RELA, and TRAF4, reaffirming the central role of NFκB as a converging point for the proliferation and survival of MZL cells. Interestingly, some microRNA species known to be involved in memory B-cell development, including, for example, miR-221, miR-223, and let-7f, were overexpressed, suggesting their potential utility in the diagnosis of nodal MZL.

Our increased understanding of the biology of MZL in the past decade has already changed how we manage these patients. Because the infectious agents have been found to be required to initiate and maintain the malignant phenotype of some MZL subtypes, antimicrobial treatment has become a highly successful strategy in many patients. The majority of patients with *H. pylori*–associated MALT lymphoma can be cured with antibiotics that eliminate the bacterium, thus sparing a large number of patients more aggressive and expensive treatments.[36] Treatment of HCV and *C. psittaci* are effective strategies to manage patients with splenic MZL and MALT lymphoma of the ocular adnexa. The discovery of antigen stimulation and the central role of the BCR and NFκB signaling in MZL certainly supports the rationale to explore inhibitors of these pathways with Syk and BTK inhibitors, and even proteasome inhibitors. Targeting NOTCH2, which has been studied predominantly in ALL, could also be an effective strategy in the treatment of splenic MZL.

In contrast to MZL, CLL/SLL are diseases with clearly identified cytogenetic aberrations that have been shown to correlate with prognosis and survival. The clonal population of B lymphocytes that characterize CLL express CD19, CD5, and CD23, with often dim expression of CD20. In addition, these cells typically exhibit reduced levels of surface immunoglobulin. Collectively, this features are the hallmark of mature and activated B lymphocytes.[37] As with many of the other lymphoid malignancies, as our understanding of the pathogenesis of these diseases evolves, our appreciation of their heterogeneity has broadened. This heterogeneity seen in CLL can be characterized at numerous levels, including the status of mutation of the V genes, the expression of CD38, ZAP-70, and other discrete cytogenetic lesions.

For example, CLL cases can be subdivided on the basis of mutations in the V genes, based on the direct comparison of the DNA sequence of germline V genes with the V genes in the CLL cells.[38] CLL cases can then be classified as mutated (that is, they exhibit a more than 2% difference from the germline sequence) or unmutated. Expression of ZAP-70, a protein that is normally expressed near the surface of T cells known to play a role in signaling through the TCR, has also been shown to be an independent prognostic factor.[39-41] In CLL it has been found to be profoundly prognostic. Patients who are ZAP 70^- have been shown to have a median survival of 8 years, compared to patients who are ZAP-70^+, who have a median survival of approximately 25 years. Collectively, these factors have been used to risk stratify patients with CLL, such that those patients with B-CLL clones having few to no V-gene mutations, or with $CD38^+$ and ZAP-70^+ B-CLL, have been found to have comparatively more aggressive, usually fatal disease. In contrast, those patients with mutated V-genes and/or little to no CD38 or ZAP-70 are typically considered to have a very indolent natural history.[42]

Recurring cytogenetic lesions have also been described and may be more valuable in risk stratifying patients with CLL, and ultimately in developing better tailored therapies for the disease. One of the most common is deletion of 13q14.3, which occurs in more than 50% of cases over time.[43] This region of the chromosome is thought to encode two miRNA genes.[44] However, some of the highest risk cytogenetic lesions include deletions of 11q22-23, 17p13, and 6q21.[45] Although the specific genes involved in these deletions remain to be precisely identified, loss of 17p13 is thought to be associated with loss of the tumor suppressor p53 function, and deletion of 11q22-23 is thought to be associated with loss of the ataxia-telangiectasia mutated (ATM) gene. Specific treatment regimens for these discrete genetic subcategories of CLL are in development, and some principles may be emerging. First, patients with loss of 17p are thought to have a very poor prognosis and are typically very refractory to chemotherapy. Some anecdotes suggest that these patients may respond well to anti-CD52–based therapy (alemtuzumab), and it is thought that BTK inhibitors might override this adverse prognostic feature. Similarly, patients who have loss of the ATM function through deletion of 11q22-23 may benefit from the introduction of alkylating agents into the treatment program.

Pathogenesis of Mantle-Cell Lymphoma

Mantle-cell lymphoma (MCL) accounts for approximately 6% of all cases of non-Hodgkin lymphoma, or about 3000 cases per year in the United States.[1] Only a decade ago, it was primarily thought to be one of the most challenging subtypes of lymphoma to treat, carrying the incurable characteristics of indolent lymphoma, and the unfavorable features of aggressive lymphoma. Over the past decade, treatment paradigms for the disease have changed rapidly, and so too has the natural history. These changes are attributed to a

number of observations: (1) the recognition that MCL is not one disease and, like DLBCL, is a very heterogeneous disease composed of more indolent and aggressive variants; (2) the finding that intensive induction chemotherapy regimens consolidated by ASCT used in the front line can consistently produce a response rate of 90% to 100% and produce prolonged progression-free survival compared to traditional R-CHOP–based chemotherapy regimens; and (3) the emergence of novel drugs affecting unique targets, such as proteasome inhibitors and immunomodulatory drugs, which have led to new opportunities to either complement existing treatment paradigms or manage relapsed or refractory disease without specific cytotoxic therapy. What has become painfully clear over the past several years, however, is that given the heterogeneity of the disease, certainly at a biologic level, failure to characterize future populations of patients with MCL on clinical study in this regard will lead to confounding of conclusions about future treatments.

The molecular hallmark of MCL is overexpression of cyclin D1.[46] Although dysregulation of cyclin D1 has been recognized for some time, it has now become evident that MCL is a disease, possibly the prototypical disease, defined by gross cell cycle dysregulation. Cyclin D1 dysregulation is the pathognomonic chromosomal translocation t(11;14)(q13;q32) of the disease, which places cyclin D1 downstream of the highly active IgH enhancer.[47] Essential to the pathogenesis of the disease, the mRNA of cyclin D1 undergoes alternative splicing to produce two unique transcripts: cyclin D1a, which has been clearly shown to drive much of the cell cycle dysregulation; and cyclin D1b, whose expression is more variable and whose role is less well defined.[48] Deletion or mutation of the cyclin D1a mRNA tail region produces a truncated version of cyclin D1a mRNA, which has been shown to be 6 to 10 times more stable than the wild-type full-length cyclin D1a mRNA.[49] In addition to the pivotal role the splice variants of cyclin D1 mRNA play, microRNAs, specifically miRNA61, downregulate cyclin D1a, potentially modulating the cell cycle kinetics. The influence of miR61 can also be influenced by mutations in the tail region of the cyclin D1a mRNA in MCL, which can abrogate the miR61 binding site, allowing for the marked overproduction of cyclin D1 protein.[50] In addition, a number of important translational events have been shown to regulate cyclin D1 level. Phosphorylation of cyclin D1 by GSK3β leads to polyubiquitination by the E3 ligase FBX4, rendering it a substrate for the proteasome and proteolytic degradation.[51] Inactivation of GSK3β would preempt cyclin D1 phosphorylation, which has been shown to occur in the setting where AKT is aberrantly activated,[52] whereas impaired proteolytic degradation of cyclin D1 can be prevented by mutation of the E3 ligase FBX4,[53] resulting in reduced ubiquitination of the D1 protein. Collectively, these overlapping mechanisms of cyclin D1 regulation ensure high levels of cyclin D1 protein in MCL and, in select settings, can lead to marked impact on the cell cycle kinetics.

Although cyclin D1 levels are central in the pathogenesis of MCL, it is by no means the only corrupted cell cycle pathway.[54] Cyclin D1 normally interacts with CDK4/CDK6 to facilitate cell cycle progression through the G1-S checkpoint.[55] CDK4 is frequently overexpressed or amplified in MCL,[56] which would further limit the checkpoint control. Conversely, impaired inhibition of cell cycle regulation can play a major role in the disease, as evidenced by the fact that patients with MCL often have little to no accumulation of the CDK inhibitors p16 and p27.[57] Loss of p16 influence has been shown in patients with MCL—this tumor suppressor is deleted in about half of all MCL cases, and either mutated or silenced by promoter hypermethylation.[58] Impaired cell cycle control due to loss of p27 has been attributed to a number of mechanisms. The protein level of p27 in MCL is regulated by the ubiquitin proteasome. The p27-specific F-box protein Skp2 is inducible and been shown to be overexpressed in some patients with MCL, in particular those with disease that is known to be more aggressive. Increased levels of Skp2 lead to more active ubiquitin ligases, which leads to more prompt and efficient ubiquitination of p27 and thus a theoretically shorter half-life for the protein. This loss of cell cycle inhibition has been noted in patients with more aggressive forms of the disease.[59] This convergence of markedly dysregulated cell cycle control processes, involving both drivers and inhibitors of cell cycle kinetics, conspires to affect the proliferative rate of the disease and, as we now know, the risk stratification of select patient subpopulations.

The notion that the proliferative rate of the disease can be prognostic has now been confirmed at a number of levels. Patients with the truncated version of the mRNA of cyclin D1a, the stabler form, are known to have disease with a higher proliferative index[49] and more aggressive histologies, such as blastoid MCL.[60] Remarkably, the median overall survival (OS) of MCL patients with the truncated cyclin D1a mRNA is only 1.38 years, compared to 3.28 years for patients with the full-length and unstable mRNA.[49] The levels of the full-length mRNA transcript of cyclin D1a have been shown to positively correlate with the proliferation index as assayed by positive immunostaining of Ki-67. Ki-67 is a nuclear protein found in all states of the cell cycle (G_1, S, G_2, and M), but is absent from resting cells (G_0). Many cell cycle regulatory factors have been shown to correlate with the protein level of cyclin D1 on immunohistochemical staining, including the percentage of MCL cells with positive nuclear staining of the protein or the amount of nuclear staining of cyclin D1.[60] Conversely, the expression of p27 is inversely associated with Ki-67, where high levels of p27 appear to be

associated with lower proliferative index and improved overall survival.[57] These lines of data strongly support the contention that MCL is a disease grossly characterized by cell cycle dysregulation, and that these features of the underlying disease biology can be highly prognostic.

Further confirming the significance of the proliferative index, several studies have shown that nuclear staining of Ki-67, and using a cutoff of 30%, predicted OS, where patients below and above the 30% cutoff experienced a median OS of 13 months and 45 months, respectively.[61] Using yet another approach, a group at the National Cancer Institute (NCI) employed GEP to characterize patients with MCL (Figure 29-5). Their profiling experience firmly established that heterogeneity of the disease, which they used to define the proliferation signature of MCL. They discovered 48 genes whose expression levels were highly correlated with survival in a statistically significant manner. Among those 48 genes were a group of 20 genes that were variably expressed, though strongly correlated with cellular proliferation. They called the pattern of gene expression the "proliferation signature," which could essentially stratify patients along a continuum from highly proliferative to less proliferative disease.[62] Calculation of the average expression levels of these 20 genes in the proliferation signature allowed for the separation of the population into quartiles. The median OS of patients with the lowest expression of proliferation signature genes (quartile 1) was 6.71 years, whereas those with the highest expression (quartile 4) exhibited an OS of only 0.83 years. Surprisingly, cyclin D1 was not among the proliferation signature genes identified using the data generated from DNA microarrays, because the chip-based technology detected only the full-length mRNA of cyclin D1, which is unstable. Employing a reverse transcriptase (RT)-PCR assay to differentiate the two species of the cyclin D1 mRNA showed that patients with the truncated mRNA of cyclin D1 (3′ UTR low) demonstrated a higher expression level of cyclin D1, a higher expression of the 20 "proliferation signature" genes, and a substantially shorter OS, compared to patients with the full-length mRNA of cyclin D1 (i.e., 3′ UTR high).[62] When RT-PCR was designed to detect only

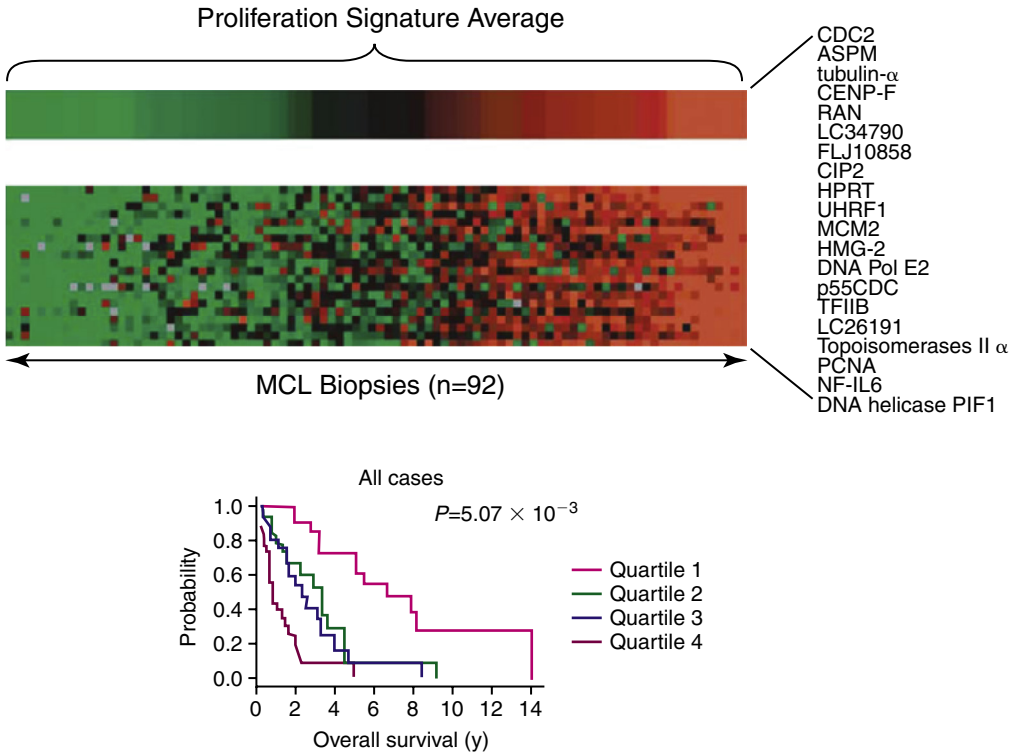

Figure 29-5 Gene expression profiling of mantle-cell lymphoma cases reveals prognostic significance of the proliferation index Gene expression profiling of primary mantle-cell lymphoma cases has demonstrated that the most aggressive forms of the disease are associated with an enrichment of genes involved in cell proliferation, a higher proliferative index, and a poorer prognosis. Cases with a lower proliferative index have a better prognosis. Proliferation gene expression signature may predict survival in MCL. These authors established a molecular diagnosis of MCL based on gene expression that can distinguish the disease from other lymphoma types. Using this diagnostic tool, they were able to investigate gene expression patterns in patient samples and evaluate whether there was a correlation with survival. In addition, they were able to investigate the genetic aberrations that are the basis of the pathobiology of MCL. This figure shows the proliferation signature average (PSA) for 92 samples from patients with MCL. The PSA is the average expression of the top 20 genes that were expressed most variably in MCL (i.e., the top third). To visualize the power of this as a predictive model, patients were ranked according to the expression of these "signature" genes in their tumors and then divided into four equal quartiles as shown. This analysis allows a suggested quantitative relationship between proliferation and survival. The Kaplan-Meier plots of overall survival of patients in each of these quartiles indicate that the proliferation signature can identify subgroups of patients with different survival times. Median survival times for each quartile were 6.71 years (1), 3.28 years (2), 2.31 years (3), and 0.83 years (4). *Data from Rosenwald A et al.* Cancer Cell. *2003;3:185-197.*

the coding region of cyclin D1 mRNA, which accounted for both the full-length and truncated mRNA, the levels of cyclin D1 were again shown to correlate with patient survival.

There is no question that the proliferative index of individual patients with MCL is prognostic. There is also no doubt that failing to characterize study populations with regard to this biologic parameter will lead to confounding influences in our interpretation of clinical trial data. The prognostic impact of the proliferation index remains relatively significant irrespective of the therapy, as had been shown with rituximab,[63] high-dose chemotherapy and stem cell transplant,[64] and the proteasome inhibitor bortezomib.[65] Moving forward, it will be critical to determine if the proliferation signature will prove useful in predicting responses to specific treatments, or even if it could be used to tailor treatment to a particular disease context. Although prognosticating patients with MCL using DNA microarray-based gene expression profiling remains an experimental approach, RT-PCR–based measurement of the expression of proliferation signature genes[62] may be validated and practical in the near future.

Pathogenesis of Lymphomas Derived from Thymic B cells: Primary Mediastinal Large B-Cell Lymphoma, Hodgkin Lymphoma, and Gray Zone Lymphomas

Lymphomas arising in the anterior mediastinum have posed significant diagnostic and management challenges over the past several decades, especially given the overlapping biologic and clinical features of these diseases. Emerging molecular data have begun to demonstrate important differences in the molecular pathogenesis of these diseases, especially the cell of origin. Both bone marrow stroma and thymic stromal cells express ligands and cytokines required for B-cell differentiation. Despite the shared roles marrow and thymic stroma play in B-cell differentiation, B-cell development in the thymus is very restricted. B-cell precursors are present in the thymus and are felt to be distinct from B-cell precursors in the bone marrow. Although the thymic microenvironment is the source of lymphopoietic factors that include interleukin-7 (IL-7), pro-B cells exposed to the thymic microenvironment are hyporesponsive to IL-7, whereas pro-B cells derived from the bone marrow are typically responsive. Thus, pro-B cells from the thymus accumulate at an early pro–B-cell stage of development, cycle less than their bone marrow counterparts, and fail to differentiate efficiently.[66] This difference in the microenvironment and its effects on the maturation of B cells may account for the unique features for lymphomas that arise from thymic B cells compared to lymphomas arising from the bone marrow and other lymphoid tissue.

Based merely on histopathologic features, including the expression of CD20, primary mediastinal large B-cell lymphoma (PMBL) had always been considered a diffuse large B-cell lymphoma (DLBCL), at least until it was recognized as a discrete entity in the REAL Classification in 1994.[67] Despite the histopathologic similarities with DLBCL, it was becoming evident in the early 1980s that the clinical presentation of PMBL and DLBCL, as well as the prognosis, was significantly different. Differences in the molecular pathogenesis of these diseases became evident when differences in gene expression profiling demonstrated extensive overlap between PMBL and classical Hodgkin lymphoma–nodular sclerosing (cHL-NS)[68] (Figure 29-6). Though unclear for years, it is now widely recognized that the Hodgkin–Reed Sternberg (HRS) cells are characterized by suppression of many components of the B-cell program, and they are incapable of immunoglobulin secretion.[69] Efforts to identify the differences between PMBL and other subtypes of B-cell lymphoma using gene expression profiling led to the surprising observation that PMBL was strikingly similar to the profiles seen for cHL rather than for other subtypes of DLBCL. In a study by Rosenwald and colleagues, more than one third of the genes that were more highly expressed in PMBL compared to DLBCLs were also characteristically expressed in Hodgkin lymphoma cells.[68] In this study, the PDL2 gene, which encodes a regulator of T-cell activation, was the gene that best discriminated PMBL from other DLBCLs. PDL2 was more highly expressed in PMBL and cHL and either not expressed or expressed to minor levels in DLBCL. The genomic loci for PDL2 and several neighboring genes were amplified in more than half of cases of PMBL and Hodgkin lymphoma and expressed to much lower levels in DLBCL. Collectively, these data gave credence to the observation that B-cell lymphomas derived from the thymus were a unique entity based on the shared pathogenetic features and likely clinical history. It also established that they were markedly different compared to those B-cell lymphomas derived from the bone marrow compartment.

Genetic studies of PMBL frequently demonstrate amplification of recurring regions on chromosome 9p and 2p, which, interestingly, have also been described in cHL, and rarely in other subtypes of DLBCL.[70] The 9p region encodes JAK2, a tyrosine kinase that phosphorylates and activates the transcription factor STAT6. SOCS1, which suppresses JAK signaling, is regularly deleted in both PMBL and cHL, contributing to further dysregulation of the JAK-STAT pathway.[71] Other genes thought to be involved at 9p include PDL1 and PDL2, whereas c-Rel may be involved at 2p. Like cHL, PMBL also has constitutively activated NFκB and loss of CIITA (MHC 2), which may help explain

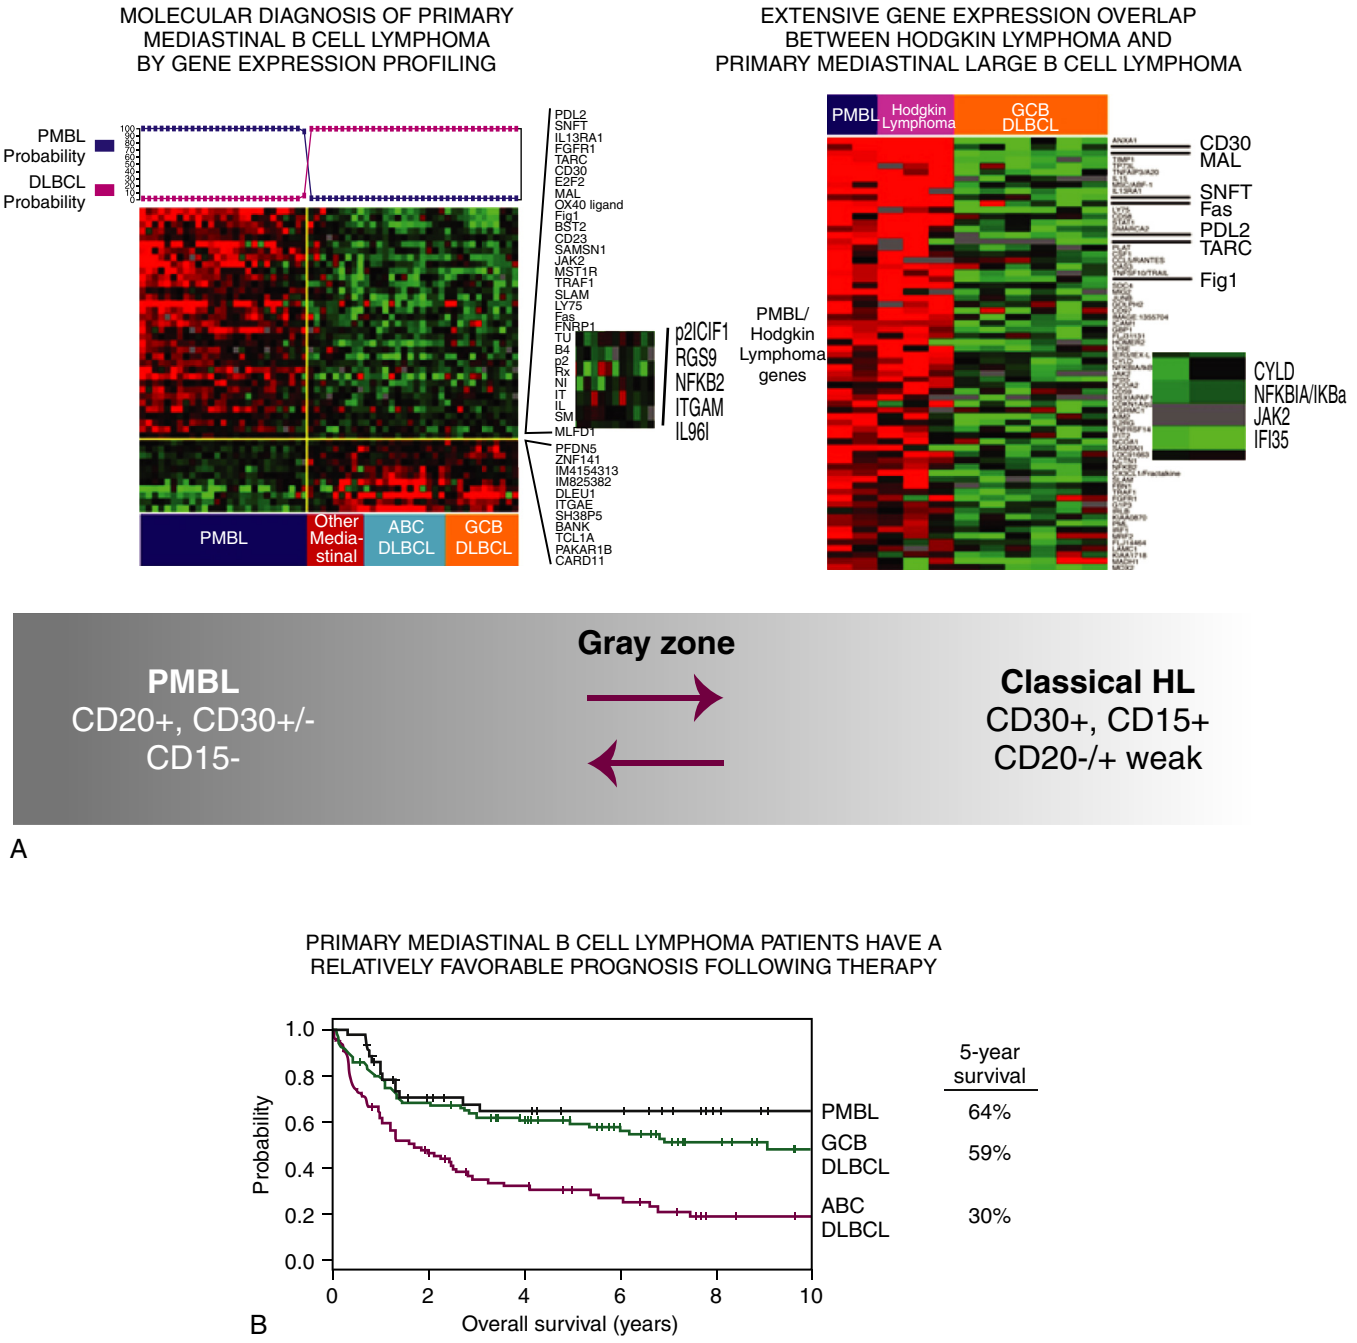

FIGURE 29-6 **(A)** Gene expression profiling of primary mediastinal B-cell and Hodgkin lymphoma reveal marked similarities with each other, and marked dissimilarity with DLBCL. **(B)** Patients with PMBL have a prognosis similar to that for Hodgkin lymphoma, and superior to that for patients with DLBCL.

the ability of these cells to evade immune surveillance.[72] Although PMBCL and cHL share a cell of origin in the form of the thymic B-cell, as well as molecular characteristics, there are still important morphologic and immunophenotypic distinguishing features between these two diseases with significant clinical and treatment implications.

Another example of a thymic B-cell lymphoma, recognized only in 2008 by the WHO Classification of Tumors of Hematopoietic and Lymphoid Tissues, is the entity known as *gray zone lymphomas* (GZL), now more widely referred to as *B-cell lymphoma* with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma.[4] GZL represents a mediastinal B-cell lymphoma that does not fulfill the morphologic and/or phenotypic criteria for PMBL or CHL, but instead represents a spectrum between these two entities.

Interphase FISH studies of GZL have demonstrated a number of recurring molecule lesions, including amplification of the REL/BCL11A locus, alterations affecting the JAK2/PDL2 locus, and rearrangement of the CIITA (MHC2)

locus, as well as gains of MYC.[73] Although the molecular signature of GZL has not been elucidated, a recent large-scale methylation analysis of PMBL, CHL, and GZL has demonstrated a number of similarities in the methylation profile of these diseases, although GZL did exhibit its own unique profile distinct from PMBL and cHL.[74] Importantly, GZL could be distinguished from cHL-NS and PMBL by differential methylation of selected CpG islands, and a class prediction model could be established to segregate the various entities. Thus, the global methylation profile of these entities may be useful not only to establish new diagnostic tools and clarify the pathogenesis of these lymphomas, but also to identify possible targets for future therapies.

While lymphomas of the thymic B-cell origin (cHL-NS, GZL, and PMBL) are closely related diseases that share clinical and biologic characteristics, there remains a spectrum of heterogeneity.

As the field of medical oncology enters the molecular and targeted therapy era, the biology that connects this disease and sets some lymphomas apart from DLBCL can pave the way for new therapeutic platforms that optimize efficacy and limit toxicity. The elucidation of pathways and molecular targets that are unique to the thymic B-cell lymphoma group of disease gives credence to therapies targeting NFκB, Janus kinases (JAK), programmed death-1 (PD-1), and epigenetic-based therapies.

Molecular Pathogenesis of the Peripheral T-Cell Lymphomas

The mature T-cell lymphomas, also referred to as *peripheral T-cell lymphomas* (PTCL), arise from thymic T cells or NK cells. These diseases are associated with often diverse presentation, arising in either the nodal or extranodal compartments.[4] Molecular and genetic characterization of PTCLs has lagged well behind that of B-cell non-Hodgkin lymphomas—in part because of their rarity and the relatively specific morphologic and immunophenotypic features of these neoplasms, which has precluded reliable identification of the cell of origin and classification into distinct disease subtypes.

Studies using conventional cytogenetic analysis over the past two decades have revealed only limited, disease-specific, recurrent karyotypic abnormalities.[75] CGH studies have helped delineate genetic differences, as well as similarities, between different subtypes of PTCL.[76] Gene expression profile analyses are providing insights into cell-intrinsic and microenvironment-related pathogenetic features in disease subsets,[77] as well as genetic signatures associated with clinical outcomes.[77] Higher resolution genetic analyses, specifically exome and genome sequencing using next-generation techniques, might help refine diagnostic categories and provide prognostic and therapeutically actionable information.

Recent advances in immunophenotypic analysis and systematic clinical characterization of large series of PTCL have led to the recognition of more than 22 different defined or provisional clinicopathologic subtypes of T-cell lymphoma that are distributed among four different subcategories in the present WHO classification (2008).[4] Molecular and genetic aspects of disease pathogenesis of some of the more common and better defined subtypes of PTCL are described here.

Anaplastic Large-Cell Lymphoma (ALCL)

Two different types of ALCLs are presently recognized, including ALK$^+$ ALCL and ALK$^-$ ALCL, the former associated with a superior outcome relative to ALK$^-$ ALCL. Although these entities share similar morphologic and immunophenotypic features, there are a number of key differences in their biologic and clinical characteristics. ALK$^+$ ALCL is characterized by the chromosome translocation t(2;5)(p23;q35) in 55% to 85% of systemic ALCL, or variant translocations involving ALK and other partner genes in a minority of cases.[78,79] The translocation t(2;5)(p23;q35) results in a fusion protein, nucleophosmin (NPM)/ALK (NPM-ALK), which leads to the constitutive activation of the ALK tyrosine kinase and alterations in multiple signaling pathways, including the Janus kinase 3 (JAK3)/signal transducer and activator of transcription (STAT3), phosphatidylinositol 3-kinase (PI3-kinase)/protein kinase (AKT)/mammalian target of rapamycin (mTOR), and the phospholipase C-γ (PLC-γ) mediated RAS-extracellular signal–regulated kinase (ERK) pathways.[78] Activation of Notch1 signaling by its ligand Jagged1, which is expressed on neoplastic and neoplastic cells, has also been proposed to play a role in the pathogenesis of ALK$^+$ ALCL.[80] Secondary MYC translocations have been reported in some cases with an aggressive behavior.[81]

It is unclear at present whether ALK$^+$ ALCL originates from cytotoxic T cells or acquires a cytotoxic phenotype, but studies have reported activation of a Th17 differentiation program in this disease.[77] Molecular alterations in signaling pathways as a consequence of the variant translocations are not adequately understood, but similarities and differences in gene expression profiles with NPM-ALK have been described.[82] Differences in gene expression profiles between certain morphologic subtypes of ALK$^+$ ALCL have also been reported,[83] but array CGH analysis of NPM-ALK and variant ALK translocations associated with ALCL have revealed similar recurrent secondary genetic abnormalities.[76]

The cell of origin of ALK⁻ ALCL is also not known at present. Array CGH analysis of ALK⁺ and ALK⁻ ALCL has highlighted differences in secondary genetic aberrations between the two subtypes,[76] and differential expression of microRNAs has also been reported.[84] Comparative gene expression analysis of ALK⁺ and ALK⁻ ALCL has revealed deregulation of common kinase signaling cascades and regulators of apoptosis, as well as differences between these subtypes, such as alterations in cell cycle regulators, signal transduction proteins, and various transcription factors.[85] ALK⁺ ALCL shows overexpression of genes implicated in immune or inflammatory responses, regulation of NFκB signaling, and lymphocyte migration and adhesion, whereas ALK⁻ ALCL exhibits overexpression of genes involved in certain cytokine signaling pathways.[83] Analysis of ALK⁻ ALCL using next-generation massively parallel sequencing has revealed a recurrent balanced translocation t(6;7)(p25.3;q32.3), leading to the juxtaposition of the DUSP22 phosphatase gene with the fragile site FRA7H, which results in the downregulation of DUSP22 and upregulation of MIR29 microRNAs located on 7q32.3.[86] This translocation was observed in 45% of ALK⁻ ALCLs with 6p25.3 rearrangements and in both systemic and cutaneous forms of ALK⁻ ALCL. The biologic consequence of this translocation awaits further investigation.

Peripheral T-Cell Lymphoma Not Otherwise Specified

PTCL-NOS is the most common subtype of PTCL, accounting for up to 25% of all PTCL occurring worldwide. It is a clinically heterogeneous entity, potentially comprising different PTCL subtypes at different stages of disease evolution. Comparison of PTCL-NOS expression profiles with those of purified T-cell subsets has suggested a relationship between PTCL-NOS subtypes with either activated CD4⁺ or CD8⁺ T cells,[87] and cases exhibiting a gene expression profile similar to cytotoxic T cells have been shown to have inferior survival.[77] PTCL-NOS lacks specific, recurrent cytogenetic abnormalities, but complex cytogenetic aberrations have been associated with a poor prognosis in PTCL-NOS.[75] Recently, the translocation t(5:9)(q33:32) was reported in 17% of PTCL-NOS, which results in the fusion of the *IL-2 inducible T-cell kinase* (ITK) gene with the *spleen tyrosine kinase* (SYK) gene.[88] Transgenic mice expressing the ITK-SYK fusion transcript develop T-cell lymphomas mimicking the human disease.[89,90] Overexpression of Syk tyrosine kinase and Syk phosphorylation, in the absence of *SYK* translocations, has also been observed in PTCL.[86]

Based on the expression levels of the NFκB pathway genes, PTCL-NOS can be segregated into two groups showing differences in survival.[91] The differential expression of a set of proliferation and cell cycle–associated genes, including CCNA, CCNB, TOP2A, and PCNA, has been shown to predict prognosis.[92] PTCL-NOS shows deregulation of pathways controlling apoptosis, cell proliferation, adhesion, matrix remodeling, and chemoresistance, and upregulation of platelet-derived growth factor receptor alpha has been observed in many cases.[87]

Distinguishing PTCL-NOS from ALK⁻ ALCL can be difficult using current cytomorphologic and immunophenotypic criteria. This is mirrored at the chromosomal and genetic level. Early gene expression profiling studies were unable to distinguish PTCL-NOS from other PTCL subtypes.[91] However, analysis restricted to nodal PTCL allowed discrimination between PTCL-NOS and other PTCL subtypes and further subclassification based on alterations of different biologic processes or signaling pathways.[9] Refined, supervised gene expression profile analysis can provide a signature allowing distinction between PTCL-NOS and ALK⁻ ALCL; however, the pathogenetic significance of the involved genes and pathways is not yet clear.[94] Recently a model comprising three genes, TNFRSF8, BATF3, and TMOD1, obtained from a meta-analysis of the transcriptional profiles of a large series of PTCL, was shown to distinguish ALK⁻ ALCL from PTCL-NOS.[95] Future studies might illuminate the biologic basis of this observation. PTCL-NOS and ALK⁻ ALCL also share karyotypic abnormalities, including gains of chromosomes 1q and 3p and losses on chromosome 6q, although the loci on 6q have been shown to differ.[75] CGH analysis has shown overlapping aberrations, including 6q and 13q losses, as well as subtype-specific abnormalities.[96] Recurrent chromosome gains of 7q that target cyclin-dependent kinase 6[97] and 8q involving the *MYC* locus[98] have been reported in PTCL-NOS. A recent genome-wide NGS analysis of PTCL led to the identification of recurrent translocations involving p53-related genes, including rearrangements of the *TP63* gene with TBL1XR1 and ATXN1 genes.[99] These gene fusions encode proteins that inhibit the p53 pathway and are associated with adverse clinical outcomes. Screening a large series of cases for *TP63* rearrangements by FISH showed similar frequencies in PTCL-NOS (9.4%), ALK⁻ ALCL (12.5%), and primary cutaneous ALCL (10.5%).

Angioimmunoblastic T-Cell Lymphoma

AITL is thought to derive from T-follicular helper (TFH) cells based on phenotypic features and overexpression of genes characteristic of normal TFH cells (CXCL13, BCL6, PD-1, CD40LG, and NFATC1).[100,101] Microenvironmental factors and signals orchestrating tumor-stroma cross talk are

thought to play a role in AITL pathogenesis. Recent studies, however, have also demonstrated a TFH phenotype for a subset of PTCL-NOS.[102] This might be one of the explanations for the inability of gene expression profiling to segregate AITL from subsets of PTCL-NOS in some instances.[87] Gains of chromosomes 3q, 5q, and 21 have been described as recurrent alterations in AITL, although the genes affected by these changes are not known.[75] Studies from transgenic mouse models and genome sequencing studies have begun to provide insights into AITL pathogenesis and its relationship with other types of PTCL. Mice engineered to disrupt the function of the *Tet2* gene showed an increase in T-cell progenitors and developed T-cell lymphomas. On sequencing human lymphoma specimens, heterozygous insertions and deletions of *Tet2* were detected in 33% of AITL and smaller subsets of other PTCLs.[103] Analysis of a large cohort of PTCL revealed a higher frequency of *Tet2* mutations in AITL (47%) and PTCL-NOS (38%) and an association with adverse clinical features.[104] Of interest, PTCL-NOS expressing TFH markers, despite showing or lacking a histopathologic resemblance to AITL, demonstrated a significantly higher frequency of *Tet2* mutations. Furthermore, *DNMT3A* mutations occur in a high frequency (73%) of cases harboring *TET2*, including PTCL-NOS and AITL, suggesting oncogenic cooperation between pathways regulated by *TET2* and *DNMT3A* such as cytosine methylation and demethylation processes in PTCL.[105] Recently, heterozygous IDH2 mutations, mostly resulting in an R172 substitution, have been described in 20% to 45% of AITL.[106] The prognostic implications of this mutation, if any, are unclear at present. It also remains to be seen whether this mutation is specific for AITL or other subtypes of PTCL derived from TFH cells. Overall, these studies indicate an important contribution of epigenetic alterations in the pathogenesis of AITL and at least a subset of PTCL-NOS.

Translating Molecular Pathogenesis into Novel Treatment Platforms

One of the many objectives for improving our understanding of the molecular basis of any disease is ultimately to use that information to treat disease in a more biologically rational manner. The explosion of detailed mechanistic studies into the pathogenesis of lymphoma has begun to create new opportunities for therapeutic intervention. Although we could point to many studies in various stages of development, the focus here is on one in ABC-DLBCL.

As discussed earlier, the emergence of new small molecules targeting BTK has provided an immediate opportunity to treat B-cell lymphomas at a fundamental level. Enrichment for dysregulated BCR signaling in ABC-DLBCL offers an opportunity to improve the outcome of a subset of DLBCL associated with an inferior prognosis. The recent development of the BTK inhibitor ibrutinib has been shown to completely block BCR signaling and induce apoptosis. Ibrutinib forms a bond with cysteine-148 in BTK, inhibiting the kinase with an IC50 of 0.5 nM, and with a relatively high degree of specificity. In a recent study reported by the NCI, 49 patients with relapsed or refractory DLBCL derived from the GC (n = 20) or ABC origin (n = 29) were treated with ibrutinib at the maximum tolerated dose. These patients were overall very heavily treated, with a median of three to four prior therapies, with a substantial number having refractory disease. With the caveats of a small unrandomized study, the overall response rates were 41% among those patients with ABC DLBCL (12 of 29 responding), compared to 5% (1 of 20) among those patients with GC-DLBCL. In addition, although no complete remissions were seen in the GC group, 17% of the responses seen in the ABC subtype were complete remissions. When the response in the ABC group was characterized as a function of CD70b and MYD88 mutation, the response rates seen among patients with mutant CD79b, wild-type CD79b, and mutant 79b/MYD88 were 71% (5 of 7), 34% (10 of 29), and 80% (4 of 5), further supporting the idea that drugs targeting specific pathways known to be dysregulated in a particular biologic subset of disease may be able to help overcome some of the adverse prognostic features of that disease.

Future Directions

Our rapidly evolving understanding of lymphoma at the molecular level has afforded new opportunities to better risk stratify patients, which will likely lead to more reasonable tailoring of treatment, and has firmly created the opportunity to more precisely treat these diseases with respect to their underlying biologic basis. At present, small molecules targeting BCR signaling mechanisms, PI3-kinase, Bcl-2 family members, and a host of monoclonal antibodies and antibody drug conjugates offer the potential to tailor the use of these small molecules with complementing current treatment paradigms, or creating new ones with less of an emphasis on specific cytotoxic therapy.

Multiple Myeloma

Multiple myeloma (MM) is a hematological cancer characterized by the accumulation of neoplastic plasma cells in the bone marrow associated with elevated serum and/or urine monoclonal paraprotein levels. During the course of the disease, patients with MM usually suffer debilitating clinical manifestations linked, directly or indirectly, to the accumulation of tumor plasma cells, including lytic bone lesions, anemia, immunodeficiency, and renal function impairment. MM accounts for more than 10% of all hematological malignancies, representing the second most frequent blood cancer in the United States after non-Hodgkin lymphoma.[1-4] MM is almost always preceded by a condition termed *monoclonal gammopathy of undetermined significance* (MGUS),[5,6] defined by the presence in the serum of a monoclonal paraprotein below 30 g/L, an accumulation of less than 10% plasma cells in the bone marrow, in the absence of clinical manifestations. MGUS is present in 1% of adults over age of 25 and evolves toward malignant MM at a rate of 0.5-3% per year.[7,8]

In the past few years, the use of more intense bone marrow transplant treatment regimens and, most importantly, the introduction in the clinic of novel therapeutic compounds such as thalidomide, the immunoregulatory drug lenalidomide (Revlimid), and the proteasome inhibitor bortezomib have considerably improved the outlook for MM patients, leading to a median overall survival above 10 years for more than 30% of patients.[4] As described herein, the ongoing comprehensive analysis of the genetic lesions affecting tumor cells and the growing awareness of the essential role exerted by the surrounding microenvironment in feeding and sustaining tumor growth is providing novel stratification tools and therapeutic opportunities that will likely further improve the patient outcome while reducing drug-related toxicity.

The Role of Tumor Genetics and the Microenvironment in the Pathogenesis of Multiple Myeloma

Overview of the Genetic Lesions Present in Multiple Myeloma

Unlike other hematological cancers such as leukemias and lymphomas that present a relatively unscathed karyotype, the MM genome is thoroughly reshuffled, more similarly in this regard to cancers of epithelial origin. Indeed, a wide array of genetic lesions have been described in MM, which include chromosome gains or losses, Ig-related chromosomal translocations, gains or losses of small chromosomal segments, and finally genetic and epigenetic modifications affecting single genes.

Amid this complexity, however, a classification framework has emerged, with important prognostic and predictive implications[9-14] (Figure 30-1). A first major distinction exists between hyperdiploid (HD) and nonhyperdiploid (NHD) MM. Approximately half of patients present a hyperdiploid karyotype (number of chromosomes ranging from 48 to 74) with concomitant gains of several odd chromosomes such as 3, 5, 7, 9, 11, 15, 19, or 21, in various combinations. The mechanism leading to this peculiar pattern is still unexplained and has no similarities in any other tumor—with the possible exception of a subgroup of acute lymphoblastic leukemia (ALL) patients, who present with concomitant gains of even chromosomes.[15] The remaining patients belong to the NHD group, which includes cases with hypodiploid, pseudodiploid, near-diploid, or tetraploid karyotypes.[13] Importantly, already at the MGUS stage patients present either an HD or an NHD karyotype,[16] which is maintained during the progression of the disease.[17]

Alongside chromosomal gains and losses, MM presents specific chromosomal translocations, so-called primary translocations, as they are again present from the MGUS phase.[12,18] These translocations involve the immunoglobulin H (IgH) locus (at 14q32.3)[19] and less frequently the IgL locus (2p12, kappa or 22q11, lambda)[20] and juxtapose strong Ig enhancers to various genes, resulting in their increased expression.[18] These rearrangements are generally mutually exclusive, although in 5% of MGUS and 25% of advanced MM cases, two independent translocations can be found in the same patient.[9] These primary translocations are for the most part confined to the NHD group.[21] In summary, MM patients are classified into two major groups, HD and NHD, and within the NHD further divided into subgroups based on the presence of specific, primary chromosomal translocations.

Over this general framework, additional genetic or epigenetic modifications are present in the MM genome, at times linked to specific patient subgroups or endowed with

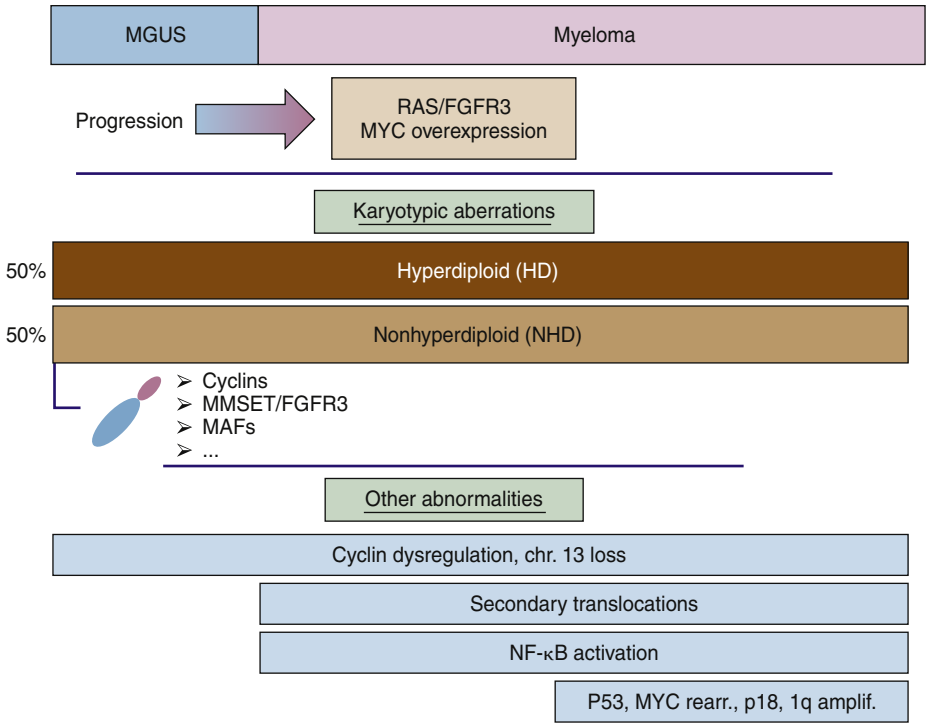

Figure 30-1 An outline of the main factors leading from multiple myeloma (MM) to monoclonal gammopathy of undetermined significance (MGUS); the distinction between HD and NHD MM; and finally additional frequent aberrations reported in MGUS and MM patients.

prognostic relevance. These lesions affect chromosomal regions (e.g., the short and long arm of chromosome 1, chromosome 13, or the short arm of chromosome 17, where the tumor suppressor TP53 is located), or single genes, such as mutations of members of the RAS or NFκB family, or dysregulated expression or chromosomal rearrangements affecting c-MYC. Focal, recurrent copy number aberrations (CNAs) have also been reported, in both cell lines and primary MM tumors, often involving regions harboring established cancer genes.[10, 22-25] For example, deletions affecting well-known or putative tumor suppressor genes such as TP53, UTX, FAM46C, and the NFκB family members BIRC2, BIRC3, and CYLD, or focal amplifications of areas including oncogenes such as MYC, HGF, MCL1, and IL6R, have been reported. Finally, recent next-generation sequencing efforts have identified a wealth of novel somatic mutations involving genes whose role in MM is not yet stringently validated.

Chromosomal Translocations in Multiple Myeloma

Chromosomal translocations in B-cell tumors including MM do not give raise to fusion chimeric proteins, but usually lead to the dysregulated expression of oncogenes through the juxtaposition of their promoters with Ig regulatory elements, via the B-cell–specific mechanisms of switch recombination and somatic hypermutation.[12,18] The primary translocations most frequently identified in MM patients include t(11;14)(q13;q32), which dysregulates the expression of the cyclin D1 gene,[26] with an incidence of approximately 15% in MGUS[27,28] and in MM.[29,30] Another translocation, t(6;14)(p21;q32), induces the dysregulation of cyclin D3 in 2% to 3% of MM patients.[31] t(4;14) is detected in approximately 15% of patients[32] and presents peculiar features. As a result of the translocation, the enhancers Eμ (at the 5′) and Eα (3′) are separated and dysregulate the expression of the juxtaposed genes on both derivative chromosomes, at der(4) and der(14). Hence, on der(14), the 3′ Eα enhancer increases the expression of the receptor tyrosine kinase fibroblast growth factor receptor 3 (FGFR3) gene. On der(4), the 5′ Eμ enhancer drives the expression of the histone methyltransferase Wolf-Hirschhorn syndrome candidate 1 gene (*WHSC1*, also called Multiple Myeloma Set Domain [*MMSET*]). MMSET is almost always upregulated in t(4;14) patients,[33] whereas FGFR3 is not overexpressed in 25% of these patients, suggesting that MMSET represents the main oncogenic culprit of t(4;14) and not FGFR3. Of note, approximately 10% of t(4;14) patients develop activating mutations on FGFR3.[34,35] Finally, the t(14;16)(q32.3;q23) is present in approximately 5% to 10% of MM patients and[12,36] induces overexpression of the oncogene MAF,[37] whereas the (14;20)(q32;q11) has been reported in 2% to 5% of MM cases and affects the family member MAFB.[12,38]

Mutated Genes in Multiple Myeloma

A recent next-generation sequencing (NGS) effort has led to the identification of novel somatic mutations in MM.[39]

This survey has identified on average 35 amino acid–altering point mutations and 21 chromosomal rearrangements per sample, a level of genomic rearrangements again more in line with the degree of mutation rate seen in epithelial cancers such as melanoma and lung carcinomas than in hematological cancers.[40] In addition, as in other blood and epithelial cancers, genes in MM are often mutated at low frequency, suggesting a remarkable and somehow disconcerting intertumor heterogeneity.[40] In fact, in MM, only 10 genes were recurrently mutated.[39] The list included genes where mutations have already been described in MM, such as NRAS (23%), KRAS (26%), and TP53 (8%). Intriguingly mutations were reported also in cyclin D1 (CCND1; 5%), indicating that not only is it frequently translocated and its expression often dysregulated in MM, but it is also mutated (see also later discussion). The remaining six genes include FAM46C (13%), which is also focally deleted; DIS3 (10%); PNRC1 (5%); ALOX12B (8%); HLA-A (5%); and MAGED1 (5%). Mutations affecting these genes have not been previously identified in cancer and reveal novel pathways potentially involved in MM pathogenesis. In particular, two of these genes, DIS3 and FAM46C, are thought to be involved in RNA metabolism and protein homeostasis.

As in other cancers,[41] however, mutations affecting specific genes in MM are in most cases rare; such mutated genes tend to coalesce into specific pathways. In the case of MM, four pathways were significantly enriched in somatic mutations. Confirming previous results,[42,43] genes belonging to the NFκB pathway were frequently mutated. Also, frequent mutations affecting histone-modifying genes such as MLL, MLL2, MLL3, UTX, MMSET, and WHSC1L1 were reported. Mutations affecting the same nucleotide were also found in the IRF4 transcription factor and in its target, PRMD1, confirming previous functional data reporting a prominent role of IRF4 for MM survival.[44] Surprisingly, a significant enrichment in five genes involved in blood coagulation was identified in MM patients. Although a role for this pathway in MM is unknown, thrombin and fibrin have been shown to serve as mitogens in other cell types and have been implicated in metastasis.

Prognostic Implications of Genetic Lesions

Extensive studies in the past 15 years have identified a link between specific genetic lesions and prognosis. HD patients present a better prognosis when compared with NHD MM.[21, 45-47] However, if HD patients acquire chromosome 13 loss and/or gains in the long arm of chromosome 1, patient overall survival worsens considerably.[10, 48, 49] Other acquired genetic lesions in HD have been linked to poor prognosis in this group—for example, IgH translocations, especially those involving unknown partners.[50] Finally, HD patients could evolve toward a pattern characterized by expression of genes associated with high proliferation and poor prognosis.[11]

As for NHD patients, the prognostic outlook varies widely depending on the chromosomal translocation present. Overall, patients with cyclin D translocations tend to present a better prognosis than NHD patients with t(4;14), t(14;16), and t(14;20).

Gains/amplifications of 1q are associated with t(4;14), t(14;16), and possibly chromosome 13 deletion,[10,51] and in general with more proliferative disease states.[52] Several studies have proposed an association between gains/amplification of this region and poor prognosis, based on cytogenetic analysis,[53] fluorescence in situ hybridization (FISH),[38] and expression profiling,[52] as well as aCGH.[10] Importantly, Zhan and colleagues have shown that among a list of 70 genes linked to early disease-related death, there was an enrichment for overexpressed genes mapping to chromosome 1q.[54]

Hemizygous deletions of chromosome 13 are present in MGUS and MM with a similar overall incidence of around 50%.[28,55-58] Given the strong correlation between the presence of 13 loss and other genetic lesions,[30,59] including t(4;14), t(14;16), and NHD, its role as an independent prognostic factor has been questioned.[28,30,46,56,57,60-64]

Finally, aCGH analysis has identified focal regions associated with poor survival containing amplifications on chromosome 8 (involving MYC) and deletion on ch17 (including TP53)— genetic events that have been previously linked to poor prognosis in MM.

It should be emphasized, however, that the significance of any prognostic marker relies heavily on the treatment regimen. In fact, most of the studies just mentioned assessing the prognostic relevance of genetic lesions included patients treated with high-dose chemotherapy followed by bone marrow transplant. A reassessment of the significance of these prognostic and predictive factors is ongoing, in light of the introduction of novel drugs for patient treatment. For example, several of the most well-established genetic prognostic markers failed to show any correlation with prognosis in patients treated with the proteasome inhibitor bortezomib.[65]

The Microenvironment in Multiple Myeloma

Blood cancers develop in secondary lymphoid organs and in the bone marrow (BM). For several acute hematological cancers, such as Burkitt's lymphoma, the genetic lesions underlying these tumor cells are sufficient to promote tumorigenesis; the role of the microenvironment is for the most part marginal. In contrast, mature B-cell malignancies including MM rely heavily on their milieu for their growth and survival[66-68] (Figure 30-2). Indeed, MM cells twist to their advantage

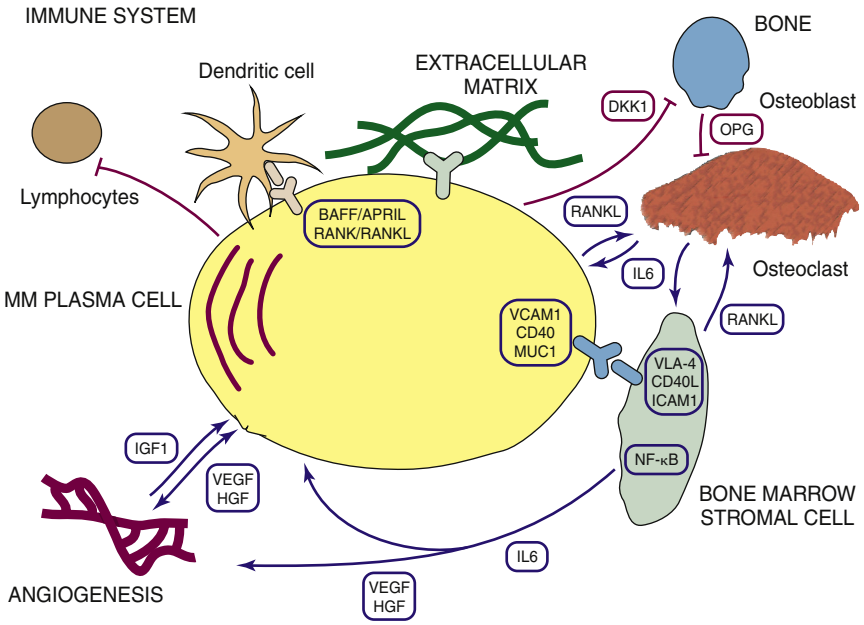

Figure 30-2 A simplified view of the interactions between the multiple myeloma plasma cell and the surrounding environment.

the physiological mechanisms underlying healthy plasma cell homing to the bone marrow and the pathways supporting long-lived plasma cells. MM plasma cells establish tight interactions with essentially all the BM components. The severance of these ties has become an essential therapeutic tool. Indeed, the main mechanism of action of the novel drugs recently introduced into the clinic (thalidomide, lenalidomide, and bortezomib) is their impact on the interactions between MM cells and their cellular counterpart.

The BM microenvironment includes an extracellular matrix (collagen, laminin, fibronectin, and osteopontin) and a rich cellular component. The cellular BM compartment consists of hematopoietic and mesenchymal progenitor and precursor cells, including hematopoietic stem cells (HSCs); BM-derived circulating endothelial precursors (CEPs) and endothelial cells (BMECs); immune cells (dendritic cells, various populations belonging to the B and T lymphocytes, NKT and NK cells, monocytes, and macrophages); erythrocytes; megakaryocytes and platelets; and nonhematopoietic cells, including an ill-defined group of cells labeled fibroblasts/bone marrow stromal cells (BMSCs). Also included are cells involved in bone homeostasis, such as chondroclasts, osteoclasts (OCs), and osteoblasts (OBs).

MM cells interact with BMSC and the extracellular matrix either directly, via adhesion molecules that include LFA1, VLA4, NCAM, ICAM1, and CD44, or indirectly, through chemokines, cytokines, and growth factors released by tumor cells and BMSC, such as interleukin 6 (IL6), insulin-like growth factor 1 (IGF1), tumor necrosis factor-α (TNFα), transforming growth factor-β (TGFβ1), and VEGF. As a result of these multiple-layered interactions, several cancer-relevant pathways become activated in both the tumor and stromal cells, such as NFκB, JAK/STAT, PI3K, and MAPK, establishing powerful positive feedback loops that further increase MM growth and survival. IL6 represents a central cytokine for the growth and survival of MM cells, although IL6-independence could ensue in the late stage of the disease. IL6 engages its receptor (IL6R), leading to the activation of the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway, the proliferation-associated MAPK cascade, and the PI3K/AKT pathway. Moreover, interaction of MM cells with BMSC induces the secretion of IL6 from BMSC through the activation of NFκB. Another paracrine factor that has recently emerged as crucial for MM development is IGF1. Stimulation of MM cell lines with IGF enhances cell proliferation and prevents apoptosis, again through the activation of the MAPK, PI3/AKT, and NFκB pathways. Of note, inhibitors against the receptors of these cytokines and growth factors have been developed, and clinical trials are ongoing to test their effectiveness as novel drugs.

The homing of MM cells to the BM triggers a strong angiogenic response.[69,70] Indeed, it has been shown that angiogenesis correlates with high MM proliferation index, with the more advanced stages of the disease, and ultimately with prognosis. The adhesion of MM cells to the BMECs increases the secretion of several pro-angiogenic cytokines, most importantly of VEGF, basic fibroblast growth factor (bFGF), and matrix metalloproteinases. Conversely, BMECs secrete growth factors, including VEGF, IL6, and IGF1.

Osteolytic bone lesions are a hallmark of MM and are associated with pathologic fractures, bone pain, and diffuse osteoporosis. MM cells increase the number and the activity

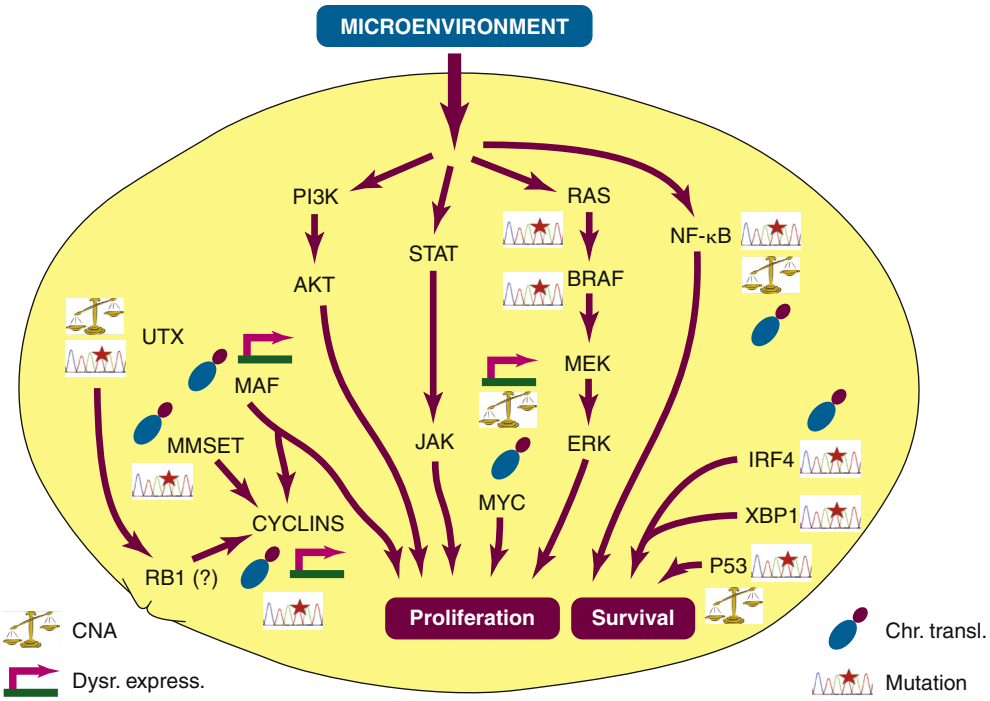

Figure 30-3 Main signaling pathways and genes activated or genetically altered in multiple myeloma. Four different types of aberrations are included: somatic mutations, chromosomal translocations *(Chr. transl)*, copy number aberrations *(CNA)*, and dysregulated expression *(Dysr. express.)*.

of OCs, while reducing the number of OBs, tilting the balance toward increased bone reabsorption. An array of factors that activates the OC is produced by both tumor as well as stromal cells. These factors include macrophage inflammatory protein-1a (MIP-1a) and receptor of NFκB ligand (RANKL). OC activity in turn modulates MM cell growth and survival via the secretion of IL6. Conversely, MM cells impair the maturation of OB cells from mesenchymal stem cells, through the secretion of the WNT-signaling antagonist DKK1, an inhibitor of OB differentiation. In addition, the binding of VLA4 on MM cells to VCAM1 on osteoblast progenitors reduces the levels of the transcription factor RUNX2, essential for OB maturation. Osteoblasts not only preserve the bone structure, but also inhibit MM growth both in vitro and in vivo. Therefore, restoring the number and activity of OBs may increase bone formation as well as provide an antitumoral effect.

Immuno-based tumor surveillance is severely impaired in MM.[71] Both the T and B responses are affected. Specifically, the expansion of regulatory T cells (Treg), reduced T-cell cytotoxic activity and responsiveness to IL2, and defects in B-cell immunity have been reported. These effects are the results of cytokines produced by BMSC, including VEGF, HGF, fibroblast growth factor (FGF), and stromal-cell–derived factor (SDF)-1α. Recently Chauhan and associates have demonstrated a significant enrichment of plasmacytoid dendritic cells (pDCs) in the BM of MM patients. These cells mediate immune deficiency characteristics of MM and are able to promote MM cell growth, survival, and migration and to enhance drug resistance.[72]

Deregulated Pathways in Myeloma and the Opening of Novel Therapeutic Opportunities

The knowledge accumulated in recent years allows a clearer definition of the pathways activated in MM tumor cells, either due to genetic lesions inside the tumor cells or emerging from activating signals from the surrounding microenvironment (Figure 30-3). In several cases, this knowledge has been turned to the patient's advantage, because it has allowed the design of novel targeted therapies specifically addressing single lesions.

MYC

Genetic rearrangements involving the MYC (c-MYC) locus are frequent in the more advanced stages of MM. The anatomy of these lesions has been defined.[73-75] In 25% of cases, the IgH or IgL locus is juxtaposed with the MYC sequence.[76] The pattern, however, is more complex than the classical reciprocal translocations present in the so-called primary translocations.[18,76] Amplifications, inversions and insertions without apparent translocations,[10,23,74,76] or translocations not involving the Ig loci[74,75] have also been described. In a large patient population, rearrangements affecting c-MYC have been reported with a frequency of 3% in MGUS and 10% to 16% in MM.[73,76] MM cell lines have more frequent rearrangements of the c-MYC locus, ranging from 55%[76] to more than 90%, depending on the study.[73,74] Hence, genetic rearrangements affecting the MYC locus likely represent late events in the course of the disease.

Recent lines of evidence suggest that MYC overexpression might represent an early event, at the critical junction

between MGUS and MM. This dysregulated expression seems independent from genetic rearrangements. MYC is overexpressed in a large proportion of MM patients, when compared with plasma cells derived from MGUS patients and healthy individuals, in the absence of evident genetic rearrangements affecting the MYC locus.[10,77,78] Indeed, Chng and colleagues have developed an MYC activation signature and have demonstrated that MYC is activated in up to 67% of MM patients, but not in MGUS. Intriguingly, the MYC activation signature was present in almost all tumors with RAS mutations and was associated with hyperdiploid MM and shorter survival. Importantly, bortezomib treatment was able to overcome the survival disadvantage in patients with MYC activation.[77] In a mouse model of MM, the Vk*MYC model, somatic hypermutation activates an MYC transgene inducing a phenotype closely resembling indolent MM.[78] These data support the notion that dysregulated expression of MYC might be sufficient for MGUS to convert into MM.

MYC is a transcription factor, therefore considered refractory to direct pharmacological inhibition.[79] Recently, Delmore and co-workers have ingeniously devised a method to inhibit MYC target genes.[80] A compound, JQ1, was designed, interfering with the acetyl-lysine recognition domains (bromodomains) of putative coactivator proteins implicated in transcriptional initiation and elongation. Surprisingly, JQ1 downregulated the transcription of the MYC gene itself, followed by genome-wide downregulation of Myc-dependent target genes, ultimately leading to potent antiproliferative effect associated with cell-cycle arrest and cellular senescence.

MAF

Two chromosomal translocations involve the MAF family gene, namely, MAF in the t(14;16)(q32.3;q23),[37] and MAFB in the (14;20)(q32;q11).[12,38] Despite their low incidence, the study of MM patient cells endowed with these translocations has provided important perspectives on the biology of the MM cell and the modality of its interaction with the microenvironment. Both translocations share an overlapping gene expression signature,[11] suggesting a similar repository of downstream targets. The oncogenic role of c-MAF in MM is established. Forced overexpression of MAF enhances myeloma proliferation, probably through the increased expression of cyclin D2, a MAF target gene consistently overexpressed in this group of patients.[9] In contrast, MAF knockdown reduced tumor formation in immune-deficient mice. Another direct MAF target, integrin β7, increases MM cell adhesion to the BM stroma and induces high levels of VEGF. Interestingly, therefore, MAF not only has a direct oncogenic activity within the MM tumor cell, but also affects the microenvironment to the tumor's advantage. An additional report has proposed ARK5, an AMP-activated protein kinase (AMPK)-related protein kinase mediating AKT signals, as a target of MAF and MAFB signaling.[81]

Surprisingly, overexpression of c-MAF has been reported even in the absence of the translocation in up to 30% of patients.[82,83] A recent report has suggested that this upregulation results from the activation of the MEK/ERK/AP-1 axis, downstream of MMSET, in the t(4;14) patient group.[84] Intriguingly, treatment of MM cell lines with a MEK inhibitor selectively induced apoptosis in MAF-expressing MM, providing a molecular rationale for the clinical evaluation of MEK inhibitors in this subgroup of patients.

Previous reports have suggested a reduced incidence of bone disease in this group of patients.[9,11] Two genes might be responsible for this phenotype. The gene DKK1, whose overexpression has been implicated in MM-related bone disease,[85] is significantly downregulated specifically in patients presenting with MAF and MAFB translocations.[11] Moreover, Robbiani and colleagues have reported that the gene osteopontin (OPN) inversely correlates with MM bone disease and is specifically overexpressed in patients with translocations affecting the MAF genes.[86]

Cyclins

Cyclin D dysregulation is a universal phenomenon in MGUS and MM, somehow surprisingly given the exceedingly low proliferation index of both conditions. Among the most recurrent chromosomal rearrangements, two involve cyclins directly: t(11;14)(q13;q32), which occurs in 15% to 20% of MM patients and induces the overexpression of cyclin D1,[26,87-89] and t(6;14)(p21;q32), present in 2% to 3% of MM cases, which increases the expression of cyclin D3.[31] In addition, patients presenting with t(4;14), t(14;16), and t(14;20) demonstrate cyclin D2 overexpression, which in the t(14;16) and t(14;20) patients has been directly linked to MAF/MAFB dysregulation.[9] By unknown mechanisms, HD patients usually show overexpression of cyclin D1, alone or in combination with overexpression of cyclin D2, whereas a subset of HD patients instead produce cyclin D2 alone. It should be noted that the few patients who do not show an evident cyclin dysregulation present RB1 inactivation, supporting the notion that the axis RB1/cyclin is universally derailed in MGUS and MM patients.[8]

Chromatin Remodeling Genes

Chromatin remodeling genes are among the most frequently mutated genes in the cancer genome. Remarkably frequent genetic lesions have been identified in genes affecting DNA methylation (e.g., DNMT3A in AML[90]), nucleosome remodelers (ARID1A in ovarian cancer[91]), and histone-modifying genes in a variety of tumors.[92] In particular, histone posttranslational modifications affecting the N termini of histones 3 and 4, such as acetylation and methylation, are heritable changes

that profoundly affect chromatin structure and gene expression. Genetic lesions involving enzymes that add or remove methylation marks from histone tails have been described, including, as mentioned, MMSET and WHSC1L1, UTX, MLL, MLL2, and MLL3.

MMSET

The recurrent translocations t(4;14)(p16;q32) involve FGFR3[93] and MMSET genes.[94] As mentioned earlier, MMSET seems to represent the real target of this translocation—a notion further confirmed by loss-of-function studies, where downregulation of MMSET with specific shRNA decreased growth and viability of t(4;14) MM cells.[95,96] MMSET presents several alternative spicing variants. Intriguingly, within the gene, the breakpoint position can vary, giving rise to different overexpressed transcripts in t(4;14) samples. MMSET interacts and is likely involved in pathways with a clear relevance in carcinogenesis. MMSET interacts with repressors including SIN3A and histone deacetylases HDAC1 and HDAC2.[95,97,98] However, the oncogenic mechanism underlying MMSET tumorigenic activity remains incompletely understood. Recently it has been shown that t(4;14) MM cases demonstrate an open, permissive chromatin state, associated with high H3K36 di- and trimethylation with concomitant low levels of the trimethylated H3K27.[96] This altered chromatin status was associated with the dysregulated expression of genes involved in cell cycle, apoptosis, DNA repair, and adhesion. Along these lines, t(4;14)-driven MM cases present a remarkable increase in DNA methylation across the genome, a pattern unique in MM.[99]

Finally, a connection between MMSET and the DNA damage response has been recently uncovered.[100] H4K20 methylation increases locally on the induction of double-strand breaks (DSB). Pei and associates have demonstrated that MMSET is responsible for this methylation, in turn facilitating 53BP1 recruitment. MMSET therefore represents a central hub in the DNA damage checkpoint activation and response.

MMSET belongs to a gene family that includes two other genes, WHSC1L1 and NSD1, with ties to cancer. Indeed, somatic mutations in WHSC1L1 have been identified in MM patients as well.[39] This gene is also involved in a chromosomal translocation in acute myeloid leukemia, t(8;11)(p11.2;p15)[101]; is amplified in breast cancer[102] and in lung cancer; and is endowed with oncogenic activity.[103] NSD1 participates in a fusion protein resulting from a chromosomal translocation in acute myeloid leukemia.[104]

UTX

UTX represents the first histone demethylase found mutated or deleted in cancer, including multiple myeloma,[105] renal carcinoma, transitional cell carcinoma of the bladder, chronic myelomonocytic leukemia, acute lymphoblastic leukemia, and prostate cancer. Intriguingly, MM is the tumor where this gene is most frequently inactivated, because truncating mutations or deletions in MM are present in up to 30% of patients[105] (also G. Tonon, unpublished data).

UTX is a JmjC-class enzyme that demethylates di- and trimethylated H3K27me, counteracting the activity of Polycomb complexes (PcGs)[106]—in particular of the histone methyltransferase enhancer of zeste homologue 2 (EZH2), which mediates H3K27 methylation, a transcription-repressive mark. Although limited information is available, one of the main tumorigenic results stemming from UTX inactivation likely results from the unbridled activity of EZH2, leading to enhanced H3K27 trimethylation. EZH2 is highly expressed in several cancer types, including breast, prostate, and lymphomas, and its expression levels correlate with advanced stages of tumor progression and poor prognosis.[107,108] In MM, EZH2 is often overexpressed. It was reported as one of the 30 genes able to distinguish normal plasma cells from MGUS and aggressive myeloma.[109] More recently, activating oncogenic mutations affecting EZH2 were identified in lymphoma.[110,111] In MM, EZH2 is induced by IL6 and enhances proliferation in MM cell lines, whereas its inhibition induces apoptosis.[112]

In addition, UTX has been implicated in cellular differentiation and growth control through transcriptional regulation of the RB1 pathway.[113] Chromatin immunoprecipitation (ChIP)-on-chip experiments have revealed that UTX is present on the promoters of RB1 pathway genes, exerting a transcriptional control on cellular proliferation and mediating cell cycle arrest of primary human fibroblasts,[113] although it remains to be demonstrated whether a similar, RB1-mediated proliferation effect is present also in MM cases with UTX inactivation.

Finally, UTX regulates HOX gene expression, whose orderly activation is essential for normal hematopoiesis.[114] HOXA genes are abnormally expressed in MM.[115] In particular, HOXA9 is normally silenced by trimethylation of H3K27 during hematopoietic differentiation and is consistently upregulated in MM patients. On HOXA9 knockdown, MM cells exhibit a competitive disadvantage.[39] These data suggest that UTX inactivation may dysregulate the expression of HOXA genes, in particular of HOXA9, contributing to the unrestrained proliferation of MM cells.

RB1, P18, and Other Members of the RB1 Pathway

The comprehensive cyclin D dysregulation detected in MM suggest a derailed activity of the RB1 axis. The tumor suppressor RB1 is located on chromosome 13, and a significant fraction of MM patients present with one copy of this chromosome. Nevertheless, a direct role of RB1 inactivation

in MM is uncertain, as inactivating mutations of this gene have not been consistently identified among patients with chromosome 13 hemizygous deletions, or focal homozygous deletions affecting the RB1 region.[12]

Other members of the RB1 pathway are altered in MM, but the pathogenetic and clinical relevance of these aberrations has not been fully elucidated. For example, the tumor suppressor CDKN2A (p16) is usually not deleted in MM,[10,22-24,116] but is methylated in 20% to 30% of MGUS and MM cases.[117-121]

On the other hand, the role of CDKN4C (p18) is more established. Overexpression of p18 in MM cell lines lacking p18 reduced proliferation, whereas it had no effect in a cell line where p18 is normally expressed.[122] p18 is homozygously deleted in up to 38% of MM cell lines and in 2% of MM tumors, but this percentage goes up to 10% in tumors with highest proliferation, as evaluated with an expression profiling signature surrogate.[122,123] Intriguingly, p18 is often overexpressed in the most proliferative MM,[122] and focal deletions at 1p32.3, where p18 resides, are associated with poor prognosis.[124]

NFκB

Lesions involving genes belonging to both the classical and alternative NFκB pathways are frequently detected in MM, namely, in 17% of patients and in approximately 40% of MM cell lines.[39,42,43] The two pathways are tightly interconnected: many signals activate both branches, and many effector proteins or target genes are shared by both cascades. As for the genetic lesions, the most common event consists of inactivating mutations of TRAF3, occurring in 13% of MM patients.[43] Other negative regulators such as TRAF2, BIRC2 and BIRC3, and CYLD carry inactivating mutations or focal homozygous deletions. Chromosome translocations and amplifications involving NFκB-inducing kinase (NIK),[42] CD40, LTBR, TACI, NFKB1, and NFKB2[43] were reported, and all resulted in constitutive activation of either canonical or noncanonical pathways. A more recent study demonstrated that compensatory and/or cooperative effects occur in MM cell lines harboring such alterations.[125] Interestingly, constitutive activation of either canonical or alternative pathways resulted in the regulation of similar sets of genes and biological pathways,[125] conferring increased autonomy from the microenvironment.

The high prevalence of mutations in NFκB family members in MM cell lines compared to MM patients suggests that alterations in the NFκB pathway are relatively late events. Moreover, NFκB dysregulation mainly occurs in NHD compared to HD patients. Of note, part of the activity of the proteasomal inhibitor bortezomib, widely used in MM treatment, is related to the inactivation of the NFκB pathway.[65]

TP53 Deletion and Mutations

Mutations in the TP53 tumor suppressor gene have been reported in MM, with a frequency ranging from 2% to 20%.[39,126-129] Although the TP53 mutation frequency has been reported to be low in MGUS,[129] it increases during the progression of the disease, approaching 80% in MM cell lines,[130] suggesting that TP53 inactivation is a late event in MM. A strong association is present between TP53 mutations and poor prognosis.[131]

Other studies have used deletions in 17p13 (mostly hemizygous) as a surrogate for the inactivation of the TP53 pathway and reported a frequency that in most cases is around 10%,[56,132-134] with a strong association with poor prognosis.[10,56,133-135] Half of MM patients with TP53 mutations had concomitant hemizygous losses at 17p13, whereas only 16% of patients with 17p13 hemizygous deletions had mutations in the remaining copy of TP53.[131] Therefore, it is still unclear whether the TP53 pathway is silenced in MM cases with hemizygous 17p13 deletions when no mutations are detected in the remaining copy of TP53. Moreover, whether deletions on 17p13 are indeed a surrogate for TP53 inactivation or are associated with other, yet undetermined, tumor suppressor pathways is still unclear.

The Proteasome Achilles' Heel

MM cells present a high protein turnover. Protein metabolism in MM cells is finely tuned to prevent overloading that could lead to apoptosis. Compounds targeting different steps of this metabolic process have become the cornerstone of the treatment of this disease, prominent among them the proteasome inhibitor bortezomib, a major breakthrough in the treatment of MM. Among the targets of the proteasome inhibitors are the IL6[136] and NFκB pathways.[137] Although mutations or, more generally, genetic lesions directly affecting the proteasome have not been reported, a recent study has suggested that 1q amplification in MM could be associated with a general dysregulation of genes belonging to the proteasome pathway, in particular of PSMD4, leading to increased resistance to bortezomib.[90] It has been proposed that the recently identified mutations in DIS3, FAM46C, XBP1, and LRRK2 may directly affect the control of protein homeostasis,[39] although this hypothesis needs to be confirmed experimentally.

The Molecular Basis of the Evolution from MGUS to MM

The mechanisms underlying the progression from MGUS to MM are still incompletely understood.[8] From a genetic standpoint, the two conditions are remarkably similar. Both

present either HD or NHD karyotypes,[16] although with modest differences in frequencies with MM; IgH/IgL chromosomal translocations; and deletions of chromosome 13.[27,28,138] Also at the transcriptome level, the two conditions are intriguingly similar, including the pattern of cyclin D expression. Indeed, gene expression profiling has repeatedly failed to discriminate between MGUS and MM.[109,139] Of interest, Zhan and colleagues have been able to show how a subset of MM, featuring a better prognosis, had an expression signature similar to MGUS. On the other hand, a small subset of MGUS clustered together with MM,[140] pointing to a subset of MGUS patients whose disease is potentially more prone to evolve into MM.

Notwithstanding, in the absence of defined phenotypic or genetic differences between MGUS and MM, it has been difficult to stratify MGUS patients, to predict their progression toward MM. Multivariate models have been proposed to address this issue, of crucial relevance from a clinical standpoint.[141,142] In particular, one study has shown that the progression risk ranges from 0.40% to 12%, based on BM plasma–cell flow cytometric immunophenotypic profiles.[141] More extensive studies will be needed to definitively validate these approaches and provide a robust tool that will be invaluable to patients and doctors to predict the progression of MGUS and dictate the treatment to be chosen.

Among the few genetic changes reported in MM and not present (or present with a lower incidence) in MGUS are mutations of two members of RAS family (NRAS and KRAS) at codons 12, 13, and 61 in 40% to 55% of MM, but in only a minority of MGUS patients,[143-148] suggesting a major role for the activation of the MAPK pathway in the progression from MGUS to MM. KRAS has never been reported to be mutated in MGUS, whereas NRAS is mutated in 7% of cases, pointing to a different role of KRAS versus NRAS in MGUS progression.[8]

t(4;14) seems to be more often present in MM than in MGUS.[9, 28, 30, 140, 149, 150] Moreover, the activating mutations affecting FGFR3 are mutually exclusive of the RAS mutations. These data point to MAPK pathway activation as a critical step at the transition from MGUS to MM, mediated by RAS or FGFR3 mutations, or, when neither of these mutations is present, by still unknown mechanisms.

Finally, as mentioned earlier, the dysregulated expression of MYC likely represents an additional universal mechanism driving the MGUS-to-MM progression.

Final Remarks

The general outline of the early events occurring in MM has been greatly elucidated in the past decade. Several questions, however, of critical relevance for the understanding of the pathogenesis of this disease and for the design of novel, more effective treatments, remain to be fully addressed. For example, little is known about the role of the primary events, including cyclin D overexpression and MMSET activity, in the early pathogenesis of the disease. Indeed, the emerging role of epigenetics in MM, and more generally in cancer, warrants extensive studies, given the potential therapeutic implications. Knowledge of the additional lesions promoting the progression of MGUS to MM and, within MM, toward a more aggressive and proliferative disease are still largely incomplete and deserve additional inquiries, given the potential for patient stratification and novel clinical approaches.

The tight interactions between MM cells and BM in the past few years have been extensively studied. Indeed, it could be argued that a considerable part of the success obtained by new compounds introduced in the clinic, such as thalidomide, lenalidomide, and bortezomib, is due to their activity in interrupting the flow of positive signals that the MM cell receives from its surrounding environment. More focused, targeted approaches to further develop compounds tackling these interactions represent a largely untapped treasure chest for novel therapies.

The more extensive application of next-generation sequencing to single patients, at different stages of their disease and of their treatment history, will likely lead to a significant revolution in the MM field—not only in the elucidation of the pathogenetic events responsible for this disease, but also for defining in much finer detail issues such as clonality and drug resistance in individual patients, ultimately driving therapeutic choices and approaches, as recently proposed in pilot studies.[151,152] In fact, even more importantly, the systematic and comprehensive integration of the data emerging from analyses of the genome, transcriptome, methylome, and miRNome should provide a paradigm shift in diagnosis, prognosis, and treatment, initially with available therapies and in the long term with more personalized therapies.

Molecular Mechanisms of Esophageal Cancer

Introduction

The cancers arising from the esophageal mucosa, primarily esophageal adenocarcinoma (EAC) and esophageal squamous-cell carcinoma (ESCC), are clinically some of the most devastating and lethal cancers in the world. Collectively, they are the eighth most common cancer diagnosed worldwide, with approximately 482,300 new cases in 2008.[1] International age-adjusted incidence rates vary drastically, with a nearly 16-fold difference between the high-incidence areas of southern and eastern Africa and eastern Asia and the low-incidence areas of middle and western Africa and Central America.[1]

Worldwide, ESCC accounts for the majority of esophageal cancers diagnosed, because of its high prevalence in the "esophageal cancer belt," an area stretching from central Asia to north and central China (Figure 31-1). In this high-risk area, 90% of all esophageal cancers are SCC, with as many as 120 to 175 new cases per 100,000 inhabitants each year.[1-3] However, the incidence rates of EAC and ESCC vary drastically among geographical regions. In the Western world, EAC has overtaken ESCC as the most prevalent form of esophageal cancer.[3,4] The United States alone has seen a fourfold increase in EAC since the 1970s.[5]

Regardless of the histology, esophageal cancer carries a high mortality rate because of its advanced stage of presentation, with an overall 5-year survival rate of 17%.[4] It is the sixth most common cause of cancer death worldwide, claiming 4,070,800 lives in 2008.[1,2] Approximately 86% of these deaths occurred in developing nations,[1,2] where more than 90% of the esophageal cancers diagnosed were stage 2 or greater.[6]

Histology

Ninety-five percent of esophageal cancers are of epithelial origin, occurring as either EAC or SCC, with the remaining tumor histologies comprising malignant melanoma, lymphoma, carcinoid, small cell carcinoma, or sarcoma.[7] Esophageal adenocarcinomas primarily occur in the distal one third of the esophagus and develop through a progressive malignant sequence beginning with cellular metaplasia, then low- and high-grade dysplasia, and eventually to invasive adenocarcinoma.[8] Esophageal squamous-cell carcinoma primarily emerges in the middle to upper third of the esophagus and follows a similar stepwise developmental sequence. However, the initiating histological lesion in the squamous histology is mild to severe dysplasia, followed by carcinoma in situ, and finally invasive squamous-cell carcinoma.[9]

Etiology and Molecular Mechanisms of Esophageal Cancer

Esophageal adenocarcinoma and squamous-cell carcinoma are two distinct cancers that differ not only in histology and geographical distribution, but also in the risk factors that contribute to their development. However, their risk factors stem from similar pathological processes and also similar molecular mechanisms that lead to tumorigenesis.[5,10] The pathological processes that initiate these tumorigenic mechanisms stem from chronic irritation and inflammation, carcinogenic exposures, or a combination of both. Unique risk factors of both EAC and ESCC will be highlighted in the context of either chronic inflammation or carcinogenic exposure. More detailed explanations of the epidemiological risk factors associated with EAC and ESCC are covered elsewhere in this text. Simply stated, examples of chronic inflammation can take the form of gastroesophageal reflux as in EAC, or chronic thermal injury of the more proximal esophagus from drinking hot beverages in ESCC. Similarly, carcinogenic exposure can include the high prevalence of tobacco smoking in both EAC and ESCC as well as the high nitrosamine content of

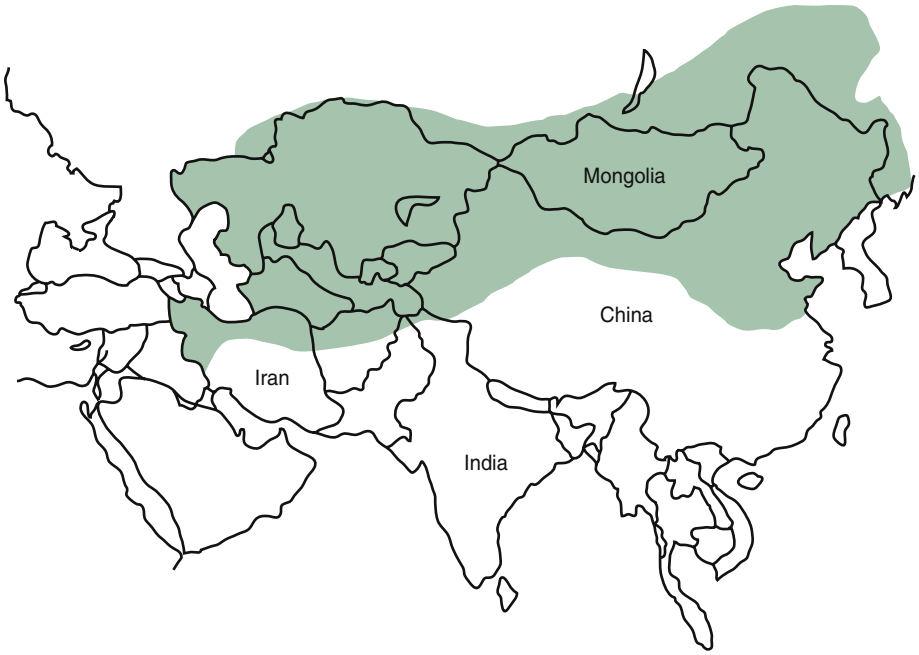

Figure 31-1 The central Asian esophageal cancer belt extending from Iran to China. *Modified from Kamangar F, Malekzadeh R, Dawsey SM, et al. Esophageal cancer in northeastern Iran: a review.* Arch Iranian Med. *2007;10:70-82.*

the soil and the high consumption of smoked foods in the esophageal cancer belt in ESCC.

Chronic Inflammation and Esophageal Cancer

The inflammatory response is a highly complex and coordinated system to promote cellular regeneration and proliferation. This response provides an environment rich in inflammatory cells, growth factors, adhesion molecules, and angiogenic mediators, all of which can potentiate and initiate tumorigenesis.[11] Rudolf Virchow first postulated a possible link between tumorigenesis and the inflammatory system in the 19th century, when he observed the presence of leukocytes within tumors.[12] Only recently, however, have many of the underlying molecular mechanisms between inflammation and cancer initiation been elucidated[11,13,14] (Figure 31-2).

Nuclear Factor-Kappa B

Nuclear factor-kappa B (NFκB) is a pro-inflammatory transcription factor initially described as a B-cell–specific factor for the immunoglobulin-κ light chain gene.[15] As part of the Rel protein family of transcription factors, NFκB exists in the cytoplasm as an inactive dimer until activated by a diverse set of extracellular stimuli and signals, such as inflammatory cytokines and growth factors.[16,17] These stimuli trigger a common pathway of phosphorylation, ubiquitination, and proteasome-dependent degradation of NFκB's regulatory protein, inhibitor of NFκB (IκB), to activate NFκB.[17] Once activated, NFκB is quickly translocated into the nucleus and binds to promoter regions responsible for the transcription of genes that encode for multiple cytokines (IL6, IL8, TNFα), cellular adhesion molecules (ICAM1, E-selectin), cell cycle regulators (p21, cyclin D1), apoptosis regulators (surviving, Bcl-2), and other transcription factors (p53, c-myc).[13,16,17]

Aberrant activation of NFκB has been implicated in the initiation and progression of many cancers, including esophageal cancer, because of its broad role in inflammation, apoptosis, and cell survival[13] (Figure 31-3). Barrett's esophagus (BE), as the main risk factor, is due to chronic epithelial damage from gastroesophageal bile and acid reflux.[22] NFκB activation has been described as a central event in the development of BE, and thus in EAC's initiation and progression.[18,19] A 2004 study was the first to show that NFκB expression was increased in the epithelial cells of BE compared to normal esophageal epithelial cells.[18] In addition, this study revealed that 61% of resected EAC tumors displayed NFκB immunoreactivity, and NFκB-positive tumors were more likely to be of advanced stage.[21] Others have also validated these data[19] and have even identified NFκB as an emerging molecular prognostic marker: NFκB tumor positivity is correlated with chemoradiation resistance and poor outcomes.[18,20,21]

Although BE and gastroesophageal reflux are well-documented risk factors for EAC, the molecular pathogenic correlation between risk factors and the development of esophageal squamous-cell carcinoma is less clear.[5,9,22]

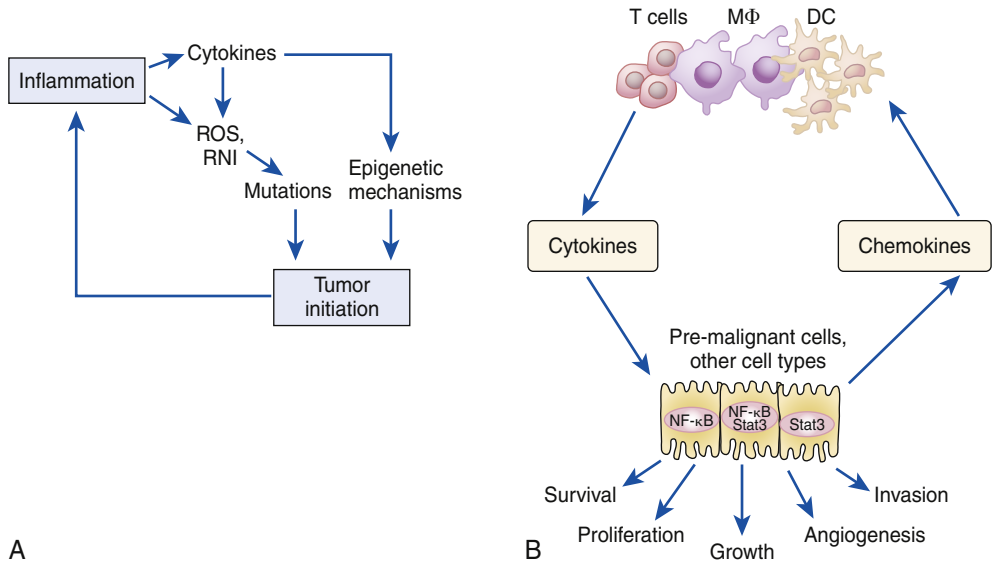

Figure 31-2 Role of inflammation in tumor initiation and promotion **(A)** Tumor initiation. Reactive oxygen species (ROS) and reactive nitrogen intermediates (RNI) produced by inflammatory cells may cause mutations in neighboring epithelial cells. Also, cytokines produced by inflammatory cells can elevate intracellular ROS and RNI in premalignant cells. In addition, inflammation can result in epigenetic changes that favor tumor initiation. Tumor-associated inflammation contributes to further ROS, RNI, and cytokine production. **(B)** Tumor promotion. Cytokines produced by tumor infiltrating immune cells activate key transcription factors, such as NFκB or STAT3, in premalignant cells to control numerous pro-tumorigenic processes, including survival, proliferation, growth, angiogenesis, and invasion. As parts of positive feed-forward loops, NFκB and STAT3 induce production of chemokines that attract additional immune/inflammatory cells to sustain tumor-associated inflammation. *Modified from Grivennikov S, Greten FR, Karin M. Immunity, inflammation, and cancer.* Cell. *2010;140:883-899.*

The mechanism for epithelial injury is quite different from that in adenocarcinoma and is usually due to thermal injury from hot liquids and foods, corrosive irritation from retained esophageal contents due to achalasia, or caustic ingestion of corrosive agents.[23-25] Nonetheless, abnormal activation of NFκB has also been linked to ESCC. In vitro models have shown that NFκB pathways are highly expressed in esophageal SCC cell lines.[26] Hatata and colleagues found that NFκB was overexpressed in 61% of ESCC resected tumors.[27] They also reported that patients with NFκB positivity in their tumors correlated with significantly poorer survival times when compared to patients with NFκB negative-staining neoplasms (15 versus 42 months, $P = .007$).

Activation of Additional Inflammatory Mediators and Esophageal Cancer

Abnormal activation of downstream NFκB targets, such as COX-2 and IL6, has also been implicated independently in the pathogenesis of esophageal cancer. Cyclooxygenase-2 (COX-2), is one of two isozymes that catalyze the rate-limiting conversion of arachidonic acid to prostaglandins, prostacyclins, and thromboxanes.[28] COX-2 protein expression has been found to be significantly increased in patient samples with BE and EAC when compared to normal esophageal tissue.[29] In addition, bile acid exposure to esophageal cells has been shown significantly to induce COX-2 expression.[29] COX-2 overexpression has also been found in ESCC tumors, specifically well-differentiated tumors, and its progressive expression correlates well with advancing clinical stage.[30] Although in vitro investigations into selective COX-2 inhibition for the treatment of EAC and ESCC have shown some promise,[31,32] clinical trials have yet to demonstrate efficacy.[33,34]

Interleukin-6 (IL6) is a multifunctional cytokine that has a range of functions from acute-phase protein induction to cellular growth and differentiation.[35] Once bound to its extracellular receptor (IL6R), IL6 induces gene transcription through two signaling pathways, the JAK-STAT (Janus family tyrosine kinase-signal transducer and activator of transcription) pathway and the Ras-MAPK (mitogen-activated protein kinase) pathway[36,37] (Figure 31-4). Like NFκB and COX-2, IL6 has been demonstrated to be a key mediator in the metaplastic conversion of normal esophageal squamous epithelium to BE as well as the further dysplastic conversion to EAC.[38,39] Because of its multifunctionality and production by multiple cells throughout the body, IL6 is readily detected in the serum and has shown promise as a noninvasive diagnostic tumor marker. In 2011, Lukaszewicz-Zajac and colleagues demonstrated that when compared to traditional esophageal cancer tumor markers of carcinoembryonic antigen (CEA) and squamous-cell cancer antigen (SCC-Ag), elevated IL6 serum concentrations correlated better with early esophageal cancer diagnosis.[40] Overall, the elevated serum IL6 concentrations could be detected in

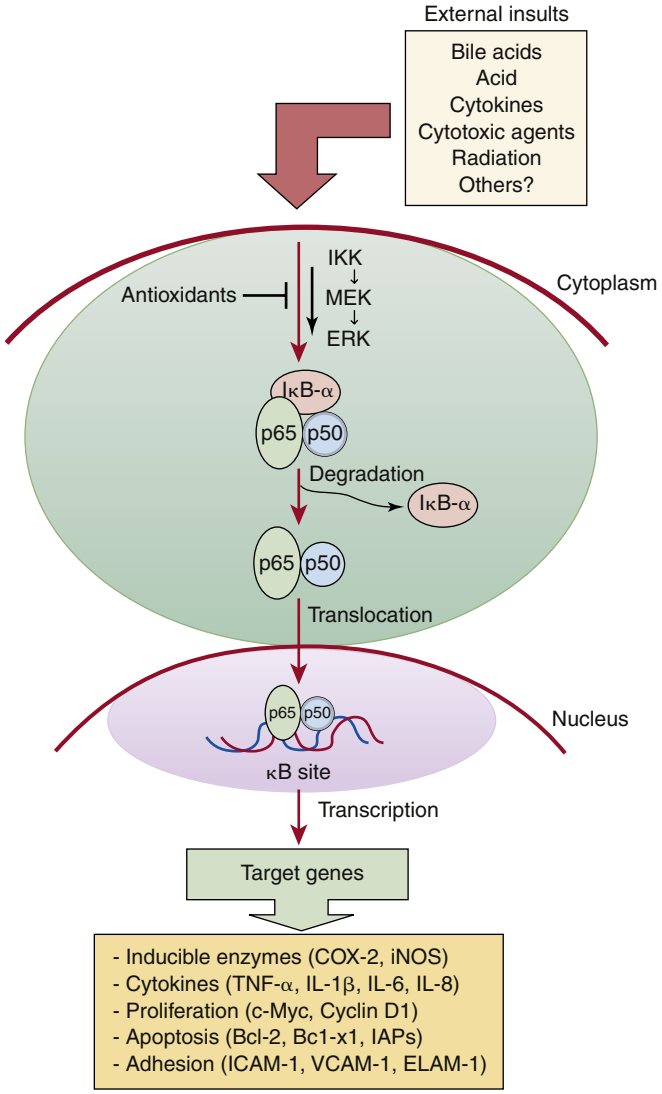

Figure 31-3 Diagram showing activation of NFκB and target genes in esophageal cancer. *Modified from Abdel-Latif MM, Dermot Kelleher K, Reynolds JV. Potential role of NF-κB in esophageal adenocarcinoma: as an emerging molecular target.* J Surg Res. *2009;153:172-180.*

either EAC or ESCC with 87% sensitivity and 92% specificity with a statistically significant area under the receiver operating characteristic curve of 0.92 when compared to either CEA or SCC-Ag.[40]

Environmental Carcinogenic Exposures and Esophageal Cancer

The link between certain environmental carcinogens, such as tobacco smoking, and tumorigenesis has been well established for many cancers. The ability of these carcinogens to promote tumorigenesis stems from their abilities to cause genomic aberrations leading to unregulated and abnormal cellular growth.[41] Both EAC and ESCC have many unique genomic and epigenomic abnormalities that have been identified and studied.[10] However, EAC and ESCC have been found to have similar aberrant genomic changes in cell-cycle regulator genes, such as p53, APC, RB, and cyclin-D1, early in their tumorigenesis[42-44] (Figure 31-5). Specific environmental risk factors for esophageal cancer and their molecular pathogenesis are now being revealed.

Tobacco Smoking

The association between tobacco smoking and lung cancer has long been recognized as due to the abundance of carcinogens in tobacco smoke. The International Agency for Research on Cancer has identified more than 60 substances in cigarette smoke for which sufficient evidence exists for carcinogenicity in either laboratory animals or humans.[45] Tobacco smoking is one of the few risk factors shared by both EAC and ESCC. In a study of 474,606 participants, current and former smokers had a significantly increased risk of developing EAC when compared to never-smokers (hazard ratio [HR] 3.7; 95% confidence interval [CI] 2.2-6.2 and 2.8; 95% CI 1.8-4.3, respectively).[46] The same study also revealed that current smokers were at an even higher risk for developing ESCC (HR 9.2; 95% CI 4.0-21.3), and individuals who had ever smoked accounted for 77% of ESCC cases.[46]

Two of the most potent and well-studied tobacco smoke carcinogens are polyaromatic hydrocarbons (PAHs) and the tobacco-specific *N*-nitrosamine, nicotine-derived nitrosamine ketone (NNK). Their tumorigenic effects arise from their ability to form DNA adducts as well as intra- and interstrand DNA crosslinks.[47] The proteins of the nucleotide excision repair pathway and specialized DNA polymerases repair and bypass various types of DNA damage acquired by PAHs or NNK.[48,49] However, because of the constant exposure to PAHs and NNK with chronic smoking, the amount of DNA damage done can overwhelm the DNA repair system, resulting in chromosomal aberrations, halted DNA replication, and mutations.[47] The resulting alterations may lead to abnormal cellular growth and transformation if proto-oncogenes or tumor suppressor genes are affected.

Alcohol

Chronic alcohol abuse is an important risk factor in the development of ESCC, but has no correlation with increased EAC risk.[46] Heavy drinkers (more than 84 drinks per week) have nearly a 25-fold increase in ESCC risk compared to light drinkers (1 to 20 drinks per week).[50] In addition, exposure to both tobacco and alcohol has been found to have a synergistic effect on the risk of developing ESCC.[51]

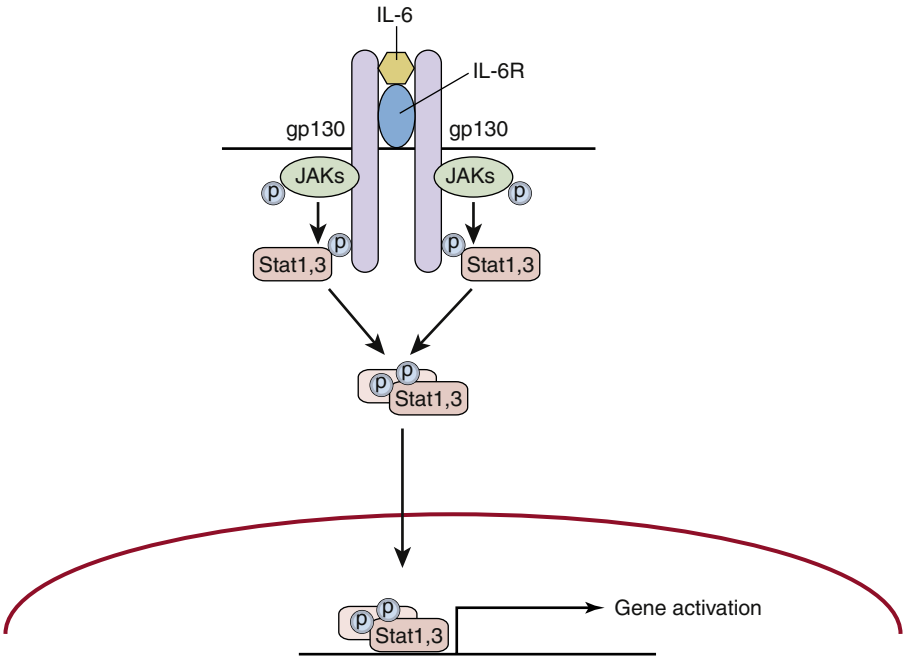

Figure 31-4 IL6 signal transduction IL6-mediated stimulation induces homodimerization of gp130, activating (phosphorylating) JAKs, and Stat1 and Stat3. Activated Stat1 and Stat3 form homodimers or heterodimers, which induce activation of various genes. *Modified from Kishimoto T. IL-6: from its discovery to clinical applications.* Int Immunol. *2010;22:347-352.*

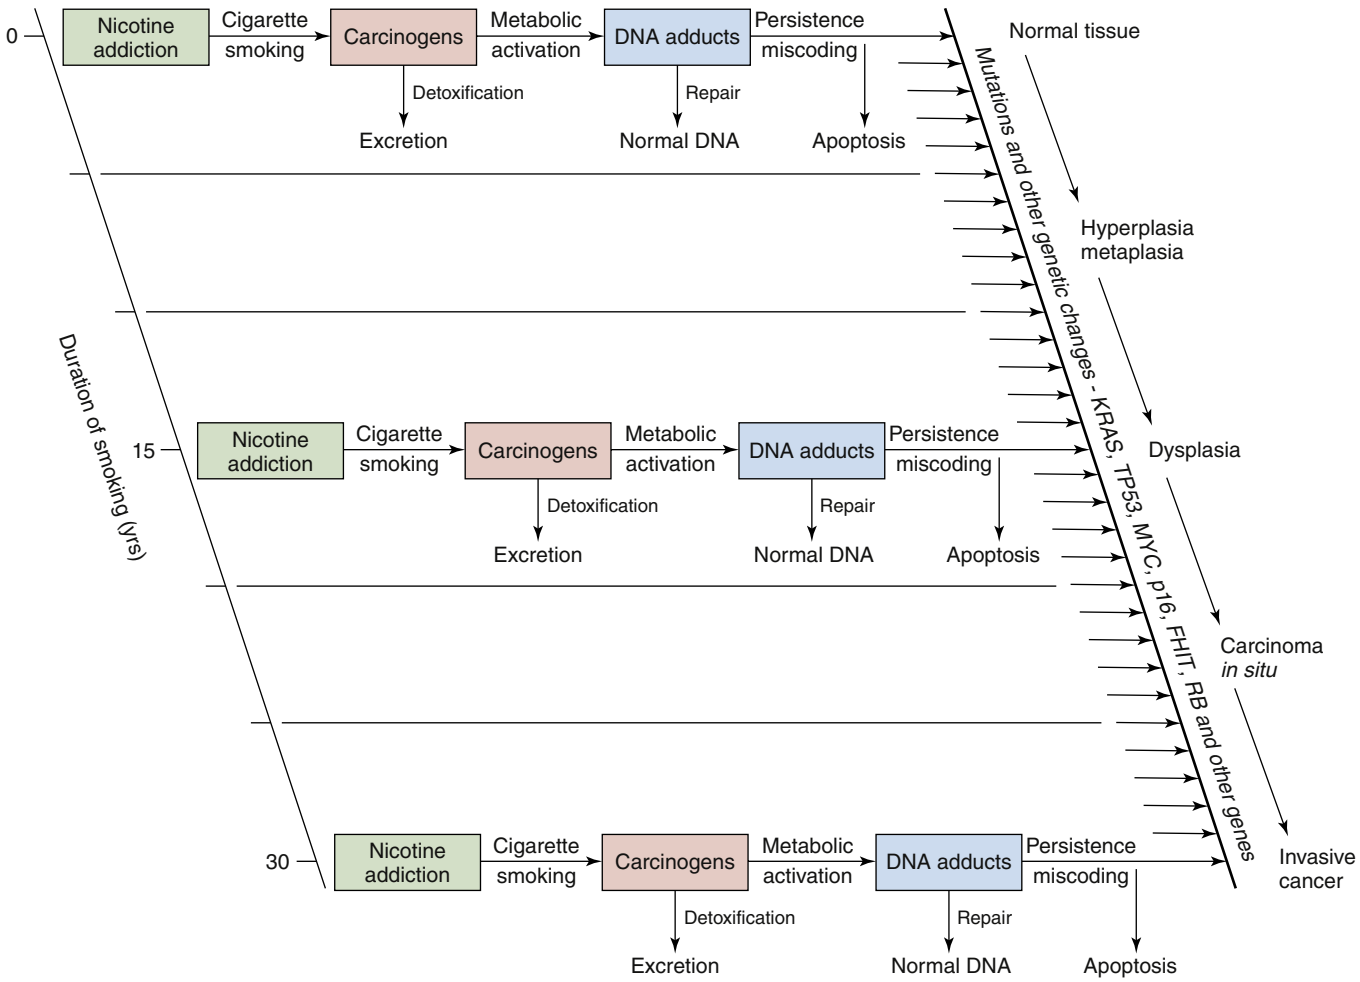

Figure 31-5 Scheme linking cigarette-smoke carcinogens with multiple genetic changes in lung cancer A key aspect is the chronic exposure of DNA to multiple metabolically activated carcinogens, leading to multiple adducts and their consequent mutations. The time period and sequence of genetic events are uncertain. *Modified from Pfeifer GP, Denissenko MF, Olivier M, et al. Tobacco smoke carcinogens, DNA damage and p53 mutations in smoking-associated cancers.* Oncogene. *2002;21:7435-7451.*

The pathophysiology underlying alcohol's role in tumorigenesis of ESCC involves esophageal irritation, through pathways previously described, and its principal metabolite, acetaldehyde, a known carcinogen causing DNA adducts.[52] The primary enzymes responsible for metabolizing acetaldehyde into an inert metabolite are aldehyde dehydrogenase-2 (ALDH2) and alcohol dehydrogenase-1B (ADH1B). ALDH2 and ADH1B are both present in the mouth, and mutations in either of these genes create increased salivary acetaldehyde concentrations, providing direct carcinogenic exposure to the esophageal mucosa.[53,54] For example, homozygotes for the ALDH2 gene have been shown to have acetaldehyde levels up to 13 times greater than normal individuals.[53] ALDH2 and ADH1B mutations are rare in Western populations; however, they are very prevalent in eastern Asian populations and are thought to contribute to the high incidence of ESCC in the esophageal cancer belt.[53,55,56]

Diet

Diets high in fruit and vegetable intake have been shown to be protective against many cancers because of the high concentrations of anticarcinogenic compounds.[57] Many dietary studies have demonstrated that diets low in fruit and vegetables have an increased risk of ESCC.[58,59] Dietary intake of nitrogen- and nitrosamine-rich foods have also been associated with ESCC development, especially in the high-risk areas of the esophageal cancer belt where nitrogen-rich foods and water are consumed in high concentrations.[59-62] In the Hebei province in China, the highest incidence areas of ESCC correlated with the highest concentrations of nitrite and ammonia nitrogen in drinking water.[59] In addition, in many of these areas cultural customs lead to widespread consumption of hot beverages, which was vital in establishing the connection between thermal irritation and esophageal cancer.[63,64]

Molecular Basis of Lung Cancer

Lung cancer is the leading cause of cancer-related death in men and women in the United States, accounting for approximately 28% of total cancer deaths in 2012 despite comprising only about 14% of new cancer cases.[1] Decades of research have contributed to our understanding that lung cancer is a multistep process involving genetic and epigenetic alterations where resulting DNA damage transforms normal lung epithelial cells into lung cancer. It is not known whether all lung epithelial cells or only a subset of these cells (such as pulmonary epithelial stem cells or their immediate progenitors) are susceptible to full malignant transformation. In addition, although the tumor-initiating cell may have only a handful of mutations, as the tumor expands, cells may acquire additional mutations.[2] Smoking damages the entire respiratory epithelium, and thus "field cancerization" or "field defects" (molecular changes) are observed in histologically normal lung epithelium, as well as a variety of histologic preneoplastic/premalignant lesions, which also harbor molecular abnormalities common to the adjacent tumor.[3] The culmination of these changes leads to lung cancers exhibiting all the hallmarks of cancer, including self-sufficiency of growth signals, insensitivity to growth-inhibitory (antigrowth) signals, evasion of programmed cell death (apoptosis), limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis.[4]

Lung cancer is a heterogeneous disease clinically, biologically, histologically, and molecularly. Understanding the molecular causes of this heterogeneity and determining how the molecular changes relate to the biologic behavior of lung cancer and their utility as diagnostic and therapeutic targets are important basic and translational research issues. The past 10 years has witnessed a revolution in genomic technologies to characterize genetic and epigenetic changes throughout the lung cancer genome. These include the recent application of "next-generation" ("NexGen") sequencing, which has led to genome-wide mutational analyses of lung cancers. Within the next several years there will be data on perhaps 1000 lung cancers, providing an unprecedented amount of information. The central issues will be to determine which of these mutations are "actionable"—that is, provide a guide for targeting therapy; which are "passenger" and which are "driver" mutations; how frequent the mutations are; how the mutations are related to other molecular changes (e.g., methylation and miRNA profiles); and which mutations provide information to identify important subgroups ("molecular portraits") of lung cancer that provide prognostic (survival information independent of therapy) and/or predictive (survival information dependent on the administration of specific therapies) utility. Identifying "acquired vulnerabilities" in lung cancer that can be therapeutically targeted is key. As a lung epithelial cell acquires oncogenic changes (such as a KRAS mutation), it must acquire other changes to allow the cell to tolerate the oncogenic changes. These acquired vulnerabilities are not present in normal tissue and thus are "synthetically lethal" with the oncogenic changes in tumors. Many of these are likely to be considered "passenger" mutations. Nevertheless, they may represent actionable targets as well as enrollment biomarkers for selecting patients.

National Cancer Institute Lung Cancer Specialized Program of Research Excellence (SPORE) (P50CA70907), N R (NNJ05HD36G). JEL supported by NHMRC Biomedical Fellowship (494511).

Molecular Epidemiology and Etiology

The two main types of lung cancer, non–small-cell lung cancer (NSCLC) (representing 80% to 85% of cases) and small-cell lung cancer (SCLC) (representing 15% to 20%) are identified based on histological, clinical, and neuroendocrine characteristics. NSCLC can be further histologically subdivided into adenocarcinoma, squamous carcinoma, large-cell carcinoma (including large-cell neuroendocrine lung cancers), bronchioloalveolar lung cancer, and mixed histologic types (e.g., adenosquamous carcinoma).

Although about 85% of lung cancers are caused by carcinogens present in tobacco smoke, 15% to 25% of lung cancer cases occur in lifetime "never smokers" (fewer than 100 cigarettes in a lifetime). Furthermore, more than 50% of newly diagnosed lung cancers in the United States occur in

Table 32-1 Molecular Differences between Smoking and Never Smoking Lung Cancers

Gene	Never Smoking	Smoking
TP53 mutations—overall	Less common	More common
TP53 mutations—G:C to T:A mutations	Less common	More common
KRAS mutations	Less common (0%-7%)	More common (30%-43%)
EGFR mutations	More common (45%)	Less common (7%)
STK11 mutations	Less common	More common
EML4-ALK fusions	More common	Less common
HER2 mutations	More common	Less common
Methylation index	Low	High
p16 methylation	Less common	More common
APC methylation	Less common	More common
Loss of hMSH2 expression	Common (40%)	Rare (10%)

Data summarized from the following reviews: References 21-23.

former smokers, in whom the damage caused by past smoking still led to the development of lung cancer. Although the general public associates lung cancer with smoking, the numbers of lung cancer cases occurring in lifetime never smokers and former smokers both present a huge public health problem. Thus, it will be important to identify non–smoking-related etiologies of lung cancer arising in never smokers, as well as methods to identify which former smokers are most likely to develop clinically evident lung cancer.

Lung Cancer in Never Smokers

Never-smoking lung cancers represent a disease that is epidemiologically, clinically, and molecularly distinct from smoking lung cancers. If considered independently, never-smoking lung cancers are the seventh most common cause of cancer death.[5] Never-smoking lung cancer occurs more frequently in women and East Asians, has a peak incidence at a younger age, targets the distal airways, is usually adenocarcinoma, and frequently is epidermal growth factor receptor (EGFR) mutant and therefore responsive to EGFR-targeted therapies. Table 32-1 outlines the molecular differences between smoking and never-smoking lung cancers.

Inherited Susceptibility to Lung Cancer

The study of inherited predisposition to lung cancer has been investigated. Multiple genome-wide association studies (GWASs) have associated single-nucleotide polymorphism (SNP) variations at 15q24-q25.1 (including genes encoding nicotinic acetylcholine receptor [nAChR] subunits [*CHRNA5*, *CHRNA3*, and *CHRNB4*]) with an increased risk of both nicotine dependence and developing lung cancer. Although meta-analyses have provided further evidence that variation at 15q25.1, 5p15.33, and 6p21.33 influences lung cancer risk, it is not yet known whether there is a mechanistic association of these polymorphisms and nicotine addiction, carcinogenic derivatives of nicotine exposure, or the effect of nicotine acting on nAChRs. In addition, a genome-wide linkage study of pedigrees containing multiple generations of lung cancer from the Genetic Epidemiology of Lung Cancer Consortium (GELCC) mapped a familial susceptibility locus to 6q23-25.[2] Regulator of G-protein signaling 17 (*RGS17*) is a putative causal gene within this locus where common variants were associated with familial but not sporadic lung cancer; however, it is likely that more than one genetic locus in the 6q region is influencing susceptibility.

Human Papilloma Virus–Mediated Lung Cancer

Human papilloma virus (HPV), an established human carcinogen (for both uterine cervical and head and neck cancer), has been proposed to play a role in lung cancer pathogenesis; however, published data remain controversial. The presence of HPV oncoproteins E6 and E7 leads to inactivation of tumor suppressors p53 and Rb, respectively. A meta-analysis of 100 publications comprising 7381 cases found that the incidence of HPV in lung cancer differed by geographical origin of the study (higher in China, Taiwan, other Asia, and South America and lower in Australia, Europe, and North America) and histological subtype, where HPV was slightly more common in squamous-cell carcinomas (SCCs). The detection of oncogenic variants of HPV in some tumors and our knowledge of HPV oncoproteins suggest that HPV infection will be a major etiologic feature in a subset of lung cancer. Given the differences in response of HPV-associated head and neck cancer to EGFR-targeted therapy, it will be important to characterize other molecular alterations in these lung cancers, and how they respond to various therapies.

Genomics: Tools for Identification, Prediction, and Prognosis

The molecular heterogeneity of lung cancer and utility in classifying lung tumors by the specific mutations driving

their growth is demonstrated in tumors harboring either the epidermal growth factor receptor *(EGFR)* tyrosine kinase (TK) mutations or the *EML4-ALK* fusion protein. These tumors exhibit exquisite sensitivity to EGFR TK inhibitors, such as gefitinib and erlotinib, or the ALK and ROS1 inhibitor crizotinib, respectively. Advances such as these have spurred considerable interest and excitement in the field of lung cancer to fully understand the complex genomic landscape.[6] It will now be possible to achieve this lofty goal with the use of massively parallel sequencing and the comprehensive cataloging of SNPs, structural variations, gene amplifications, deletions, methylation, messenger RNA (mRNA) expression, and alterations in microRNAs (miRNAs) and miRNA binding sites present in a genome. Initial sequencing studies of either a subset of cancer-related genes or single-lung tumors or cell lines found the lung cancer genome displayed high protein-altering mutation rates, perhaps indicative of the inherent heterogeneity found in lung tumors compared with tumors from other tissues. A comprehensive and systematic analysis of cancer genomes from large numbers of patients with lung cancer is critical to identify significant molecular alterations that drive the cancer phenotype and eventually to develop rational therapies.

Challenges: Sample Procurement and Informed Consent

Technical and ethical factors such as sample procurement and informed consent remain a significant challenge to the application of these technologies. Serial collection of tumor samples at various points during disease progression would contribute to our understanding of the clonal evolution of tumors and better define the molecular mechanisms underlying metastatic process and resistance to targeted therapy.

Transcriptome Profiling

Profiling the lung cancer transcriptome has imparted biologically and clinically relevant information such as novel dysregulated genes and pathways and gene signatures that can predict patient prognosis, response to treatment, and histology.[7] Predictive and prognostic mRNA profiling has real potential for refining the care of lung cancer patients, but progress has been limited. In an effort to overcome limitations of sample size and heterogeneity in previous studies, a multisite, blinded validation study of 442 lung adenocarcinomas examined whether the mRNA profile of primary tumors could robustly predict patient outcome either alone or in combination with clinicopathological factors.[8] This study developed several models (or signatures) which, for the most part, predicted outcome better than current clinical methods. However, critical review of published prognostic signatures in lung cancer found little evidence of any published signature being ready for clinical application, mostly because of limitations in study design and analysis. Expression of nuclear receptors (and later their co-regulators) in lung cancer may provide as good or better prognostic information than other mRNA expression signatures. Because nuclear receptors are also targets for therapeutic manipulation (via hormone agonists and antagonists), expression patterns in individual lung cancers may also provide insight for targeted therapy. Despite the complexities of mRNA profiling, the success of prognostic signatures in breast cancer suggests the importance of further research efforts.

Genome-Wide Copy Number Profiling

High-resolution mapping of copy number alterations in the lung cancer genome has identified single genes as targets of genomic gain or loss through improved definition of known aberrant regions or by the identification of focal alterations undetectable with earlier technology. The analysis of primary lung adenocarcinomas identified significant recurrent copy-number alterations, of which a majority were focal events, including some mutations previously unrecognized in lung cancer—for example, amplification at 14q13.3 targeting the transcription factor NKX2-1, which is discussed later. The ongoing work led by the National Cancer Institute's The Cancer Genome Atlas (TCGA) project has revealed regions of significant copy number alterations in lung SCCs. These include previously reported regions of copy number alteration containing SOX2, PDGFRA/KIT, EGFR, FGFR1/WHSC1L1, CCND1, and CDKN2A genes as well as novel findings, including amplifications containing NFE2L2, MYC, CDK6, MDM2, BCL2L1, and EYS and deletions of FOXP1, PTEN, and NF1.[9] Similar studies in NSCLC and SCLC cohorts have identified other novel drivers of lung carcinogenesis.

Genome-Wide Sequencing of Lung Cancers

TCGA plans to comprehensively characterize the genomic alterations in 1000 patients with NSCLC. Sequencing of squamous, adenocarcinoma, and SCLC has been completed, yielding a list of "significantly mutated genes" (SMGs) (Table 32-2). Analysis of 178 patients with SCC is complete and has revealed that lung SCC displays a bewildering array of genomic changes with a mean of 360 mutations in the exons

Table 32-2 Significantly Mutated Genes in Lung Cancer Subtypes Identified with Exome Sequencing

Adenocarcinoma	Squamous-Cell Carcinoma	SCLC
ARID1A	ANP32C	ADCY1
ATM	APC	BCLAF1

	WWOX	

Genes in **bold** are present in more than one histological subtype.
Data generated through of analysis of 183 lung adenocarcinomas[24]; TCGA project of 178 previously untreated, stage I-IV primary lung squamous cell carcinoma[9]; and 34 primary SCLC tumors and 17 SCLC cell lines.[25]

(including 228 nonsilent mutations), 165 genomic rearrangements, and 323 segments of copy number alterations per tumor.[9] Similar rates of genomic alterations have been reported from studies of genomic changes in lung adenocarcinoma, where the average mutation frequency in smokers with adenocarcinoma of the lung was 10-fold higher compared with lifelong never smokers. Substantial differences were also found not just in mutational burden but also in the mutational spectra of affected genes between the smokers and lifelong never smokers with lung adenocarcinoma. Ongoing analyses of lung adenocarcinoma and other lung cancer subtypes such as SCLC by TCGA and other groups (see Table 32-2) will better determine significant "actionable" genes.

Identification of Novel Pathways

TCGA project found a significant number of lung SCCs had alterations in genes involved in oxidative stress response and squamous differentiation. Genomic alterations included point mutations and copy number alterations. More specifically, alterations in one of the three genes *NFE2L2*, *KEAP1*, and *CUL3* were identified in nearly a third of tumor samples studied. The master antioxidant transcription factor NFE2L2 promotes survival following cellular insults that trigger oxidative damage and is regulated by KEAP1, an oxidative stress sensor. In unstressed conditions, KEAP1 binds and subsequently represses NFE2L2. KEAP1 also forms a ubiquitin E3 ligase complex with CUL3, resulting in constant ubiquitination of NFE2L2. Mutations in *NF2L2* occurred nearly exclusively in one of the two KEAP1 interaction motifs. Mutations in *KEAP1* and *CUL3* showed a pattern consistent with loss of function. In addition, mutations in *KEAP1* and *CUL2* were mutually exclusive with *NFE2L2*. Alterations in genes that are known to play a role in squamous differentiation were identified in 44% of lung SCC samples. The changes include overexpression and amplification of SOX2 and TP63 and loss-of-function mutations involving *NOTCH1* and *NOTCH2*. Truncating mutations involving *NOTCH1* and *NOTCH2* have been reported previously in squamous cell cancer of the skin and lung.

Recurrent somatic mutations in the splicing factor gene *U2AF1*, truncating mutations affecting *RBM10* and *ARID1A*, and in-frame exonic alterations within EGFR and SIK2 kinases were identified in an exome and genome analysis of lung adenocarcinoma. *SOX2* mutations and amplification and a recurrent *RFL-MYCL1* fusion were common in an exome, transcriptome, and copy number analysis of 34 primary SCLC tumors and 17 SCLC cell lines. Suppression of *SOX2* in *SOX2*-amplified cell lines or *MYCL1* in *RLF-MYCL1* cell lines both resulted in decreased proliferation, suggesting that these alterations may represent SCLC subtype vulnerabilities.

Identification of Therapeutic Targets

The lung SCC TCGA project reported a number of potentially targetable alterations using a gene-centered and pathway-directed approach. Using fairly stringent criteria (availability of a targeted agent, confirmation of altered allele in transcriptome sequencing, and Mutation Assessor Score), a potentially targetable gene was identified in 64% of samples studied. Alterations in one of the three core pathways (PI3K/AKT/mTOR, RTKs, and RAS/RAF/MAPK) were found in 69% of samples even after restricting the analysis to include only those where mutations were confirmed by transcriptome sequencing and those amplifications associated with overexpression of the target gene. Some of the notable targets altered include PI3KCA, PTEN, AKT3, BRAF, FGFR, and EGFR. Another novel target identified with whole-transcriptome analyses of tumor samples is in-frame fusion transcripts

involving *KIF5B* (the Kinesin family 5B gene) and the *RET* oncogene, which is found in 1% to 2% of patients with lung adenocarcinoma and is discussed later.

Lessons Learned and Future Directions

Preliminary TCGA analysis of lung SCCs has demonstrated the importance of integrating mutational data with other genomic data such as methylation, mRNA expression, and copy number. *CDKN2A*, a tumor suppressor gene (TSG) that encodes two cell cycle inhibitor proteins, p16 and p14, is frequently altered in lung SCC. *CDKN2A* is inactivated through multiple mechanisms from epigenetic silencing by methylation (21%), to inactivating mutation (18%), to other events such as exon skipping (4%) and homozygous deletion (29%). Thus considering only one set of genomic data could lead to inaccurate conclusions on the role of the gene.

It is clear that next-generation sequencing has enormous potential to unravel the complexities of the lung cancer genome and identify the molecular mechanisms underpinning therapeutic responses and progression of lung cancer. Although the challenges in gathering reliable and clinically and pathologically annotated data are not trivial, high-throughput technologies and publicly stored genome-wide databases related to lung cancer are resources with the potential to drive a global collaborative effort in identifying new targets for lung cancer diagnostics and therapeutics. Large-scale multidisciplinary and international collaborations such as the TCGA project, the NCI Lung Cancer Mutation Consortium (LCMC),[10] as well as international lung cancer sequencing consortiums will enable the uniting of clinically annotated with molecularly annotated lung cancer specimens. Enabling free access to all of these genome-wide studies will allow independent confirmation on the role of the various molecular changes for prognosis, prediction, and targeting of therapy of lung cancer.

Genome-Wide Functional (siRNA, shRNA Library) Screening

"Synthetic lethal" screens using RNAi (siRNAs and shRNA libraries) technology have allowed unbiased, genome-wide approaches to identification of genes whose perturbation can selectively kill lung cancer cells. The ability to identify "synthetic lethality"[11] associated with oncogenic changes in tumor cells has particular utility in identifying new therapeutic targets or molecules to treat traditionally hard-to-target tumors, such as those with oncogenic KRAS. Small interfering RNA (siRNA) and short-hairpin RNA (shRNA) screens have identified genes whose perturbation can selectively sensitize NSCLC cell lines to sublethal doses of chemotherapeutic agents, sensitize KRAS mutant cells to targeted drugs, suppress tumorigenicity in cells with specific gene dysregulation such as oncogenic KRAS or aberrant EGFR, and identify novel genes critical for tumorigenic processes such as metastasis.

Epigenetic Changes in Lung Carcinogenesis

Epigenetic events can lead to changes in gene expression without any changes in DNA sequence and therefore, importantly, are potentially reversible.

Methylation and Histone Modification

Aberrant promoter hypermethylation (the addition of a methyl group to CpG islands in the promoter region of a gene that results in transcriptional silencing) is a common method for inactivation of TSGs in tumor cells and occurs early in lung tumorigenesis. In fact, whole-genome microarray profiling of DNA methylation patterns in lung cancer—termed the *lung cancer epigenome* or *methylome*—suggests that the role of methylation in lung tumorigenesis may have been previously underestimated. Because aberrant methylation is an early event in lung cancer pathogenesis and is detectable in DNA circulating in the blood, many studies have investigated methylation status as a biomarker for risk assessment, early detection, disease progression, and prognosis in lung cancer (Table 32-3).

DNA is methylated by DNA methyltransferases (DNMTs) which are responsible for both de novo and maintenance of preexisting methylation in a cell. Histone modification is another mechanism for epigenetic control of gene transcription: histone deacetylation results in condensing of chromatin, resulting in transcriptionally inactive DNA. Inhibitors of DNMTs or histone deacetylases (HDACs) resulting in pharmacologic restoration of expression of epigenetically silenced genes is an exciting targeted therapeutic approach and shows promise in lung cancer (Table 32-4).

microRNA-Mediated Regulation

There is currently a strong research focus on microRNAs (miRNAs) as potential diagnostic and prognostic biomarkers and therapeutic targets for lung cancer. miRNA profiles for histologic and prognostic classification of lung tumors and detection of miRNAs in peripheral blood and sputum illustrate the potential of miRNAs as diagnostic and early

detection biomarkers in lung cancer. Table 32-5 summarizes some experimentally validated miRNAs important in lung cancer. miRNAs are a class of non–protein-encoding small RNAs capable of regulating gene expression by either directly cleaving a targeted mRNA or inhibiting translation by interacting with the 3′ untranslated region (UTR) of a target mRNA. A single miRNA often targets multiple genes, and multiple miRNAs may target the same mRNA, which results in a complex network of molecular pathways where a single miRNA (to date, more than 1400 human miRNAs have been identified) can potentially affect multiple cellular processes. Aberrant expression of miRNAs has been found to play an important role in the pathogenesis of lung cancer as either oncogenes or TSGs. miRNAs can function as either TSGs or oncogenes. Restoration of aberrantly expressed miRNAs can be achieved in vitro and in vivo using miRNA mimics (for underexpressed miRNAs) or miRNA inhibitors (termed *antisense oligonucleotides* or *antagomirs;* for overexpressed miRNAs). Concurrent inhibition or overexpression of miRNAs with conventional therapies has resulted in an

Data summarized from the following reviews: References 31-34.
*Correlation with poor prognosis.
†In KRAS and EGFR wild-type tumors.

increased response to EGFR TKIs, radiotherapy, and chemotherapy. These studies illustrate the potential of miRNAs in lung cancer therapeutics development; however, limitations in pharmacokinetics, delivery, and toxicity need to be addressed.

The *let-7* family is a cluster of miRNAs that function as tumor suppressors and is frequently underexpressed in lung tumors, particularly NSCLC, compared to normal lung, and decreased expression has been associated with poorer prognosis. *Let-7* regulates multiple oncogenes including RAS, MYC, and HMGA2 via binding to the let-7 binding sites in their respective 3′ UTRs. *Let-7* replacement therapy shows potential, with reduced tumor burden observed in vivo; however, tumor response in patients will be affected by a SNP in the *let-7* complementary site (LCS6) of KRAS, which is significantly associated with lung cancer risk and results in increased KRAS expression in vitro.

An example of an important oncogenic miRNA—oncomir—in lung cancer is RAS-regulated *miR-21* which promotes cellular growth and invasion and metastasis by targeting multiple genes with tumor suppressive effects such as negative regulators of the RAS/RAF/MAPK pathway, pro-apoptotic, and anti-metastatic genes. Expression of *miR-21* is also suggested to be positively regulated by the EGFR signaling pathway, specifically EGFR mutations. Some miRNAs have also been shown to be important mediators of metastasis. The expression of miR-200 family members is commonly lost in aggressive lung cancers and can prevent epithelial to mesenchymal transition (EMT)—and consequently, invasion and metastasis—by repressing transcriptional repressors of E-cadherin.

Oncogenes, Tumor Suppressor Genes, and Signaling Pathways in Lung Cancer

The "hallmarks of cancer"[4] describe the complexities of neoplastic disease and stratify the complexities by mechanistic function. Genomic instability is an underlying "enabling" characteristic of lung cancer cells where alterations such as chromosomal rearrangements can generate rare genetic events in cells that eventually give rise to cancer. Mapping amplifications and deletions in copy number throughout the cancer genome has led to the identification of many oncogenes and TSGs. Recent whole-genome genomic approaches have yielded further insight into the complexities of the lung cancer genome with the identification of driving mutations and other key signaling pathways (see Table 32-2). The following section summarizes known driver mutations (*EGFR*, *KRAS*, and EML4-ALK) and key signaling pathways (including RAS/RAF/MAPK, PI3K/AKT/mTOR, p53, and p16/RB) in lung cancer organized by "hallmarks" (Figure 32-1).[12] There are several targeted therapy agents in the clinic or in development for lung cancer (see Table 32-4).

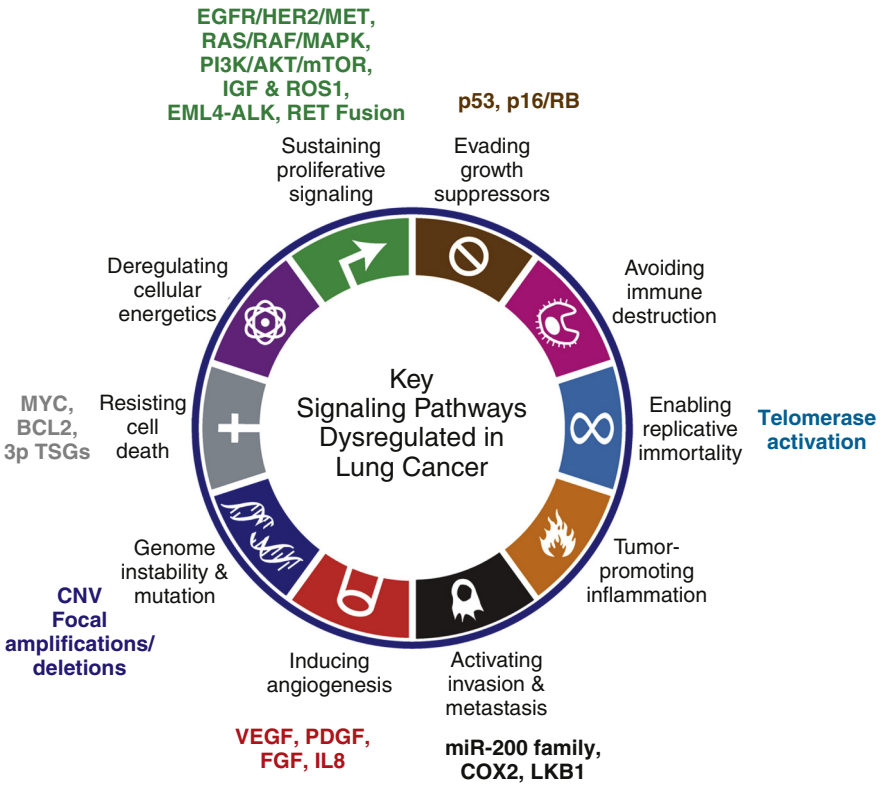

Figure 32-1 Key signaling pathways discussed in this chapter that are commonly dysregulated in lung cancer in relation to the "Hallmarks of Cancer" proposed by Hanahan and Weinberg[4] Currently, most of our knowledge of the molecular changes in lung cancer converges on the six original hallmarks (sustaining proliferative signaling; evading growth suppressors; resisting cell death; enabling replicative immortality; inducing angiogenesis; and activating invasion and metastasis), as well as the newly categorized "enabling characteristic" genome instability and mutation. *(Reprinted from Hanahan D, Weinberg RA. Hallmarks of cancer: the next generation.* Cell. *2011;144:646-674, with permission from Elsevier.)*

Oncogene activation probably occurs in all lung cancers (typically by gene amplification, overexpression, point mutation, or DNA rearrangements), resulting in persistent upregulation of mitogenic growth signals, which induce cell growth. Importantly, it can also result in "oncogene addiction" in which the cell becomes dependent on this aberrant oncogenic signaling for survival.[13] These "driver" oncogenes or oncogene "addictions" represent acquired vulnerabilities in lung cancer cells and present as significant therapeutic targets by offering the specificity of killing tumor but not normal cells.

Loss of TSG function is an important step in lung carcinogenesis and usually results from inactivation of both alleles, with loss of heterozygosity (LOH; through chromosomal deletion or translocation) inactivating one allele, and point mutation or epigenetic or transcriptional silencing inactivating the second allele. Commonly inactivated TSGs in lung cancer include *TP53*, *RB1*, *STK11*, *CDKN2A*, *FHIT*, *RASSF1A*, and *PTEN*. Historically, tumor suppressors have been more difficult to target with therapeutic agents because restoration of lost activity is much more difficult than inhibition of increased activity (as with oncogenes), and consequently most endeavors were targeted at downstream effectors. Increased understanding of the function of tumor suppressor proteins may identify novel therapeutic targets, as shown with p53, where compounds that stabilize the mutant protein or restore wild-type conformation demonstrate clinical utility.

Hallmark: Sustaining Proliferative Signaling

EGFR/HER2/MET Signaling

EGFR

The ErbB family of tyrosine kinase receptors includes four members: EGFR, ERBB2 (HER2), ERBB3, and ERBB4. The receptors can activate multiple signal transduction cascades, including the RAS/RAF/MAPK, PI3K/AKT/mTOR, and STAT pathways, by forming homo- and heterodimers with different ligand specificity. EGFR is overexpressed or aberrantly activated in 50% to 90% of NSCLCs. EGFR-targeted inhibitors include monoclonal antibodies that target the EGFR extracellular domain and tyrosine kinase inhibitors (TKIs), which are small molecules that inhibit intracellular tyrosine kinase activity of EGFR. A significant advance was made in the treatment of NSCLC with the observation that lung cancer somatic mutations in the kinase domain of EGFR strongly correlated with sensitivity to EGFR TKIs. EGFR mutant lung tumors exhibit exquisite sensitivity and marked tumor response with EGFR TKIs (such as erlotinib and gefitinib) and antibodies (such as cetuximab)—an example of oncogene addiction in lung cancer where tumors driven by EGFR mutation-activation of EGF signaling rely on continued EGF signaling for survival. "Classic" EGFR mutations in the tyrosine kinase domain (by either exon 19 deletion or exon 21 L858R mutation, which each account for about 45% of EGFR mutations) show an increased amount and duration of EGFR activation compared with wild-type receptors and have preferential activation of the PI3K/AKT/mTOR and STAT3/STAT5 pathways rather than the RAS/RAF/MAPK pathway. By contrast, the remaining 10% of EGFR tyrosine kinase mutations, in exons 18 and 20, do not confer sensitivity to EGFR TKIs and in some cases are associated with EGFR TKI resistance. EGFR mutations of all types are particularly prevalent in certain patient subgroups: adenocarcinoma histology, women, never smokers, and East Asian ethnicity. Despite an initial response, patients treated with EGFR TKIs eventually develop resistance to TKIs that is linked (in approximately 50% of tumors) to a T790M mutation in EGFR exon 20. In such cases, it is likely that a small population of cancer cells harboring T790M mutations is present at diagnosis and selected for during EGFR TKI therapy. Proposed mechanisms of the T790M-associated therapeutic resistance include a conformational change resulting in steric hindrance to EGFR TKI binding and increased EGFR affinity for ATP. Resistance to TKI therapy has also been associated with EGFR exon 20 insertions; KRAS mutation; amplification or activation of the *MET* proto-oncogene, which provides an alternative signaling pathway; and occasionally a switch of tumor differentiation to an SCLC-like phenotype. Second-generation EGFR TKIs (such as PF00299804, afatinib, and neratinib) bind irreversibly to EGFR tyrosine kinase, induce much less therapeutic resistance, and appear effective against secondary resistance mutations such as T790M.

ERBB2 (HER2)

The ligand for HER2 remains unknown, but HER2 is activated following homo- or heterodimerization (with EGFR or HER3 preferentially). Unlike breast and gastric cancers, HER2 amplification or overexpression in NSCLC does not confer sensitivity to HER2 antibodies or TKIs. However, exon 20 mutations in HER2 mutations (occurring in 3% to 10% of lung adenocarcinomas) do confer sensitivity to lapatinib in NSCLC cell lines. HER2 mutations also confer resistance to EGFR TKIs regardless of EGFR mutation status as HER2 replaces EGFR in driving growth signals.

MET

Similar to EGFR, MET is a receptor tyrosine kinase capable of driving RAS/RAF/MAPK and PI3K/AKT/mTOR pathway signaling following activation on hepatocyte growth factor (HGF) binding. Amplification of *MET* is also thought to mediate resistance to EGFR TKIs, independent of the

T790M mutation, where MET activates the PI3K/AKT/mTOR pathway through phosphorylation of HER3, independent of EGFR and HER2. Inhibition of MET is being successfully approached with antibodies (such as MetMAb) and small-molecule MET inhibitors (tivantinib/ARQ-197) (see Table 32-4).

RAS/RAF/MAPK Pathway

The RAS proto-oncogene family (KRAS, HRAS, NRAS, and RRAS) encodes four highly homologous 21-kDa membrane-bound proteins involved in signal transduction. Activation of the RAS/RAF/MAPK pathway occurs frequently in lung cancer, most commonly via activating mutations in KRAS (approximately 20%, particularly adenocarcinomas). In lung cancer, 90% of mutations are located in *KRAS* (80% in codon 12, and the remainder in codons 13 and 61), with *HRAS* and *NRAS* mutations only occasionally documented. Proteins encoded by the *RAS* genes exist in two states: an active state, in which GTP is bound to the molecule, and an inactive state, where the GTP has been cleaved to GDP. Activating point mutations confer oncogenic potential through loss of intrinsic GTPase activity, resulting in an inability to cleave GTP to GDP. This results in constitutive activation of downstream signaling pathways, such as PI3K and MAPK, rendering KRAS mutant tumors independent of EGFR signaling and therefore resistant to EGFR TKIs as well as chemotherapy. KRAS mutations are mutually exclusive with EGFR and ERBB2 mutations and are primarily observed in lung adenocarcinomas of smokers. The prevalence and importance of KRAS in lung tumorigenesis make it an attractive therapeutic target. Two unsuccessful approaches were farnesyltransferase inhibitors, to inhibit posttranslational processing and membrane localization of RAS proteins, and antisense oligonucleotides against RAS. More recently, efforts have been centered on downstream effectors of RAS signaling: RAF kinase and mitogen-activated protein kinase (MAPK) kinase (MEK).

BRAF is the direct effector of RAS. Although it is commonly mutated in melanoma (about 70%), mutations are rare in lung cancer (about 3%), predominantly in adenocarcinoma, and mutually exclusive to EGFR and KRAS mutations. Strategies to inhibit RAF kinase include degradation of *RAF1* mRNA through antisense oligodeoxyribonucleotides, and inhibition of kinase activity with small molecule kinase inhibitors such as the multikinase inhibitor sorafenib (which inhibits VEGFR, PDGFR, FLT-3, RAF, MEK, and KIT) as well as some BRAF mutant-specific inhibitors such as vemurafenib, PLX-4720, and GDC-0879. Several potent and selective MEK inhibitors such as selumetinib (AZD6244) and GSK1120212 show potential in inhibiting RAS/RAF/MAPK signaling (see Table 32-4). Attempts to directly inhibit or perturb mutant KRAS continue with the advent of whole-genome approaches. Synthetic lethal siRNA screens have identified siRNAs that specifically kill human lung cancer cells with KRAS mutations in vitro. In addition, the combination of anti-KRAS strategies (such as depletion with shRNAs) with other targeted drugs has shown potential therapeutic utility.

PI3K/AKT/mTOR Pathway

Phosphoinositide 3-kinases (PI3Ks) are lipid kinases that regulate cellular processes such as proliferation, survival, adhesion, and motility. The PI3K/AKT/mammalian target of rapamycin (mTOR) pathway is downstream of several receptor tyrosine kinases including EGFR, and downstream effectors are involved in cell growth, angiogenesis, cell metabolism, protein synthesis, and suppression of apoptosis directly or via the activation of mTOR. In lung tumorigenesis, activation of the PI3K/AKT/mTOR pathway occurs early in pathogenesis, generally through mutations or amplification of (oncogenes) PI3K (as well as EGFR or KRAS), activation of AKT, or PTEN loss of function (TSG), and promotes cell survival through inhibition of apoptosis. PTEN, TSC1, TSC2, and STK11 (LKB1) are tumor suppressors that function as negative regulators of the pathway, and thus their loss of function activates the pathway. PTEN antagonizes the PI3K/AKT/mTOR pathway by dephosphorylating phosphatidylinositol 3,4,5-trisphosphate (PIP3), a product of PI3K, to PIP2 and is commonly inactivated in lung cancer by mutations or loss of expression. TSC1 and TSC2 form a complex that inhibits activity of small G protein Rheb, leading to inhibition of the mTOR complex mTORC1. TSC1/TSC2-mediated inhibition of mTORC1 can be activated by LKB1 and AMPK and inhibited by AKT-mediated phosphorylation of TSC2. The serine/threonine kinase mTOR, a downstream effector of AKT, is an important intracellular signaling enzyme in the regulation of cell growth, motility, and survival in tumor cells. Molecular characterization of PI3K/AKT/mTOR pathway biomarkers (such as loss of PTEN) will enable better selection of tumors responsive to mTOR, AKT, and PI3K inhibition.

STK11 (LKB1)

The serine/threonine kinase STK11 (also called LKB1) functions as a TSG by regulating cell polarity, motility, differentiation, metastasis, and cell metabolism. Germline inactivating mutations of STK11 cause Peutz-Jeghers syndrome, but somatic inactivation through point mutation and frequent deletion on 19p13 occurs in approximately 30% of lung cancers—making it the third most commonly mutated gene in lung adenocarcinoma after p53 and RAS. STK11 mutations often correlate with KRAS activation and result in the promotion of cell growth. Its tumor-suppressing

effect is thought to function, in part, through inhibition of the mTOR pathway via AMP-activated protein kinase. STK11 inactivation appears to be particularly prevalent in NSCLC but rare in SCLCs; inactivating mutations are more common in tumors from males and smokers and in poorly differentiated adenocarcinomas. Mutation in both *KRAS* and *STK11* appears to confer increased sensitivity to MEK inhibition in NSCLC cell lines compared to either mutation alone.

Insulin Growth Factor (IGF) Pathway and ROS1

The insulin growth factor (IGF) pathway mediates the growth and differentiation of bone and skeletal muscle and comprises two receptors (insulin receptor [IR] and insulin-like growth factor-1 receptor [IGF-1R]) and three principal ligands (IGF-1, IGF-2, and insulin). IGF-1R is a receptor tyrosine kinase that forms homo- and heterodimers with IR and HER2. Activation on ligand binding results in upregulation of various signaling pathways including the PI3K/AKT/mTOR and RAS/RAK/MAPK pathways. Dysregulation of IGF signaling in lung cancer is evidenced by frequent (up to 70%) overexpression of IGF-1R in NSCLC, where increased signaling results in tumor growth and drug resistance. Furthermore, increased plasma levels of IGF-1 are associated with increased risk of lung cancer.

ROS1 is a receptor tyrosine kinase in the insulin receptor family. Rearrangements involving the *ROS1* gene were initially described in glioblastoma but have now been reported in lung cancer and other malignancies. *ROS1* rearrangement, as determined by FISH, has been reported in 1% to 2% of patients with NSCLC. Patients whose tumor cells exhibit *ROS1* rearrangement tend to be younger (median age around 50 years) and lifelong nonsmokers. Crizotinib appears to have promising activity in this molecular subset of NSCLC.

Other Fusion Proteins: EML4-ALK and RET

EML4-ALK

A novel fusion gene with transforming ability was reported in a small subset of NSCLC patients. Formed by the inversion of two closely located genes on chromosome 2p, fusion of PTK echinoderm microtubule-associated protein like-4 (EML4) with anaplastic lymphoma kinase (ALK), a transmembrane tyrosine kinase, yields the EML4-ALK fusion protein. The fusion results in constitutive oligomerization leading to persistent mitogenic signaling and malignant transformation. Meta-analysis of 13 studies encompassing 2835 tumors reported that the EML4-ALK fusion protein is present in 4% of NSCLCs. *EML4-ALK* fusions are, in nearly every case, found exclusive of *EGFR* and *KRAS* mutations and occur predominantly in adenocarcinomas, never or light smokers, younger patients, and males. Tumors with EML4-ALK fusions exhibit dramatic clinical responses to ALK targeted therapy, and the ALK and MET inhibitor crizotinib (PF-02341066) is now approved for use for lung cancer treatment in patients harboring the fusion protein.

RET

Whole-transcriptome analyses of tumor samples revealed the presence of in-frame fusion transcripts involving *KIF5B* (the Kinesin family 5B gene) and *RET* oncogene in 1% to 2% of patients with lung adenocarcinoma. In vitro studies have shown that *KIF5B-RET* is capable of inducing malignant transformation and its effect can be reversed with a *RET* kinase inhibitor. Although further studies are needed to evaluate the therapeutic role of *RET* fusions in lung cancer, this demonstrates how next-generation sequencing has opened a new field of investigation for therapeutic approaches.

Hallmark: Resisting Cell Death and Evading Growth Suppressors

MYC

One of the major downstream effectors of the RAS/RAF/MAPK pathway is the MYC proto-oncogene. In normal conditions, this transcription factor functions to keep tight control of cellular proliferation; however, aberrant expression through amplification or overexpression is commonly found in lung cancer. MYC proto-oncogene members (MYC, MYCN, and MYCL) are targets of RAS signaling and key regulators of numerous downstream pathways such as cell proliferation,[14] where enforced Myc expression drives the cell cycle in an autonomous fashion. It can also sensitize cells to apoptosis through activation of the mitochondrial apoptosis pathway—thus, Myc-driven tumorigenesis often requires coexpression of anti-apoptotic BCL2 proteins. Activation of MYC members often occurs through gene amplification, with MYC most frequently activated in NSCLC and all three members (MYC, MYCN, and MYCL) activated in SCLC by amplification. Recently, genome-wide analyses have identified MYCL translocations as a frequent mechanism of activation in SCLC.

The 3P Tumor Suppressor Genes: Regulators of Apoptosis

Loss of one copy of chromosome 3p is one of the most frequent and early events in human cancer, found in 96% of lung tumors and 78% of lung preneoplastic lesions. Mapping of this loss identified several candidate TSGs, including *FHIT* (3p14.2), *RASSF1A*, *TUSC2* (also called *FUS1*),

and semaphorin family members *SEMA3B* and *SEMA3F* (all at 3p21.3), and *RAR*β (3p24). In addition to LOH or allele loss, some 3p genes often exhibit decreased expression in lung cancer cells because of promoter hypermethylation. *FHIT*, located in the most common fragile site in the human genome (*FRA3B*), has been shown to induce apoptosis in lung cancer. *RASSF1A* can induce apoptosis, stabilize microtubules, and affect cell cycle regulation. *TUSC2* mediates apoptosis in cancer cells but not normal cells by upregulation of the intrinsic apoptotic pathway and inhibits several protein tyrosine kinases such as EGFR, PDGFR, c-Abl, c-Kit, and AKT. The candidate TSG *SEMA3B* encodes a secreted protein that can decrease cell proliferation and induce apoptosis when reexpressed in lung, breast, and ovarian cancer cells, in part by inhibiting the AKT pathway. Another family member, *SEMA3F*, may inhibit vascularization and tumorigenesis by acting on VEGF and ERK1/2 activation. *RAR*β exerts its tumor-suppressing function by binding retinoic acid, thereby limiting cell growth and differentiation.

The p53 Pathway

TP53 (17p13) encodes a phosphoprotein that prevents accumulation of genetic damage in daughter cells. In response to cellular stress, p53 induces the expression of downstream genes such as cyclin-dependent kinase (CDK) inhibitors, which regulate cell cycle checkpoint signals, causing the cell to undergo G_1 arrest and allowing DNA repair or apoptosis. Regulation of p53 can occur through MDM2, which reduces p53 levels through ubiquitination degradation. MDM2 in turn can be induced by p53 in a negative feedback loop or inhibited by the tumor suppressor $p14^{ARF}$ (encoded by *CDKN2A*). As such, *MDM2* and *CDKN2A* are commonly altered in lung cancer through amplification and loss of expression, respectively. p53 mutations are the most common alterations in lung cancer, where 17p13 frequently demonstrates hemizygous deletion and mutational loss of function of the remaining allele. Unlike most TSGs, which are predominantly inactivated by deletion or truncation, the majority of mutations in *TP53* are missense mutations. Most common are mutations in the DNA binding domain, which generally confer a loss-of-function phenotype by preventing p53 from binding to DNA and acting as a transcription factor. However, mutations in the homo-oligomerization domain can have a dominant negative effect, where mutant p53 exerts a dominant-negative effect on the remaining wild-type protein, abrogating the ability of wild-type p53 to inhibit cellular transformation. Because of the prevalence of p53-inactivating mutations in human cancers, large-scale efforts have been focused on therapeutic strategies to restore normal p53 function. These include re-introduction of wild-type p53 using gene therapy, pharmacological rescue of mutant p53 with small-molecule agents and peptides, blocking of MDM2 expression, inhibiting MDM2 ubiquitin ligase activity, and targeting the p53-MDM2 interaction with small-molecule inhibitors.

The $p16^{INK4a}$-RB Pathway

The $p16^{INK4a}$-RB1 pathway controls G_1-to-S-phase cell cycle progression. Hypophosphorylated retinoblastoma (RB) protein, encoded by *RB1*, was the first tumor suppresser gene identified in lung cancer and halts G_1/S phase transition by binding to the transcription factor E2F1 and repressing the transcription of necessary genes. RB is inhibited by hyperphosphorylation by CDK-CCND1 complexes (complexes between CDK4 or CDK6 and CCND1), and in turn, formation of CDK-CCND1 complexes can be inhibited by p16 (encoded by *CDNK2A*). Absent or mutant RB protein is found in approximately 90% of SCLCs compared to only 10% to 15% of NSCLCs, in which abnormalities in p16 are more common. Other components of the CDKN2A/RB pathway are also commonly altered in lung cancer through mutations (*CDK4* and *CDKN2A*), deletions (*RB1* and *CDKN2A*), amplifications (*CDK4* and *CCDN1*), methylation silencing (*CDKN2A* and *RB1*), and phosphorylation (RB).

Hallmark: Enabling Replicative Immortality

The enzyme telomerase prevents loss of telomere ends beyond critical points and is essential for cell immortality. Although silenced in normal cells (except stem cells), telomerase is activated in more than 80% of NSCLCs and almost uniformly in SCLCs, making it an attractive therapeutic target. Approaches to telomerase inhibition include using antisense oligonucleotides that bind to human telomerase RNA (such as imetelstat, which has started Phase II trials) and immunotherapy, in which a patient's immune system is stimulated with a vaccine to recognize tumor cells containing a major histocompatibility complex–presenting hTERT peptide on the cell surface.

Hallmark: Inducing Angiogenesis

The tumor microenvironment describes the complex and dynamic milieu of stromal cells that surround tumor cells. Cells that make up the tumor microenvironment interact both with each other and with tumor cells. As a consequence, they can affect tumor growth, invasion, and metastasis. Modulation of critical tumor microenvironment biomarkers could improve the current treatment of lung cancers.

Angiogenesis is one of the hallmarks of cancer, being essential for a microscopic tumor to expand into a macroscopic, clinically relevant tumor. A number of angiogenic proteins have been characterized, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), interleukin-8, and angiopoietins 1 and 2; most have been found to be dysregulated in some lung cancers. VEGF signaling is stimulated by tumor hypoxia, growth factors and cytokines, and oncogenic activation. VEGF is an important inducer of angiogenesis and is known to stimulate proliferation and migration, inhibit apoptosis, promote survival, and regulate endothelial cell permeability. It is highly expressed in both NSCLC and SCLC and is associated with poor prognosis in NSCLC. Two main approaches to anti-VEGF therapy are blocking VEGF from binding to its extracellular receptors using VEGF-specific antibodies and recombinant fusion proteins, or using small-molecule TKIs that bind to the intracellular region of VEGFR. The humanized monoclonal antibody bevacizumab blocks the binding of VEGF-A to its receptors VEGFR1 and VEGFR2 and is now approved for use in lung cancer. Interestingly, VEGF expression does not always correlate with response to bevacizumab, possibly because of SNPs in *VEGF*.

Hallmark: Activation Invasion and Metastasis

Epithelial-to-mesenchymal transition (EMT), involved in embryogenesis and normal development of multiple tissues and organs, has been implicated in tumor progression and metastasis.[15] EMT describes the loss of cell polarity into a motile, mesenchymal phenotype typically characterized by loss of E-cadherin expression. Conversion of epithelial tumor cells to a mesenchymal state promotes motility and invasiveness, allowing the tumor cells to detach from the primary tumor and relocate to a secondary site. Tumor cells then undergo a mesenchymal-to-epithelial transition (MET) to revert to an epithelial state to enable proliferative growth. Although EMT is involved in invasion and metastasis, it is also associated with early events in carcinogenesis, the acquisition of stem cell–like properties, and resistance to cell death, senescence, and conventional chemotherapies. In lung cancer, tumors expressing mesenchymal markers and EMT inducers (e.g., Vimentin, Twist, and Snail) have poor prognosis.[16] EMT has also been linked to lung cancer resistance to EGFR TKIs whereas COX-2 expression and loss of LKB1 have been shown to promote EMT in lung cancer. The miR-200 family of miRNAs is an important negative regulator of EMT and, as discussed previously, miR-200 expression is frequently lost in lung cancer, resulting in EMT.

Lung Cancer Stem Cells

The cancer stem cell (CSC) model hypothesizes there is a population of rare, stem-like tumor cells capable of self-renewing and undergoing asymmetric division, thereby giving rise to differentiated progeny that form the bulk of the tumor. The first evidence for CSCs (also termed *tumor-initiating cells*) was reported in acute myeloid leukemia, but support for their existence in solid tumors, including lung cancer, is becoming increasingly common.[17] Although identification of lung CSCs is technically challenging, several cell surface biomarkers have been reported for the detection and isolation of putative lung CSCs. It is also likely that markers of lung CSCs will differ between lung cancers, potentially related to lung cancer oncogenotype. Regulation of lung CSCs is likely by the Hedgehog (Hh), Wnt, and Notch stem cell signaling pathways. Normally tightly regulated processes important in normal lung development, genes whose products make up these pathways are often dysregulated or mutated in human cancers, including SCLC and NSCLC. The Wnt pathway has critical roles in organogenesis, cancer initiation and progression, and maintenance of stem cell pluripotency. It is suggested to be one of the most important signaling pathways in lung cancer as evidenced by dysregulation of many pathway members. Canonical Wnt signaling results in nuclear accumulation of β-catenin, causing transcriptional activation of many target genes. During embryogenesis, the Hh pathway is involved in organ development and body patterning, whereas in adults it is primarily activated during tissue repair. Activation of the Hh pathway has been reported in both NSCLC and SCLC. Notch signaling is important in cell fate determination and can promote and maintain survival in many human cancers; dysregulated Notch pathway components are therapeutic targets in lung CSCs.

CSCs are thought to have higher resistance to cytotoxic therapies and radiotherapy than the bulk tumor cells and contribute to tumor recurrence, leading to approaches to specifically treat the CSC population through inhibition of important signaling pathways. Specific inhibitors of Hh and Notch signaling have shown efficacy in lung cancer preclinical models and are now in clinical trials (see Table 32-4).

Lineage-Dependent Oncogenes: *SOX2* and *NKX2-1* (*TITF1*)

Genome-wide screens for DNA copy number changes in primary NSCLCs has led to the identification of recurrent, histologic subtype-specific focal amplification at 14q13.3 (*NKX2-1 (TITF1)*) (adenocarcinoma) and 3q26.33 (*SOX2*) (SCC). Functional analysis identified *NKX2-1* (also termed *TITF1*) and *SOX2* as the respective targets of these

amplifications. Amplification of tissue-specific transcription factors in cancer has been previously observed in other cancers, leading to the development of a "lineage-dependency" concept in tumors[18] where the survival and progression of a tumor is dependent on continued signaling through specific lineage pathways (i.e., abnormal expression of pathways involved in normal cell development) rather than continued signaling through the pathway of oncogenic transformation, as seen with oncogene addiction.

NKX2-1 encodes a lineage-specific transcription factor essential for branching morphogenesis in lung development and the formation of type II pneumocytes—the cells lining lung alveoli. Initial studies reported on the oncogenic role of *NKX2-1* in lung adenocarcinoma; however, recent in vivo data suggest that it also has a tumor-suppressive role by promoting differentiation and suppressing metastasis. In patients with advanced lung adenocarcinoma, patients with NKX2-1–negative tumors had poorer survival. ROR1 has been shown to be a direct transcriptional target of NKX2-1 and is crucially involved in sustaining a favorable balance between pro-survival PI3K-AKT signaling and the pro-apoptotic p38 pathway.

Sex determining Y-box 2 (SOX2) amplification was identified specifically in SCCs and is required for normal esophageal squamous development. Together with Oct4, Klf4, and c-Myc, Sox2 comprises one of the four "Yamanaka" transcription factors that are able to reprogram differentiated cells into induced pluripotent stem cells (iPSCs). SOX2 has been shown to have a tumor- and metastasis-promoting role in lung cancer and is implicated in the early pathogenesis of lung SCC. In addition, genome-wide analyses have identified SOX2 as frequently overexpressed by several genetic mechanisms in SCLC. Knockdown studies show it has a direct functional role in the growth of SCLC.[25]

Preclinical Model Systems for Lung Cancer

Although genome-wide approaches have the capacity of identifying novel genes or interactions in relation to lung cancer, the functional relevance of these findings needs to be characterized in preclinical model systems of lung carcinogenesis. Lung cancer cell lines, cell-line xenografts (implantation of cell lines into immunocompromised mice), and patient-derived xenografts (direct implantation of small tumor fragments into immunocompromised mice) are important models of spontaneously occurring lung cancer and enable analysis of response to therapeutic agents. Furthermore, patient-derived xenografts also provide a realistic representation of tumor cell subpopulation heterogeneity and tumor microenvironment (at least in early passages). However, lung cancers and their derived cell lines and xenografts usually have hundreds to thousands of genetic and epigenetic changes. By contrast, two much simpler and more valuable models to study the progression of lung carcinogenesis are immortalized human bronchial epithelial cells (HBECs) and genetically engineered mouse models (GEMMs). These systems provide methods to reduce the inherent complexity and heterogeneity of the lung cancer genome and allow characterization of single or sequential genetic alterations in relation to the development, maintenance, and progression of lung cancer. HBECs are derived from primary human airway epithelial cells and immortalized with either viral oncoproteins (such as SV40 early region) or *Cdk4* with hTERT. These systems can model the stepwise oncogenic transformation of lung epithelial cells following the introduction of defined genetic manipulations commonly found in lung cancer. GEMMs allow the study of lung cancer pathogenesis with defined changes in the setting of the whole organism, and as with patient-derived xenografts, they provide a realistic representation of the tumor microenvironment. GEMMs were critical in developing our understanding of oncogene dependence, as observed in conditional $Kras^{D12}$-induced lung adenocarcinomas, where switching off the driving oncogene was sufficient to induce tumor regression even in the presence of other nondriving oncogenic alterations. Ensuing research has characterized several conditional lung tumor–inducing combinations of oncogenic activations in mice,[20] which have been used to test new targeted therapies, improve the effectiveness of conventional chemotherapies, identify biomarkers and imaging strategies for early detection, and study disease relapse and metastasis. Recently, GEMMs targeting oncogenic alterations to specific lung epithelial cell subpopulations has provided a clearer understanding of the specific cells giving rise to lung cancer.

Translation of Molecular Data to the Clinic: Rationale-Based Targeted Therapy

Characterization of the molecular changes in lung cancer and associated preneoplastic cells is becoming increasingly well defined, aided immeasurably by the continued advancement of both clinical and genomic tools. These advances promote our understanding of the development and progression of lung cancer, which is of fundamental importance for improving the prevention, early detection, and treatment of this disease. Ultimately these findings need to be translated to the clinic by using these molecular alterations as biomarkers for early detection and risk assessment; as targets for prevention; as signatures for personalizing

prognosis and therapy selection for each patient; and as therapeutic targets to allow selective killing or growth inhibition of lung cancer.

Improved detection and sampling of clinical samples using fluorescent bronchoscopy, endobronchial ultrasounds, and laser capture microdissection techniques, for instance, enables precise analysis of abnormal epithelial cells. Although some significant advancements have been targeted therapy (in EGFR mutant and EML4-ALK-positive lung tumors), we have yet to move any biomarkers for risk or early detection of lung cancer into clinical use. This chapter has outlined some of the significant molecular alterations known to be involved in the initiation and/or progression of lung cancer, but continued development of biomarkers and targeted therapies is dependent on increased understanding of involved molecules and pathways.

The recent rapid pace of progress in the field of genomics and bioinformatics now gives researchers the tools to correlate patient subsets with augmented sensitivity to conventional or targeted therapeutics, distinguish driver versus passenger mutations, and better focus the design on novel therapeutic targets. To achieve these goals, we will continue to need high-quality samples from patients with a wide variety of lung cancer types collected at initial diagnosis and at various points during disease progression; incorporation of comprehensive genomic studies in clinical trials with molecularly targeted agents; timely mutation testing of clinically available materials (such as FFPE specimens) using clinical laboratory practices (CLIA-certified laboratory methods); and a new cadre of clinical investigators conversant with cancer genomics trained to effectively translate these findings in the clinic. Finally, identifying and unraveling the intricate and interlinked pathways will require integrating laboratory and clinical investigations. The strong interplay among cancer genomics, bench research, and clinical trials will advance our understanding of lung cancer biology and lead to improved detection, diagnosis, treatment, and prognosis of lung cancer by achieving "personalized medicine," the selection of the best treatment for each patient based on tumor-associated biomarkers.

Acknowledgments

We thank the many current and past members of the Minna lab for their contributions to lung cancer translational research and our especially our long-term collaborator, Dr. Adi Gazdar. Also we apologize to other investigators for the omission of any references.

The Molecular Pathogenesis of Head and Neck Cancer

Epidemiology and Clinical Considerations

Head and neck squamous cell carcinoma (HNSCC) arises in the oral cavity, oropharynx, hypopharynx, and larynx. It accounts for more than 90% of the cancers of the head and neck and is the sixth most common cancer by incidence worldwide. In the United States, approximately 40,250 new cases of HNSCC were expected in 2012, with the incidence in men being more than twice the incidence in women. Rates of death due to HNSCC have declined only slightly in the United States over the past 3 decades, and the all-stage survival rates of 61% and 50%, at 5 and 10 years, respectively, illustrate the need for improved therapy.[1-3]

Tobacco use and alcohol consumption are the two most important risk factors for the development of HNSCC, and their contributions to risk are synergistic. In addition, the human papillomavirus (HPV), especially HPV-16, is now a well-established independent risk factor. Present in approximately 20% of all HNSCC, HPV is believed to be responsible for more than 60% of oropharyngeal SCC, specifically, from 2004 to 2008.[4,5] HPV(+) HNSCC is currently considered, based on clinicopathological and molecular characterizations, to be a unique subtype of HNSCC and has been shown to generally be associated with a favorable prognosis, compared to HPV(−) subtypes.[6,7] Greatly increased susceptibility to HNSCC is seen in some heritable conditions of impaired genome maintenance, such as Fanconi anemia.[8] The Epstein-Barr virus is a known risk factor for nasopharyngeal carcinoma.[9]

Stage at presentation correlates strongly with prognosis; HNSCC is staged via the tumor, node, metastasis (TNM) staging system.[10] It has also been demonstrated, however, that HPV status and tobacco use are of important prognostic value as well, offering potentially greater predictive value than the traditional TNM staging in the case of oropharyngeal cancers.[6] The field cancerization theory, proposed in 1953 by Slaughter and colleagues to describe the developmental pattern of invasive HNSCC from a precancerous field of atypical mucosal epithelium as depicted in Figure 33-1, has been implicated in the high incidence of recurrence and second primary tumor formation. Early-stage tumors generally have a favorable prognosis and are treated with surgery or radiotherapy. Advanced-stage tumors are treated with a combination of surgery, radiation, and chemotherapy, with primary surgery for oral cavity tumors followed by adjuvant radiation or chemoradiation, and organ-preservation protocols with combined chemoradiation for pharyngeal and laryngeal cancers. Recently, the use of targeted therapeutics has emerged in HNSCC treatment. The most mature target to date is the epidermal growth factor receptor (EGFR). Anti-EGFR antibodies, in combination with traditional radiotherapy, have demonstrated increased overall survival and progression-free survival in the newly diagnosed setting and improved survival with chemotherapy in the recurrent/metastatic setting.[11,12]

Oncogenic Progression of HNSCC

The well-documented histological progression of HNSCC from oral leukoplakia through progressive phases of hyperplasia, dysplasia, carcinoma in situ, and ultimately invasive carcinoma is believed to correspond with the accumulation of genetic alterations.[13] In HNSCC, one of the earliest initiating events is likely the clonal proliferation of precancerous cells with *TP53* mutations.[14] This is followed by the accumulation of additional genetic alterations within clonal subpopulations, in an order that is not well defined and very likely varies among patients. A hypothetical model of development and genetic progression of the primary subtypes of HNSCC is presented in Figure 33-2. Recently, whole-exome sequencing studies of HNSCC have begun to reveal the genetic underpinnings of this disease. These data, in combination with previous genomic analyses, have identified the most commonly mutated genes in HNSCC as outlined in Table 33-1.[15,16]

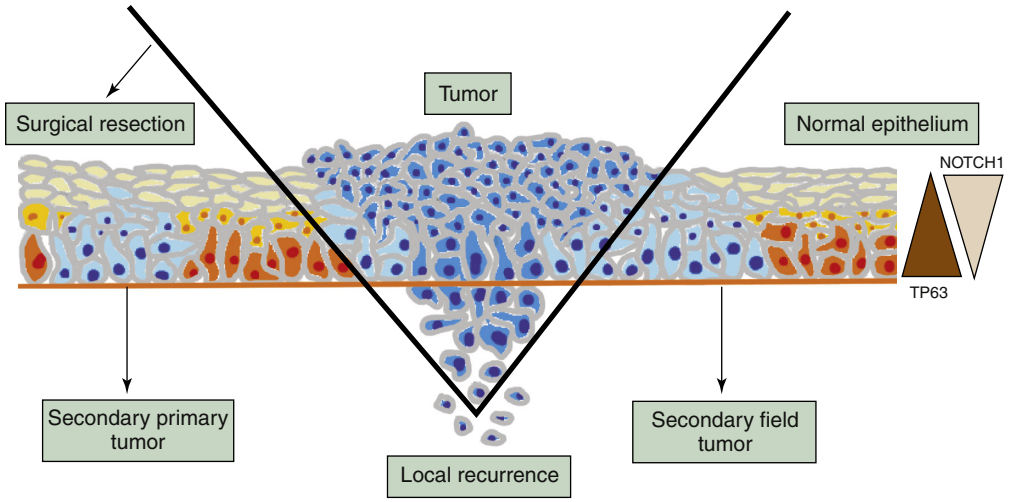

Figure 33-1 The Field Cancerization Theory is defined as the presence of one or more mucosal areas consisting of epithelial cells with cancer-associated genetic or epigenetic alterations. A precursor field *(light blue)* is monoclonal but does not show invasive growth or metastatic behavior, which are the hallmarks of an invasive carcinoma *(dark blue)*. A field is preneoplastic by definition; it may or may not have histological alterations characteristic of dysplasia.[4] A leukoplakia is the clinical manifestation of a field, though most fields are clinically invisible. Additional genetic changes are needed to transform a field into a carcinoma. The field and primary tumor share genetic alterations and have a common clonal origin. Clinically, a field may be the source of local recurrences, second field tumors, and second primary tumors after surgical resection of the initial carcinoma. These legions are distinguished on the basis of their distance from the index tumor, or the time interval after which they develop. A local recurrence *(lower center)* arises from residual tumor cells and is less than 2 cm away from, and/or occurs within 3 years of, the primary tumor. A second primary tumor *(lower left)* is more than 2 cm away from, and/or occurs more than 3 years after, the primary tumor. Tumors that arise from a contiguous portion of the same field that gave rise to the original primary tumor have been described as second field tumors *(lower right)*.[4] Studies attempting to identify specific genetic characteristics that determine the risk of a field developing into cancer have shown that genetic changes at chromosome 9p, decreased cytokeratin 4 expression, and decreased cornulin expression are potential biomarkers.[69,70] Leukoplakia studies have demonstrated that the presence and number of genetic changes, typically chromosome 9p loss, chromosome 3p loss, and chromosome 17p loss, are associated with the risk of progression.[4] At *far right*, the *TP63/NOTCH1* expression gradient of normal epithelium is illustrated. Perturbation of this gradient is believed to be a component of precancerous fields and invasive HNSCC legions. The normal process of squamous differentiation in mucosa is controlled in part by *TP63* and *NOTCH1*. *TP63* is expressed in keratinocytes of the basal layer, where it maintains their proliferative potential and regulates expression of basal keratins. Expression of *NOTCH1* results in terminal differentiation of cells in the spinous and granular layers expressing alternative keratins.[44,46-48,52,53] *(Adapted from C. René Leemans, Boudewijn J. M. Braakhuis, and Ruud H. Brakenhoff. (2010). The molecular biology of head and neck cancer. Nature Reviews Cancer. doi:10.1038/nrc2982.)*

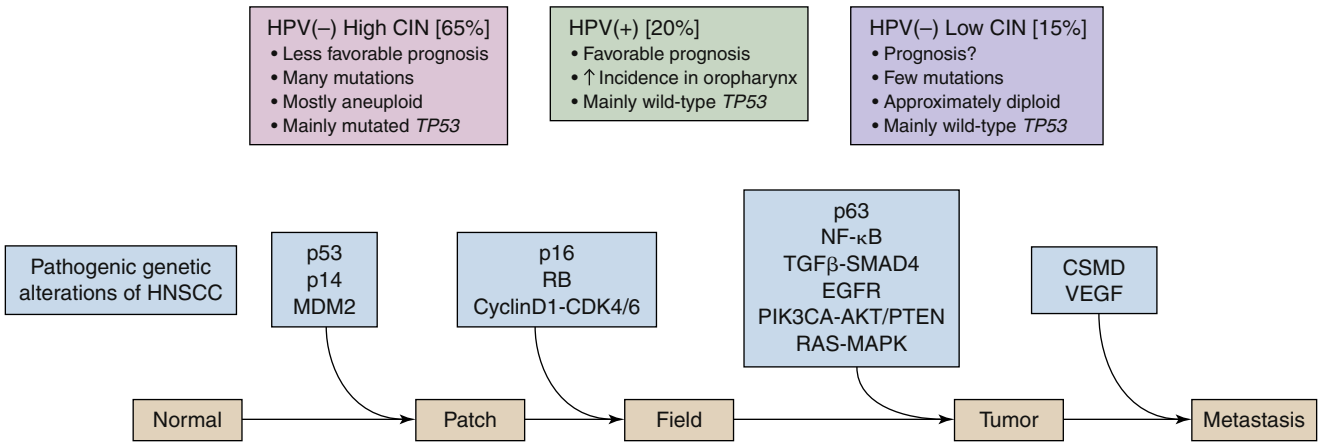

Figure 33-2 A hypothetical model of HNSCC development depicting the genetic alterations implicated in the process by current data. The model is a generalization and thus is varyingly accurate among subtypes of HNSCC. Three steps are critical in this model: A progenitor or adult stem cell acquires one (or more) genetic alterations, usually including an alteration of p53, and forms a patch containing clonal, genetically altered daughter cells. Then, by escaping normal growth control and/or gaining growth advantage, this clonal patch develops into an expanding field. Eventually, through a further accumulation of genetic alterations, a subclone in the field evolves into an invasive cancer and progresses to metastasis. Both aneuploidy and the accumulation of cancer-associated genetic changes in fields are linked to the risk of malignant progression. In addition, the three main clinicopathologic subtypes of HNSCC are depicted: HPV(+) HNSCC, HPV(–) HNSCC with many numerical genetic changes (high CIN), and HPV(–) HNSCC with few genetic changes (low CIN).[4] Although drawn as distinct steps for the purpose of illustration, the actual order of acquisition of distinct alterations is not known at this time. *CDK,* Cyclin-dependent kinase; *CSMD*, CUB and SUSHI multiple domain protein; *NF-κB,* nuclear factor-κB; *PIK3CA,* phosphoinositide-3 kinase subunit-α; TGFβ, transforming growth factor-β; *VEGF*, vascular endothelial growth factor. *(Adapted from C. René Leemans, Boudewijn J. M. Braakhuis, and Ruud H. Brakenhoff. (2010). The molecular biology of head and neck cancer. Nature Reviews Cancer. doi:10.1038/nrc2982.)*

Table 33-1 Common Genetic Alterations in HNSCC

Gene*	Description	Mutated (Activating/Missense/Inactivating)
TP53[a,b]	Transcription factor	53% (NA/28%/25%)
CCND1[b]	Cell cycle activator (Cyclin D1)	25% (25%/NA/NA)
CDKN2A[a,b]	Cell cycle inhibitor/p53 activator	21% (NA/3%/18%)
NOTCH1[a,b,*]	Receptor/transcription factor	15% (NA/8%/8%)
CSMD3[a,b]	Putative adhesion factor	13% (NA/12%/1%)
USH2A[a,b]	Basement membrane protein	12% (NA/11%/1%)
PIK3CA[a,b,*]	PI3 kinase catalytic subunit	10% (7%/7%/NA)
PRDM9[b,*]	Histone methyltransferase	8% (NA/8%/1%)
COL22A1[b,*]	Pro-apoptotic effector	8% (NA/7%/2%)
RIMS2[b,*]	Putative synaptic vesicle regulator	8% (NA/8%/NA)
ZFHX4[b]	Zinc finger homeodomain	8% (NA/8%/NA)
MLL2[b,*]	Histone methyltransferase	8% (NA/4%/4%)
NAV3[b]	Axonal/cytoskeleton guide	8% (NA/7%/1%)
CASP8[a.b]	Pro-apoptotic proteolyase	7% (NA/2%/5%)
TP63[a,b]	Transcription factor	7% (NA/5%/1%)
NSD1[b]	Histone methyltransferase	7% (NA/3%/4%)
EGFR[b]	Growth factor Rtk	7% (7%/NA/NA)
PTEN[b]	Lipid phosphatase—PI3K inhibitor	6% (NA/3%/3%)
FBXW7[a,*]	Ubiquitin ligase	5% (NA/3%/2%)
HRAS[a,b,*]	RTK signaling protein	4% (4%/4%/NA)
IRF6[b]	Interferon regulatory factor	4% (NA/3%/1%)
NOTCH2[b]	Receptor/transcription factor	4% (NA/3%/1%)
NOTCH3[b,*]	Receptor/transcription factor	4% (NA/2%/2%)

Displays the percentage of samples in the [a]Agrawal et al.[15] and [b]Stranksy et al.[16] exome sequencing studies with at least one mutant allele or copy number loss/amplification of a given gene. It also identifies the percentage of each respective mutation that is activating (known activating mutation or copy number amplification), missense, and inactivating (nonsense, splice site, frame shift, insertion/deletion, or copy number loss).
*Mutations present in at least one HPV(+) tumor.

Molecular Pathogenesis of HNSCC: Interfacing Genomic Pathways

Conceptually, there are six major hallmarks that define the current understanding of a cancerous cellular phenotype: sustaining proliferative signaling, evading growth suppressors, resisting cell death, enabling replicative immortality, inducing angiogenesis, and activating invasion and metastasis.[17] Research to date indicates that the altered oncogenes and tumor suppressors of HNSCC act primarily in functional pathways known to largely determine cellular proliferation, cell survival, squamous epithelial differentiation, and invasion and metastasis. Individual genes may function in more than one pathway, and the pathways themselves interface with, and influence, each other, as depicted in Figure 33-3. The following sections discuss some of the most common gene alterations believed to contribute to HNSCC oncogenesis in the context of these pathways.

Cell Cycle and Proliferation: TP53/CDKN2A/RB/CCND1/TERT

Though oncogenes have been identified, the high mutation rates seen in most cases of HNSCC, along with the recent exome sequencing data, suggest that loss-of-function mutations in tumor suppressor genes represent the predominant genetic pathology observed in HNSCC.[4,15,16] Foremost among these tumor suppressors is the *TP53* gene product: p53. A nuclear phosphoprotein that signals through its key

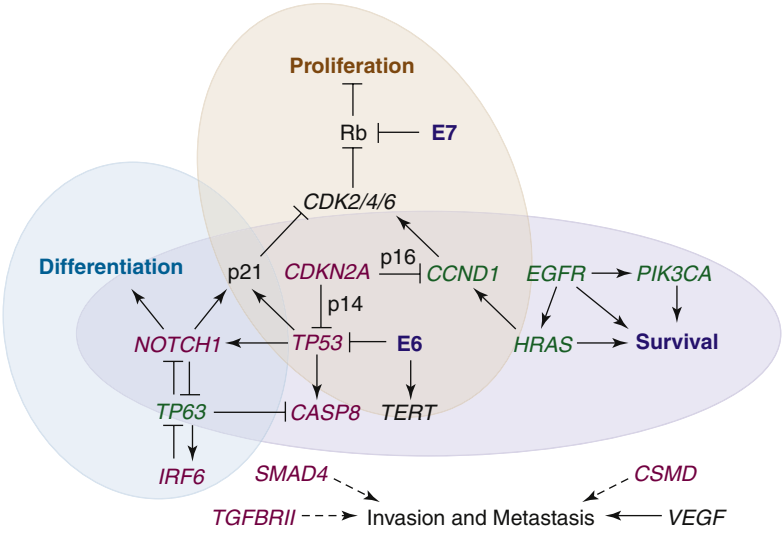

Figure 33-3 The interfacing genetic alterations of putative oncogenes *(green)*, tumor suppressors *(red)*, and signaling pathways that mediate the hallmarks of HNSCC. Loss of *TP53* and *CDKN2A*, either through mutation or expression of the HPV E6 and E7 proteins *(blue)*, along with amplification of *CCND1* favors survival and permits proliferation through the increased activity of cyclin-dependent kinases (CDKs) and loss of p53-dependent apoptosis. Although intact differentiation programs and alternative apoptotic programs may restrict abnormal cell cycling for a time, loss of *NOTCH1* and/or abnormal expression of *TP63*, along with the acquisition of alterations in other survival genes, such as *CASP8*, *PIK3CA*, and *EGFR*, remove additional barriers to tumor cell proliferation and survival. Upregulation of pro-angiogenic genes permits the growth of tumors, and the loss of cell adhesion genes allows for the release of cells from the mucosal lining. Invasion through the basement membrane is promoted by *TGFβ-SMAD* signaling, the loss of which initially contributes to tumorigenesis, and whose later reactivation drives metastasis. Several genes and signaling pathways, including *TP53*, *TP63*, and *NOTCH1*, contribute to more than one hallmark by influencing each other's expression and/or activity.

downstream partner, cyclin-dependent kinase inhibitor 1 (p21), p53 can influence both the G_1 and G_2 checkpoints of the cell cycle, although it is traditionally thought of as being the primary G_2 checkpoint regulator. Canonically, in response to DNA damage, p53 activation inhibits cell cycle progression and prevents apoptosis, allowing the cell time to repair the damaged DNA. If the DNA damage cannot be repaired, apoptosis ensues. Loss of p53 function allows cells with damaged DNA to proliferate freely, resulting in the accumulation of potentially oncogenic mutations in the genome of affected cells.

Mutation of *TP53* is the earliest and most frequent mutation event observed in HPV-negative HNSCC. Occurring in more than 50% of cases, mutation is significantly associated with decreased survival.[18] The majority of *TP53* mutations are found in exons 5 through 9, the DNA binding region, with mutations at several specific codons known to be associated with tobacco exposure.[7] In a large portion of HNSCC without somatic *TP53* mutations, the activity of p53 is compromised by other mechanisms, including E6 expression in HPV(+) cancers, which inactivates p53, and overexpression and/or amplification of *MDM2*, which promotes the degradation of p53.

Chromosomal loss of 9p21 has been reported in 70% to 80% of dysplastic oral mucosa legions progressing to HNSCC.[19] This illustrates an interface between pathways, as the *CDKN2A* locus is found within 9p21. Two *CDKN2A* protein products, $p16^{INK4A}$ and $p14^{ARF/INK4B}$, are involved in cell cycle regulation. Specifically, $p14^{ARF/INK4B}$ is known to downregulate *MDM2*, thereby regulating p53 levels.[20] In all, p53 function is believed to be downregulated through one or more mechanisms in at least 80% of HNSCC.[4]

A second *CDKN2A* transcript, $p16^{INK4A}$, implicates the Retinoblastoma (*RB*) pathway, which is the primary G_1 checkpoint regulator, in HNSCC. $p16^{INK4A}$ inhibits the Cyclin D1/Cyclin-Dependent Kinase (CDK) complex, which normally functions to inactivate *RB*-encoded pocket proteins via phosphorylation, allowing for the dissociation and activation of Elongation Factor-2 and subsequent entry into S phase. Inactive, phosphorylated *RB* pocket proteins are unable to block the G_1-to-S phase transition in the setting of $p16^{INK4A}$ loss.[20] In addition to chromosomal loss of 9p21, recent studies have demonstrated *CDKN2A* mutations in approximately 7% of tumors and copy number losses in another 20% to 30%.[15,16] The mechanism of $p16^{INK4A}$ loss has been shown to be of prognostic value in oral SCC: epigenetic silencing was found to be associated with higher recurrence rates, and deletion with increased rates of nodal metastases.[21] Analogous to the inhibition of p53 by HPV E6 expression, E7 expression in HPV(+) HNSCC inactivates the *RB* pathway by binding RB1. Because E7 expression can inhibit the *RB* pathway, there is less selective pressure for $p16^{INK4A}$ loss in HPV(+) HNSCC. As a result, immunohistochemical staining for $p16^{INK4A}$ is used clinically in establishing the HPV status of HNSCC, along with polymerase chain reaction (PCR)-based methods.[22]

Further evidence of the important role played by the *RB* pathway in HNSCC is that the commonly found amplification of 11q13, which contains *CCND1*, in combination with other potential mechanisms, results in the overexpression of Cyclin D1 in up to 80% of HPV(−) tumors.[4]

Intriguingly, *CDKN2A* loss and *CCND1* gain, though seemingly redundant mechanisms to evade the G_1 checkpoint, are not mutually exclusive events in HNSCC. Both occur frequently and remain under investigation as independent and synergistic markers of poor prognosis. [23] Cyclin D1 has been found to sequester certain *CDK* inhibitors and to bind transcription factors such as PPARγ, and various DNA repair proteins such as Rad51.[24] It remains to be established whether any of these interactions contributes to a noncanonical consequence of *CCND1* functional loss in HNSCC.

Finally, the role of telomerase in promoting limitless replicative potential must be considered. The activity of telomerase (TERT) is detectable by immunostaining in approximately 80% of HNSCC cases analyzed. In most in vitro HNSCC models, TERT activity is necessary for immortalization of cell lines. However, keratinocytes may elongate their telomeres in a TERT-independent fashion, and *TERT* (5p15.33) is not known to be frequently gained or amplified in HNSCC. Although the exact role of *TERT* is still unclear, it remains a candidate cancer gene in HNSCC.[4]

Apoptosis and Survival: EGFR/RAS-MAPK/PIK3CA-AKT/CASP8

Cell cycle alterations, reduced immunogenicity, promotion of angiogenesis, and inhibition of apoptosis are just some of the many mechanisms underlying the enhanced survival of HNSCC. These cancerous traits are generated by genetic and epigenetic alterations in several pathways. Of particular importance in HNSCC are the receptor tyrosine kinase (RTK)-based signaling pathways. The class 1a phosphatidyl-inositol-3 kinases (PI3K) are heterodimers coupled to RTKs, such as the EGFR, or adaptor molecules. The PI3K-AKT kinase (AKT) signaling pathway mediates resistance to apoptosis and survival. Activated PI3K generates the lipid second-messenger phosphatidylinositol-3,4,5-P3 (PIP3), which serves to activate AKT. AKT is a serine/threonine kinase that, when activated, phosphorylates many downstream transcription factors, apoptosis inhibitors, cell cycle inhibitors, and other proteins, ultimately promoting cell survival and proliferation. This pathway is held in check by the action of the tumor suppressor phosphate and tensin homologue (PTEN), which dephosphorylates PIP3, thereby deactivating AKT. If PTEN activity is compromised, PI3K-AKT signaling can be irreversibly activated by RTK stimulation.[25]

Inactivating *PTEN* mutations have been reported in approximately 10% of HNSCC, PTEN expression is undetectable in nearly 30% of tongue cancers, and loss of heterozygosity of the *PTEN* locus has been observed in up to 40% of HNSCC.[26] Furthermore, recent evidence suggests that loss of even a single *PTEN* allele can contribute to tumorigenesis.[27] Three different "hotspot" activating mutations have been reported in *PI3KCA*, which codes for the catalytic subunit of PI3K.[28] Notably, the frequency of *PI3KCA* mutations is higher in HPV(+) HNSCC, suggesting a possible interaction between the PI3K pathway and the E6/E7 proteins of HPV. This has been suggested to be contributory to the development of invasive SCC in cervical cancer.[15,16,29] The PI3K-AKT axis is of consequence therapeutically in HNSCC as well, with numerous targeted inhibitors now in clinical trials.[29,30]

RAS family GTPases (HRAS, KRAS, and NRAS) are molecular switches that cycle between two conformational states: an active GTP-bound form, and an inactive GDP-bound form. The first RAS effector pathway to be identified was the RAS-RAF-MEK-MAPK pathway. The pathway is a common and essential element of mitogenic signaling driven by RTKs, resulting in a diverse array of cellular responses. RAF proteins are serine/threonine kinases that bind to the effector region of RAS-GTP. This interaction induces translocation of the protein to the plasma membrane. There, RAF proteins are activated and phosphorylated by different protein kinases. Active RAF phosphorylates MEK that, in turn, phosphorylates and activates MAPK. Activated MAPK serves as the terminal effector of the pathway, influencing cellular growth, differentiation, inflammation, apoptosis, and senescence. Mutant RAS, in which it assumes a permanently active conformation, is a well-established oncogene, found in approximately 25% of human tumors.[31]

HNSCC is unique in that *HRAS* mutations, being found in 3% to 5% of HNSCC, are more prevalent than *KRAS* or *NRAS* mutations.[15,16] These *HRAS* mutations are known to be associated with HNSCC in smokers, and in mouse models exposed to chemical carcinogens.[32] The exact contribution of the *HRAS* mutations to oncogenesis has yet to be elucidated in HNSCC. The RAS-MAPK and PI3K-ATK pathways interact directly and indirectly, through multiple intermediates.[31] In addition, *HRAS* mutations have been detected in HPV(+) tumors, allowing for the possibility of cooperation with oncogenic viral proteins.[15,16] Recent in vitro evidence suggests that even a single *HRAS* mutation, in the background of HPV and *MYC* alteration, can contribute to tumorigenesis.[33] Although the success of therapies targeting RAS proteins has been limited to date, several attempts to target their downstream effectors have shown promising results in preclinical models.[34]

RTKs lie upstream of both the RAS-MAPK and PI3K-ATK pathways. Most importantly for HNSCC, is *EGFR* (7p12), which codes for the prototypical ErbB family Type I RTK. Signaling through EGFR represents another interface between pathways, as it is involved in a variety of cellular processes, including survival and differentiation. EGFR has an extracellular ligand-binding domain, a transmembrane portion, and an intracellular kinase domain with five autophosphorylation sites. Ligand binding by EGFR monomers drives homodimerization or heterodimerization with another RTK, resulting in the initiation of downstream survival and proliferation signaling pathways. Two important and well-studied pathways activated by EGFR ligand binding are the RAS-MAPK and PI3K-ATK pathways. These independent cascades converge via the ultimate upregulation of Cyclin D1. Furthermore, when bound to EGF, EGFR itself can translocate to the nucleus, where it acts as a transcription factor for several genes including *CCND1*, and as a co-activator for other transcription factor proteins, such as the STAT proteins.[4]

EGFR is expressed in most epithelial tissues, and its dysregulation has been repeatedly shown to contribute to epithelial oncogenesis. In HNSCC, EGFR expression levels are nearly ubiquitously elevated in tumor and tumor-adjacent tissue compared to corresponding normal mucosa. Higher expression levels and copy number gain correlate with decreased survival but have not been highly indicative of improved response to EGFR-directed therapy. There are three FDA-approved EGFR targeting agents in clinical use: gefitinib and erlotinib, both TKIs, and cetuximab, a monoclonal antibody against EGFR, which is the only agent approved for use in HNSCC. All have shown modest efficacy as monotherapies to date, with EGFR-targeted therapies being effective in about 20% of patients in large multicenter trials, generally in combination with radiation and/or chemotherapy.[35] Expression of EGFRvIII, an *EGFR* allele harboring a large in-frame deletion of exons 2 through 7, can confer resistance to anti-EGFR therapy. The prevalence of the EGFRvIII variant remains controversial in HNSCC, with various studies reporting its expression to be present in anywhere from 0% to 42% of the tumors assayed.[36-39] Investigations into EGFRvIII mechanism(s) of oncogenesis continue, as therapies specifically directed against EGFRvIII have shown promise in glioblastoma and may be applicable in refractory HNSCC.[39] Another genetic alteration, reported in some cases of HNSCC, that is believed to contribute to anti-EGFR therapy resistance is mutation or amplification of the *MET* gene, which codes for another RTK.[40,41] *MET* has been implicated as a cancer gene in HNSCC that influences cell growth, motility, and angiogenesis.[4] This, too, may be of particular clinical consequence because there are both monoclonal antibodies and small-molecule inhibitors, FDA-approved in other cancers, with the ability to inhibit MET kinase activity.[42,43]

Finally, in addition to the growth factor signaling pathways that indirectly influence apoptosis, recent studies in HNSCC have found alterations directly within the apoptosis cascade itself. *CASP8*, a proteolyase responsible for initiating the caspase cascade that drives apoptosis, was found to be mutated in 8% of HNSCC by exome sequencing; *BCL2*, which prevents apoptosis, has been observed to be overexpressed in some HNSCC cell lines, usually coincident with the underexpression of p63.[16,44]

Differentiation and Mesenchymal Transition: NOTCH/TP63

Many of the expression profile studies in HNSCC contain a large number of genes that are thought to reflect the process of epithelial-to-mesenchymal transition (EMT), especially profiles of metastatic HNSCC. EMT is a biological process, wherein cells change from an epithelial phenotype to a mesenchymal-like phenotype. Because epithelial cells do not possess the cellular plasticity for metastatic dissemination, this process is a common occurrence in cancer cells.[4] *TP63* codes for p63, a p53-related transcription factor that, via its target genes, regulates differentiation in stratified epithelium, lineage specification, and subsequently proliferative potential. Mice lacking *TP63* undergo total failure of epidermal maturation.[45,46] In normally differentiated mature epithelium, *TP63* expression is present as a gradient. The highest level occurs in the basal epithelial cells, where it serves to antagonize *NOTCH1* expression. Rising superficially through the strata, *TP63* levels decrease and *NOTCH1* levels increase, driving terminal differentiation of the epithelial cell type (see Figure 33-1). In dysplastic mucosa, this patterning is lost, and *TP63* expression is evident throughout all layers of the epithelium. In addition, *TP63* overexpression and/or amplification are seen in the majority of HNSCC, and mutations were found in approximately 7% of tumors by exome sequencing.[15,16,47] An isoform of *TP63*, ΔNp63, known to contribute to cell survival, senescence suppression, and growth factor signaling, was also found to be specifically upregulated in HNSCC.[16,44]

Another recent finding that emerged from the HNSCC exome sequencing studies is the discovery of *NOTCH* family mutations in 15% to 20% of tumors, with most being present in *NOTCH1* (12% to 15%).[15,16] NOTCH signaling has been shown to influence cell survival, self-renewal capacity, and cell cycle exit, in addition to driving epithelial differentiation in concert with p63 and other signaling pathways. Ligands on adjacent cells bind to

the NOTCH receptor, resulting in the cleavage of intracellular portions of the receptor that subsequently translocate to the nucleus and drive the transcription of NOTCH target genes.[48] Overactivation of this pathway is believed to be tumorigenic in diffuse large B-cell lymphoma, T-cell acute lymphoblastic leukemia, and chronic lymphocytic leukemia. In those hematologic malignancies, translocations and activating mutations within NOTCH receptor genes have been observed.[49-51] In contrast, the observed *NOTCH* mutations in HNSCC are believed to be largely inactivating, loss-of-function–type mutations, suggesting a possible tumor suppressor role.[15,52] The exact role of NOTCH signaling in HNSCC remains to be elucidated and is likely tissue and/or context dependent, as has been observed in mouse models of epidermal and hematopoietic malignancies.[53,54]

Invasion and Metastasis: MMP/TGFβ-SMAD/NFκB/CSMD/VEGF

Like many cancers, HNSCC tumors metastasize primarily to the regional lymph nodes. The number of lymph node metastases in the neck, in more distant tissues, and the presence of extranodal spread are important prognostic factors, predictive of disseminated disease and survival. Although expression profile signatures of primary tumors that are predictive of metastasis have been identified, attempts to elucidate the mechanisms driving HNSCC metastasis are preliminary and in some cases conflicting.[4] Metastasis is a multifaceted process that ultimately results in a primary tumor "seeding" a distant anatomical site in the body. It involves several steps, one of which is invasion via the degradation of the extracellular matrix surrounding the primary tumor, in order to gain access to other areas of the body via the bloodstream or lymph system. Many studies have investigated the involvement of the matrix metalloproteinases (MMPs), which facilitate the degradation of the extracellular matrix. To date, strong associations have not been found, and treatments targeting MMPs have not achieved appreciable success in HNSCC.[55]

In the context of invasion, transforming growth factor β pathway (TGFβ), which normally functions to inhibit growth, has been implicated in HNSCC. TGFβ ligands bind to the receptors TGFBR1 and TGFBR2, resulting in phosphorylation of TGFBR1, which then activates the proteins SMAD2 and SMAD3. A SMAD complex is formed with the addition of SMAD4. This complex enters the nucleus and binds transcription factors, co-activators, and co-repressors, which modulate the expression of TGFβ target genes. Several of these are known to suppress cell proliferation, such as the cell cycle inhibitors cyclin-dependent kinase inhibitor 2. In addition, the TGFβ pathway has been identified as a key player in the EMT process.[56]

The TGFβ pathway has been implicated in HNSCC—most commonly through 18q deletion, which contains *SMAD2*, *SMAD3*, *SMAD4*, and the *TGFBRII* gene.[4] A recent mouse model found that conditional deletion of *SMAD4* in the head and neck epithelium was sufficient to generate invasive HNSCC. The loss of *SMAD4* expression in these animals correlated with increased expression of *TGFBRI* and increased activation of SMAD3, and the Fanconi anemia DNA repair pathway was found to be downregulated.[57] Previous studies reported missense mutations in *TGFBRII* in primary HNSCC, as well as mutations in *SMAD2* and *SMAD4* in some HNSCC cell lines.[58,59] The prevalence of such mutations, however, has been called into question by recent exome sequencing studies, which did not report any in the 106 tumors that were fully analyzed.[15,16] Recently, it has been demonstrated that reduced activity of the TGFβ pathway correlates with increased NF-κB signaling in HNSCC. Though alterations in TGFβ and NF-κB signaling have long been implicated in cancer, the exact mechanism(s) of their interaction, as well as their independent and/or cooperative contributions to invasion and metastasis in HNSCC, still need to be precisely elucidated.[60,61]

Tumors require blood vessels in order to grow to sizes larger than a few millimeters in diameter. These vessels facilitate nutrient and oxygen delivery, as well as metabolic by-product disposal. The exploitation of neo-angiogenesis, usually by producing angiogenic factors, is common to all solid tumors. Of the many inducers of angiogenesis, the strongest is vascular endothelial growth factor (VEGF). Many studies have linked VEGF expression to HNSCC prognosis, including a meta-analysis that found a significantly increased risk of 1.88, as well as an association with VEGF expression and metastasis to lymph nodes.[4] Although these data suggest a link between VEGF expression and outcome, neither VEGF nor EGFR expression has thus far been found to be a better prognostic indicator than HPV status.[62]

Both of the recent exome sequencing studies reported mutations in *CSMD3*, a putative adhesion factor that maps to 8p23 along with its family member, *CSMD1*. *CSMD1* is a putative tumor suppressor, the loss of which is associated with high tumor grade and poor prognosis in other cancers, and whose role in HNSCC remains under investigation.[15,16,63] Though functional studies have not yet been performed, these mutations may underlie a mechanism permitting the dissociation of cells from an otherwise cohesive sheet of cancerous epithelium, ultimately allowing for migration and metastasis of HNSCC tumors.

Future Directions

The elucidation of molecular pathways responsible for the pathogenesis of HNSCC has already led to the development and implementation of several targeted therapies.[25,30,35] Given the heterogeneity of this disease, future efforts will be required to identify effective targets in specific patient populations. One potential target may be miRNAs: several preliminary studies have identified a set of 66 commonly deregulated miRNAs in HNSCC that may in fact contribute to many of the cancerous phenotypes observed in this disease and are predictive of metastasis.[64,65] A recent study reports distinct miRNA expression profiles in HNSCC dependent on HPV status.[66] Similarly, epigenetic studies have identified promoter hypermethylation patterns that correspond to HPV status, as well as a series of changes that correspond to the development of cancer from a precancerous plaque.[67,68] The continuation of these early investigative efforts, in molecular markers of prognosis and treatment response, will be vital to our ability to generate tumor-tailored therapies for individual patients.

34 Colon and Rectal Cancer

Colorectal cancer (CRC) development is a complex process. Causal agents and mechanisms include environmental and dietary factors and inherited and somatic mutations. Great progress has been made over the past 30 years toward defining the constellation of molecular alterations contributing to colorectal tumor development. Specific oncogene and tumor suppressor gene defects have been identified in tumors of various stages, with oncogenes being broadly defined as those genes affected by gain-of-function alterations in cancer, and tumor suppressor genes as the genes affected by loss-of-function alterations. Oncogenic activation of proto-oncogenes can result from many different mechanisms, including specific point mutations and rearrangements that alter gene structure and function, as well as from chromosomal rearrangements and gene amplifications that disrupt the regulated expression of the proto-oncogene. Tumor suppressor gene inactivation can also result from many different mechanisms, including localized mutations, such as nonsense or frameshift mutations, or complete loss of the gene. Besides mutational mechanisms, it is now clear that changes solely in the expression but not the structure or sequence of proto-oncogenes and tumor suppressor genes can lead to lead to oncogene activation or tumor suppressor gene inactivation. Although many proto-oncogenes and tumor suppressor genes encode proteins, they can also encode various noncoding RNAs, including microRNAs (miRNAs) and long noncoding RNAs (lncRNAs). Thus the definitions of *oncogene* or *tumor suppressor gene* are essentially agnostic with respect to the function of the gene in the cell, but instead refer to whether the resultant genetic or epigenetic defect in a given gene leads to increased or novel gene function (i.e., oncogene) or loss of gene function (i.e., tumor suppressor gene). Finally, although the vast majority of gene defects found in colorectal cancer are somatic, inherited mutations in selected tumor suppressor genes have a critical role in a number of CRC predisposition syndromes.

The principal objectives of this chapter are to review the following topics: (1) the epidemiology of CRC; (2) the sequence of histopathologic alterations in the course of the progression to malignancy; (3) the genetic basis of various inherited CRC syndromes and the relevance of certain inherited syndromes to sporadic CRC development; (4) somatic oncogene and tumor suppressor gene defects and epigenetic changes in CRC; (5) some of the apparent variations in gene defects associated with different precursor lesions at risk of progressing to CRC; and (6) the potential clinical utility of the genetic alterations in early detection and clinical management of patients and families affected by CRC.

Epidemiology

CRC is the second leading cause of cancer deaths in the United States.[1] In 2013, it is anticipated that nearly 143,000 individuals in the United States will be diagnosed with colon or rectal cancer, and about 51,000 will die from the disease.[1] Male and female incidence and survival are very similar.[1] Important differences in prognosis have been observed in different racial groups in the United States.[1] These differences may reflect a combination of factors, including differences in access and adherence to screening tests, tumor location and size at diagnosis, and appropriateness of treatment.[2,3] At this point, there is less evidence that differences in molecular alterations among tumors (intertumoral genetic and epigenetic heterogeneity) have a major contributing role in accounting for differences in prognosis among racial groups, though further work is needed.[3]

Most cases of CRC are considered to be sporadic, indicating that clear-cut familial or genetic predisposition factors are not readily apparent. However, based in part on family studies (i.e., twin and kindred studies), it is estimated that more than 25% to 30% of CRC cases may have a hereditary component.[4,5] Less than a fourth of this collection of cases with a presumptive hereditary component (i.e., less than 5% of all cases) occur in a setting with a family history and/or clinical features indicative of a highly penetrant, single-gene-mutation cancer syndrome predisposing

to CRC development.[4,5] Gene alterations or DNA sequence variations with key contributing roles in most familial cases remain to be defined. The familial cases may be a heterogeneous group, in which modest to moderate predisposition to CRC is possibly conferred by an undetermined number of potentially common or rare genetic variations.[4]

In addition to family history, other risk factors for CRC include older age, chronic inflammatory bowel disease, heavy alcohol use, and diets rich in unsaturated fats and red meat and refined starches and low in fruits and vegetables.[6,7] Evidence for a protective effect against CRC for aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) as well as hormone supplementation in postmenopausal women has been offered, albeit with attendant risks for these agents.[6] An unfortunate reality is that many of the key dietary, lifestyle, and environmental factors contributing to CRC in the United States and other Western countries are uncertain, and the majority of incident CRCs arise in people with no well-defined risk factor. On a more optimistic note, a large fraction of CRC deaths seem to be preventable by early detection. By some estimates, improved adoption and implementation of current screening recommendations for colorectal cancer could save thousands of lives per year.[8]

Histopathologic Changes in Colorectal Carcinogenesis: The Adenoma-Carcinoma Sequence

The surface of the large intestine is covered by an epithelium, characterized by finger-like invaginations into the underlying stroma; the invaginations are termed *crypts*. Stem cells near the base of each crypt give rise to distinct cell types required for the intestine's resorptive, secretory, and endocrine functions. During their differentiation, epithelial cells migrate from the base of the crypt to the surface, and the cells are ultimately shed into the gut lumen. With the exception of the stem cells, the colon epithelium is turned over within a few days.

Among the different types of benign gastrointestinal lesions, a generic term for any localized lesion protruding above the surrounding mucosal surface is *polyp*. Many polyps, particularly small polyps 5 mm or less in size, are of the hyperplastic type, with characteristic serrated glands and distended goblet (mucus-producing) cells. However, although the role of certain serrated polyp lesions other than hyperplastic polyps in CRC development is discussed later, the adenomatous polyp or adenoma is believed to be the precursor lesion to the vast majority of CRCs.[9,10] Both gross and histopathologic features can be used to distinguish adenomas. Grossly, the size is measured and the morphology can be described as pedunculated (with a stalk), sessile (flat), or semisessile. Among the histopathologic features, the degree of dysplasia and glandular architecture are used to distinguish lesions, and these features may have value for predicting the likelihood that a lesion contains a focus of cancer or its risk of progression to cancer.

The proposal that many CRCs arise from adenomatous lesions is supported by at least three lines of evidence. First, a few longitudinal studies have assessed the risk of subsequent CRC development in individuals with adenomatous polyps.[11] In these studies it became apparent that patients who did not have their adenomas removed had an approximately eightfold increased risk of CRC compared with the group that had their adenomas removed. Notably, after polypectomy, patients did not show a clear increase in CRC incidence in comparison with a control group without adenomas, suggesting that adenomatous polyp removal had a therapeutic effect.[11] Second, histopathologic studies have shown that foci of carcinoma can often be detected in adenomatous polyps, particularly those with increased size, dysplasia, and villous histopathology. Third, individuals affected by syndromes that strongly predispose to the development of hundreds of adenomas, such as familial adenomatous polyposis (discussed later), invariably develop colorectal cancers by the third to fifth decades of life, if their colons are not removed.

Although adenomatous polyps as a group are well established to have a risk of progression to cancer,[12] some studies have suggested that patients who develop hyperplastic polyps may have an increased risk of adenomas.[13,14] Also, patients with numerous hyperplastic polyps (e.g., patients with juvenile hyperplastic polyposis syndrome) have a clearly increased risk of CRC. As suggested previously and as discussed further later, it has been increasingly appreciated that certain polypoid lesions—such as "sessile serrated adenomas," which share some serrated morphologic features with hyperplastic polyps—do indeed show an increased cancer risk.[9,10] Most carcinomas arising from sessile serrated adenomas seem to be associated with distinct molecular defects that are discussed later (e.g., CpG island methylation phenotype, CIMP).

At least two other pathways leading to CRC and that are not associated with overt development of adenomatous polyps as precursors can be noted: chronic inflammatory bowel diseases (particularly ulcerative colitis [UC] and to a lesser extent Crohn disease) and flat adenoma syndromes. UC is a chronic inflammatory disease of largely unknown etiology. The possible precursor lesions to cancer in patients with UC include dysplasia and flat adenomatous plaques.[15] In a subset of patients with hereditary cancer syndromes, as well as some sporadic cases, colon cancer seems to develop directly from flat adenoma or intraepithelial dysplasia.[16] In these cases the progression from benign lesion to overt

Table 34-1 Genetics of Inherited Colorectal Tumor Syndromes

Syndrome	Features Commonly Seen in Affected Individuals	Gene Defect
Familial adenomatous polyposis (FAP)	Multiple adenomatous polyps (>100) and carcinomas of the colon and rectum; duodenal polyps and carcinomas; fundic gland polyps in the stomach; congenital hypertrophy of retinal pigment epithelium (CHRPE)	*APC*
Gardner syndrome	Same as FAP; also desmoid tumors and mandibular osteomas	*APC*
Turcot syndrome	Polyposis and colorectal cancer with brain tumors (medulloblastoma)	*APC*
Colorectal cancer and brain tumors	Colorectal cancer without polyposis and brain tumors (glioblastoma)	*MLH1, PMS2*
Attenuated adenomatous polyposis coli (AAPC)	Fewer than 100 polyps, though marked variation in polyp number (from 5 to >1000 polyps) is seen in mutation carriers within a single family	*APC* (predominantly 5′ mutations)
Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC])	Colorectal cancer without polyposis; other cancers include endometrial, ovarian, stomach cancer; urothelial, brain	*MSH2, MLH, PMS2, MSH6*
Peutz-Jeghers syndrome	Hamartomatous polyps throughout the gastrointestinal tract; mucocutaneous pigmentation; estimated 9-to 13-fold increased risk of gastrointestinal (GI) and non-GI cancers	*LKB1/STK11*
Cowden disease	Multiple hamartomas involving breast, thyroid, skin, central nervous system (CNS), and GI tract; increased risk of breast, uterus, and thyroid cancer; risk of GI cancer unclear	*PTEN*
Juvenile polyposis syndrome	Multiple hamartomatous/juvenile polyps with predominance in colon and stomach; variable increase in colorectal and stomach cancer risk; facial changes	*DPC4* *BMPR1A* *PTEN*
MYH-associated polyposis (MAP)	Multiple adenomatous gastrointestinal polyps, autosomal recessive often associated with somatic K-Ras mutations	*MYH*
Multiple adenoma and colorectal cancer	Multiple colorectal adenomas and colorectal cancer; endometrial cancer and brain tumors in some individuals and families	*POLD1, POLE*
Hereditary mixed polyp syndrome	Multiple types of colorectal polyps (e.g., Peutz-Jeghers polyps, juvenile polyps, serrated lesions, conventional adenomas) and colorectal cancer	*GREM1*

carcinoma may be more rapid than in the normal adenoma-carcinoma progression.

Hereditary Colorectal Cancer Syndromes and Molecular Pathways of Colorectal Carcinogenesis

It is now generally accepted that the accumulation of somatic mutations and epigenetic defects drives the initiation and progression of tumor development. The constellation of somatic mutations that commonly accumulate in a clonal fashion in CRCs has largely been defined.[17-20] However, only a limited subset of this collection of gene defects is usually present in any individual tumor. Thus far, the somatic mutations of greatest initial interest to the field have been those that are recurrent and clonal (i.e., present in all, or nearly all, neoplastic cells of a primary tumor at a given stage, but not present in the normal cells of the patient). It is inferred that such recurrent, clonal mutations are causal in promoting further tumor outgrowth/progression, because somatic mutations can only become clonal by a limited number of mechanisms. The genetic alteration itself could have been selected for because it provided the cell with a growth advantage, allowing it to become the predominant cell type in the tumor (clonal expansion). Alternatively, the specific alteration detected might have arisen coincident with another, perhaps undetected, alteration that was the crucial change underlying clonal outgrowth.

As noted previously, only about 5% of all CRC cases are associated with defined highly penetrant cancer syndromes. The bulk of these cases are attributable to hereditary nonpolyposis colorectal cancer syndromes (HNPCCs), with another significant subset associated with the familial adenomatous polyposis (FAP) syndrome (Table 34-1). A few other syndromes comprise the remaining highly penetrant CRC syndrome cases.

Adenomatous polyposis coli Gene: Gatekeeper in Familial Adenomatous Polyposis and Sporadic Cancer

Familial Adenomatous Polyposis

FAP is an autosomal dominant syndrome affecting about 1 in 8000 individuals in the United States and accounting for about 0.5% of CRCs.[4,5] Hundreds to thousands of adenomas

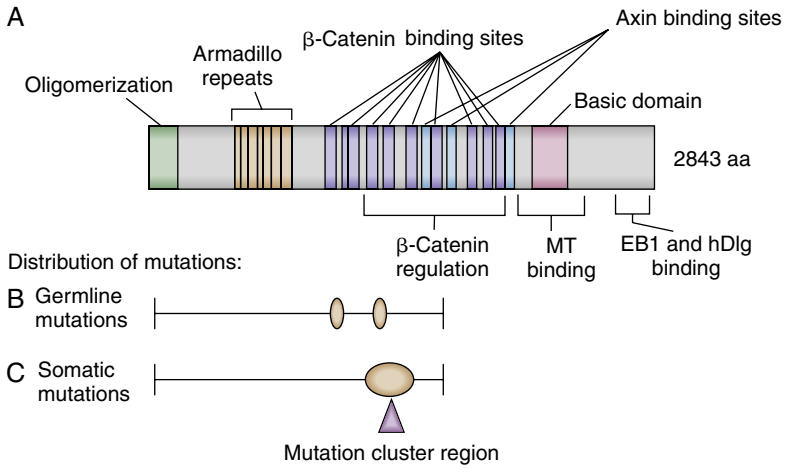

Figure 34-1 Schematic representation of the adenomatous polyposis coli (APC) protein and mutation histograms **(A)** Selected sequence motifs of the 2943-amino-acid APC protein and its interaction partners are indicated. The amino-terminal region has a domain that regulates its oligomerization. Repeated sequences with similarity to the *Drosophila* armadillo protein and its vertebrate homologue β-catenin (so-called armadillo repeats) are localized in the amino-terminal third of APC. Multiple independent 20-amino-acid repeats mediating binding to β-catenin and several binding sites for the Axin protein (termed *SAMP repeats*) are localized in the central third of APC. The carboxy-terminal third contains a basic region that is involved in microtubule (MT) binding and mediates interactions with the proteins EB1 and hDlg. **(B)** The frequency and distribution of germline mutations in familial adenomatous polyposis (FAP) patients are indicated with respect to the *APC* coding region. Virtually all mutations result in premature truncation at or very close to the mutation position. Two apparent mutational hotspots are seen at codons 1061 and 1309. **(C)** Frequency and distribution of somatic *APC* mutations in sporadic colorectal cancers are indicated. The mutations appear to predominate in the "mutation cluster region" (MCR), and mutations at codons 1309 and 1450 are most common. ***(A-C** with permission from Polakis P. Mutations in the APC gene and their implications for protein structure and function.* Curr Opin Genet Develop *1995;5:66).*

arise in the large bowel and rectum beginning in the second decade of life. Although only a fraction of the adenomas may progress to cancer, the lifetime incidence of colorectal cancer in untreated FAP patients approaches 100% with a mean age at diagnosis of 39 years, necessitating the prophylactic removal of the patient's colon early in adult life.[4] The gene that when mutated underlies FAP is the *adenomatous polyposis coli* (*APC*) tumor suppressor gene on chromosome 5q21. Germline mutations have been identified in one *APC* allele of affected individuals in 90% to 95% of families with FAP studied. More than 95% of mutations lead to premature truncation of APC protein synthesis—about two thirds by small insertions or deletions leading to a frameshift, and the remainder by introducing a stop codon[21] (Figure 34-1). Up to 25% of FAP cases seem to be caused by de novo germline mutations and therefore do not show the characteristic autosomal pattern of inheritance.[4] Moreover, about 20% of individuals with a de novo *APC* mutation display somatic mosaicism for the mutation in their tissues, with the mutant *APC* allele present in only subsets of cells within a given tissue and/or in germ cells.[4] Some of these cases with somatic mosaicism may manifest milder polyposis phenotypes than individuals carrying inherited germline *APC* mutations, as the defective *APC* allele is present in only a fraction of cells in the somatic mosaicism situation.

Several extracolonic tumors and symptoms are associated with FAP (see Table 34-1). The combination of polyposis with brain tumors (in particular, medulloblastoma in pediatric cases) has been termed *Turcot syndrome*.[22] Gardner syndrome comprises extensive polyposis with epidermoid cysts, desmoid tumors, and osteomas and seems to be correlated with mutations between *APC* codons 1403 and 1578.[23,24] Upper gastrointestinal polyps are responsible for a large proportion of morbidity and mortality in FAP patients after prophylactic total colectomy. This is particularly true for the duodenal cancers that develop in 4% to 12% of patients.[4,25,26] Benign gastric fundic gland polyps and gastric adenomas, potential premalignant precursor lesions of gastric cancer, are observed with increased frequency, ultimately leading to stomach cancer in 0.5% of cases.[4,25,26] In only a small percentage of FAP cases, thyroid cancer, bile duct cancer, hepatoblastoma (pediatric), and central nervous system tumors such as medulloblastoma are observed. In addition to FAP, rare germline *APC* variants appear to play a role in other familial CRC cases.[27] Epidemiologic studies have revealed that the *APC* I1307K (isoleucine-to-lysine substitution at codon 1307) allele is present only in individuals of Ashkenazi Jewish origin, and those who carried the I1307K allele had a roughly twofold increased risk of developing CRC.[27] The mechanism underlying increased risk of adenomas and CRC in carriers of the *APC* I1307K allele is that the allele appears to be more susceptible than the wild-type APC allele to somatic mutations—particularly insertion and deletion of one or a few nucleotides near the homopolymeric adenine tract created by the lysine 1307 codon substitution, resulting in frameshift mutations.[27]

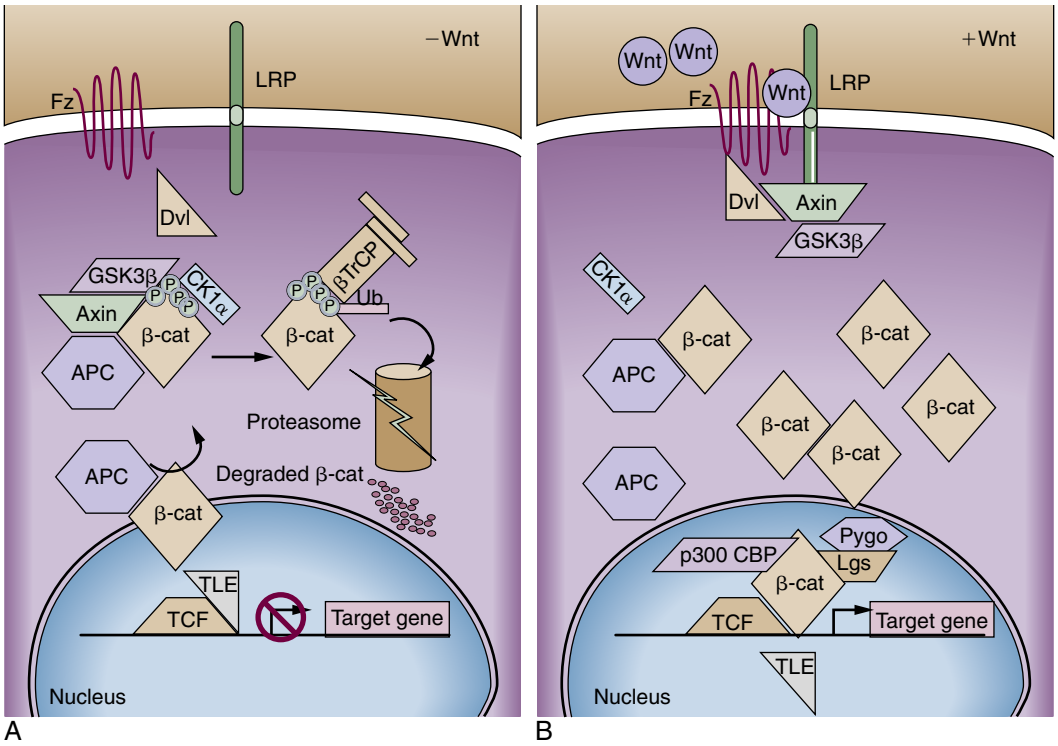

Figure 34-2 Model of adenomatous polyposis coli (APC) and β-catenin function **(A)** The APC protein is part of a "destruction complex" containing glycogen synthase kinase 3β (GSK3β), Axin, and casein kinase 1α (CK1α), which phosphorylates β-catenin in conserved serine and threonine residues in the N terminus. This phosphorylation creates an epitope for recognition by the F-box protein β-TrCP as part of a ubiquitin ligase complex, which leads to polyubiquitination and proteasomal degradation of β-catenin. Hence, in most cells free β-catenin levels are kept low and transcription of target genes is repressed by recruitment of repressors of the transducin-like enhancer of split family (TLE). **(B)** On binding of Wnt ligands to a cognate receptor complex consisting of one member of the Frizzled (Fz) family and one member of the low-density-lipoprotein receptor-related protein family (i.e., LRP5 or LRP6), the destruction complex is disassembled in part by recruitment of Axin to the LRP receptors and in part by not clearly defined action of disheveled proteins (Dvls). Similarly inactivating mutations of the APC protein or the Axin1 protein or mutations of the conserved phosphorylation sites of β-catenin lead to the accumulation of free β-catenin, which enters the nucleus and activates transcription of target genes by displacement of co-repressors and recruitment of coactivators such as CBP/p300 and a complex of the homologues of *Drosophila* Legless (Lgs) and Pygopus (Pygo).

Somatic *APC* Mutations in Sporadic Tumors

Notwithstanding the critical role of the *APC* gene in FAP and related variant syndromes, the *APC* gene has an even more prominent role in sporadic colorectal tumors, as about 80% of sporadic colorectal adenomas and carcinomas have somatic mutations inactivating *APC*,[28] the overwhelming majority of which lead to premature truncation of the APC protein. *APC* mutations have been found in a number of the earliest sporadic lesions analyzed, including microscopic adenomas composed of only a few dysplastic glands.[29] As predicted by Knudson's two-hit model for tumor suppressor genes, both *APC* alleles appear to be inactivated in the majority of colorectal adenomas and carcinoma, as a result of localized mutations in both alleles or localized mutation in one allele and chromosomal loss of the remaining allele.[28]

APC Protein Function

The APC tumor suppressor gene encodes a large protein of approximately 300 kDa (see Figure 34-1). The APC protein likely has multiple functions in the cell,[30] but the best understood function of APC is as a major binding partner and regulator of the β-catenin protein.[31] β-Catenin was first identified because of its role in linking the cytoplasmic domain of the E-cadherin cell-cell adhesion molecule to the cortical actin cytoskeleton, via binding to the adaptor molecule α-catenin. Based on studies from many different investigators, a model has been developed to explain the biologic significance of APC's interaction with β-catenin.[31] The model proposes that in the absence of an activating Wnt ligand signal, APC binds to and collaborates with the scaffold protein Axin to promote sequential phosphorylation by casein kinase I and glycogen synthase kinase-3β (GSK3β) of several conserved serine/threonine residues in the N-terminal region of β-catenin, thereby targeting β-catenin for ubiquitination and proteasomal degradation (Figure 34-2). In a physiologic setting, the activating Wnt ligands inhibit degradation of β-catenin via binding to their cognate receptor complex of a Frizzled and an LRP5/6 protein.

In the roughly 80% of CRCs where both *APC* alleles are defective, the coordinated destruction of β-catenin is

severely impaired, essentially mimicking constitutive activation of Wnt ligand-mediated signaling (see Figure 34-2). As a result, β-catenin accumulates in the cytoplasm, complexes with DNA binding proteins of the TCF (T-cell factor family)/Lef (lymphoid enhancer family) family, and translocates to the nucleus. Once there, β-catenin functions as a transcriptional co-activator, activating the expression of TCF-regulated genes. In a subset of the cancers that lack mutations in APC, somatic mutations in β-catenin have been found.[32] A critical net consequence of β-catenin stabilization by APC inactivation or other somatic mutations in CRCs is that the constitutive activation of β-catenin/TCF transcription appears to promote a stem or progenitor cell phenotype in the affected epithelial cells independent of their position in the crypt compartment.[31] Normally, β-catenin/TCF activation is restricted to the crypt base, especially in the so-called crypt base columnar stem cells that are characterized by expression of the Wnt-regulated Lgr5 gene and protein.[31]

Further work has implicated β-catenin stabilization not only in the establishment of a crypt progenitor program but also in the spatial organization and migratory pattern of the cells in the continuous renewal of crypt.[31] Strikingly, feedback inhibitors functioning in the Wnt/β-catenin/TCF pathway are prominent among the critical proteins encoded by β-catenin/TCF-regulated genes, such as the AXIN2, DKK1, NKD1, APCDD1, and WIF-1 proteins, all of which function in some fashion to antagonize Wnt signaling.[31] In CRCs with *APC* mutations, the ability of the induced feedback regulator proteins to interfere with stabilized β-catenin is largely or entirely abrogated, because the induced Wnt-pathway feedback regulators function upstream of or at the level of the APC protein in the pathway.[31] Interestingly, some of the induced Wnt pathway feedback regulators that are highly expressed in CRCs with *APC* mutations, such as AXIN2, may play important contributing roles in CRC progression, such as through the ability of AXIN2 to interact with other proteins and pathways in the promotion of epithelial-mesenchymal transition and invasive phenotypes.[33]

Mouse Models of FAP and Genetic and Epigenetic Modifiers

An important mouse genetic model of intestinal tumorigenesis known as the *Min* (for *multiple intestinal neoplasia*) mouse was described more than two decades ago.[34] The *Min* mouse carries a germline mutation in the murine homologue of the *APC* gene, resulting in truncation of the murine Apc protein at codon 850. The intestinal tumor phenotype of *Min* or *Apc(Min)* mice is similar, but not identical, to that seen in FAP patients, with *Apc(Min)* mice developing largely small intestinal tumors, in contrast to the colorectal lesions seen in FAP patients.

Other cellular genes can significantly influence the number of polyps that arise in mice that are heterozygous for the *Apc(Min)* mutant allele or other mutant Apc alleles. For instance, when the Apc*(Min)* mutation was introduced into mice of varying genetic backgrounds, significant variability in the number of intestinal tumors was seen. This finding was attributable to the effects of strain-specific modifier genes unlinked to the *Apc* locus, particularly the modifier gene Pla2g2a, which encodes a secreted phospholipase A2 protein.[35] Other genes that substantially modify intestinal tumorigenesis in *Apc*-mutant mice include genes encoding DNA methyltransferases. Specifically, mice that carry the *Apc(Min)* mutation and a germline defect in one allele of the maintenance DNA methyltransferase *Dnmt1* or a gut-specific deletion of both *Dnmt3* alleles have a two- to threefold reduction in macroscopic polyp number.[36,37] Treatment of *Apc(Min)* mice with 5-azacytidine, a pharmacologic inhibitor of DNA methyltransferases, resulted in a more than fivefold reduction in polyp number.[36] Combining the genetic and pharmacologic manipulations of DNA methyltransferase activity synergistically reduced the polyp number roughly 50-fold.[36] Treatment of mice with NSAIDs that inhibit COX-1 and COX-2 or agents that specifically inhibit COX-2 activity also markedly inhibited adenoma formation.[38,39] The findings highlight the utility of the mouse genetic models for identifying novel genes and pharmacologic agents that modify intestinal tumor development.

Other Forms of Intestinal Polyposis

Some patients with germline mutations in the *APC* gene have a milder or attenuated FAP (AFAP) phenotype, due to the nature of the germline *APC* mutation that they carry and/or other genetic variants that they may carry that modify the severity of their polyposis phenotype.[4,5] However, many of the individuals who have an AFAP phenotype and typically present to clinical attention between 40 and 60 years of age with fewer than a dozen to a hundred polyps do not carry a germline *APC* mutation.[4,5] Rather, these affected individuals carry homozygous mutations in the *MYH* gene encoding the base-excision repair pathway protein MutYH. The syndrome is often termed *MAP* for *MYH*-associated polyposis syndrome.[4,5] The mutations in the *MYH* gene lead to constitutional defects in the repair of oxidative DNA damage in cells, with increased GC-to-AT base-pair transversions arising. As a result of the increased mutation frequency, in the colon, somatic mutations in various genes likely arise at increased frequency, with the somatic mutations contributing to adenoma formation.

Some individuals and families who develop 10 to 100 or more adenomas during adult life, and who also develop CRC at an increased rate unless managed clinically, have been found to lack germline mutations in the *APC* or *MYH*

genes. Recent studies have shown that some of these affected individuals and families carry heterozygous germline mutations in the *POLD1* and *POLE* genes encoding DNA polymerases δ and ε, respectively.[40] The mutations appear to affect the proofreading domains of the polymerases. In the case of *POLD1* mutations, affected individuals appear to be predisposed not only to adenomas and CRC but also to endometrial cancer and perhaps brain tumors.[40] The colon tumors arising in *POLD1* and *POLE* mutation carriers were found to have inactivated the remaining wild-type copy of the gene by loss of heterozygosity (LOH). As a result, the tumors lack intact polymerases δ or ε function, depending on the nature of the patient's germline mutation, and the tumors manifest a markedly greater frequency of base-substitution mutations relative to similar stage colon tumors with intact polymerase δ and ε function, presumably as a direct result of the deficits in polymerase δ or ε function.[40]

Other intestinal polyposis syndromes in which patients manifest numerous nonadenomatous lesions have also been described.[4,5] Several of these syndromes have an increased risk of gastrointestinal and/or non-gastrointestinal cancers (see Table 34-1). Starting from childhood, patients with the autosomal dominant juvenile polyposis syndrome (JPS) develop multiple hamartomatous polyps throughout the gastrointestinal tract with some preference for the colon and the stomach. JPS is a genetically heterogeneous disease, with inactivating mutations in the SMAD4 and BMPR1A genes among the underlying genetic bases. Cowden syndrome is an autosomal dominant syndrome in which affected individuals develop macrocephaly and hamartomas in many organ sites, including the breast, thyroid, skin, central nervous system, and gastrointestinal tract.[4,5] The gene responsible for Cowden syndrome is the *PTEN* tumor suppressor gene on chromosome 10q23. Acting as a phospholipid-phosphatase, the PTEN protein is a major antagonist of the phosphatidylinositol-3-kinase (PI3K) survival pathway. In a small number of nonfamilial cases of juvenile polyposis lacking other features of Cowden syndrome, *PTEN* germline mutations have been reported.[4,5] Peutz-Jeghers syndrome, a rare autosomal dominant condition affecting fewer than 1 in 25,000, is characterized by gastrointestinal hamartomatous polyps and mucocutaneous melanin deposition.[4,5] The hamartomatous polyps contain essentially normal epithelial cells, but the mucosal components are arranged abnormally. Germline mutations in the *LKB1/STK11* tumor suppressor gene on chromosome 19p can be seen in a significant fraction of cases.[4,5] Inactivation of this tumor suppressor gene leads to the hyperactivation of the mammalian target of rapamycin (mTOR) pathway, which is responsible for integrating the nutritional supply with cell proliferation and growth. Finally, recent studies of a rare inherited syndrome known as hereditary mixed polyposis syndrome (HMPS), in which individuals are predisposed to develop a range of lesions, including Peutz-Jeghers polyps, juvenile polyps, serrated lesions, conventional adenomas, and CRC, is due in some families to germline mutations that lead to overexpression of the bone morphogenetic protein (BMP) antagonist GREM1.[41] Thus, although HMPS is connected to JPS, based on the fact that BMPs signal through the transforming growth factor β (TGF-β) pathway, further work is needed to understand how derangements in TGF-β and BMP signaling contribute to predisposition to colorectal tumors.

DNA Mismatch Repair Deficiency and Lynch Syndrome

Hereditary nonpolyposis colorectal cancer (HNPCC) was arguably the first inherited cancer syndrome to be well described in the literature. In 1913, Warthin presented a particularly striking example of a three-generation family with CRC and other cancers, including gastric cancer and tumors of the female reproductive tract.[42] Following Warthin's lead, Lynch and others described kindreds with autosomal dominant patterns of CRC, not accompanied by extensive polyposis.[43] In such families, CRCs of early onset were seen, often along with cancers in some other organs including gastric, uterine endometrial, ovarian, small bowel, renal, and hepatobiliary cancers.[44] In recognition of Dr. Henry Lynch's major contributions to the field, HNPCC is often referred to as *Lynch syndrome*.

Criteria for the diagnosis of Lynch syndrome in families have often included the following: affected families must show Lynch syndrome–typical tumors in three relatives (one being a first-degree relative to the other two) in at least two successive generations, with one of the tumors occurring before age 50 (so-called 3-2-1 rule). The sensitivity of these diagnostic criteria is considerably less than 100% for identifying those affected by Lynch syndrome, and the specificity of the criteria is also an issue.[4] However, the diagnostic criteria proved critical for the initial discovery of the germline mutations underlying Lynch syndrome, and the criteria have also been useful in clinical assessment over the past 15 to 20 years since the genetic bases of Lynch syndrome were uncovered. By way of a brief background, the early genetic work indicated genetic heterogeneity for Lynch syndrome, with mapping of the predisposing gene to chromosome 2p in some families[45] and to chromosome 3p in other families.[46] In yet other families with Lynch syndrome, no evidence for linkage to chromosome 2p or 3p was found.

To explore the relevance of Knudson's two-hit hypothesis for Lynch syndrome genes, investigators initially sought to demonstrate loss of parental heterozygosity for chromosome 2p in cancers from individuals carrying a defect in

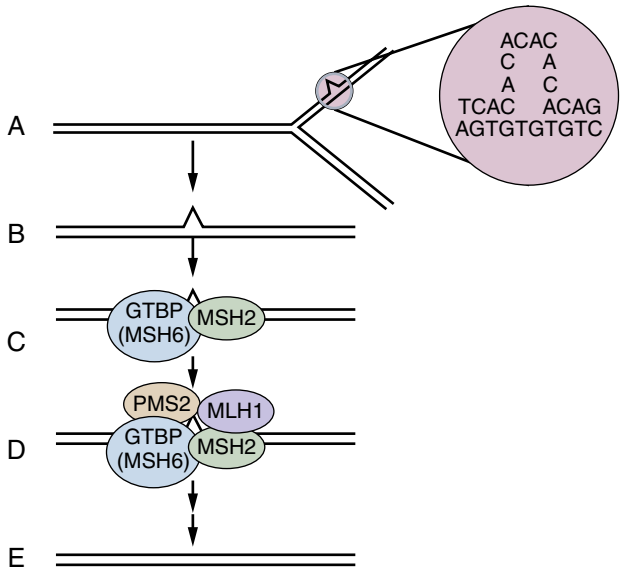

Figure 34-3 Mismatch repair pathway in human cells (A, B) During DNA replication, DNA mismatches may arise, such as from strand slippage (shown) or misincorporation of bases (not shown). **(C)** The mismatch is recognized by MutS homologues, perhaps most often MSH2 and GTBP/MSH6, although MSH5 may substitute for GTBP/MSH6 in some cases. **(D, E)** MutL homologues, such as MLH1 and PMS2, are recruited to the complex, and the mismatch is repaired through the action of a number of proteins, including an exonuclease, helicase, DNA polymerase, and ligase. ***A-E*** *with permission from Kinzler KW, Vogelstein B. Lessons from hereditary colorectal cancer.* Cell. *1996;87:159-170.*

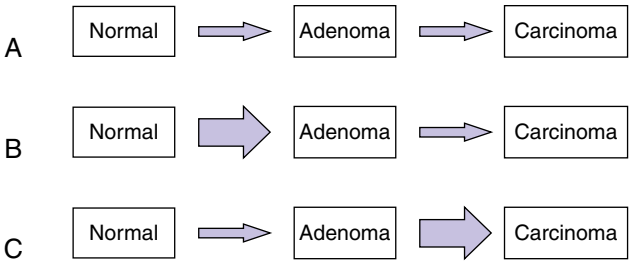

Figure 34-4 Relative effects of germline mutations on tumor initiation and progression (A) In sporadic cancers, both initiation of a neoplastic lesion (e.g., the adenoma) and progression to an advanced lesion (i.e., the carcinoma) are rate-limiting events because two somatic mutations are required for inactivation of tumor suppressors such as adenomatous polyposis coli (APC) (initiation of adenoma) and p53 (tumor progression). **(B)** In the case of familial adenomatous polyposis (FAP), germline inactivation of one APC allele markedly increases the formation of adenomas, because inactivation of both APC alleles is a critical (rate-limiting) event in adenoma formation, and those with inactivation of one allele in all colonic cells need only inactivate the remaining APC allele to initiate adenoma formation. **(C)** In the case of Lynch syndrome (hereditary nonpolyposis colorectal cancer [HNPCC]), germline inactivation of one of the mismatch-repair genes (e.g., *MSH2* or *MLH1*) coupled with somatic inactivation of the remaining allele in an initiated lesion (e.g., an early adenoma) greatly increases the mutation rate, and subsequently the rate and speed of progression to more advanced lesions. *With permission from Bettingon et al. The serrated pathway to colorectal cancer: current concepts and challenges. Histopathology. 2013; 62:367-386.*

that particular predisposition gene.[45] However, not only was there no LOH of chromosome 2p sequences in the cancers, but microsatellite DNA sequences examined in the analyses demonstrated marked length variations in tumor tissues compared with the patient's normal tissue. Microsatellite changes were seen at many different loci scattered throughout the genome and in all tumors from patients with Lynch syndrome.[45] The phenotype was termed the *microsatellite instability*" (MSI) or *replication error* (RER) phenotype. Cancers with evidence of microsatellite instability at more than 40% of a panel of mononucleotide and dinucleotide sequences are termed *high-frequency MSI* (MSI-H) cancers. Although most CRCs display no instability when a panel of microsatellite tracts are studied—so-called microsatellite stable (MSS) cases—a subset of cancers show low-frequency instability of the microsatellite markers, termed *MSI-L*.

The finding of MSI-H in the cancers was noteworthy because similar DNA instability phenotypes had previously been seen in mutant yeast strains with defective DNA mismatch repair genes. The prediction that defects in one or more DNA mismatch repair genes might underlie Lynch syndrome was quickly borne out (Figure 34-3). A human homologue of the bacterial *mutS* mismatch repair gene, designated *MSH2*, was mapped to chromosome 2p, and one allele was found to be mutated in the germline of a subset of Lynch syndrome patients, with the remaining allele inactivated in cancers arising in the mutation carriers. Other genes involved in DNA mismatch repair were studied and found mutated in other groups of Lynch syndrome patients, including the *MLH1* gene on chromosome 3p, the *PMS2* gene on 7q, and the *GTBP/MSH6* gene on chromosome 2p.[47] Mutations in the *MSH2* and *MLH1* genes are a far more common cause of Lynch syndrome than mutations in the other mismatch repair genes, with *MSH2* and *MLH1* mutations together accounting for about 70% to 75% of the known mutations in Lynch syndrome patients.[47]

In the normal cells of a patient with Lynch syndrome, DNA repair is rarely impaired, because the cells have a wild-type copy of the gene (i.e., the copy inherited from the nonaffected parent). However, during cancer development, the remaining wild-type allele is inactivated by a somatic mutation. Following inactivation of the wild-type allele, full mismatch repair activity is lost (see Figure 34-3). Then, affected cells manifest a mutator phenotype and accumulate mutations in a much more rapid fashion. Lynch syndrome is, therefore, a disease with more rapid tumor progression from a benign, initiated clone to frank malignancy (Figure 34-4).

Although germline mutations in the known mismatch repair genes have been detected in only 2% to 4% of CRC patients, roughly 15% of all CRCs display the MSI-H phenotype.[47] The somatic inactivation of *MLH1* via epigenetic mechanisms, including hypermethylation of its promoter, seems to be responsible for most MSI-H CRC cases outside of Lynch syndrome families.[47]

Many of the mutations that arise in cells with the MSI-H phenotype may be detrimental to cell growth or may exert no positive selection pressure. However, a subset of mutations could potentially activate oncogenes or inactivate tumor suppressor genes. An example of a gene containing a mononucleotide tract in its coding sequence that is frequently mutated in MSI-H CRCs is the TGF-β type II receptor.[47] Some other genes commonly altered in MSI-H CRCs are described later.

Inflammation and Colon Cancer

Chronic inflammatory bowel disease (IBD), especially ulcerative colitis, confers an increased risk of CRC. In the case of UC, the risk of CRC is associated with both the duration and extent of the inflammatory disease. From a pathogenetic standpoint it is notable that UC-associated CRCs often develop without the formation of a polyp as a precursor lesion, although dysplasia is a common factor.[15,48] Reducing the degree of inflammation in IBC seems to reduce the risk for CRC.[49] Some insights into the factors and pathways by which inflammation contributes to colitis-associated CRC (CAC) have begun to emerge[50] and likely include important roles for NF-κB signaling in both immune cells and epithelial cells and local activation of various cytokines and lymphokines, including tumor necrosis factor, interleukin 1 (IL-1), IL-6, IL-17, and IL-23.[50]

The responses of the innate and cellular immune systems to variations in intestinal microbial communities as well as inflammatory mediators all seem to have important and potentially much broader contributing roles in intestinal neoplasia beyond the setting of CAC. For instance, a human colonic commensal—enterotoxigenic *Bacteroides fragilis*—can affect tumor progression in the *Apc(Min)* mouse model of intestinal tumorigenesis in part via inflammation and the generation of IL-17–expressing T helper 17 [T(H)17] cells.[51] Recent studies have further highlighted the role of microbes and microbial products, along with IL-23 and T(H)17 cells in *Apc*-mutation–dependent colon tumor progression in the mouse.[52] Future studies are likely to further clarify the likely complex relationships among the intestinal microbiota, host immune cells, and epithelial cells in the initiation and progression of colon neoplasia in mouse models and in humans.

Recurrent Somatic Alterations in Colorectal Cancer

Somatic alterations have key roles in the initiation and progression of colorectal tumors, in patients with inherited predispositions to CRC as well as in the majority of CRC patients whose tumors are apparently sporadic. A sizeable number of mutational alterations in CRCs were identified over the past 30 years, largely by various combinations of genetic and genomic approaches.[18] Among the major targets for somatic mutations in CRCs identified before whole genome sequence-based approaches included oncogenic (activating) point mutations affecting *KRAS* (about 40% of CRCs), *NRAS* (about 5%), *PIK3CA* (20%), and *BRAF* (5% to 10%), as well as amplifications of the *EGFR* (5% to 10%), *CDK8* (10% to 15%), *CMYC* (5% to 10%), and *ERBB2* (5%) genes.[18] Similarly, among the tumor suppressor genes known to be frequently affected by somatic mutations in CRCs as a result of the "old-school," focused sequencing approaches were the following: *APC* (80%), *TP53* (60%), *FBXW7* (20%), *SMAD4* (10% to 15%), *PTEN* (10%), *SMAD2* (5% to 10%), *ACVR2A* (10%), and *TGFBR2* (10%).[18]

Over the past few years, comprehensive sequencing approaches have allowed for expansive analyses of the nature and spectrum of mutational alterations in CRCs.[17,19,20] One of the major advances of the comprehensive sequencing-based approaches has been knowledge of the variation in total somatic mutations among CRCs. For example, in an exome-sequence analysis of 224 tumor and normal pairs from CRC patients, it was found that 84% of the tumors had a median number of nonsilent (predicted to change protein-coding sequence) somatic mutations of 58 per tumor; the remaining 16% of the tumors were reported to manifest a "hypermutated" phenotype, with a median of 728 somatic nonsilent mutations per tumor.[19] These findings that about 16% of CRCs had a hypermutated phenotype was not entirely unexpected. As described earlier in the discussion of mismatch repair gene defects in Lynch syndrome and also apparently sporadic CRCs, about 15% of all CRCs manifest the MSI-H phenotype, in the majority of MSI-H CRCs because of epigenetic silencing of the *MLH1* gene.[18,47] As a result of their defective mismatch repair pathway function, the MSI-H CRCs were known to have a hypermutable phenotype. However, what was a bit unexpected about the hypermutated CRCs identified via the comprehensive sequencing approaches was that about 25% of the hypermutated tumors lacked the MSI-H phenotype and had intact function of *MLH1*. Instead, the hypermutated non-MSI-H cases had somatic mutations in other mismatch repair genes (e.g., *MSH2*, *MSH3*, *MLH3*, *MSH6*, *PMS2*) or in the *POLE* gene encoding DNA polymerase ε.[19] One somewhat puzzling issue is why somatic mutations in certain mismatch repair genes do not invariably lead to demonstrable instability in the microsatellite sequences that define the MSI-H phenotype, whereas epigenetic silencing of MLH1 does apparently lead to the MSI-H phenotype in almost all cases.

Table 34-2 Localized Somatic Mutations in Oncogenes and Tumor Suppressor Genes in Hypermutated and Non hypermutated CRCs

Gene	Estimated Mutation Frequency*
Hypermutated Tumors	
Oncogenes	
BRAF	40%-45%
Tumor Suppressor Genes	
ACVR2A	60%-65%
APC	50%-55%
TGFBR2	50%-55%
MSH3	40%
MSH6	40%
MYO1B	30%-35%
TCF7L2	30%-35%
Nonhypermutated Tumors	
Oncogenes	
KRAS	40%-45%
PIK3CA	15%-20%
NRAS	5%-10%
CTNBB1	5%-10%
Tumor Suppressor Genes	
APC	80%-85%
TP53	60%
FBXW7	10%-15%
SMAD4	10%
TCF7L2	5%-10%
FAM123B	5%-10%
SMAD2	5%-10%

*Mutation estimates from References 18 and 19.

Perhaps part of the explanation might be the relative timing of the defects in mismatch repair function in the natural history of a given CRC.

Besides clarifying the mutation rate in CRCs and illuminating the molecular basis for the markedly increased mutation rate in the roughly 16% of CRCs that are hypermutated, comprehensive molecular characterization efforts have yielded additional insights, such as refinements in the estimated frequencies for known oncogene and tumor suppressor gene defects in CRC, the identification of some new oncogene and tumor suppressor gene defects contributing to CRC, and some initial insights into how epigenetic changes and gene expression patterns may be associated with certain mutation patterns as well as biologic and clinicopathologic subsets of CRC. Table 34-2 summarizes some of the genes most frequently affected by somatic mutations in nonhypermutated and hypermutated CRCs.[19,20]

In addition to the extensive data on localized mutation frequencies, comprehensive molecular characterization efforts have begun to further inform understanding of recurrent gene amplification, deletion, and translocation in CRCs. Besides largely confirming the gene amplification events previously uncovered in CRCs, such as *CDK8*, *EGFR*, *CMYC*, and *ERBB2* gene amplifications,[18] the work uncovered gene amplification and overexpression of the *IGF2* gene in about 10% to 15% of CRCs.[19,20] Gene deletions affecting well-defined tumor suppressor genes were confirmed in a subset of CRCs, such as those affecting *APC*, *PTEN*, or *SMAD3*.[19,20] In addition, frequent deletions affecting the *FHIT* presumptive tumor suppressor gene were seen in about 20% to 30% of CRCs.[19,20] Recurrent translocations activating two different genes encoding R-spondin protein family members that cooperate with Wnt ligands to activate canonical β-catenin-dependent Wnt signaling were seen in 5% to 10% of CRCs.[20]

Genetic Instability: Chromosomal Instability versus DNA Mismatch Repair Deficiency

In general, the roughly 15% of CRCs that manifest the MSI-H phenotype tend to have largely diploid or near-diploid karyotypes, whereas the remaining 85% of CRCs are aneuploid.[53,54] Key factors and mechanisms underlying the numerical chromosome instability (CIN) phenotype in CRC and other cancers are poorly defined, but some clues have emerged. Rare mutations and more commonly changes in the expression of genes that encode proteins that regulate chromosome segregation in mitosis or other genes that encode DNA repair response proteins have been suggested to play roles in the CIN phenotype in CRC.[54] However, because the mutations appear to be quite rare in primary CRCs and the changes in gene expression observed have been difficult to conclusively implicate in the CIN phenotype, unambiguous data on the gene defects with significant roles in the CIN phenotype in CRC are lacking.[54]

Recently, three genes from a region of chromosome 18q affected by frequent copy number loss in CRC—PIGN, MEX3C, and ZNF516—have been implicated as potential contributing factors in CIN.[55] Specifically, experimental silencing of any one of the three genes led to the CIN phenotype in CRC cells in culture.[55] The genes appear to regulate the cellular response to DNA replication stress, and reduced DNA replication stress appears linked to reduced chromosome segregation defects.[55] Nonetheless, although the recent work on these three chromosome 18q genes appears to be an encouraging lead in terms of defining

common molecular defects that may play important contributing roles in the CIN phenotype in CRC, much further work is needed to substantiate the contribution of the genes as well as the means by which loss of their function might lead to CIN.

Epigenetic Changes in Colorectal Carcinogenesis: the CpG Island Hypermethylation Phenotype

In mammalian genomes, most 5′-CpG-3′ dinucleotides have been lost during evolution.[56] DNA methylation covalently modifies more than 80% of the remaining CpG sites, except for localized regions of high CpG-dinucleotide content, which have been termed *CpG islands*.[56] The promoter and proximal regulatory regions of about 50% of all genes contain CpG islands. Dense methylation or hypermethylation of these CpG islands seems to be associated with gene silencing, implicating CpG methylation as a potentially quite significant epigenetic mechanism to reinforce or "lock in" long-term gene silencing following more transient posttranslational chromatin modifications that are linked to inhibition of transcription (e.g., certain histone tail methylation and deacetylation changes).[56] Although the global trend in the majority of CRCs is in fact a decrease in total DNA methylation—that is, global DNA hypomethylation—the CpG island hypermethylation of selected promoters has been implicated in transcriptional silencing in CRC and other cancers.[56,57] Indeed, it is likely that a large fraction of CRCs reduce or silence expression of one or more critical growth-controlling genes (e.g., tumor suppressor genes) in part through epigenetic mechanisms, such as promoter DNA hypermethylation.[57]

The functional significance of global DNA hypomethylation in CRC is more enigmatic than DNA hypermethylation, but some findings have suggested a potential contributing role for global DNA hypomethylation in chromosome missegregation events and the CIN phenotype.[57] Other work has suggested that global DNA hypomethylation might also lead to altered gene expression, such as the reactivation of certain imprinted genes that are normally silenced during early development.[18]

A subset of CRCs manifest DNA hypermethylation at a sizeable number of distinct CpG islands scattered around the genome, compared to the DNA methylation patterns seen in adjacent normal colon epithelium or the bulk of other CRCs that lack the significant increase in DNA methylation. This phenotype has been termed the *CpG island hypermethylation phenotype* (CIMP).[57,58] A subset of CIMP CRCs shows hypermethylation of the *MLH1* mismatch repair gene, and this group of CRCs constitutes the major fraction of sporadic MSI-H CRCs discussed at several earlier points. The specific factors and mechanisms that underlie CIMP status in CRC are not understood. However, it is noteworthy that the MSI-H CIMP subset of CRCs often harbors *B-RAF* oncogenic mutations.[9,10,57]

Altered Gene Expression in Colorectal Cancer

Besides the genes whose expression is affected by DNA methylation, many other genes show major differences in gene expression in CRCs relative to normal tissues as well as among CRCs. This is likely a result of complex and heterogeneous mechanisms, such as the following: (1) somatic mutations deregulating key cellular signaling pathways that affect downstream gene expression in CRCs, along with significant intertumoral heterogeneity among CRCs with respect to the specific collection of signaling pathways and factors affected by oncogene and tumor suppressor gene mutations in any given CRC; (2) a subset of CRCs with mutations or epigenetic defects affecting specific chromatin regulatory factors, such as ARID1A[19,58]; and (3) potential intertumoral heterogeneity in the specific cell of origin, with some CRCs arising from presumptive crypt base columnar stem cells and other CRCs potentially arising from more differentiated cell types. As a result of the potential differences in cell of origin and/or the specific signaling pathways and chromatin regulatory factors that are dysregulated in one CRC versus another, there are likely to be major variations among CRCs in terms of the expression of key transcriptional activators and repressors that directly regulate gene expression. There are also likely to be major variations in the structure and posttranslational modifications of chromatin and chromatin-associated proteins in CRCs. It will not be possible to review in any detail the very large collection of published studies on differentially expressed genes in CRC relative to normal tissues or the variations in gene expression among different subsets of CRC. Rather, one goal here is to offer some thoughts about the potential significance of gene expression changes in CRC that are not directly linked to specific mutations. A second goal is to introduce the notion that gene expression changes in CRCs affect not only mRNAs encoding proteins, but also various noncoding RNAs, such as miRNAs and long noncoding RNAs (lncRNAs).

The key somatic mutations in CRC highlighted earlier are clonal and recurrent, and the mutations lead to novel or increased function of oncogenes or inactivation of tumor suppressor genes. As described for the *MLH1* gene, epigenetic changes, such as promoter hypermethylation and perhaps posttranslational modifications of histone or other chromatin-associated proteins, silence *MLH1* expression in nearly all of the apparently sporadic MSI-H CRCs. Based on this powerful example, it could be that many other genes with dysregulated expression in CRC—either increased or decreased expression—might have a functionally significant role as an oncogene or TSG, respectively. However, the altered expression of many genes in CRCs may largely reflect

rather than cause the altered growth and differentiation properties of cancer cells compared to normal cells. Hence, all available data on the function of any differentially expressed gene must be evaluated to establish whether the gene likely has a major contributing role in CRC and whether it might appropriately be designated as an oncogene or tumor suppressor gene.

The stability of mRNA transcripts as well as their ability to be translated into proteins is regulated by microRNAs (miRNAs), which are processed from longer precursor transcripts by the Drosha and Dicer proteins to roughly 18 to 24 nucleotides in length. Recognition of target transcripts predominantly occurs by binding of the miRNA to imperfect complementary sequences in the 3′ untranslated region (3′UTR) of various transcripts. Not unexpectedly, because the primary RNA transcripts that are ultimately processed to mature miRNAs are transcribed by RNA polymerase II (as are mRNAs), miRNA levels in CRCs vary considerably from levels in normal colonic mucosa.[57] miRNA expression differences have been reported in comparisons of MSS CRCs to MSI-H CRCs.[57,59] Many of the reported differences in miRNA levels in CRCs versus normal colon tissues and among different subsets of CRCs may be due to differential expression of the primary transcripts that are processed to miRNAs. However, p53 missense mutations have been hypothesized to exert specific effects on the processing of certain miRNAs.[60] Other somatic mutations in CRC could also conceivably exert major effects on the processing and/or nuclear-cytoplasmic transport of miRNAs. Similar to the situation discussed earlier for protein-coding mRNAs, in most cases it is largely uncertain which miRNA changes have causal roles in CRC development and which are secondary events associated with the process. Unlike the situation in some other cancer types where the genomic location of certain miRNAs with altered expression maps close to recurrent chromosomal breakpoints or deletions, few if any of the miRNAs with altered expression in CRC have been linked to recurrent chromosome lesions in CRC.[61] Besides the likely contribution of oncogene and TSG defects to changes in the levels of various miRNAs in CRC, it is likely that the expression of key components in critical oncogene and TSG pathways in CRC is modulated by many different miRNAs. Finally, although there are no conclusive data to implicate alterations in the function or expression of lncRNAs in CRC development and progression, it seems likely that at least a few of the estimated 5000 or more lncRNAs will have major contributing roles in CRC, such as through the ability of some lncRNAs to function as scaffolds for various chromatin-regulatory proteins.[62] Similar to the situation for both protein-encoding mRNAs, critical assessment of the collective expression and functional data will be required to implicate any given miRNA or lncRNA as a causal factor in CRC development and progression.

Multistep Genetic Models of Colorectal Tumor Development

Based on the accumulation of selected somatic oncogene and tumor suppressor gene defects together with methylation changes in CRCs, an initial genetic model of colorectal tumorigenesis was proposed more than 20 years ago.[63] The model relied on the assumption that many carcinomas arise from preexisting adenomas and that certain genetic alterations tended to accumulate at particular stages of tumor development, such as APC mutations in adenoma formation and p53 mutations in the transition to carcinomas. Hence, this was the basis for assigning a relative order to the alterations in a multistep pathway. However, the order of the mutations in the development of any given CRC was not viewed as invariant, as a few small adenomas with *p53* mutations had been identified and *KRAS* mutations were sometimes associated with progression to carcinoma in some late-stage adenomas.[18,63]

Since the initial genetic model for CRC development was proposed, other distinct molecular pathways to CRC have been suggested, some of which involve other precursor lesions than adenomatous polyps.[9,10] Some of the alternative molecular scenarios are presented in Figure 34-5. The initial genetic model suggested in Reference 63 is outlined at the far right as one of the so-called conventional pathways. As indicated in Figure 34-5, the roughly 2% to 4% of CRC cases arising in individuals carrying germline mutations in a DNA mismatch repair (MMR) gene—Lynch syndrome—likely share some similarities with conventional pathway lesions in terms of the somatically acquired gene lesions that give rise to adenomatous lesions, such as *APC* mutations. As for the approximately 10% to 12% of apparently sporadic cancers that manifest the MSI-H phenotype, many of these are presumed to arise from serrated adenomatous lesions, such as sessile serrated adenomas (SSAs).[9,10] Some of the molecular lesions associated with the genesis of SSAs and the subsequent progression of SSAs to CRCs are distinct from those somatic defects that contribute to the conventional CRCs and the Lynch-type MSI-H CRCs, including frequent *B-RAF* mutations and the silencing of certain genes via promoter hypermethylation (i.e., CIMP CRCs). Finally, though not depicted in Figure 34-5, it is worth noting that the nature and order of mutational events seem to be different in UC-associated CRCs than in sporadic CRCs. For instance, *p53* mutations are typically observed at an earlier time point, perhaps even occurring in the nonneoplastic inflamed mucosa of some patients.[48]

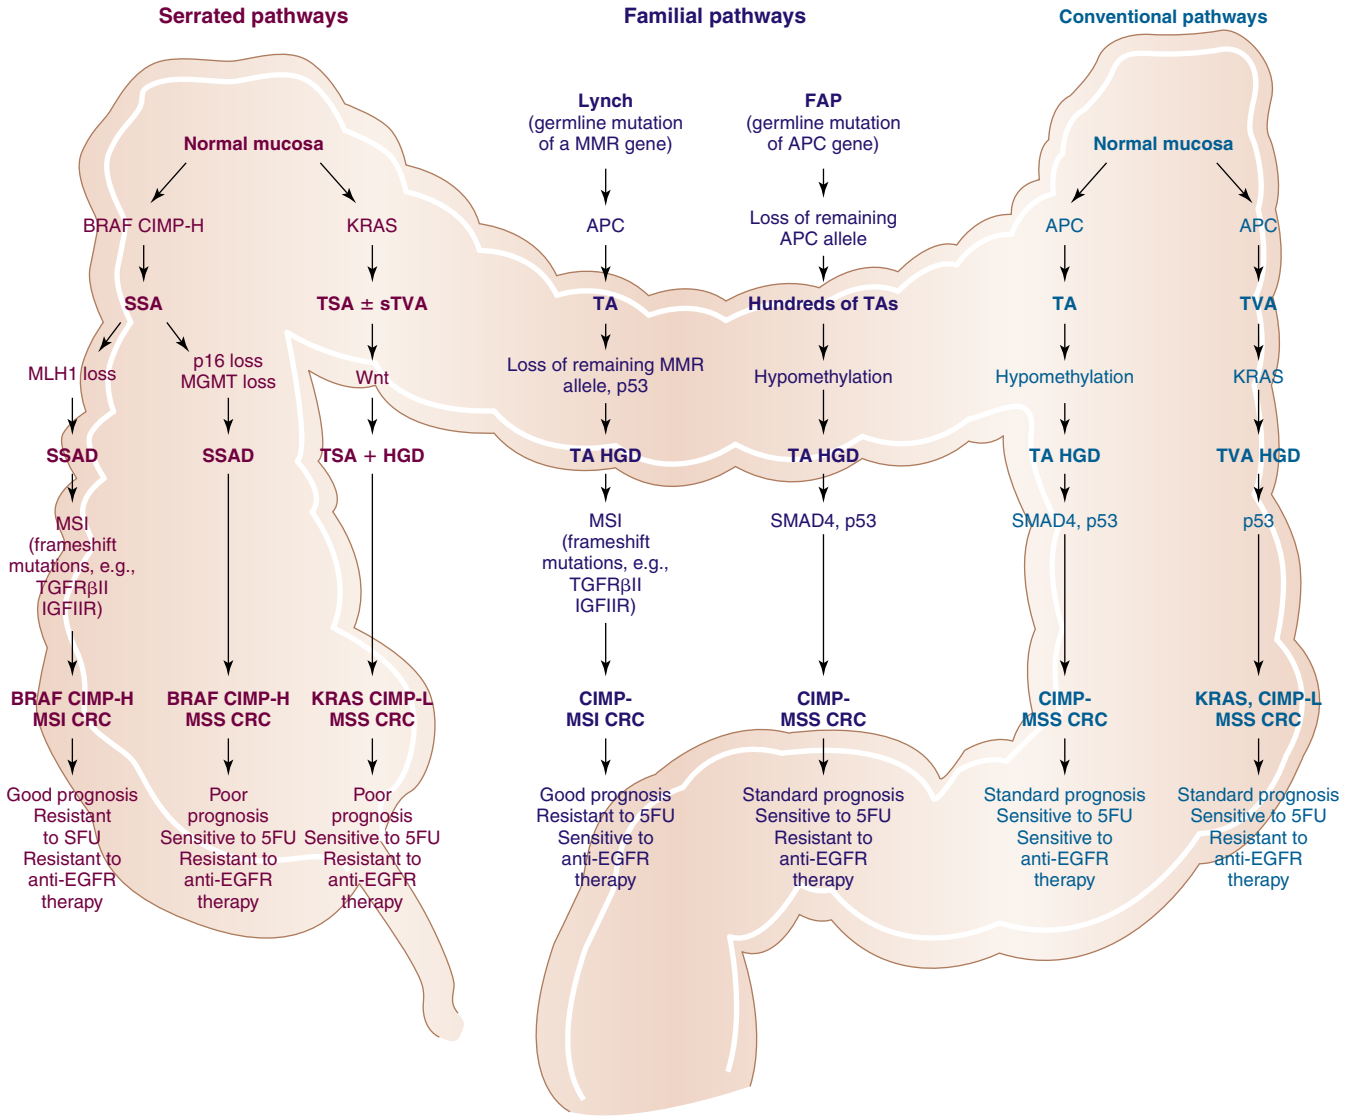

Figure 34-5 Putative pathways to colorectal cancer (CRC) Shown in the figure are potential precursor lesions and selected molecular defects suggested to play important roles in the serrated pathways, familial pathways, or conventional pathways for CRC. The conventional pathways highlight the fact that the majority of CRCs are believed to arise from adenomatous precursor lesions over a period of years or even decades, with progression from a TA or TVA lesion to one that has high grade-dysplasia (TA HGD or TVA HGD). Some of the potential somatic alterations in tumor suppressor genes (APC, SMAD4, p53) and oncogenes (KRAS) that might contribute to tumor initiation and/or progression are illustrated. Possible global phenotypic changes in the CRC cells that are discussed in the text are noted, such as CpG island methylator phenotype-negative (CIMP-) or CIMP-low (CIMP-L) and microsatellite stable (MSS), along with the potential prognostic and therapeutic generalizations. Two familial pathways to CRC that together account for about 2% to 4% of CRC are highlighted in the scheme. The role of gene lesions and presumptive mutational mechanisms are extensively discussed in the text. The figure indicates the relationship of molecular lesions to prognosis and therapy response. A significant fraction of CRCs, especially lesions in the proximal colon, are thought to arise from a serrated precursor lesion, such as a sessile serrated adenoma (SSA) or a traditional serrated adenoma (TSA), with progression through lesions that manifest dysplasia or high-grade dysplasia (SSAD and TSA + HGD). A sizeable subset of SSAs and the resultant CRCs that arose from SSAs manifest the CIMP-high (CIMP-H) phenotype. The possible relationships of the various serrated pathway lesions to prognosis and therapeutic response are noted. *anti-EGFR,* Epidermal growth factor receptor inhibitors; *5-FU,* 5-fluorouracil therapy; *IGFIIR,* insulin-like growth factor receptor II; *p16,* p16 inhibitor of cyclin-dependent kinase 4; *TA,* tubular adenoma; *TGFRβII,* TGF-β receptor II; *TVA,* tubulovillous adenoma. *With permission from Bettington et al. Clinical Applications of Molecular Genetic Insights

The advances in our understanding of inherited and somatic defects in CRCs have made possible certain clinical applications and have highlighted the potential for additional clinical strategies that collectively should greatly improve the diagnosis and care of patients and families affected by CRC. Although many possible future clinical applications can be envisioned, just a few that are being actively pursued are described in the following sections.

Risk Assessment

The accurate presymptomatic diagnosis of FAP or Lynch syndrome is of significant value to individuals and families affected by these syndromes. The identification of germline mutations in the APC gene in more than 80% of families with FAP and Gardner syndrome provides the basis for genetic counseling and clinical management of families and individuals at risk for polyposis.[4,5] Similar major progress has been made in defining the germline mutations in Lynch syndrome patients and families.[4,5] Given the progress reviewed here and summarized in Table 34-1 in defining other genetic variants that confer a significantly increased risk of CRC development, the early identification of individuals and families at greatly elevated risk of CRC should lead to improved clinical management of such individuals and families, in large part via the incorporation of optimal screening and prophylactic surgery approaches and potentially even new chemopreventive agents and regimens.

Early Detection

The results of clinical trials indicate that the colonoscopic removal of larger (greater than 1 cm) adenomas and early CRCs has a major impact on CRC incidence.[8] The development of highly specific and sensitive molecular tests for early detection of CRC is an important goal, given the reduced specificity and sensitivity of current noninvasive tests, such as fecal occult blood testing.[8] If inexpensive and reliable molecular diagnostic tests could be developed to detect the presence of advanced adenomas or early-stage CRCs, such as through the analysis of analytes in the blood or in stool specimens, then such tests might serve an adjunctive role along with more invasive and expensive methods for early detection, such as colonoscopy. Findings from studies of DNA isolated from stool samples of patients known to have CRCs or large, advanced adenomas indicate that stool-based tests for mutant oncogenes and tumor suppressor genes may have utility.[64] More recent stool-based DNA tests incorporate detection of mutant KRAS alleles and DNA methylation of specific sequences, along with hemoglobin quantification, and the results seem potentially quite promising compared to earlier generation stool DNA tests.[65] Some early work analyzing DNA methylation of multiple genes in cell-free DNA in plasma from patients with colorectal cancer and adenomatous polyps suggests the future potential for using a panel of DNA methylation and/or somatic mutation markers for screening.[66] Extensive further studies are needed to clarify whether any plasma-based tests for circulating nucleic acid markers (e.g., DNA hypermethylation and somatic mutations) are strong competitors for the stool-based DNA tests and what the optimal strategies will be for deploying any stool-based and/or plasma-based DNA tests in populations at high risk and/or average risk for adenomas and CRC.

Prognostic and Predictive Markers

In addition to presymptomatic diagnosis (risk assessment) and early detection of tumors, several studies indicate that characterization of the specific genetic alterations in a cancer may provide improved/increased prognostic information about the likelihood of local and distant tumor recurrence. Perhaps among the most robust prognostic markers defined thus far for colorectal cancer are those for the MSI-H phenotype. In particular, this phenotype has been convincingly associated with improved survival in stage II and stage III colorectal cancer patients.[67] Interestingly, the use of 5-fluorouracil (5-FU)-based adjuvant chemotherapy did not appear to show any benefit in survival for patients with MSI-H tumors.[68] In fact, although not a statistically significant result in the initial study, the trend was for poorer survival in 5-FU–treated patients whose tumors displayed the MSI-H phenotype. Some of the data on molecular pathways to CRC and the relationship of the pathways and somatic alterations to prognosis and response to therapies are highlighted in Figure 34-5. Moreover, a number of studies have suggested that oncogenic mutations in KRAS are associated with resistance to EGFR-based therapies,[69] and some recent studies indicate that there is strong biologic selection for the outgrowth of KRAS-mutant CRCs when EGFR blockade is used therapeutically in CRC.[70]

Summary and Future Directions

Molecular genetic studies of colorectal tumors have yielded profound insights into inherited predispositions to colorectal cancer as well its pathogenesis. A relatively limited number of oncogenes and tumor suppressor genes—the KRAS, APC, and TP53 genes, and a few others—have been found to be frequently mutated in CRCs, and intensive studies of the function of these critical genes in normal and neoplastic cell growth continue. The relative significance to the cancer cell phenotype of each of the various inherited and somatic mutations has not been well defined. Comprehensive sequence analyses indicate that a considerable number of additional oncogenes and tumor suppressor genes with roles in the development and progression of subsets of CRC likely exist. Identification of these genes and characterization of their contribution to cancer will be an important, albeit a challenging, task. At present, there is little understanding of

the relationship between dietary and environmental agents associated with increased risk of colorectal cancer and the mutation rate and nature of the mutations that arise in normal and neoplastic cells in the colon and rectum. Only limited insights have been obtained into the true significance and generality of the findings from the clinical correlative studies undertaken to date. Nevertheless, it is clear that further efforts will yield insights into the molecular basis of CRC and can be expected to result in advances in the diagnosis and clinical care of patients with colorectal tumors.

Molecular Pathogenesis of Pancreatic Adenocarcinoma

The most common exocrine pancreatic neoplasm is pancreatic ductal adenocarcinoma, which accounts for more than 95% of all pancreatic malignancies. Other pancreatic malignant neoplasms include acinar cell carcinoma, serous cystadenocarcinoma, mucinous cystadenocarcinoma, intraductal papillary-mucinous neoplasm, osteoclast-like giant cell tumor, solid pseudopapillary carcinoma, and pancreatoblastoma.

It has been hypothesized that the development of pancreatic adenocarcinoma follows progressive stages of neoplastic growth through precursor lesions to adenocarcinoma, similar to the models proposed for colorectal cancer and prostate cancer. The precursor lesions are best defined for invasive ductal adenocarcinoma and have been termed *pancreatic intraepithelial neoplasia* (PanIN). PanINs are characterized by architectural changes manifested by change of the normal cuboidal epithelium to a columnar epithelium, nuclear hyperchromasia and atypia, loss of epithelial polarity, pseudostratification and papillary folding, and eventually to carcinoma in situ and invasive carcinoma (Figure 35-1[1]).

Molecular Alterations in Pancreatic Cancer

Pancreatic carcinogenesis is driven by multiple genetic and epigenetic events, including inactivation of tumor-suppressor genes and activation of proto-oncogenes. Table 35-1 lists the most frequently identified genetic alterations. K-*ras* mutation is believed to be an early genetic event, followed by loss of functional *p16*, p53, SMAD4, and many other changes.

Whole-exome sequencing of 24 different pancreatic cancer specimens at Johns Hopkins University has helped further elucidate some of the "driver" genes in pancreatic carcinogenesis.[2] More than 20,000 genes were sequenced from these tumors, representing 99.6% of the coding genome of pancreatic cancer, and from this 69 sets of genes were identified as being altered in the majority of the 24 specimens. Of these tumors, 67% to 100% had genetic alterations that could be clustered into 12 signaling pathways and processes felt to be pivotal in tumorigenesis (Figure 35-2). The specific genes altered in these pathways varied greatly among samples; however, only one gene in each of these pathways was altered in each tumor. This suggests that there are core pathways that play a role in pancreatic cancer, and that understanding these alterations will provide further insight into pancreatic cancer biology.

Work from the rapid autopsy program in pancreatic cancer that was established by Iacobuzio-Donahue and colleagues at Johns Hopkins University has further identified various genetic subtypes of pancreatic cancer based on clinical and pathologic features.[3] Seventy-six patients underwent rapid autopsy, with 88% having metastatic disease at the time of death. Interestingly, the metastatic burden varied greatly among these patients. Genetic analysis of K-*ras*, p53, and *SMAD4* status demonstrated that patients with a higher volume of metastatic disease more commonly had a loss of *SMAD4* expression. These findings need to be confirmed with additional studies, but they imply that specific molecular features of pancreatic primary tumors influence the behavior of this disease as it progresses over time. This chapter focuses on some of the key molecular changes that characterize exocrine pancreatic cancer.[4]

Events Targeting Signal Transduction Pathways

K-*ras* Mutation

K-*ras* mutations can be detected in approximately 30% of early PanINs and increase in frequency with disease progression. K-*ras* mutations can be identified in nearly 95% of invasive ductal pancreatic adenocarcinomas.[5] The early onset of K-*ras* mutations supports a role in tumor initiation.

Multicomponent analysis of the pancreatic adenocarcinoma progression model using a pancreatic intraepithelial neoplasia tissue microarray.* Mod Pathol. *2003;16:902-912, with permission.)*

Table 35-1 Frequent Molecular Alterations in Pancreatic Adenocarcinoma

Molecular Alteration	Frequency of Event in Exocrine Pancreatic Cancer, %
Oncogene Activation	
K-ras	90
RTK Overexpression	
EGFR	95
HER2	10
Tumor Suppressors	
p^{INK4A}	95
P53	55
$SMAD_4$	50
PTEN	60
Transcription Factor Activation	
NF-κB	67

RTK, Receptor tyrosine kinase.

Transgenic mouse models have provided further evidence that support this notion. A first-generation transgenic mouse model was generated in which K-*ras* was driven by an elastase promoter and the resultant transgene was expressed in pancreatic acinar cells. Transgenic mice bearing this transgene exhibit acinar hyperplasia, acinar-ductal metaplasia, and noninvasive intrapapillary mucinous neoplasia (IPMN). Frequently, these lesions were accompanied by focal dysplasia, fibrosis and/or lymphocytic infiltration, and occasional carcinoma in situ.[6] PDX-1 and p48 are critical transcription factors in early pancreas development, and these genes have been employed in most recent transgenic mouse models. Hingorani and colleagues generated a mouse model in which K-*ras*(G12D) mice are crossed with mice expressing Cre-recombinase through PDX-1 or p48 promoters. The result is a heterozygous mutant mouse, K-*ras*(+/G12D) that recapitulates the temporal sequential development of high-grade PanIN lesions with a small percentage progressing to invasive and metastatic adenocarcinoma.[7] Most lesions in this model appear arrested at a preinvasive stage despite confirmed expression of the K-*ras* gene, suggesting that K-*ras* mutation is not always sufficient to induce progression to invasive pancreatic carcinoma and that other genetic events are required.

To overcome these effects, a second mutation, such as inactivation of tumor suppressor genes, *p16*, *SMAD4*, and/or *p53* may be necessary for the development of invasive/metastatic pancreatic adenocarcinoma. Consistent with this hypothesis, more recent transgenic models have used genetically engineered mice with promoters that are developmentally expressed in progenitors of all pancreatic cell types. For example, genetically engineered mice expressing the mutant K-*ras*(G12D) allele mutation develop focal premalignant

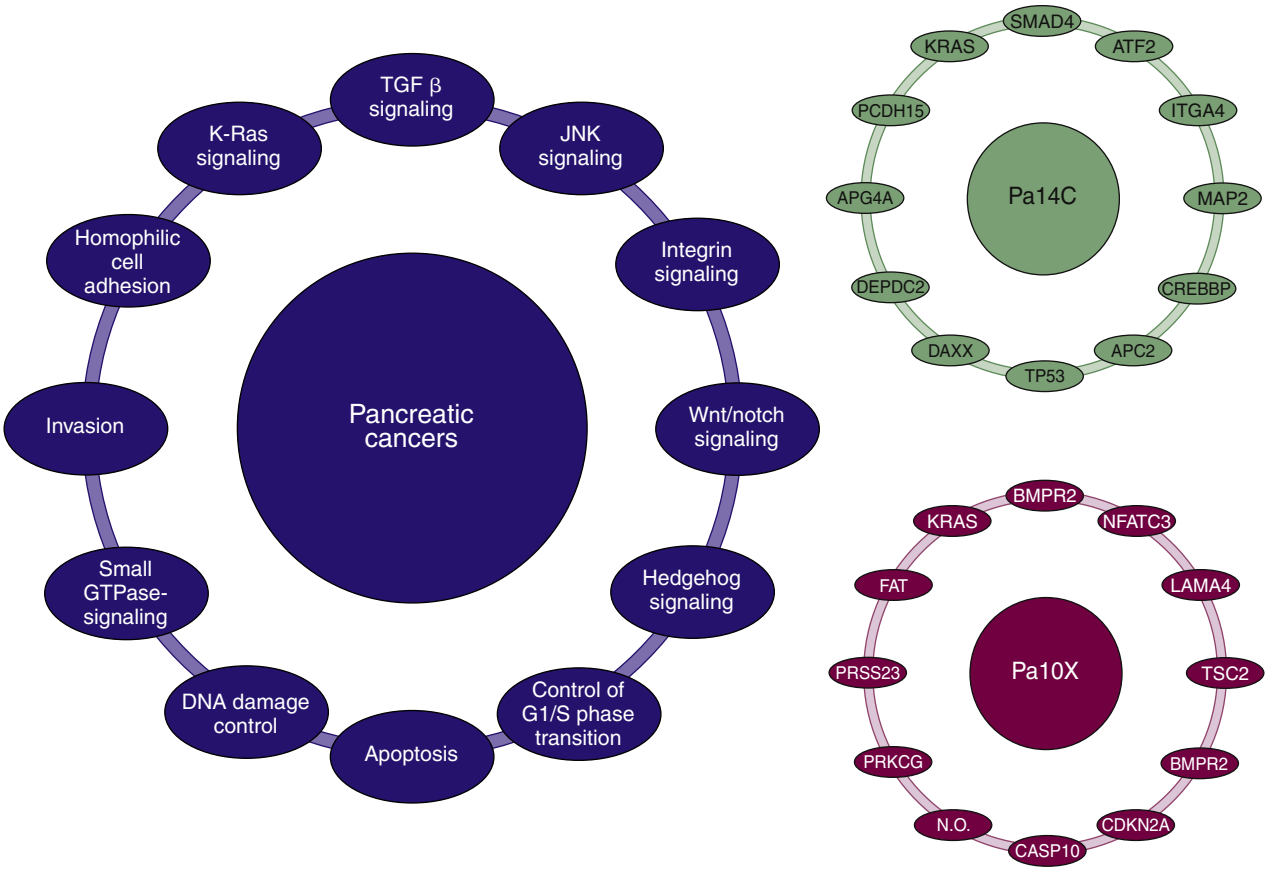

Figure 35-2 Major pathways and processes that are genetically altered in most pancreatic cancers. *From Jones S, Zhang X, Parsons DW, et al. Core signaling pathways in human pancreatic cancers revealed by global genomic analyses.* Science. *2008;321:1801-1806.*

lesions consistent with human PanIN,[8] but a mouse with activation of a mutant K-*ras* allele (*Kras(G12D)*) and deletion of a conditional *Ink4a/Arf* tumor suppressor allele resulted in an earlier appearance of PanIN lesions, and these neoplasms progressed rapidly to highly invasive and metastatic cancers.[9] Similarly, the KPC mouse model was created by interbreeding mice with mutant K-*ras*(G12D) and Trp53(R172H) alleles with the PDX-1-Cre transgenic mice. These mice developed pancreatic adenocarcinoma rapidly and demonstrated a widely metastatic phenotype with a markedly shorter life span.[10] The evolution of these tumors bears striking resemblance to the human disease, possessing a proliferative stromal component and ductal lesions with a propensity to advance quickly. These findings in the mouse provide experimental support for the widely accepted model of human pancreatic adenocarcinoma in which activated K-*ras* serves to initiate PanIN lesions, and other tumor suppressors function to constrain the malignant conversion of these PanIN lesions into lethal ductal adenocarcinoma.

Recently, an inducible, genetically engineered mouse model of oncogenic K-*ras* revealed the integral role that K-*ras* plays in tumor maintenance and metabolism.[11] This mouse model supports the view that advanced pancreatic cancer remains dependent on K-*ras* expression. Furthermore, transcriptomic and metabolomic analyses demonstrated that mutant K-*ras* controls glycolysis by regulating glucose transporters as well as shunting glucose metabolism to anabolic pathways. These findings demonstrate how K-*ras* modifies metabolic pathways in pancreatic tumors to support the high energy requirements of tumor metabolism. These metabolic targets may also serve as novel targets for pancreatic cancer therapy.

Although K-*ras* mutation appears critical to the initiation of human pancreatic carcinogenesis and the initiation and maintenance of pancreatic cancer in genetically engineered mouse models, its role in the maintenance of established human pancreatic adenocarcinoma remains less clear. In addition, although K-*ras* mutation is widely detected in pancreatic adenocarcinoma, its expression can also be detected in nonmalignant conditions such as chronic pancreatitis. Disappointingly, novel therapies that target mutant K-*ras* have not been effective.

Epidermal Growth Factor Receptor

The role for epidermal growth factor receptor (EGFR) and its downstream signaling molecules in tumorigenesis is evidenced by their ability to transform normal cells to a neoplastic phenotype when expressed in mutated, unregulated

forms or when expressed to an abnormally high level. Overexpression of EGFR and its downstream signaling molecules occurs frequently in a variety of human cancers, including pancreatic cancer. A prospective study indicated that EGFR was detectable in more than 95% of patients with advanced pancreatic cancer.[12] In most cases, EGFR is concomitantly expressed with its ligands, EGF or TGF-β. It has been hypothesized that the increased expression of ligand and receptor forms an autocrine loop that constantly stimulates cell proliferation. A study found that pancreatic cancer cell lines display heterogeneous sensitivity to the EGFR inhibitor gefitinib. Three of nine cell lines studied displayed significant sensitivity to pharmacologically relevant concentrations of gefitinib (1 μmol/L) as measured by two independent assays for G_1-S cell cycle arrest.[13] Clinically, erlotinib, an oral small-molecular inhibitor of EGFR, was approved for the treatment of advanced pancreatic cancer based on a study by Moore and colleagues.[14] In this study, 569 patients were treated with either gemcitabine alone or gemcitabine with daily erlotinib. Median overall survival was significantly improved with the addition of erlotinib (6.24 months vs. 5.91 months, $P = .038$). Although the incremental survival benefit is small, it does suggest a role for the EGFR pathway in a subset of patients with pancreatic cancer.

Activation of Nuclear Transcription Factors

Nuclear Factor κB

Nuclear factor κB (NF-κB) is a family of pleiotropic transcription factors that regulate the expression of a spectrum of genes important in growth, oncogenesis, differentiation, and apoptosis. NF-κB proteins are normally sequestered in the cytoplasm in an inactive form through their association with the inhibitor IκBα, which masks the nuclear localization signal (NLS) of NF-κB, thereby preventing its nuclear translocation. NF-κB is activated through activation of the IκB kinase complex (IKK), which phosphorylates IκBα and, as a result of proteasomal degradation, releases NF-κB from the complex, exposing the NLS. Constitutive NF-κB activation has been detected in approximately 70% of pancreatic adenocarcinomas and 9 of 11 human pancreatic tumor cell lines, but not in normal pancreatic tissue.[15]

Many upstream events can potentially affect NF-κB and other transcription factors. PTEN loss in conjunction with oncogenic K-*ras* activates NF-κB and its vast cytokine network. This results in a stromal response and inflammatory infiltration with tumorigenic potential.[16] Furthermore, proinflammatory cytokines such as tumor necrosis factor α (TNFα) and interleukin 1 induce rapid degradation of IκBα, resulting in nuclear translocation of NF-κB and sustained activation of NF-κB mediated through IκBβ. The EGFR-mediated signaling cascade and Ras signaling pathways may induce constitutive NF-κB activity as well.

Once activated, NF-κB mediates transcription of numerous genes encoding growth factors, cytokines, and apoptotic and cell cycle regulators. The expression of the apoptosis inhibitors that are regulated by NF-κB include c-IAP1, C-IAP2, Traf1, Traf2, A20, IEX-1_L, and the Bcl-2 homologues Bfl-1/A1 and Bcl-x. NF-κB also activates the expression of genes that are important in invasion and metastasis, including matrix metalloproteinases, urokinase plasminogen activator, and ICAM-1. Like NF-κB, numerous other nuclear transcription factors such as AP1,[17] Sp proteins,[18,19] and Stat3[20] have been shown to be activated in exocrine pancreatic cancer. In some cases these proteins are being actively targeted for therapy.[21]

Loss of Tumor Suppressors

INK_4A and *ARF* Tumor Suppressors

Studies have demonstrated that the 9q21 locus encodes two important and overlapping tumor suppressor proteins: *p16*(INK4A) and p19(ARF). Loss of *p16*(INK4A) appears to be critical for the development of exocrine pancreatic cancer, occurring in up to 95% of cases.[22] Genetically, loss of the INK4A locus can occur through mutation, deletion, or promoter hypermethylation. Functionally, loss of *p16*(INK4A) allows CDK4/6 to phosphorylate RB, thereby facilitating entry into the S-phase of the cell cycle. The importance of *p16*(INK4A) in pancreatic carcinogenesis has been highlighted by studies of Bardeesy and co-workers, where *p16*(INK4A) mutations cooperate with mutant K-*ras* and *p53* mutations in the development and progression of exocrine pancreatic carcinomas.[23]

p53

The *p53* tumor suppressor is mutated in at least 50% of patients with exocrine pancreatic cancer and appears to be most important during the later stages of tumor progression.[24] Loss of *p53* may also contribute to the drug resistance and chromosomal instability that are characteristic of pancreatic cancer.

SMAD4

SMAD4 is a tumor suppressor gene.[25] Smad proteins belong to a family of proteins that are part of the TGF-β signaling pathway and negatively regulate the growth of epithelial cells. On binding of TGF-β, TGF-β receptor II activates TGF-β receptor I by phosphorylation. TGF-β receptor I in turn activates Smad2 and Smad3. The activated Smad2 and Smad3 form a hetero-oligomer with Smad4. This Smad complex translocates to the nucleus, where it interacts with

DNA directly or indirectly through other DNA-binding proteins, regulating transcription of target genes. *SMAD4*, also known as DPC4 (homozygously deleted in pancreatic carcinoma locus 4), is frequently deleted or mutated in pancreatic carcinoma. Nearly 90% of pancreatic carcinoma cases show loss of heterozygosity for SMAD4, and 30% to 37% have a homozygous deletion of the *SMAD4* region. In addition, there are intragenic inactivating mutations, including nonsense, missense, and frameshift mutations. In total, approximately 55% of pancreatic carcinomas have deletion or an inactivating mutation of *SMAD4*. Loss of *SMAD4* occurs with a frequency of 10% or less in other malignancies, which suggests a specific role for *SMAD4* in pancreatic carcinogenesis.[26] Inactivation of the *SMAD4* gene correlates with loss of expression of its protein and can be monitored during progression of PanINs. In one study, of 188 PanIN lesions examined, Smad4 was not expressed in 31% of the high-grade lesions, whereas all low-grade PanIN lesions had detectable Smad4 protein.[27] This observation is consistent with the notion that K-*ras* is the initiation factor in pancreatic carcinogenesis followed by alterations of a variety of genes, including *SMAD4*, *p16*, *p53*, and others.

SMAD4 may also be a prognostic factor. Using immunohistochemistry, the SMAD4 protein status of 249 pancreatic adenocarcinomas from patients who underwent pancreaticoduodenectomy was examined. The *SMAD4* gene status of 56 (22%) of 249 pancreatic carcinomas was also determined. It was found that patients with pancreatic adenocarcinomas with Smad4 protein expression had significantly longer survival (unadjusted median survival was 19.2 months as compared with 14.7 months in patients with pancreatic cancers lacking Smad4 protein expression; $p = 0.03$). This Smad4 survival benefit persisted after adjustment for other known prognostic factors including tumor size, margins, lymph node status, pathologic stage, blood loss, and use of adjuvant chemoradiotherapy.[28] These findings may be explained by the correlation between *SMAD4* status and metastatic burden described earlier in this chapter.

PTEN

The tumor suppressor gene *PTEN* is known to play a major role in embryonic development, cell migration, and apoptosis.[29] *PTEN* acts as a lipid phosphatase that regulates major signal transduction pathways and effectively inhibits phosphatidylinositol-3-kinase (PI3K)-mediated signaling. *PTEN* mutation, which occurs frequently in many solid tumors, is associated with constitutive activation of the PI3K/Akt pathway, resulting in tumors that are generally resistant to apoptosis. In pancreatic cancer, *PTEN* is not mutated but functionally abrogated through loss of expression. It was found that more than 60% to 70% of pancreatic cancer cell lines and tumor tissues have decreased or loss of expression of *PTEN*.[16,30] The role *of PTEN* in pancreatic carcinogenesis was also studied using a pancreas-specific *PTEN* knockout mouse model.[31] Knockout mice display pancreatic ductal metaplasia as the predominant phenotype and occasional PanINs. These lesions are characterized by progressive replacement of the acinar pancreas with highly proliferative ductal structures that contain abundant mucins and express Pdx1 and Hes1, two markers of pancreatic progenitor cells. A fraction of these mice develop ductal malignancy. Further studies showed that ductal metaplasia resulted from the expansion of centroacinar cells rather than transdifferentiation of acinar cells into ductal cells. These results suggest that *PTEN* actively maintains the balance between different cell types in the adult pancreas and that dysregulation of the *PTEN* pathway in centroacinar cells may contribute to the initiation of pancreatic carcinoma in vivo.

Reactivation of Developmental Biology Pathways

Hedgehog, Notch, and Wnt Pathways

The relationship between developmental pathways for pancreatic organogenesis and pancreatic cancer has recently gained in appreciation.[32] The hedgehog (Hh) family of genes—sonic hedgehog (Shh), Indian hedgehog (Ihh), and desert hedgehog (Dhh)—encode signaling molecules that regulate multiple functions during organ development and in adult tissues. Hedgehog signaling plays an important role in determining the fate of mesoderm in the primitive gut tube, as well as in early pancreatic development and islet cell function. Multiple groups have reported that the hedgehog, Notch, and Wnt developmental cascades might be reactivated during the development of pancreatic cancer through the upregulated expression and/or activation of these complex signaling pathways.[33] The hedgehog signaling molecules, Shh, Ihh, Ptc, Smo, and Gli1, are frequently overexpressed in pancreatic cancer tissues and cell lines as well as in PanIN lesions.[34,35] Specific inhibition of Hh activity in pancreatic cancer cells using cyclopamine can reduce pancreatic cancer cell growth both in vitro and in vivo (Figure 35-3). The reduction of the proliferative activity of pancreatic cancer cells is mediated through G_0/G_1 cell cycle arrest in vitro or induction of apoptosis in vitro and in vivo. Clinical studies with hedgehog inhibitors in pancreatic cancer are currently in progress. Results from these studies will better define the clinical relevance of this target in pancreatic cancer.

Downstream Events

To elucidate additional genetic alterations that can interact with K-*ras* in pancreatic carcinogenesis, the *Sleeping Beauty*

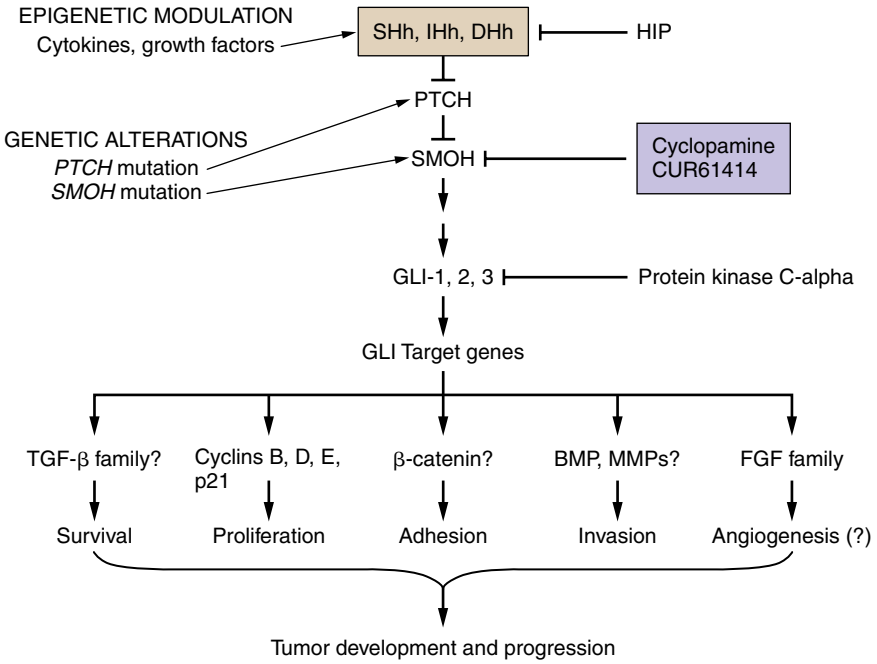

Figure 35-3 Hedgehog signaling, carcinogenesis, and potential therapeutic targets Upregulation of Hh ligands may be mediated by epigenetic events. Mutations in PTCH and SMOH result in activation of hedgehog signaling and are causative in basal cell carcinoma and medulloblastoma. Gli proteins are thought to mediate activation of Hh transcriptional targets potentially important in tumorigenesis, progression, and metastasis. *DHh,* Desert hedgehog; *Gli,* cubitus interruptus-like transcription factor involved in glioma formation; *Hh,* hedgehog; *HIP,* hedgehog interacting protein; *IHh,* Indian hedgehog; *PTCH,* patched; *SHh,* sonic hedgehog; *SMOH,* smoothened. *From Xie K, Abbruzzese JL. Developmental biology informs cancer: the emerging role of the hedgehog signaling pathway in upper gastrointestinal cancers.* Cancer Cell. *2003;4:245-247, with permission.*

transposon system has been recently employed in these K-*ras* mutant mouse models. Mann and colleagues performed a mutation screen using this system and identified 543 potential candidate cancer genes, of which 75 had known mutations in pancreatic cancer.[35] From this, they were able to categorize these genes based on function and clinical outcomes, providing a rich source of information on these potential targets. In a similar experiment, Perez-Mancera and associates used the *Sleeping Beauty* transposon system and identified certain driver mutations that overlapped with those found by Mann and colleagues. These mutations act in concert with K-*ras* to promote progression of pancreatic cancer. Interestingly, introduction of this inducible system also demonstrated a number of candidate genes for the development of pancreatic adenocarcinoma that were unique to this set of experiments.[36] In particular, the X-linked gene deubiquitinase *Usp9x* was inactivated in more than 50% of the tumors. Loss of this gene promoted cellular transformation and correlated clinically with poor prognosis, making it a potential target for future therapeutics.

Desmoplastic Reaction (Tumor Stroma)

One of the morphologic hallmarks of pancreatic adenocarcinoma is its desmoplastic reaction, or tumor stroma. Desmoplastic tissue consists of fibroblasts (the main cellular component), infiltrating inflammatory and immune cells, endothelial cells, and extracellular matrix (ECM) proteins, such as fibronectin and collagen.[37] Pancreatic adenocarcinoma exhibits a threefold increase in interstitial fibrillar collagen (types I and III) compared with the normal pancreas.[38,39] The desmoplastic reaction is also associated with proliferation of fibroblastic cells, which in some cases outnumber tumor cells. Evidence suggests that these are mesenchymal cells, known as stellate cells, which have differentiated into an activated myofibroblastic phenotype. These activated myofibroblasts have been identified as the principal source of type I collagen in the desmoplastic stroma.[40] Pancreatic stellate cells are quiescent and can be identified by the presence of vitamin A–containing lipid droplets in the cytoplasm. In response to pancreatic injury or inflammation, pancreatic stellate cells are transformed from quiescent phenotypes into highly proliferative myofibroblast-like cells that produce ECM proteins. Activated pancreatic stellate cells are observed in abundance in pancreatic tumor tissue, suggesting that they are responsible for the deposition of matrix components and the desmoplastic reaction that surrounds the pancreatic tumor, although pancreatic tumor cells are also capable of producing ECM proteins. Cell culture experiments have demonstrated that pancreatic tumor cells stimulate the growth of pancreatic stellate cells and ECM formation. The growth-stimulating effects are probably mediated by platelet-derived growth factor, fibroblast growth factor 2, and TGF-β1 secreted by pancreatic cancer cells. On the other hand, pancreatic stellate cells can stimulate the growth of pancreatic cancer cells, as demonstrated by an in vivo study in which co-injection of pancreatic stellate cells and tumor cells subcutaneously produced larger and faster growing tumors than injection of pancreatic tumor cells alone. Pathologic examination of tumor tissues showed that an intense desmoplastic reaction in tumors developed after injection of pancreatic stellate cells and tumor cells.[41]

TGF-β is one of the major growth factors stimulating the growth of pancreatic stellate cells. Evidence indicates that the predominant source of TGF-β may be infiltrating granulocytes, although pancreatic tumor cells are capable of producing TGF-β.[42] Immunohistochemical staining of pancreatic tumor tissue showed that isolated cells, mainly located at the invasive edge surrounding cancerous nests, prominently stained for TGF-β. Those cells contain a segmented nucleus and are negative for anti-macrophage (CD68) and positive for anti-granulocyte antibodies, indicating that they are granulocytes.[43]

Hedgehog signaling has also been implicated in the dense stromal reaction associated with pancreatic cancer. A hedgehog paracrine loop between neoplastic cells and stromal cells promotes stromal desmoplasia. The genetically engineered KPC mouse model of pancreatic cancer that closely mimics the tumor-stroma relationship was evaluated to understand the interaction between the hedgehog pathway and the stromal barrier.[44] This model generated poorly vascularized and perfused tumors, similar to those seen in human pancreatic cancer. The researchers showed that drug delivery was impeded in this environment. Furthermore, response to gemcitabine was seen in only a small percentage of the tumors, which closely reflects what is seen clinically with this chemotherapeutic agent. The investigators subsequently demonstrated that a hedgehog pathway inhibitor, IPI-926, could disrupt the stromal barrier and enhance gemcitabine delivery to the tumor, thereby improving cytotoxicity and survival. Although the importance of the stromal barrier in chemoresistance needs to be better understood, stromal cells may be a potential target for future therapies.

Cytokine Production

Pancreatic cancer is known to secrete growth factors that stimulate cancer growth through paracrine or autocrine mechanisms. In addition, pancreatic cancer secretes many cytokines that affect cancer development through interaction with its microenvironment but also have an effect on overall host physiology.[45] Patients with pancreatic carcinoma often have elevated circulating levels of IL-6, IL-10, IL-8, and IL-1RA compared with the levels in healthy individuals.[46] Furthermore, elevation in one cytokine often correlated with elevation in others. For instance, high IL-10 levels were correlated with high IL-8 and high IL-6 levels. It was found that high IL-6 levels in patients with pancreatic carcinoma were correlated with worse survival and weight loss.[47] Further evidence suggested that IL-6 is involved in the development of cachexia, which is a clinical hallmark of pancreatic carcinoma. The pathobiology of cachexia is poorly understood; however, IL-6 and other cytokines may contribute to its development.[48] In one study, gene chip analysis of resected pancreatic cancer tissue including 5600 human genes revealed a significant difference between patients with and without cachexia in only four factors: IL-6, neuropeptide Y Y3 receptor, neurotensin, and islet amyloid polypeptide. IL-6 was significantly overexpressed in pancreatic specimens and elevated in the serum of cachectic patients. A coculture system revealed that pancreatic cancer cells can stimulate IL-6 production exclusively from peripheral blood mononuclear cells derived from cachectic patients, and this effect could be reduced by IL-6–neutralizing antibodies. These data indicate that IL-6 may represent a prominent cachexia-associated factor in pancreatic cancer.

IL-8 expression is also frequently elevated in both serum and pancreatic tumor tissue. IL-8 was originally identified as a neutrophil chemotactic factor. As a member of the CXC chemokine family, IL-8 plays an important role in inflammation and inflammation-induced angiogenesis.[49] It is now known that IL-8 is produced by a variety of normal and tumor cells. It was found that about 80% of pancreatic cancer lines constitutively express high levels of IL-8 in vitro. The role of IL-8 in tumor growth and metastasis has been studied using tumor cell lines, xenograft models, and human tumor tissue.[50] Using orthotopic xenograft models that express different levels of IL-8, it was clearly demonstrated that the level of IL-8 expression correlated with local tumor invasion and distant metastasis. Abrogation of IL-8 expression by antisense oligonucleotides inhibited IL-8 expression and consequently tumor growth and metastasis. In addition, decreased microvascular density of tumor lesions was correlated with decreased levels of IL-8.

Conclusion

Exocrine pancreatic cancer remains a challenging disease. Early diagnosis is infrequent, and therapy has only a limited impact on the survival of patients with advanced pancreatic cancer. Despite these ongoing challenges, our understanding of pancreatic carcinogenesis and the molecular biology of pancreatic cancer has expanded rapidly over the past 5 years. It is anticipated that these advances coupled with the development of biomarkers for early diagnosis will provide the means for early detection of pancreatic cancer and rapidly accelerate the development of effective therapies.

The Molecular Biology of Breast Cancer

Molecular Biology of Breast Cancer Initiation and Progression

Normal Breast Development

Studies of breast cancer from the 1970s to the mid-1990s focused mainly on changes in breast cancer with little regard for normal tissue or development. A lack of knowledge of normal mammary gland development and function limited the understanding of tumor-specific changes. In 1998, the NCI-directed Breast Cancer Progress Review Group stated, "Our limited understanding of the biology and developmental genetics of the normal mammary gland is a barrier to progress."[1] This statement led to a major increase in such studies, with mouse models giving invaluable insights into the molecular biology of both normal mammary gland development and breast cancer.[2] Extensive genetic and molecular analysis of mammary gland development in small and large animals has rapidly defined many of the intricate molecular networks, such as interactions between steroid hormone and growth factors, that are critical for all stages of development and function.[3] Intriguingly, many of these same pathways have major roles in breast cancer development and progression and thus are major therapeutic targets.[4] One of the greatest advances has been the recent identification and characterization of mouse mammary stem cells. Sorting cell populations using cell surface markers has shown that the myoepithelial cell layer contains adult mammary stem cells and that a single cell transplanted into the mouse can produce every epithelial cell of the mammary gland.[5,6] Evidence that mammary stem cell number and function are regulated by hormones such as progesterone and RANK ligand is consistent with the major functions of hormones in mammary gland function and may have implications for human breast cancer development and treatment.[7,8] Intriguingly, BRCA1 has also been found to regulate mammary stem cell number and function,[9] and evidence suggests that BRCA1 cancers may arise from a blockade of progenitor cell development.[10]

Clonal and Stem Cell Hypotheses

There are two main models for cancer initiation and progression, the clonal evolution hypothesis[11] and the cancer stem cell (CSC) hypothesis.[12] In the clonal evolution hypothesis, any cell is susceptible to sporadic random mutation, and a particular combination of mutations allows selection of a cell to evolve to become immortal and tumorigenic. Thus any cell within a tumor can maintain tumorigenesis. In contrast, the CSC hypothesis posits that only stem and progenitor cells, which are a minor fraction of cells within a tumor, can give rise to self-renewing tumor cells. These two hypotheses have major implications for understanding breast cancer development and therapeutic intervention.[13] However, the two hypotheses both rely on major assumptions that are virtually impossible to assess, given the inherent difficulty in tracking cell transformation and differentiation in human breast tumors. Although both hypotheses are often presented as competing ideas, it is highly likely that tumorigenesis is a combination of both models.[14] Future studies will be required to define cancer cell growth and differentiation and better define the role of clonal and cancer stem cell function, as this will likely have major implications for the prevention and treatment of the disease.

Preneoplastic Progression

Advances in molecular biology have had a major impact in the understanding of premalignant progression. Early studies using anatomic pathology and epidemiology revealed that certain premalignant breast lesions such as atypical ductal hyperplasia (ADH) and ductal carcinoma in situ (DCIS) were associated with an increased risk of developing subsequent invasive ductal cancer (IDC).[15] Analysis of changes in DNA copy number and loss of heterozygosity showed that synchronous and metachronous DCIS and IDC showed almost identical genetic changes indicating

that DCIS is the precursor for IDC.[16,17] Consistent with this, the diversity of transcriptomic change and IDC subtypes is similarly found in DCIS.[18] Although 80% to 90% of breast cancer is of ductal origin, a smaller percentage (but still large number of breast cancers) are of lobular origin. These are much less studied; however a similar pattern of progression from atypical lobular hyperplasia to lobular carcinoma in situ to invasive lobular cancer is thought to occur.[19]

Pathophysiology and Risk Factors

Genetics and Family History

Approximately 5% to 10% of breast cancer cases have a familial or hereditary component.[20] Advances in molecular biology have had a profound effect on the diagnosis, risk reduction, and treatment of hereditary breast cancer.[21] Classic genetic mapping and cloning studies identified mutations in two genes, BRCA1 and BRCA2, that account for the majority of hereditary breast cancer. Screening for mutations in BRCA1 and BRCA2 is now standard of care in women with clinical features suggestive of hereditary breast cancer, and recent advances in DNA sequencing permit advanced screening at a reduced price.[22] BRCA1 and BRCA2 are large multifunctional proteins that have a major role in DNA repair.[23] Genetic deletion of these genes in mice and in cells results in genomic instability and sensitivity to transformation.[24] Mutations in other genes such as BRIP1, RAD51, CHEK2, ATM, and PALB2 are also associated with hereditary breast cancer, and importantly, these genes also participate in DNA repair, indicating that loss of DNA repair is a major contributor to familial breast cancer.[23]

The most recent clinically relevant advance to come from understanding the molecular biology of BRCA1 and BRCA2 function has been the finding that cells with mutations in these genes are sensitive to blockade of polyADP ribose polymerase (PARP) and the alternative base-excision DNA repair (BER) pathway.[25] This finding is founded on the genetic precept of synthetic lethality, whereby a cancer cell with wild-type BRCA1 can compensate for inhibition of BER by using the classical homologous recombination pathway. In contrast, cells with loss of BRCA function have no pathway to overcome the loss of BER and thus undergo cell death. The result is a dramatic relative increase in sensitivity to PARP inhibition in cells with loss of BRCA.[26] This concept of synthetic lethality has led to clinical trials showing dramatic responses to PARP inhibitors in cancer patients with germline mutations in BRCA1 or BRCA2.[27]

Hormones

Many risk factors for breast cancer are related to estrogen exposure.[28] These include age at menarche and menopause, parity and age at first-time pregnancy, and breast feeding. The common link among these factors is the number of menstrual cycles that women experience, and thus it is hypothesized that cumulative length of exposure of the breast to sex hormones may increase risk of breast cancer. These data are supported by evidence that surgical or pharmacological suppression of ovarian function significantly reduces breast cancer risk,[29] and prolonged postmenopausal use of combined estrogen and progesterone therapy increases risk.[30]

Environment

Although there are clear geographic differences in the rate of breast cancer, tying these different rates of breast cancer to specific environmental exposures (defined broadly) has been challenging. For example, there is a strong association between risk of breast cancer and fat intake across countries[31]; however, direct proof that fat intake correlates with risk of breast cancer has been challenging to obtain.[32] A recent comprehensive review by the Institute of Medicine reported that alcohol consumption, postmenopausal weight gain, smoking, lack of exercise, and hormone replacement therapy are associated with increased risk of breast cancer.[33] There is also evidence for increased risk with exposure to benzene, 1,3-butadiene, ethylene oxide, chemical pollutants in vehicle exhaust, gasoline fumes, and smoking. Recent studies have begun to link risk factors to specific subtypes of breast cancer and potentially highlight the different etiologies of breast cancer subtypes.[34] A greater understanding of the molecular biology of breast cancer initiation and progression is likely to provide greater clarity about breast cancer risk factors.

Molecular Subtyping

Histopathology and Molecular Pathology

Multiple lines of evidence demonstrate that breast cancer is not a single disease, but a mixture of different subtypes. Within these subtypes, there exists further significant diversity. By histopathology, the majority of breast cancers are invasive ductal cancer (IDC) (about 75%), invasive lobular cancer (ILC) (about 10%), or mixed IDC/ILC (about 5%). Minor populations are mucinous, tubular, medullary, papillary, and metaplastic breast cancers.[19] Histopathology

has been very useful to define these subtypes and then further assess tumor aggressiveness by measures such as tumor grade.[35] Molecular analysis of breast cancers allows further subclassification of the major subtypes, such as IDC, into subtypes with different outcome. The first biomarker, initially discovered and studied more than 40 years ago, was the estrogen receptor alpha (ER). ER-positive breast tumors generally have a somewhat better prognosis, and patients with these tumors are candidates for antihormone therapy.[36] ER-positive tumors can be further subdivided by levels of the estrogen-inducible gene progesterone receptor (PR), with loss of PR indicating lack of ER action and poor outcome.[37] The second subclassification came with the discovery of ErbB2 (HER2) amplification. Approximately 20% of IDC have amplification and overexpression of HER2. Patients with HER2-positive tumors have a poorer natural history, but many respond to anti-HER2 therapy.[38] Tumors that lack expression of ER, PR, or HER2 have been termed *triple-negative breast cancer* (TNBC). There has been intense study of this subset of breast cancer in the past 10 years as they have poor outcome and are insensitive to targeted therapies such as antihormonal or anti-HER2 therapy.[39]

Transcriptomics

The ability to undertake simultaneous measurement of thousands of genes, via microarray technology, allowed a fundamental shift in the study of the molecular biology of breast cancer.[40] The information provided a much finer delineation of breast cancer subtypes than that afforded by histopathology, and also gave insight into the biological underpinning that highlights potential new therapeutic targets. Perou and colleagues performed the first microarray analysis of human breast cancer and identified a set of "intrinsic" genes that defined five major subtypes (luminal A, luminal B, normal-like, HER2-enriched, and basal-like) with different outcomes.[41] These results have remained highly reproducible.[42] A major breakthrough in these studies was the push to make these large datasets publicly available,[43] a move that has greatly facilitated breast cancer research via in silico analysis. Many resources are available for the analysis of large publicly available datasets of breast cancer (e.g., Oncomine.org; gene expression omnibus GEO—www.ncbi.nlm.nih.gov/geo).

From these analyses has come the understanding that luminal tumors express ER and ER-regulated genes. Luminal A tumors tend to have low expression of proliferation genes and have a very good prognosis,[44] whereas Luminal B tumors have lower levels of ER and ER-regulated genes, exhibit markedly higher proliferation and mutation of p53, and have a worse prognosis.[45] Some luminal B tumors are ER+/HER2+. The HER2+ subclass contains tumors that have high levels of HER2 and HER2-regulated genes. A recent integrated analysis of copy number aberrations (CNA) and gene expression showed that the HER2 subtype is largely regulated by the amplification of HER2 (in a cis manner) rather than amplification of other genes that act to increase HER2 expression (in a trans manner).[46]

A large subset (approximately 80%) of TNBC express genes associated with basal/myoepithelial breast cells (such as cytokeratin 5) and has been termed *basal-like breast cancers*. It should be noted that basal-like tumors are not synonymous with TNBC but represent a subset of TNBC.[47]

The normal-like classification of breast cancer is controversial. These tumors account for approximately 5% to 10% of breast cancer and show gene expression profiles similar to normal breast tissue or fibroadenomas such as adipose genes. Many investigators believe that the normal-like subtype is an artifact of low tumor cellularity. Indeed, studies using gene expression profiling of microdissected breast cancer cells do not identify the normal-like subtype.[48] Similarly, gene expression profiling of breast cancer cell lines also does not identify normal-like cell lines.[49] However, the identification of this subtype does highlight the issue of tumor heterogeneity and cellularity when performing microarray analysis of breast cancers. Although tremendous advances have been made in microarray profiling, most of these profiles represent an average of gene expression across multiple cell types within a tumor (including leukocytes, adipose, vascular cells, etc.). It is likely that new approaches, such as single cell transcriptomic profiling,[50] will provide a new level of detailed insight into breast cancer molecular biology.

Although microarray technology allowed genome-wide analysis of mRNA levels, recent advances in massively parallel sequencing of RNA are giving new insight into not only RNA levels, but also changes in RNA splicing and polyadenylation usage[51,52] and noncoding RNAs[53] in breast cancer. In addition, sequencing of two ends of RNA allows the identification of neo-RNA fusion genes that are generated by fusion of two RNAs. A recent comprehensive analysis by paired-end RNA-sequencing of 89 breast cancer cell lines and tumors identified 384 expressed fusion RNAs. However, only one (SEC16A-NOTCH1) was found in more than one tumor.[54] Several genes appeared fused multiple times, but often with different partner genes. Overall this study highlighted the molecular diversity of human breast cancers and the complexity of targeting specific mutations.

Genomics

Genomic instability, the change in DNA structure and copy number, is a hallmark of virtually all breast cancers. Early studies of genomic change relied on cytogenetics and

fluorescence in situ hybridization (FISH) and revealed large chromosome changes and discrete copy number changes such as amplification of HER2. Microarray technology transformed the study of genomics by allowing genome-wide study using comparative genomic hybridization.[55] Genomic instability permits changes in multiple genes required for cancer progression. Consistent with this, analysis of DNA copy number aberrations (CNA) during breast cancer progression shows a large increase in such changes at the transition from ADH to DCIS.[56] Early studies identified recurrent oncogene-containing amplifications such as 8q12 (FGFR1), 8q24 (myc), 11q13 (CCND1), and 17q21 (ErbB2). However these amplified regions often contain numerous genes that may play a role in breast cancer.[56]

Several large studies of CNA in breast cancer have identified three major broad types.[57] The first type, termed *simple*, exhibits few CNA and tends to have gain (1q and 16p) or loss (16q) of whole chromosome arms. This form of CNA tends to be associated with luminal A tumors with good outcome. The second type, termed *amplifier* or *firestorm*, is associated with focal high levels of amplification within a background of other complex gains and losses. A third type, termed *complex* or *sawtooth*, is associated with numerous low-level amplifications and losses across the genome. This pattern is most common in the aggressive TNBC and is associated with TP53 mutation. Many public resources of CNA in breast cancer are available in user-friendly formats such as Tumorscape (www.broadinstitute.org/tumorscape) or the UCSC Cancer genome browser (https://genome-cancer.ucsc.edu).

Several large consortia, including the Cancer Genome Atlas (TCGA), the International Cancer Genome Consortium (ICGC), and the Molecular Taxonomy of Breast Cancer International Consortium (METABRIC), are examining genome-wide CNA and gene expression changes in large numbers of breast cancers. METABRIC recently reported a comprehensive analysis of 2136 cases of breast cancer and examined how CNA alters transcriptional profiles, in a cis- or trans-acting manner.[46] Interestingly, they found that the HER2 and basal-like subtypes of breast cancer were most associated with the cis effects of CNA, implying that the genes that undergo CNA themselves tend to be drivers of the diseases rather than the gene products acting in a trans manner to activate other drivers of the disease. Perhaps most striking was the initial observation that an integrated analysis of both CNA and gene expression levels led to the identification of 10 subtypes of breast cancers, each having different outcomes.[46] It will likely be many years before the full implication of datasets such as METABRIC are fully understood and translated into clinical care.

While assays for measuring CNA have rapidly advanced, analysis of structural DNA changes, such as inversions and translocations, has lagged behind. Indeed, high-throughput methods have only recently become available with the advent of massively parallel sequencing.[58] Sequencing of paired ends of DNA allows determination of genomic structure. The initial comprehensive analysis of the MCF-7 cell line revealed numerous structural changes including translocations and novel fusion genes.[59] Paired-end sequencing of other human breast cancers and cell lines unveiled patterns of translocations, and the greatest number of events was seen in aggressive TNBC.[60] Sequencing of cell lines has provided many new insights, one of the most intriguing being chromothripsis,[61] in which cancer genomes seem to have undergone a single catastrophic damaging event with numerous mistakes in the repair, resulting in a large-scale rearrangement of part of the genome. Although it is currently unclear how these complex rearrangements are generated, it is possible that they are due to replication-induced DNA damage and repair.[62]

Determination of somatic base-pair mutations in candidate genes has been undertaken in breast cancers for many years; however, it is only recently that a comprehensive catalog has been obtained via massively parallel sequencing.[63-66] A comprehensive database of somatic mutations in breast cancer can be found at COSMIC, the Catalog of Somatic Mutations in Cancer (sanger.ac.uk/genetics/CGP/cosmic). Similar to other cancers, TP53 is commonly mutated (23% of breast cancers), but the most frequently mutated gene is PIK3CA, the catalytic subunit of phosphatidylinositol-3′-kinase.

Multiplexed Genomic and Transcriptomic Prognostic Tests

A dozen years have passed since the initial description of the five intrinsic subtypes of breast cancers,[41] and many thousands of breast cancers have been subjected to microarray analysis. Although these studies have defined the transcriptional landscape of breast cancer and identified new therapeutic targets,[67] translation of this work to clinical use has been slow.[40] The first multigene assay to be used clinically was OncotypeDx (Genomic Health Inc, Redwood City, Calif). This is a RT-PCR test, based on the measurement of expression of 16 genes and 5 reference genes in ER+ node-negative disease, which can predict risk of recurrence on tamoxifen.[68] More importantly, the test reclassifies standard National Comprehensive Cancer Network guidelines (which place most breast cancer patients at high risk of recurrence) and results in identification of patients with disease with a low risk of recurrence and little benefit from adjuvant chemotherapy. A second microarray-based approach (Mammaprint) for determining breast cancer prognosis is based on the measurement of the expression of 70 genes (Agendia Inc, Irvine, Calif). It classifies breast cancers as either low or high

Table 36-1 Breast Cancer Multiplexed Gene Tests

FDA status	Unknown	Exempt	IVDMIA 510(k)-cleared	Unknown	Unknown	Unknown	Unknown	Unknown

This table is not comprehensive, but provides an example of breast cancer multiplexed gene tests that are currently in development or have been commercialized. The type of sample, number of genes, indication, and ability to predict therapy may change based on commercial development. Prediction of response to therapy has been shown for many of the tests; however, for some of the tests this may not be used or approved as an indication for the test.
Chemo, Chemotherapy; *ER*, estrogen receptor; *FDA*, U.S. Food and Drug Administration; *FFPE*, formalin-fixed paraffin-embedded; *IVDMIA*, In Vitro Diagnostic Multivariate Index Assay; *RT-PCR*, reverse transcriptase polymerase chain reaction; TAM, tamoxifen.

risk for recurrence[69,70] and predicts for benefit from chemotherapy only in the high-risk group.[70] Both OncotypeDx and Mammaprint assays have been validated only in retrospective analyses and are currently under investigation in prospective clinical trials including TAILORx, RxPONDER, and MINDACT. Biotheranostics has developed a breast cancer index assay based on the measurement of seven genes, which, like OncotypeDx, classifies breast cancers as low, intermediate, or high risk and predicts therapeutic benefit from tamoxifen.[71] Also, the initial "intrinsic gene list" identified by Perou and colleagues has been reduced to a 50-gene test (PAM50), and this test has recently been shown to predict risk of recurrence in ER+ node–negative breast cancer.[72] Examples of multigene tests and their application are given in Table 36-1. More recent studies are focusing less on determining the prognosis of breast cancer and more on developing assays for predicting benefit from therapeutic agents. Thus, there are now "gene expression signatures" of estrogen response, serum action, and IGF signaling, many of which may predict benefit from targeted agents.[73]

Despite extensive analysis of DNA changes (copy number, somatic mutation, and structural change) in breast cancer, relatively few multianalyte tests are currently available.

Molecular Basis of Breast Cancer

ER Action

The steroid hormone estradiol signals through two related receptors, ERα and ERβ.[74] Data from in vitro studies and mouse models, as well as studies using clinical specimens, have provided concrete evidence that ERα is the dominant regulator of both normal breast development[3] and breast cancer.[75] ERα (referred to hereafter as ER) is a nuclear hormone receptor that binds the estradiol with very high affinity. Ligand binding changes receptor conformation to allow binding to enhancer elements in DNA. Initial studies suggested that these DNA elements were close to promoters and provided a simple model of how ER directly affects promoter activity. However, advances in genome-wide DNA binding (e.g., ChIP-seq), chromatin conformation (e.g., Chia-PET), and RNA transcription assays (e.g., GRO-seq) have shown that ER action is much more complicated than previously thought.[76,77] ER often binds hundreds of kilobases upstream of promoters to regulate transcription via looping of large segments of DNA. ER's action is regulated through its interaction with numerous co-regulatory proteins, which can either activate or repress its transcriptional activity.[78] Several of those co-regulators have been shown to be associated with endocrine resistance, such as SRC1,[79,80] SRC3,[81,82] and NCoR1.[83]

Although ER clearly functions as a classical ligand-dependent DNA-binding transcription factor, it may also function in an extranuclear nongenomic manner.[84] This is, at least in part, mediated via growth factor activated signaling pathway, ultimately leading to phosphorylation of ER, especially at S118, S167, and S305, and subsequent recruitment of co-regulators and DNA binding.[85] Although such a role is mechanistically attractive, especially with regard to ER being associated with metastatic processes through interaction with SRC, PI3K, and MAPK signaling, the clinical relevance of ER nongenomic action in breast cancer is controversial. A well-controlled large study using more than

3000 clinical specimens showed that cytoplasmic ER expression occurs at a very low incidence rate of less than 2%.[86] More recent genome-wide studies of ER action are revealing new insight into ligand-independent action. For example, ER ChIP-seq of breast cancer cells treated with EGF identifies an ER cistrome that mediates regulation of genes involved in endocrine resistance in HER2-overexpressing tumors[87] and has also demonstrated critical roles for the chromatin pioneer factor, FoxA1.[88]

Molecular biology studies of the structure and function of ER have had a profound effect on the development and use of anti-ER therapies for breast cancer. The first anti-ER ligand, tamoxifen, was originally developed as a contraceptive but never proved useful.[89] However, several studies showed that tamoxifen was highly successful as a targeted antihormonal therapy for women with all stages of ER-positive breast cancer.[90] Tamoxifen binds the ER, but does not activate gene expression (and indeed it represses many genes). A crystal structure of the ER showed that estradiol binding alters the conformation of the protein to cause movement of helix 12 and allow coactivators to bind ER and increase transcription.[91] Tamoxifen, in contrast, does not cause this molecular switch, in part explaining its antagonistic activity. However, tamoxifen exhibits tissue-specific activity and can be an agonist in tissues such as the uterus and bone, leading to its identification as a selective estrogen receptor modulator (SERM) that exhibits mixed agonist/antagonist activity.[92] Unfortunately, tumors can often exploit the agonist activity of tamoxifen and thus reduce its clinical effectiveness. Many molecular mechanisms for the well-studied area of tamoxifen resistance have been deciphered, with the most studied being increased growth factor signaling.[75]

Another approach to inhibiting ER action is to block production of estradiol via inhibition of the enzyme aromatase in postmenopausal women or suppression of ovarian steroid production (by luteinizing hormone releasing hormones or LHRH agonists) in premenopausal women.[93] The advantage of this method over tamoxifen is that neither aromatase inhibitors nor LHRH agonists show agonist activity. Indeed, aromatase inhibitors have been shown to be superior to tamoxifen for the treatment of early and advanced ER-positive disease in postmenopausal women.[93] Interestingly, however, the metabolism of steroid hormones is complex, and other metabolites may activate the ER to circumvent the loss of activity due to a reduction in estradiol.[94,95] A recent whole-genome sequencing of breast tumors before neoadjuvant aromatase inhibitor therapy has revealed mutations in primary breast cancer that map to several signal transduction pathways, and increased mutation of the TP53 pathway (38%) in aromatase inhibitor–resistant tumors compared to those that responded to therapy (17%).

Perhaps the most logical approach to blockade of ER action in breast cancer would be the total removal of ER protein such that no ligand-dependent or independent activation could occur. ICI 182780 (fulvestrant, AstraZeneca) is a selective estrogen receptor downregulator (SERD) that is similar in structure to estradiol, binds ER with the same affinity, and leads to rapid receptor degradation.[96] The actual mechanism of degradation is unknown but likely involves the proteasome. Clinical development of fulvestrant has been hampered by the fact that it requires regular intramuscular injection, and early trials likely used doses (250 mg) that were not sufficient to saturate ER. A recent Phase II trial comparing first-line fulvestrant (500 mg) to the aromatase inhibitor, anastrozole, showed superiority in time to tumor progression for fulvestrant.[97] Furthermore, anastrozole plus fulvestrant was recently reported to be superior to anastrozole alone.[98] Further delineation of the molecular mechanisms whereby ER activates gene transcription, and how SERMs and SERDs inhibit ER activity, will likely lead to the development of improved anti-ER therapies that minimize the emergence of therapeutic resistance.

Chromatin Remodeling

It is now commonly accepted that epigenetic changes such as DNA methylation, chromatin changes, and regulation of gene expression by miRNA play a role in carcinogenesis in many tumors, including breast cancer.[99] Aberrant DNA methylation has been studied extensively, both at the single gene and genome-wide levels. A number of genes have been reproducibly shown to be methylated in breast tumors, such as RASSF1A, PR, RARβ, CCND2, and BRCA1. However, at this point, no predictive or prognostic marker includes measurement of methylation.[100]

Unexpectedly, sequencing studies of tumors have revealed very frequent somatic mutations in chromatin-modifying genes, including in the family of ATP-dependent chromatin remodeling proteins, enzymes modifying post-translational modification of histones, and histone variants. For example, mutations in the H3K4 methyltransferase MLL are among the most frequent in breast tumors.[63,101] Other histone-modifying enzymes are highly expressed in aggressive breast tumors, such as the H3K27 methyltransferase EZH2, which was also shown to contribute to the expansion of progenitor cells.[102]

It is therefore not surprising that there are many efforts to target deregulated epigenetic pathways in breast cancer. In contrast to hematopoietic malignancies, there are currently no approved breast cancer epigenetic therapies. However, trials are ongoing with drugs that inhibit HDACs and DNA

methyltransferases as well as efforts to target other histone-modifying enzymes, such as EZH2.[99]

Growth Factors

Growth factors play a major role in both mammary gland development and breast cancer and have been studied intensely as therapeutic targets.[103] The best studied growth factor receptor in breast cancer is HER2 (ErbB2). HER2 is amplified in approximately 20% of breast cancers, and its amplification and/or overexpression is associated with poor prognosis.[104] HER2 is a member of the larger HER/ErbB family consisting of epidermal growth factor receptor (EGFR/ErbB1/HER1), ErbB3/HER3, and ErbB4/HER4. Amplification of HER2 is thought to cause increased homo- and heterodimerization with other family members, resulting in constitutive activation of downstream signaling pathways leading to cancer cell growth and survival. The identification of this dominant activating oncogene led to one of the first examples of bedside-to-bench translational research with the development of monoclonal antibodies that block HER2. Trastuzumab (Herceptin, Genentech, South San Francisco, Calif) is a humanized monoclonal antibody that binds the extracellular domain of ErbB2. Trials of trastuzumab plus chemotherapy as first-line therapy in advanced breast cancer improved response rate, time to progression, and overall survival.[105] Similarly, adjuvant use of trastuzumab significantly improves disease-free and overall survival.[106]

Despite major advances in the management of HER2-positive breast cancer with trastuzumab, de novo and acquired resistance is common. This has led to a number of alternative strategies to target ErbB2.[107] Pertuzumab (Perjeta, 2C4; Genentech, South San Francisco, Calif) is a monoclonal antibody that, like trastuzumab, binds the extracellular domain of ErbB2. However, it binds a different part of the domain that is critical for dimerization of ErbB2 to ErbB3. Preclinical and early clinical trials suggest that pertuzumab is active in trastuzumab-resistant breast cancers and can also enhance trastuzumab efficacy when given in combination. This was recently demonstrated in the Phase III CLEOPATRA trial in women with advanced HER2-positive breast cancer[108] and is under further study in the MARIANNE, NEOSPHERE, TRYPHAENA, and APHINITY trials.

Therapeutic drugs targeting the ErbB family tyrosine kinase domains have been developed.[109] Lapatinib (Tykerb, GlaxoSmithKline, London, UK) is a small-molecule reversible inhibitor of both ErbB1 and ErbB2 kinase domains and has been approved for the treatment of HER2+ metastatic breast cancer. Neratinib (HKI-272, Pfizer, New York, NY), in contrast to lapatinib, is an *irreversible* inhibitor of all ErbB kinase domains. Similar to pertuzumab and lapatinib, neratinib has documented activity in trastuzumab-resistant preclinical models and clinical trials and is currently in multiple trials to define its role in the treatment of HER2+ breast cancer.

An alternative and novel approach to strictly targeting HER2 activity is trastuzumab emtansine (T-DM1; Roche, South San Francisco, Calif), a conjugation of an antimicrotubule agent (maytansine) to trastuzumab. Importantly, a comparison of T-DM1 to trastuzumab/docetaxel for first-line treatment of metastatic breast cancer showed both improved response (response rate and investigator-reported progression-free survival) and reduced toxicity for T-DM1.[107]

Growth factors are major regulators of mammary gland development, but they act via an intricate regulation by the steroid hormones estrogen and progesterone.[2] Intriguingly, normal steroid receptor positive mammary epithelial cells do not proliferate in response to steroid hormones, but they send a paracrine signal (most likely IGF and other growth factors) to neighboring cells that then proliferate.[110] This paracrine regulation is thought to be critical for the branching morphogenesis of the developing mammary gland. The intricate interaction between steroid hormones and growth factors is likely one of the first pathways to become dysregulated in tumorigenesis, as transcriptomic analysis of early premalignant lesions found elevation of both ER and growth factor (EGF and IGF) signaling.[111] Crosstalk between steroid hormones and growth factors is apparent not only in normal mammary development, but also in breast carcinogenesis. For the EGFR/ErbB2 pathway, increased hormone signaling is generally associated with reduced signaling. For example, there is a negative correlation between ErbB2 and ER levels, and ER is a repressor of ErbB2 levels via PAX2.[112] In contrast, for the IGF/insulin pathway, ER and PR are both positive regulators, with estrogen in particular upregulating ligand, receptor, and downstream signaling component expression.[113] Although IGF-IR and ER are highly correlated in breast tumors, and thus IGF-IR correlates with good prognosis, recent studies examining IGF-IR specifically in TNBC have shown that it correlates with poor outcome and may be a good therapeutic target.[114]

Experimental evidence from breast cancer cell lines has suggested that a major mechanism of resistance to antihormonal therapy is via upregulation of growth factor receptor pathways.[75] However, until recently, results from clinical trials testing this hypothesis have been disappointing, with relatively little benefit from adding anti-EGFR or anti-IGFR therapies to antihormonal therapy. However, in one promising trial, targeting of a signaling molecule mTOR, which is downstream of both IGF-IR and EGFR, showed that the

combination of an mTOR inhibitor (everolimus) and an aromatase inhibitor was superior to the aromatase inhibitor alone in the treatment of hormone-resistant advanced breast cancer in postmenopausal women.[115]

Angiogenesis

Tumors are generally avascular when they first start to grow; however, as the tumor progresses and increases in size, the distance of cells to blood vessels and nutrients necessitates the new formation of blood vessels (angiogenesis). This angiogenic switch is seen as a critical barrier to tumor growth.[116] Preclinical research has identified many critical factors in the angiogenic switch, and blocking this switch with inhibitors of vascular endothelial growth factor (VEGF) has shown benefit in many preclinical models. Clinical testing of VEGF inhibitors (monoclonal antibodies and tyrosine kinase inhibitors) in addition to chemotherapy for women with advanced breast cancer has shown improvements in progression-free survival but little or no effect on overall survival.[117] Although it was believed that targeting the host blood supply would circumvent cancer cell intrinsic mechanisms of resistance, resistance to VEGF inhibitors is rapid and via multiple mechanisms.[118] Future use of angiogenesis inhibitors in breast cancer will likely require the identification of biomarkers of response to optimize clinical benefit.

Conclusion and Outlook

Investigating the molecular biology of breast cancer has given tremendous insight into the development and evolution of the disease and highlighted pathways for therapeutic intervention. However, as techniques for interrogating the molecular underpinnings of breast cancer have allowed deeper insight, it is clear that the levels of molecular alteration are much greater than previously anticipated. Indeed, although tumors clearly share certain features (such as ER+ and/or ErbB2+), no two tumors are the same, and the difference in their evolution and expansion provides great challenges for targeted therapies. It is anticipated that the next generation of research will likely tackle two main areas: the heterogeneity of molecular alterations in tumors and the clonal origin of breast cancer. Answers to these two questions are likely to have broad implications for the prevention and treatment of breast cancer.

Molecular Pathogenesis of Ovarian Cancer

Ovarian cancer is neither a common nor a rare disease. In 2013 in the United States, 22,240 women were diagnosed with ovarian cancer and 14,030 died from this malignancy.[1] The lifetime risk for a woman to develop ovarian cancer is approximately 1 in 70. A fraction of ovarian cancers can arise from germ cells (3%) or from granulosa-theca cells (7%), but approximately 90% of ovarian cancers arise from epithelial cells. Traditionally, epithelial ovarian cancers have been thought to develop from a single layer of flattened cells that cover the ovary or, more frequently, that line cysts immediately beneath the ovarian surface.[2] Neoplasms with similar morphology and behavior can, however, arise from fallopian tube, endometriosis, endosalpingiosis, and the peritoneum.[3] Recent studies have implicated the fimbria of the fallopian tube as the site of origin for as many as 30% of high-grade serous epithelial ovarian cancers, particularly in women with germline mutations of *BRCA1* and *BRCA2*.[4]

Advancing age, an increased number of menstrual cycles, and a positive family history are associated with an increased risk for ovarian cancer, whereas oral contraceptives reduce risk in later life by as much as 50%. Approximately 85% to 90% of epithelial ovarian cancers are sporadic and arise in the absence of a family history of the disease, often associated with spontaneous somatic mutations of *TP53*.[5] Among the 10% to 15% of familial ovarian cancers, germline mutations of *BRCA1* and *BRCA2* are found in the majority, associated with a family history of breast, prostate, and pancreatic cancers. In carriers of germline *BRCA* mutations, TP53 is somatically mutated during malignant transformation and the wild-type BRCA allele is lost, resulting in survival during telomeric crisis, genetic instability, and a homozygous deficiency in homologous DNA repair. Ovarian cancers can also occur in Lynch syndrome families with germline abnormalities in DNA mismatch repair genes, associated with colon and uterine cancers. Rare cases of ovarian cancer are encountered in Li-Fraumeni kindreds with germline mutations of TP53, associated with sarcomas and brain tumors. The lifetime risk of developing ovarian cancer depends on the genetic defect: *BRCA1* (30% to 60%), *BRCA2* (15% to 30%), *HNPCC* (12%), and *TP53* (<1%). Importantly, modifiers of the effects of *BRCA1* and *BRCA2* that can improve the ability to predict risk are being rapidly identified and characterized. Other lower penetrance susceptibility genes such as Rad51C and Rad51D likely contribute to familial predisposition to ovarian cancers.

Epithelial ovarian cancers exhibit a distinctive pattern of progression and metastasis (Figure 37-1). Initially, ovarian cancer cells proliferate within the walls of cysts, invade underlying stroma, and enlarge the ovary, forming a pelvic mass. Although epithelial ovarian cancers can spread hematogenously or through lymphatics, the most frequent route of metastasis is over the surface of the peritoneum. In the absence of anatomic barriers, ovarian cancers that arise from the surface of the ovary or the lining of the fallopian tube can spread through the peritoneal cavity before a palpable mass is formed. Ovarian cancer frequently spreads throughout the pelvis and to the right hemidiaphragm, the bowel mesentery, and the omentum. Multiple nodules of metastatic cancer can stud the peritoneal surface and form dense fibrous adhesions that bind adjacent loops of intestine, producing mechanical obstruction (Figure 37-2). Ovarian cancer can also invade the retroperitoneum, affecting the myenteric plexus and producing paralytic ileus. Intestinal obstruction from either mechanism produces nausea, vomiting, and malnutrition. Ovarian cancer patients generally die from inanition, often complicated by intercurrent infection. As control of intra-abdominal metastasis improves, other sites including the lung and brain are becoming more prevalent.

Another distinctive feature of ovarian cancer is the formation of ascites fluid that contains leukocytes, mesothelial cells, and a varying fraction of tumor cells. Accumulation of ascites fluid produces abdominal distention, which can be the initial symptom of disease. Fluid generally drains from the peritoneal cavity through diaphragmatic lymphatics (see Figure 37-1), which can become occluded by tumor cells, preventing outflow.[6] In addition, tumor angiogenesis produces incompetent vessels that permit greater efflux of proteinaceous fluid from the vascular compartment into the

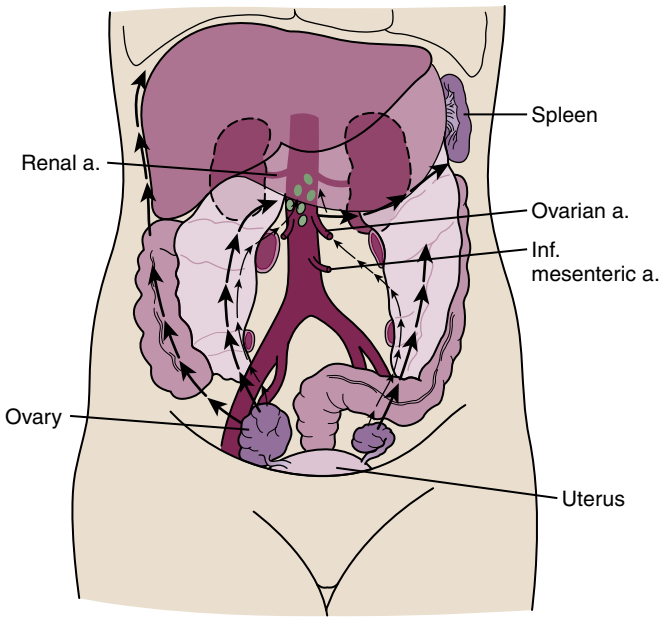

Figure 37-1 Intra-abdominal spread of ovarian cancer. Ovarian cancers metastasize through lymphatics to lymph nodes at the level of the renal hilus, through blood vessels to the liver and other organs, but most frequently over the surface of the parietal and visceral peritoneum from pelvis to diaphragm. *Blast Jr RC, Mills GB. Molecular pathogenesis of epithelial ovarian cancer. In: Mendelsohn J, Howley P, Israel M, Gray JW, Thompson CB, eds. The Molecular Basis of Cancer, 3rd ed. Philadelphia, Pa: Saunders-Elsevier; 2008:441-454.*

Figure 37-2 Intraperitoneal metastases from epithelial ovarian cancer studding the peritoneal surface.

peritoneal cavity. Ovarian cancer cells can produce copious amounts of vascular endothelial growth factor/vascular permeability factor (VEGF/VPF) that is both an angiogenic factor and a permeability-enhancing factor.[7] Neutralization of VEGF with monoclonal antibodies can block ascites formation in murine transplant models[2] and in the clinical setting.[2]

Given the location of the ovaries within the pelvic cavity and the difficulty in assessing abnormalities on routine gynecologic examination, the disease is diagnosed only after it has metastasized in approximately 80% of cases. Ovarian cancer is often described as a "silent killer," but the disease is generally symptomatic, even at early stages in 89% of cases.[8] Symptoms are not, however, specific and are generally attributed to benign gastrointestinal, genitourinary, musculoskeletal, or gynecologic conditions. Detection of a pelvic mass by physical examination or transvaginal sonography generally prompts exploratory surgery to remove the primary tumor and as much of the metastatic disease as possible—so-called cytoreductive surgery. Chemotherapy is generally given for 18 weeks thereafter using a combination of cytotoxic drugs including a taxane (paclitaxel or docetaxel) and a platinum derivative administered intravenously or directly into the peritoneal cavity.

In the 20% of patients with disease that is still localized to the ovaries (stage I), the prognosis is excellent, with up to 90% survival at 5 years using currently available surgery and chemotherapy. As the disease spreads to the other pelvic organs (stage II), to the peritoneal cavity and retroperitoneum (stage III), or to the hepatic parenchyma, pleural cavity, or lymph nodes outside the abdomen (stage IV), the prognosis becomes progressively worse, with a 5-year survival of less than 10% in the last group. Overall, 5-year survival rates have improved significantly ($P < .05$) from 37% in the 1970s to 45% in the 2000s,[2] related in large part to improvements in cytoreductive surgery and combination chemotherapy with carboplatin and paclitaxel. Over the past decade, however, median 5-year survival has not improved for patients with newly diagnosed advanced-stage ovarian cancer treated on clinical protocols of the Gynecologic Oncology Group. Moreover, long-term survival for women with advanced disease has not improved dramatically over the past three decades, and 70% of patients eventually succumb to the disease.

Cellular and Molecular Characteristics of Ovarian Cancer Cells

Heterogeneity of Ovarian Cancers

As in many other malignancies, epithelial ovarian cancer is a clonal disease that arises from a single cell in more than 90% of cases.[9] Despite a clonal origin, epithelial ovarian cancers exhibit marked heterogeneity at a molecular, cellular, and clinical level.

Cell Proliferation

Among cancers from different patients with invasive cancer, the fraction of cycling cells can vary from 1% to 79%

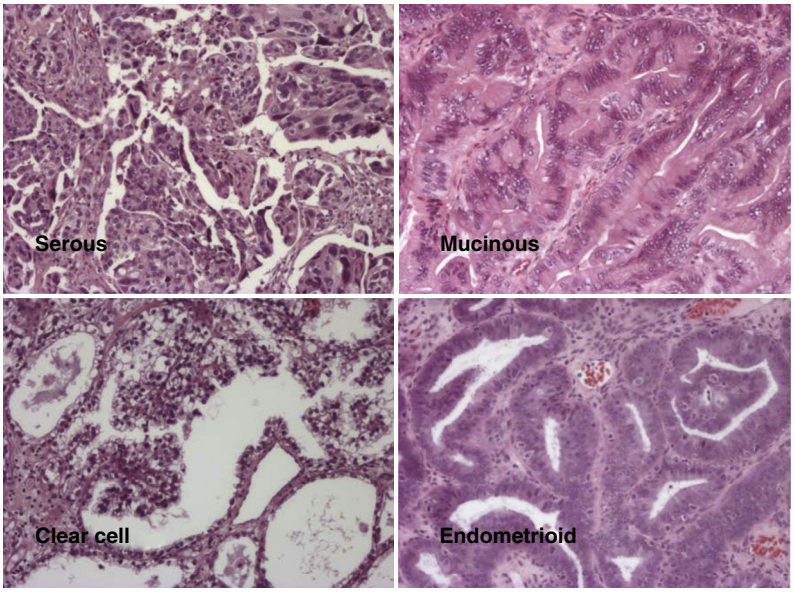

Figure 37-3 Different histotypes of epithelial ovarian cancer.

with a mean of 9% to 34% in different series.[10] Cyclin D1, cyclin E, and CDK2 are upregulated in a minority of cancers with their DNA copy numbers or protein levels correlating inversely with survival. Conversely, the p16, p21, and p27 CDK inhibitors are downregulated or mislocalized in a fraction of cancers, associated with a poorer outcome.

Histotypes

Ovarian cancers exhibit distinct histotypes—serous, endometrioid, clear cell, mucinous—that resemble epithelial components of normal fallopian tube, endometrium, vagina, endocervix, or intestine (Figure 37-3). Histotypes differ with regard to risk factors, genetic abnormalities, expression of tumor markers, and response to chemotherapy.[10] Each histotype exhibits a distinctive pattern of gene expression judged by array analysis, real-time reverse transcriptase–polymerase chain reaction (RT-PCR), and immunohistochemistry.[11] Molecular alterations in ovarian cancers of different histotypes correlate with changes in the normal tissues that they resemble morphologically. The HOX family of homeobox genes plays an important role in determining the histotype of ovarian cancers.[12] During normal development, *HOXA9* is solely expressed in the primordia of the fallopian tubes, *HOXA10* in the developing uterus, *HOXA11* in the lower uterine segment and cervix, and *HOXA13* in the future upper vagina. Expression of these HOX genes is retained in adult tissues but is not observed in ovarian surface epithelia. Expression of *HOXA9, HOXA10,* and *HOXA11* is recapitulated in serous, endometrioid, and mucinous epithelial ovarian cancers, and enforced alterations in expression alter cellular histotype, indicating a causal role.[12]

Low and High Grade (Type I and II)

Low- and high-grade ovarian cancers differ not only in histologic differentiation, but also in pathogenesis, genotype, rate of growth, prognosis, and response to therapy, permitting separation into Type I (low-grade) and Type II (high-grade) lesions.[13-15] Type I cancers include low-grade serous, mucinous, endometrioid, and clear cell histotypes and are often diagnosed in early stage (I or II), grow slowly, and resist conventional chemotherapy. Low-grade tumors frequently express estrogen receptors and may respond to tamoxifen or aromatase inhibitors. The more prevalent Type II cancers include high-grade serous, endometrioid, or undifferentiated histotypes, present at late stage (III or IV), grow aggressively, and respond to conventional chemotherapy, but only occasionally to endocrine therapy. Thus, the distinction between Type I and Type II ovarian cancers can inform choice of treatment.[15,16]

Whereas Type II serous cancers appear to arise de novo from the walls of ovarian cysts or the surfaces of the ovary or fallopian tube, Type I low-grade serous cancers can grow from noninvasive serous "borderline" tumors of low malignant potential in 60% of cases. High-grade Type II ovarian cancers respond to primary chemotherapy with carboplatin and paclitaxel in approximately 70% of cases. Low-grade serous tumors are resistant, but not refractory, to primary platinum-based therapy. Recurrent low-grade serous ovarian cancer has a very low rate of response.[17] Low-grade mucinous and clear cell histotypes respond to conventional chemotherapy in only 26% and 15% of cases, respectively.[2,17]

Low-grade serous cancers exhibit a relatively normal karyotype with wild-type *TP53* and *BRCA1/2*, but exhibit frequent mutations in *KRAS* genes in 19% to 54% of cases. Low-grade serous cancers express the insulin-like growth factor receptor, and the majority overexpress the IGF-1 growth factor, providing a potential target for therapy. Frequent mutations of *KRAS* are found in mucinous cancers and in adjacent borderline tumors, consistent with the mutated gene driving malignant progression. A similar pattern of gene expression has been observed in clear cell and low-grade endometrioid carcinomas, consistent with a common cell of origin.[18] Similar mutations have been found in both histotypes. Inactivating mutations of *ARID1A*, a chromatin remodeling gene, have been reported in 49% of ovarian clear cell carcinomas and 30% of endometrioid ovarian cancers.[19,20] Mutations of *PPP2R1A*, the regulatory subunit of a serine-threonine phosphatase required for chromosome segregation, have been found in 7% of clear cell ovarian cancers.[19] Phosphatidylinositol-3-kinase (PI3K) signaling is activated in low-grade endometrioid cancers through inactivating mutations and epigenetic silencing of *PTEN* and activating mutations of *PIK3CA*. In nonepithelial granulosa cell tumors, recurrent single base mutations (402C-G) of *FOXL2*, a transcription factor implicated in granulosa cell differentiation, have been found in 97% of cases.[21]

Thus, low-grade Type I cancers appear to be driven by mutations that activate Ras/MAP and PI3K signaling in the context of a relatively normal karyotype with wild-type *TP53* and *BRCA1/2*. By contrast, Type II high-grade serous cancers exhibit numerous copy number abnormalities with frequent amplifications and deletions, but with mutations in a very limited number of genes including *TP53* and *BRCA1/2*. The Cancer Genome Atlas Research Network (TCGA) analyzed copy number abnormalities in 489 high-grade serous ovarian cancers, detecting amplification of more than 30 growth stimulatory genes.[22] Amplification and overexpression of genes in the PI3K family occur in more than 50% of Type II cancers, activating the PI3K pathway and conferring "PI3Kness."[23] In the absence of germline abnormalities of *BRCA1/2*, homologous DNA repair can be compromised by somatic mutations of *BRCA1* and *BRCA2* within the cancer alone, BRCA2 can be silenced, and upstream mutations can downregulate BRCA function combined with mutations in other genes potentially involved in homologous recombination, producing "BRCAness" in up to 50% of patients with Type II cancers.[24] DNA sequencing of exons from 316 cancers detected mutations of TP53 in 96%, most of which appeared to be inactivating.[22] Of the 26,000 genes, only a few were mutated in 2% to 4% of cases, including *NF1*, *Rb1*, *BRCA1*, *BRCA2*, and *CDK12*. Unlike Type I cancers, fewer than 1% of Type II cancers had mutations of *BRAF*, *PI3KCA*, *KRAS*, or *NRAS*. Despite the low prevalence of *Rb1* mutations, dysfunction of the Rb pathway was found in 67% of high-grade serous cancers. As in the case of epithelial cancers at other sites, both TP53 and Rb were inactivated in two thirds of Type II ovarian cancers. As indicated earlier, low-grade tumors have a high frequency of mutations in *PIK3CA*, *KRAS*, *ARID1A*, and other putative oncogenes and tumor suppressor genes, whereas high-grade ovarian cancers are characterized by mutations in *TP53* and *BRCA1/2* and marked alterations in DNA copy number. These distinct molecular characteristics indicate that interconversion from Type I to Type II cancers is either a very rare event or does not occur, and thus Type I and Type II tumors likely represent independent diseases. Embracing this concept and performing independent clinical trials and tailored therapy for Type I and Type II tumors will be necessary to improve patient outcomes.

Other Prognostic Subtypes Based on Gene Expression

The pattern of gene expression has been used to identify prognostic subgroups. The Australian Ovarian Cancer Study Group profiled 285 serous and endometrioid tumors to identify six molecular subtypes.[25] Two subtypes were associated with low malignant potential serous tumors and low-grade endometrioid ovarian cancers, whereas the other four transcriptional profiling based subtypes included high-grade serous and endometrioid histotypes including a "mesenchymal" subtype. The immunoreactive subtype expressed T-cell chemokine ligands CXCL11 and CXCL10 and the receptor CXCR3, consistent with a higher level of infiltration by leukocytes. Importantly, lymphocytic tumor infiltration has been associated with an improved outcome. Cases in the proliferative cluster exhibited high expression of the HMGA2 and SOX11 transcription factors, low expression of MUC1 and MUC16 mucins, and high expression of proliferation markers such as MCM2 and PCNA. Differentiated cases have high expression of MUC16, MUC1, and the secretory fallopian tube marker SLPI. Mesenchymal cancers were associated with high expression of HOX genes and markers for stromal components including myofibroblasts (FAP) and microvascular pericytes (ANGPTL2 and ANGPTL1). These subtypes were not associated with changes in overall survival, although a prognostic signature was developed that included 193 genes. Subsequent analyses developed a prognostic "Classification of Ovarian Cancer" (CLOVAR) using gene expression that distinguished groups with markedly different median survival (23 vs. 46 months) and resistance to platinum therapy (63% vs. 23%).[26] Although these classifications can help to stratify future trials, profiles with higher positive and negative predictive value for response to conventional and novel agents will be required in order to affect clinical management.

Immortalization

Telomerase activity is increased in 80% to 90% of ovarian cancers. Substantially greater telomerase activity is found in ovarian cancers than in borderline lesions or normal ovaries. High-grade serous ovarian cancers demonstrate high degrees of genomic instability and copy number abnormalities, possibly related to bridge-fusion breakage that occurs at telomeric crisis, before the upregulation of telomerase. Immortalization of human ovarian epithelial cells can be achieved by the introduction of human telomerase reverse transcriptase (hTERT) after disruption of the TP53 and/or Rb pathways using SV40T/t antigen or siRNA against Rb.[27] Cells immortalized with SV40 T/t and hTERT can be transformed with mutant Ras, producing cancers resembling low-grade human ovarian cancers that grow as nodules on the peritoneum and exhibit serous papillary histology (Figure 37-4).[2] Other combinations of gene aberrations can generate tumorigenic lines from normal ovarian or fallopian tube epithelium, providing a potential approach to explore the roles of specific genomic aberrations in ovarian oncogenesis.

Genomic Abnormalities in Sporadic Ovarian Cancers

A number of genetic and epigenetic abnormalities have been detected in DNA from sporadic ovarian cancers, including amplification, mutation, hypomethylation, chromatin modification, deletion, loss of heterozygosity, and promoter methylation (Table 37-1).[2,14,22] High-grade Type II ovarian cancers are genetically unstable both in terms of DNA copy number and in exhibiting a moderate mutation rate (Figure 37-5). For unknown reasons, areas of genomic aberration are associated with changes in RNA splicing. The *CDK12* gene has been implicated in splicing and is mutated and probably inactivated in 3% of high-grade serous cancers. Aberrant expression of different splicing factors has been observed in ovarian cancer, and altered splicing may affect not only adhesion (*CD44*), but also the activity of putative oncogenes (*EVI-1b* and *AML-1*), as well as the metabolism of xenobiotics (*CYP1A1*) or of multidrug resistance (SPF45).[2] Processing of miRNAs is also impaired in a fraction of ovarian cancers, with decreased levels of Dicer and Drosha in more than half of ovarian cancers.[28] Low Dicer expression was significantly associated with advanced tumor stage (P = .007) and poor survival (P = .02), whereas low Drosha expression was associated with suboptimal surgical cytoreduction (P = .02). Gene silencing with shRNA, but not

Table 37-1 Genetic and Epigenetic Abnormalities in Epithelial Ovarian Cancer[14,22,30]

Activating Events	
Amplification by CGH	1q22 (RAB25), 3q26 (PKCiota, EVI1, PIK3CA), 5q31 (FGF-1), 8q24 (MYC), 19q (PI3Kp85, AKT2), 20p, 20q13.2 (BTAK)
Mutation*	*K-Ras, BRAF, CTNNB1, CDKN2A, PIK3CA, KIT, MADH*
Hypomethylation	*BORIS, CLDN-4, IGF2, MCI, SAT2, SNCG*
Histone modification	*cyclin B1, GATA4, GATA6, p21/WAF1*
miRNA	*BAP1, DLK1, MSX2, PTEN, SIP1, VEGFA, ZEB1/2*
Inactivating Events	
Deletion by CGH	4q, 5q, 16q, 17p, 17q; Xp, Xq
LOH	(>50%): 17p13, 17q21(>30%): 1p, 3p, 5q, 5q, 6q, 7q, 8q, 9p, 10q, 11p, 13q, 18q, 19p, 20; Xp
Mutation	*ARID1A, TP53, Rb1a, APC, BRCA1, BRCA2, CDK12, NF1, PTEN, PPP2R1A*
Promoter methylation	*APC, ARHI, ANGPTL, ARLTS1, BRCA1, DAPK, FBX032, H-CADHERIN, hMLH1, HOXA10, HOXA11, Hsulf-1, ICAM-1, LOT-1, MCJ, MUC2, MYO188, OPCML, PACE-4, PALP-B, PAR-4, PEG3, p16, p21, RASSF1, SOCS1, SOCS2, SPARC, TMS/ASC, TUBB3, 14-3-3σ*
Histone modification	Adam 19, GATA4, GATA6, RASSF1
miRNA	BCL2, FGF2, MMP13, PAR8, c-SRK, VEGFA
Inhibition of growth by chromosome transfer	2, 3, 7, and 22

siRNA, may be impaired in cells with low Dicer expression. Mutations of Dicer and Drosha are rare in high-grade serous cancer, but mutations of Dicer have been detected in 29% of nonepithelial ovarian cancers.[29] Abnormalities in miRNAs have been found in many different types of cancers related to gain or loss of DNA copies, methylation, or mutation.[30] In ovarian cancers, copy number abnormalities have been found in 37% of 283 loci known to contain miRNAs.[2] A number of miRNAs may act as tumor suppressors and are downregulated in high-grade serous ovarian cancers, including Let-7a/b/d/f and miRs -15/16, -22, -31, -34a/b/c, -125b, -127-3p, -140, -145, -152, -155, -181a, -199a, and -382.[22,30] Conversely, several miRNAs are upregulated and can promote ovarian oncogenesis or chemoresistance, including miRs -15a/16, -20A, -23a/b, -30a/b/c, -92, -93 and -106a, -135b, -141, -200a/b/c, -244, -299-5p, -302d, and -373. Upregulated miRNAs are being evaluated as biomarkers.

Copy number abnormalities (CNAs) are particularly common in epithelial ovarian cancers. Candidate oncogenes and tumor suppressor genes have been mapped to most but not all of the abnormal sites. Amplification of 1q22 includes the RAB25 oncogene. Among the genes encoded on the 3q26 amplicon, protein kinase C iota (PKCiota), SnoN, MDS1-ecotropic viral integration site-1 (mecom/EVI1), and the p110-α catalytic subunit of phosphoinositide-3-kinase (PIK3CA) are overexpressed in a fraction of ovarian cancers and are associated with a poor prognosis.[2] PKCiota protein is required for the establishment and maintenance of epithelial cell polarity. Levels of aberrant PKCiota are markedly increased and/or mislocalized in the majority of serous ovarian cancers and are associated with increased cyclin E protein expression and proliferation.[2] Cyclin E1 amplification and protein levels correlate with a worsened outcome in ovarian cancer. The FGF-1 peptide growth factor encoded by a gene in the amplicon at 5q31 can stimulate cancer growth, stromal growth, and angiogenesis. An amplicon at 8q24 contains c-myc, which is amplified in up to 40% of ovarian cancers, inducing factors required for proliferation and activating telomerase. Another amplicon on chromosome 19q contains the p85 β subunit of PI3K as well as AKT2, a target of PI3 kinase. Another major amplicon at 20q13.2 contains the *BTAK/Aurora kinase* gene that upregulates c-Myc and activates telomerase.

Loss of tumor suppressor function has been observed in ovarian cancers (Table 37-2). [2,14] In some cases, inactivating mutations have been associated with loss of heterozygosity (LOH) (*BRCA1, BRCA2, TP53, PTEN*), but in others epigenetic changes alone (*RASSF1A, DLEC1*) or in combination with LOH (*ARHI, BRCA1, LOT-1, PEG3, WWOX*) have silenced suppressor function. As described earlier, somatic mutation of *TP53* is observed in nearly all high-grade type II ovarian cancers. Because of the dominant negative activity of some mutant TP53 protein, *TP53* function can be lost with a single genetic event. The pattern of transitions, transversions, and deletions within mutated *TP53* genes resembles the pattern of mutations in factor IX

Table 37-2 Putative Tumor Suppressor Genes in Epithelial Ovarian Cancer[14,22]

Gene	Chromosome	Downregulated or Inactivated	Mechanisms of Downregulation	Function
ARHI (*DIRAS3*)	1p31	60% of all histotypes	Imprinting; LOH; promoter methylation; transcription downregulated by E2F1 and E2F4	26-kDa GTPase; inhibits proliferation and motility; induces autophagy and dormancy; upregulates p21; inhibits cyclin D1, PI3K, Ras-MAP, Stat3
ARID1A	1p35.5	49% of clear cell and 30% of endometrioid histotypes	Mutation	Chromatin remodeling
RASSF1A	3p21		Hypermethylation	Inhibits proliferation and tumorigenicity in many different cancers. Interacts with Ras, inhibiting downregulating cyclin D and signaling through JNK, stabilizes microtubules, regulates spindle checkpoint and fas- and TNF-induced apoptosis
DLEC1	3p22.3	73%	Promoter hypermethylation and histone hypoacetylation	166-kDa cytoplasmic protein that inhibits anchorage dependent growth
SPARC	5q31	70%-90% decreased expression; 9% lost	Transcription, hypermethylation	32-kDa Ca^{2+} binding protein; prevents adhesion
DAB-2 (*DOC2*)	5q13	58%-85% lost	Transcription	105-kDa protein binds GRB2 preventing Ras/MAP activation, prevents c-fos induction, and decreases ILK activity, contributing to anoikis and inhibiting proliferation and anchorage-independent growth and tumorigenicity
LOT-1 (*ZAC1*)	6q25	39%	Imprinting; hypermethylation LOH; transcription downregulated by EGF, TPA	55-kDa nuclear zinc finger protein inhibits proliferation and tumorigenicity
RPS6KA2	6q27	64%	Monoallelic expression in ovary; LOH	90-kDa ribosomal S6 serine threonine kinase that inhibits growth, induces apoptosis, decreases pERK and cyclin D1, increases p21 and p27
PTEN (*MMAC-1*)	10q23	3%-8% mutated; expression lost in 27%, particularly in endometrioid and clear cell histotypes	Promoter methylation; LOH; mutation	PI3 phosphatase; decreases proliferation, migration and survival; decreases cyclin D and increases p27
OPCML	11q25	56%-83%	Promoter methylation; LOH; mutation	GPI-anchored IgLON family member; induces aggregation; inhibits proliferation and tumorigenicity
BRCA2	13q12-13	3%-6%	Mutation; LOH	Binds RAD51 in repair of DNA double strand breaks (DSBs)
ARLTS1	13q14	62%	Promoter methylation	ADP ribosylation factor induces apoptosis
WWOX	16q23	30%-49%, particularly in mucinous and clear cell histotypes	LOH; mutation	Decreases anchorage-independent growth and tumorigenicity; mouse homologue required for apoptosis
TP53	17p13.1	50%-70% overall; 96% of high-grade serous histotype	Mutation	53-kDa nuclear protein induces p21 with cell cycle arrest promoting DNA stability; induces apoptosis
OVCA1	17p13.3	37%	LOH	50-kDa protein; decreases proliferation and clonogenicity; decreased cyclin D1
BRCA1	17q21	6%-8%	Mutation; LOH, promoter methylation	E3 ubiquitin ligase that participates directly in repair of DNA DSBs through homologous recombination; regulates c-Abl; induces *TP53*, androgen receptor, estrogen receptor, and c-Myc
PEG3	19q13	75%	Imprinting; LOH; promoter methylation; transcription	Induces *TP53* dependent apoptosis
PPP2R1A	19q13.44	7% of clear cell histotype	Mutation	Protein phosphatase 2 regulatory subunit inhibits proliferation

Candidate tumor suppressor genes with preliminary reports in the literature also include *APC, BRMS1, CTGF, EPB41L3, MAP2K4, MKK4, RNF43, RP36RA7, PINX1, SFRP4, SLIT2, SOX11, TUSC3, and 53BP1.*
LOH, Loss of heterozygosity.

Table 37-3 Oncogenes Associated with Epithelial Ovarian Cancer[14,22]

Oncogenes	Chromosome	Amplified	Overexpressed	Mutated	Function
Rab25	1q22	54%	80%-89%		Cytoplasmic GTPase/apical vessel trafficking
Evi-1	3q26				Transcription factor
eIF-5A2	3q26	—	—		Elongation factor
PKCi	3q26	44%	78%		Cytoplasmic serine-threonine kinase
PIK3CA (PI3K p110α)	3q26	9%-80%	32%	8%-12%	Cytoplasmic lipid kinase
FGF-1	5q31	—	51%		Growth factor for cancer and angiogenesis
Myc	8q24	20%	41%-66%		Transcription factor
EGFR	7p12	11%-20%	9%-28%	<1%	Tyrosine kinase growth factor receptor
Notch-3	9p13	20%-21%	62%		Cell surface growth factor receptor
K-Ras	12p11-12	5%-53%	30%-52%	2%-24%	Cytoplasmic GTPase
HER-2	17q12-21	6%-11%	4%-12%		Tyrosine kinase growth factor receptor
p85 PI3K	19q				Cytoplasmic lipid kinase
Cyclin E	19q12	12%-53%	42%-63%		Cyclin
AKT2	19q13.2	12%-27%	12%		Cytoplasmic serine-threonine kinase
BTAK/Aurora A	20q13	10%-15%	48%		Nuclear serine-threonine kinase/activates telomerase

Additional targetable genes with low or high gain of copy number in >20% of high-grade serous ovarian cancers include *AKT1, AKT3, CDK2, IL8RB, EPCAM, ERBB3, FGFR2, HDAC4, HSP90AB1, HSP90B1, IGF1, IGFR1, LPAR3, MAP3K6, MAPK15, MAPKAPK2, MAPKAPK5, MECOM, MSTN, MTOR, NCAM1, NOS1, NOS3, PIK3CD, POLB, POLE, RHEB, RICTOR, PPS6KC1, RAPTOR, SKI1, STAT1, STAT4, TERT, TGFB1, TGFB2, TGFBR3, TNFRSF9, VEGFA*.[22]

deficiency (hemophilia B) in the germline that is thought to be related to spontaneous deamination during DNA replication.[5] If spontaneous mutation during proliferation is a critical mechanism driving carcinogenesis, genetic events requiring only a "single hit" may be favored.

Function of imprinted growth regulatory genes can also be lost in a single genetic or epigenetic event. Approximately 70 human genes are imprinted with only one allele expressed at conception, during embryonic development, and in each normal adult cell. Silencing of the maternal or paternal allele is inherited epigenetically. Among the candidate tumor suppressor genes whose function is downregulated in ovarian cancer (see Table 37-2), at least four are imprinted: *ARHI* (*DIRAS3*), *LOT-1*, *NDN*, and *PEG3*. *ARHI* encodes a 26-kDa GTPase that has 50% to 60% homology to Ras and Rap and that is downregulated in more than 60% of ovarian cancers, associated with decreased time to progression.[31] Expression can be downregulated by multiple mechanisms including LOH, methylation and silencing of the functional allele, transcriptional regulation with E2F1 and E2F4, and shortened mRNA half-life.[32] Re-expression of *ARHI* at physiologic levels inhibits clonogenic growth and motility of ovarian cancer cells that lack its expression, inhibiting STAT3 translocation, downregulating cyclin D1 and inducing $p21^{WAF1/CIP1}$ and $p27^{KIP1}$, producing G1 arrest. *ARHI* reexpression decreases levels of HIF1-α and inhibits signaling through Ras/MAP and PI3K/TSC2/mammalian target of rapamycin (mTOR), inducing autophagy and tumor dormancy.[33] Among the other imprinted tumor suppressor genes, *LOT-1* is a zinc finger protein that presumably acts as a transcription factor[2] and *PEG3* is required for TP53-induced apoptosis.[2] Consequently, imprinted genes may regulate the proliferation, motility, and survival of ovarian epithelial cells through multiple mechanisms.

Activation of oncogenes occurs through amplification, overexpression, or mutation in ovarian cancers (Table 37-3).[2,14] The two most common aberrations, mutations of members of the PI3K/AKT pathway and of the Ras/RAF pathway, are discussed in the following sections. The FOXM1 and NOTCH pathways are also aberrant in high-grade serous ovarian cancers, albeit at a lower frequency. Abnormalities of receptor and nonreceptor kinases have also been documented.

In contrast to breast cancer, where HER-2 is amplified and overexpressed in 20% to 30% of cases, HER-2 overexpression was found in only 11% of 837 epithelial ovarian cancers in a Gynecologic Oncology Group trial in which trastuzumab produced objective responses in only 7% of tumors with HER-2 overexpression.[2] Unlike lung cancer, the tyrosine kinase domain of *EGFR* is rarely mutated in ovarian cancer, but the receptor can be amplified in up to 20% of cases. A characteristic constitutively activating deletion in the extracellular domain of EGFR (EGFRvIII), first demonstrated in glioblastomas, has also been detected in a

small fraction of ovarian cancers.[2] Constitutive activation of *EGFR* has, however, not been detected in ovarian cancer cell lines. Inhibition of the EGFR with erlotinib and gefitinib produced only modest clinical activity in ovarian cancer, where objective regression has been observed in 4% to 6% of cases.

Cyclin E maps to an amplicon that is found in a significant minority of ovarian cancers. Knockdown of neighboring genes has shown that *CCNE1* is a driver required for clonogenicity that is associated with chemoresistance.[2] Proteomic studies using reverse phase protein analysis have shown that overexpression of CCNE1 protein marks a distinct cluster of cases with poor prognosis.

BTAK/Aurora A kinase, a serine-threonine kinase required for chromosome segregation and centrosome function, is amplified in 10% to 25% and activated in 48% of ovarian cancers.[2] BTAK/Aurora A kinase regulates telomerase activity. Forced expression of Aurora A induces centrosome amplification, cell cycle progression, and chemoresistance to cisplatin and paclitaxel mediated through AKT in a *TP*53-dependent manner. Chemical inhibition of BTAK/Aurora A kinase downregulates NF-κB, Bcl-XL, and Bcl-2 and enhances sensitivity to chemotherapy. Another cytoplasmic serine-threonine kinase, salt-induced kinase 2 (SIK2), localizes to centrosomes and phosphorylates c-NAP1, permitting centrosome splitting.[34] SIK2 is overexpressed in 30% of ovarian cancers associated with a worse prognosis. Downregulation of SIK2 enhances sensitivity to paclitaxel.

RAB25, a member of the RAB family of small G-proteins implicated in apical vesicle trafficking and polarity, is amplified and overexpressed in approximately half of ovarian cancers and is associated with a poor prognosis. Forced expression of RAB25 protein markedly increased anchorage-dependent and anchorage-independent proliferation; prevented apoptosis and anoikis, including that induced by chemotherapy; and enhanced growth in xenografts.[2] Inhibition of apoptosis was associated with a decrease in the expression of the pro-apoptotic molecules BAK and BAX, as well as activation of the PI3K/AKT pathway. RAB25 is sufficient to increase cellular metabolism and render cells resistant to acute metabolic stress, demonstrating a link between polarity, vesicle trafficking, and cellular metabolism.

In addition to the kinases, growth factors, and signal transducing proteins, members of the family of eukaryotic initiation factors (eIFs) have been implicated in ovarian oncogenesis. The initiation factor eIF-5A2 maps to a region on 3q26 that is amplified in ovarian cancers. Overexpression of eIF-5A2 is associated with advanced-stage ovarian cancer.[2] Forced expression of eIF-5A2 stimulates and antisense inhibits ovarian cancer growth and tumorigenicity.

Several transcription factors are also overexpressed in ovarian cancers. The c-Myc gene is amplified in up to 40% of ovarian cancers, and protein levels are increased in approximately one third of cases, including clear cell and endometrioid histotypes.[2] The c-Myc protein induces E2F1, E2F2, E2F3, and telomerase while blocking TP53-mediated transcription of p21. Despite the probable importance of c-Myc amplification in oncogenesis, no apparent association with survival has been found. A number of approaches to target cells with c-Myc aberrations are beginning to emerge. The association of cMyc with metabolism and particularly in the role of glutamine in cancer biology provides a potential avenue to therapy. The Hippo pathway translational co-activator YAP has also been implicated as a possible oncogene in ovarian cancer that can drive progression and induce resistance to chemotherapy.[35]

Aberrant Signaling

Several tyrosine kinase growth factor receptors can be activated in epithelial ovarian cancers, including EGFR, HER-2/HER-3, M-CSFR, IGFRI, FGFR4, and PDGFR. Binding of relevant ligands to one or more of these receptors can activate signaling through Ras/MAP, PI3K, JNK, JAK/STAT, PKC, and PLCγ or PLC-*x* with a concomitant alteration in calcium fluxes. Among these several signaling pathways, the Ras/MAP and PI3K pathways appear to be particularly important in regulating the growth, survival, metastatic potential, and drug resistance of ovarian cancer cells. Although the RAS/MAPK and PI3K pathways exhibit few mutations in high-grade serous ovarian cancers, the pathways are frequently activated. The PI3K pathway may be activated by changes in copy number of multiple pathway components as well as by loss of PTEN and INPP4B. Indeed, in the TCGA dataset, the RB1 pathway was dysregulated in 67% of high-grade serous cancers and the PI3K pathway in 45%.[22] The NOTCH signaling pathway was dysregulated in 22%. Stimulation of FGFR4 by FGF-1 activates mitogen-activated protein kinase (MAPK), nuclear factor-κB (NF-κB), and the WNT signaling pathways.[36]

In many tumor types, K- or H-Ras is activated by mutations at codons 12 or 61, permitting constitutive binding of GTP rather than GDP to the Ras protein. Activated Ras can signal through the MAPK, PI3K, or Ral pathways, affecting proliferation, survival, motility, invasion, and drug resistance. As noted earlier, the *Ras* gene is mutated in approximately half of Type I low-grade serous cancers, but rarely in Type II high-grade cancers. Nevertheless, Ras activity as assessed by GTP binding is increased in many Type II high-grade cancers.

The PI3K pathway regulates survival, proliferation, motility, angiogenesis, glucose metabolism, and drug resistance. Activation of the PI3K pathway is observed in 50% of ovarian cancers through multiple mechanisms including amplification or activating mutation of the PI3K p110

α, activating mutation of the PI3K regulatory subunit p85, inactivating mutation of the PTEN phosphatase and amplification of AKT2 (see Table 37-3).[2] The p110 subunit of PI3K is amplified in 9% to 22% of ovarian cancers, overexpressed in 32%, and mutated in 9% to 12%, predominantly in low grade.[2] The pattern of PIK3CA mutation is histotype dependent, being common in endometrioid and clear cell tumors, but rare in serous cancers. The AKT serine-threonine kinase is generally activated physiologically by the products of PI3K. However, in 12% to 27% of ovarian cancers, the *AKT2* kinase gene is amplified and is associated with an increase in AKT kinase activity.[2] The p70S6 kinase is downstream of both PI3K and AKT kinase in the signaling cascade. The p70S6 kinase may have a critical role in modulating drug resistance in that rapamycin, an inhibitor of p70S6 kinase, can potentiate sensitivity of some ovarian cancer cell lines to cisplatin-induced apoptosis.[2] Inhibition of activated PI3K decreases cell growth, induces apoptosis, and potentiates paclitaxel chemotherapy. The PI3K pathway is being explored as a therapeutic target in many cancer lineages, including ovarian cancer.

Normal ovarian surface epithelium expresses small amounts of macrophage colony stimulating factor (M-CSF, CSF-1), but little if any of fms, the tyrosine kinase receptor for this ligand. At least 70% of ovarian cancers express and secrete substantially greater amounts of M-CSF, and approximately 50% of cancers express the fms receptor.[2] Interaction of M-CSF with fms stimulates invasiveness and upregulates urokinase-like plasminogen activator (uPA). Expression of uPA correlates with tumorigenicity of ovarian cancer cell lines in xenograft models.[2]

Among the nonreceptor tyrosine kinases, the Src tyrosine kinase can be physiologically activated in ovarian cancer cell lines, but the *Src* gene is rarely amplified or mutated in surgical specimens.[2] Stat3 is phosphorylated by the Janus kinase (JAK) and Src kinase. Phosphorylated Stat3 forms dimers that can be translocated to the nucleus, binding DNA and inducing transcription of genes required for proliferation (*cyclin D*, *c-Myc*, *c-Fos*), survival (*Bcl-2*, *Bcl-XL*, *XIAP*, *survivin*), and angiogenesis (*VEGF*). Stat3 can be activated on the intracellular domains of peptide growth factor receptors (EGFR) and cytokine receptors (IL-6R) or by direct interaction with either Src or Abl. Activated pStat3 has been detected in 86% of 322 ovarian cancers.[2] Nuclear localization of pStat3 has been observed in 71% of cases, associated with decreased overall survival. Autocrine and paracrine stimulation with IL-6 activates Stat3, increasing both proliferation and motility. Inhibition of JAK inhibits IL-6–stimulated chemotaxis toward serum and haptotaxis toward fibronectin.[2] Knockdown of Stat3 with siRNA inhibits motility and prevents translocation of Stat to focal adhesions. The imprinted tumor suppressor gene *ARHI* inhibits proliferation and motility, binds to Stat3, and sequesters it in the cytoplasm, preventing translocation to the nucleus and to focal adhesions.[2] In addition, *ARHI* can prevent binding of Stat3 to DNA Stat Response Elements in promoter regions.

The endothelin A peptides (ET-1, ET-2, and ET-3) are potent mitogens for several human tumors. ET-1 and its ETA receptor (ETAR) are overexpressed in primary and metastatic ovarian cancers, providing the potential for autocrine stimulation.[2] Interaction with ET-1 also transactivates EGFR, stimulates proliferation, blocks apoptosis, activates integrin-like kinase (ILK), upregulates matrix metalloproteinases (MMPs), and increases vascular endothelial growth factor (VEGF) expression, enhancing angiogenesis.

Lysophosphatidic acid (LPA) is produced constitutively by mesothelial cells and some ovarian cancer cells and accumulates at high levels in the ascites of nearly all ovarian cancer patients.[37] LPA can be detected in the plasma of most patients at all stages of disease. The LPA-2 and LPA-3 receptors are markedly upregulated in ovarian cancers.[2] Interacting with these receptors, LPA stimulates calcium influx, proliferation, motility, chemotaxis, invasion, and resistance to chemotherapeutic agents, signaling through the RAS/MAP and PI3K pathways. LPA is a potent inducer of VEGF, IL8, IL6, and gro, implicating LPA in the accumulation of ascites, neovascularization, and metastasis. LPA can cross activate the EGFR receptor family and other receptor tyrosine kinases, potentially contributing to the activity of these receptors in ovarian cancer. Both the enzyme producing LPA, autotaxin, and the enzymes degrading LPA (LPPs) are aberrant in ovarian cancer. Drugs targeting LPA production and action are potent inhibitors of metastasis.

All three TGF-β isoforms are expressed by normal ovarian surface epithelial cells and regularly inhibit their proliferation, maintaining autocrine growth inhibition.[2] Loss of expression of TGF-β or loss of responsiveness to the growth inhibitory factor is detectable in a fraction of ovarian cancers. Moreover, TGF-β can stimulate the motility and invasiveness of transformed cells. Although mutation in Smad4 is observed in a fraction of ovarian cancers, both TGF-βRI and TGF-βRII receptors are generally intact, as is Smad signaling.[2] Loss of growth inhibition and increased invasiveness may relate to *EVI-1* overexpression that is observed in 43% of ovarian cancers[2] and is thought to inhibit transcription of TGF-β–responsive genes. SnoN and AML1, which bind to and regulate Smads, are also aberrant in ovarian cancer.

Müllerian inhibition substance (MIS) bears homology to TGF-β, binds to a receptor with similar structure and function, and is produced by the Sertoli cells of the testis and granulosa cells of the ovary.[2] During embryonic development of gonadal structures, MIS induces atrophy of the Müllerian duct in male mammals. MIS inhibits growth of human

epithelial ovarian cancer cells in culture and in xenografts. Binding of MIS to MISII G-protein–coupled receptors upregulates p16, produces G_1 cell cycle arrest through an Rb-independent mechanism, and induces apoptosis. Some 56% of human ovarian cancers express MISII receptors, and clonogenic growth can be inhibited with MIS in more than 80% of cancers bearing receptors. MIS enhanced the anticancer activity of suboptimal doses of chemotherapeutic agents against human and murine ovarian cancer cell lines in culture and as xenografts.[2]

Stem Cells

Both normal and malignant tissues are thought to contain small subpopulations of stem cells with unlimited replicative potential that can be passed serially from mouse to mouse in vivo or as spheroids in cell culture. In cancers, tumor-initiating cells that have stem cell–like characteristics are generally resistant to chemotherapy and radiotherapy. The phenotype of human ovarian cancer stem cells remains to be fully defined. Increased tumor-initiating potential has been associated with $CD133^+ALDH1^+$ and $CD44^+CD117^+$ subpopulations in ovarian cancer cell lines and clinical specimens.[38] CD133 has been associated with stem cells from normal and malignant tissues arising at multiple sites. Aldehyde dehydrogenase mediates resistance to certain drugs and toxins. CD44 is the hyaluronate receptor required for adhesion, and CD117 is the transmembrane tyrosine kinase growth factor receptor, c-Kit. CD24 can be associated with both subpopulations and marks ovarian cancer cells with tumor-initiating capacity and chemoresistance. $CD24^+$ ovarian cancer cells express a number of stem cell biomarkers including Nestin, Beta-catenin, Bmi-1, Oct3/4, Notch1, and Notch4. Recent studies suggest that normal ovarian stem cells occupy a niche in the hilus of the mouse ovary at the junction between the ovarian surface epithelium, the peritoneal mesothelium, and the tubal (oviductal) epithelium. The cells cycle slowly and express a number of stem cell markers including ALDH1, LGR5, LEF1, CD133, and CK6B. Spheroids can be passaged serially in culture, and cells can be transformed by inactivating *TP53* and *Rb1*.[39]

Animal Models

Among the animal models, spontaneous ovarian cancers occur in approximately 40% of egg-laying hens 4 years of age.[40] Some 46% of ovarian cancers have mutations of *TP53*, and the majority express MUC16. Chickens have been used to test different hormonal strategies for preventing epithelial ovarian cancer.

Murine ovarian epithelial cells have been engineered to express different combinations of oncogenes and tumor suppressors.[40] When target cells were derived from transgenic mice that lacked TP53 expression, the addition of any two of three oncogenes—c-Myc, activated K-Ras, and activated AKT—were sufficient to induce high-grade cancer in ovarian surface epithelial cells. In mice that were deficient for both *TP53* and *BRCA1*, *Myc* overexpression is sufficient to induce cancers. In a serous murine ovarian cancer model, disruption of either *Rb* or *TP53* produced relatively few ovarian cancers, whereas disruption of both *Rb* and *TP53* produced a greater number of high-grade epithelial ovarian cancers, albeit with long mean latency (227 days). High-grade ovarian epithelial cancers were induced in a third model when SV40 T antigen, which blocks both *TP53* and *Rb*, was driven by the Müllerian hormone type 2 receptor (*Ambr2*) promoter. A model for low-grade ovarian cancer has been generated in mice in which the *PTEN* gene was disrupted and an oncogenic form of *KRasG12D* was expressed selectively in ovarian surface epithelial cells, using mice in which Cre recombinase was driven by the *Ambr2* promoter. Finally, high-grade serous cancers of the fallopian tube have developed in in mice where *PTEN* and *Dicer* were conditionally depleted using the *Ambr2-Cre* mouse strain. Consequently, ovarian cancers have been associated with loss of TP53, Rb, PTEN, and Dicer function, as well as activation of Ras, AKT, and Myc. To date, however, murine models have not succeeded in mimicking the abnormal DNA copy numbers observed in human ovarian cancers, possibly related to the telomere length in murine cells and relative resistance to telomeric crisis.

Interaction of Ovarian Cancer Cells with the Microenvironment

Loss of Adhesion, Epithelial-Mesenchymal Transition, Invasion, and Metastasis

Several molecular alterations contribute to the distinctive pattern of metastasis observed in ovarian cancer. For those cancers that arise from the surface of the ovary or fimbriae of the fallopian tube, cancer cells must dissociate from the basement membrane and then survive anoikis within the peritoneal cavity. Whereas normal ovarian surface epithelial cells bind to both laminin and to collagen in the basement membrane, loss of adhesion to laminin occurs following malignant transformation.[2] In the normal ovary, the $\alpha_6\beta_4$ integrin laminin receptor is detected over the entire basal surface of epithelial cells at points of contact with the basement membrane, whereas solid ovarian cancers exhibit only focal expression of this integrin. Ascites tumor cells have markedly

decreased expression of α_6 and β_4, consistent with the possibility that downregulation of integrin expression releases tumor cells from the basement membrane. Transformed cells can dissociate individually or as multicellular aggregates or spheroids that are carried passively by peritoneal fluid to sites of metastasis in the peritoneum and omentum. Interaction of integrins with other cancer cells in aggregates can regulate activation of FAK, ILK, PI3K, and AKT. Signaling through these pathways can determine whether cancer cells undergo apoptosis or anoikis on dissociation from the substratum. In addition to changes in integrin expression, alterations occur in the cadherins that regulate adhesion between epithelial cells. Normal surface epithelial cells of the ovary and fallopian tube have low levels of E-cadherin and may depend on N-cadherin to maintain association between epithelial cells.[41,42] In contrast to cancers that arise from many other organs, E-cadherin levels can actually increase during malignant transformation as ovarian cancers differentiate into multiple histotypes, but only low levels of E-cadherin are found in poorly differentiated ascites cells where N- and P-cadherin are often upregulated.

Epithelial-to-mesenchymal transition (EMT) occurs during metastasis in many carcinomas, including those that arise in the ovary. Increased expression of the transcription factors Slug and Snail are associated with loss of intercellular adhesion, as well as specific repression of adherens junction components (E-cadherin and β-catenin), tight junction components (occludin and ZO-1), desmosomal junction components (Dsg2), and neutrophil gelatinase-associated lipocalin (NGAL).[2] However, as noted earlier, the histologic differentiation of ovarian cancer cells potentially driven by homeobox genes can override the effects of EMT and result in increased E-cadherin levels. N-cadherin and vimentin are increased and Rac1, Rho A, and cdc42 GTPases are activated, as ovarian cancer cells assume a spindle shape and become more motile. EMT of ovarian cancer cells can be driven by endothelin A, EGF, LPA, Rab25, bone morphogenic protein-4 (BMP4), hypoxia, and 17β-estradiol. EMT can facilitate invasion of basement membrane and local stroma for those epithelial ovarian cancers that arise in cysts.

To implant on the peritoneal surface, ovarian cancer cells must attach to mesothelial cells through β1 integrins, CD44, and MUC16. β1 integrins on the cancer cell surface bind to VCAM-1, fibronectin, laminin, and type IV collagen on mesothelial cells and to type I and III collagens on the underlying basement membrane.[2,43] Antibodies that block anti-β1 integrin or matrix proteins can prevent adherence of some, but not all, ovarian cancer cell lines to mesothelial monolayers.

Mesothelial cells also express hyaluronic acid, to which the CD44 hyaluronate receptor can bind. Whereas normal ovarian cells express the canonical CD44S receptor, more than 70% of ovarian cancers exhibit a diverse mixture of CD44 splice variants.[2] Anti-CD44 antibodies can partially block adhesion of ovarian cancer cells to peritoneal mesothelial cells and can reduce the frequency of peritoneal metastases.[2] Ezrin, part of the submembrane linking complex that connects CD44 to the cytoskeleton, is strongly expressed in 49% of ovarian cancers and is associated with reduced overall survival.[2] Knockdown of ezrin with siRNA inhibits invasiveness. Interestingly, ascites tumor cells have decreased CD44 expression.

MUC16 on the surface of ovarian cancer cells can bind to mesothelin, a glycosylphosphatidylinositol-anchored glycoprotein expressed on the surface of mesothelial cells. MUC16, expressed by 80% of ovarian cancers, is a high-molecular-weight (more than 1 million Da), highly glycosylated mucin with a cytoplasmic tail. The extracellular domain of MUC16 contains at least 40 repeating subunits of 154 amino acids.[44] MUC16 peptides dock with mesothelin, and binding of ovarian cancer cells to mesothelial cells can be blocked with anti-mesothelin antibodies.[2] Interaction appears to depend on interaction with N-glycans associated with MUC16. Knockdown of MUC16 decreases the invasiveness of ovarian cancers.[2]

Shed MUC 16 (CA125) has provided a serum biomarker for monitoring the course of ovarian cancer during treatment.[45] Increases or decreases in CA125 have correlated with disease course in more than 80% of patients with elevated serum levels of the marker. CA125 has been used to distinguish malignant from benign pelvic masses, identify persistent disease, and detect disease recurrence.[46] Although individual values of CA125 or annual transvaginal sonography (TVS) have not been sufficiently sensitive or specific for early detection of ovarian cancer,[47] sequential two-step strategies have demonstrated greater specificity where rising CA125 identifies a small fraction of patients who would benefit from TVS.[48] Greater sensitivity can be attained with multiple biomarkers.[49]

Degradation of basement membrane at the site of local invasion and in metastases requires upregulation of type 1-MMP, MMP-2, MMP-9, uPA, and kallikrein activity, resembling changes during ovulation. The ability of tumor cells to migrate and to invade matrigel membranes is increased by VEGF, EGF, heregulin, TGF-β, BMP4, hepatocyte growth factor, M-CSF, TNF-α, heregulin, and LPA. Signaling through Ras/MAP, PI3K/AKT/p70S6K, Src and Stat has been implicated in migration and invasion. Recent work points to the importance of fibronectin-mediated activation of α5β1 integrin, which signals through c-Met, Src, and FAK to stimulate invasion and metastasis.[50] Effector proteases, including MMP2, MMP7, MMP9, IGFBP2, uPA, and the kallikreins, have all been associated with ovarian cancer cells in culture and in pathologic

specimens. MMP-2 and MMP-9 are associated with very early dysplastic lesions where basement membrane is breaking down.[2] Ovarian stromal cells are an important source for several of the proteases, including MMP-9, which has been associated with infiltrating monocytes.

The human kallikreins (hKs) include some 15 different serine proteases with a high degree of homology that map to a cluster on chromosome 19q13.4.[2] Twelve are transcriptionally upregulated in ovarian cancer. In aggregate, the kallikreins degrade multiple matrix components including fibronectin, vitronectin, laminin, and collagen I, II, III, and IV. Transfection of hK4, hK5, hK6, and hK7 does not affect proliferation, but increases invasiveness in vitro and formation of peritoneal metastasis in *nu/nu* mice. Kallikrein activity is inhibited physiologically by serpins and antithrombin-3. Several kallikreins are being evaluated as biomarkers for detection or prognostication in ovarian cancer where hK5, hK6, hK7, hK8, hK10, and hK11 are upregulated and hK14 downregulated in tissue and in serum. Elevated hK5, hK6, hK7, and hK15 have been associated with a poor prognosis and elevated hK8 and hK9 with a good prognosis.

Binding of cancer-associated integrins to extracellular matrix can stimulate chemotaxis and invasion. Adhesion of ovarian cancer cells to collagen and clustering of collagen binding integrins activates integrin-mediated signaling via SRC kinases to induce expression of *EGR1*, resulting in transcriptional activation of the *MT1-MMP* promoter and subsequent MT1-MMP–catalyzed collagen invasion.[2] Laminin, fibronectin, and collagen can all enhance chemotactic activity associated with activation of Ras/MAP, whereas enhanced invasion is observed only with laminin and collagen. The α_3, α_6, and β_1 integrin-mediated signaling through Ras/MAP, Erk, and AKT have been implicated in chemotaxis and invasion.

Stress hormones—including epinephrine, norepinephrine, and cortisol—have been shown to upregulate MMP-2 and MMP-9 in ovarian cancer cells, enhancing invasion and angiogenesis. Chronic behavioral stress produced higher levels of tissue catecholamines, greater tumor burden, and more invasive growth in an orthotopic murine model of ovarian cancer.[51] β2 adrenergic receptor-driven cyclic AMP (cAMP)-protein kinase A (PKA) and Src signaling increase migration, invasion, and vascularization, enhancing tumor growth and increasing expression of VEGF, MMP-2, and MMP-9.[52] Moreover, among ovarian cancer patients, the use of beta blockers was significantly associated with reduced cancer-related mortality.

Ovarian cancer metastases grow efficiently within the peritoneal cavity, but not as well at other sites.[43] In the past, peritoneovenous shunts were used to palliate intractable ascites, resulting in the systemic infusion of large numbers of ovarian cancer cells. At postmortem, the majority of ovarian cancer patients did not develop widely disseminated macroscopic hematogenous metastases, consistent with the possibility that the "soil" is indeed as important as the "seed."[53] Predilection for the omentum may be explained by the ability of adipocytes to secrete adipokines including IL-8 that promote chemotaxis and invasion of ovarian cancer cells, as well as their ability to provide fatty acids as an energy source for rapid cancer growth.[54]

Angiogenesis

Angiogenesis is an important component of metastatic potential. In primary ovarian cancers, microvessel density has correlated directly with the propensity to metastasize and inversely with disease-free survival.[2] VEGF, PDGF, acidic FGF, basic FGF, angiopoietin 1 and 2, IL-6, and IL-8 can all contribute to angiogenesis in different ovarian cancers.[2,55-57] Most ovarian cancers express VEGF, which stimulates proliferation of endothelial cells and serves as a survival factor both for endothelial cells and for ovarian cancer cells that express VEGFR family members. Treatment with the anti-VEGF antibody bevacizumab has produced an objective response rate of 16% in patients with recurrent ovarian cancer and has stabilized disease for 5.5 months in 50%.[56] In randomized trials in first line, the addition of bevacizumab to conventional chemotherapy has increased progression-free survival by 2.7 to 3.8 months ($P = .004$, $P < .001$).[58,59] Robust predictive biomarkers for response to bevacizumab are still being sought. Platelet-derived growth factor (PDGF) has been detected in areas of increased blood flow in ovarian cancer.[2] Pericytes—cells that cover endothelial cells and stabilize vessels—express PDGFR and secrete VEGF, creating a paracrine loop with vascular endothelial cells that secrete PDGF and express VEGFRs. Consequently, both receptors and both cell types might be targeted for more effective antivascular therapy.

Other targets may prove useful for antivascular therapy.[57] FAK is overexpressed in more than two thirds of human ovarian cancers associated with shorter survival. In addition to enhancing migration, invasion, and metastasis of cancer cells, FAK activation increases VEGF transcription, angiogenic cytokine production, and pericyte migration. Chemical inhibition or siRNA knockdown of FAK in xenograft models has slowed cancer growth, inhibited angiogenesis, and enhanced taxane sensitivity. Dll4, one of the Delta-like ligands for NOTCH, is overexpressed in 72% of ovarian cancers and is an independent predictor of poor survival. Inhibiting Dll4 inhibits tumor growth by inducing nonproductive angiogenesis with increased vascular density and decreased perfusion of tumors. Combining Dll4-targeted siRNA with bevacizumab resulted in greater inhibition of

tumor growth, compared with bevacizumab alone in animal models. The availability of gamma secretase inhibitors and anti-Dll4 antibodies should facilitate translation to the clinic. Zeste homolog 2 (EZH2) is a polycomb protein that has been detected in tumor-associated endothelial cells in a fraction of ovarian cancers with a poor prognosis. VEGF from cancer cells induces EZH2, which methylates and silences vasohibin1 (VASH1), a potent anti-angiogenic factor.[60] Silencing EZH2 in tumor-associated endothelial cells with siRNA inhibited angiogenesis and reduced xenograft growth by reactivating VASH1. Finally, EphA2 is a transmembrane tyrosine kinase receptor that is overexpressed in 76% of ovarian cancers with later stage and higher grade. EphA2 receptor activation is required for VEGF-mediated endothelial cell migration and has been associated with vasculogenic mimicry by cancer cells. Microvessel density is increased and MMp-2 and MMP-9 increased in clinical samples that overexpress EphA2. Agonistic monoclonal antibodies, receptor-TRAPs, and siRNA have all proven effective in preclinical models.

Immunologic and Inflammatory Factors

Cytokines and Chemokines

Ovarian cancers can express up to 1000 times more TNF-α than normal ovarian epithelial cells. Some 80% of ovarian cancers express TNF-α, regulated translationally and transcriptionally through NF-κB. Ovarian cancer cells can also express both TNFRI and TNFRII, receptors that permit both autocrine and paracrine stimulation. Exogenous TNF-α or IL-1α enhances the expression of endogenous TNF-α and increases levels of IL-1α, IL-6, CCL2, CXCL8, and M-CSF.[61] TNF-α can exert contrasting effects on different ovarian cancers by inhibiting, failing to effect, or stimulating tumor cell proliferation. In 10% to 25% of tumor cells taken directly from patients, TNF-α can stimulate clonogenic growth. Knockdown of endogenous TNF-α has inhibited the growth and dissemination of ovarian cancer xenografts.[2] Clinical trials have been undertaken with infliximab, which blocks TNF-α in ovarian cancer patients. Interaction of TNF, CXCL12, and IL6 in an autocrine cytokine network can influence angiogenesis, myeloid cell infiltration, and NOTCH signaling.

Interleukin-6 (IL-6) also plays an important role in mediating paraneoplastic thrombocytosis. Thrombocytosis is associated with a poor prognosis and elevated plasma levels of thrombopoietin and IL-6.[62] Silencing thrombopoietin and interleukin-6 abrogated thrombocytosis in tumor-bearing mice. Anti–IL-6 antibody treatment significantly reduced platelet counts in tumor-bearing mice and in patients with epithelial ovarian cancer. In addition, neutralizing IL-6 significantly enhanced the therapeutic efficacy of paclitaxel in mouse models of epithelial ovarian cancer. Treatment with an anti-platelet antibody significantly reduced tumor growth and angiogenesis in tumor-bearing mice.

Immunosuppression

Immunodeficiency has been documented in patients with ovarian cancer. Advanced disease has been associated with defects in delayed cutaneous hypersensitivity and in the humoral immune response. Before treatment, T-cell numbers and subsets in peripheral blood have been comparable to controls, but functional defects of B cells have been detected.[2] Following primary chemotherapy, T-cell function is also compromised. T cells isolated from ascites fluid or tumor tissue exhibit decreased expression of the TCR-zeta chain, and downregulation of the TCR-zeta chain can be produced ex vivo by co-culture of T cells with macrophages or soluble tumor-derived factors.[2] The presence of $CD4^+CD25^+FOXP3^+$ regulatory T cells suppresses specific T-cell–mediated immunity in tumor masses but not in stroma and has been associated with decreased survival.[2] Plasmacytoid dendritic cells favor the induction of tolerance.[63] Tumor cells and microenvironmental macrophages produce the chemokine CCL22, which mediates trafficking of Treg cells. Ovarian cancers can also produce TGF-β and several immunosuppressive factors including IL-10, VEGF, fibronectin, and mucins.[2]

Humoral Immune Response

Despite an immunosuppressive environment, antibodies against tumor-associated antigens can be found in the blood of ovarian cancer patients. Correlation of antibodies against MUC1 with favorable risk factors has raised the interesting hypothesis that immunity to mucins might suppress the development of ovarian cancers, although there may be many different reasons for the development of anti-MUC1 antibodies.[2] Antibodies against mesothelin, *TP53*, and HER2 have been found in ovarian cancer patients and are being explored as potential biomarkers for early diagnosis and monitoring.

Cellular Immune Response

T cells from ovarian cancer patients can kill autologous tumor cells following in vitro activation. Cytotoxic T cells can be generated by incubating peripheral blood lymphocytes with dendritic cells that have been pulsed with extracts

of autologous, but not allogeneic, ovarian cancers.[2] Cytotoxic T cells bear Fas ligand and induce apoptosis in cells that express Fas, which includes most ovarian cancers. Restricted expression of T-cell receptor V-β subtypes has been observed in tumor-associated lymphocytes, consistent with antigen-driven expansion of specific clones. Aberrantly glycosylated mucins, including MUC1, are expressed by most ovarian cancers, and T cells reactive with MUC1 and MUC16 molecules have been obtained from ovarian cancer patients. *TP*53 is mutated in approximately 70% of all ovarian cancers and in virtually all high-grade serous ovarian cancers, and T cells reactive with TP53 can be detected in some 50%, but are also found in a similar fraction of controls with benign disease.[2] T cells reactive with HER-2 epitopes have been isolated from the ascites fluid of ovarian cancer patients. Other antigens have been recognized by T cells from ovarian cancer patients, including folate receptor-α, NY-ESO-1, MAGE, Sp17, survivin, and telomerase.

T-cell antigen epitopes are recognized in the context of specific major histocompatibility complex (MHC) determinants. Normal ovarian surface epithelial cells express class I but not class II MHC components. In ovarian cancers, class I determinants are expressed in approximately 80%, and class II determinants are expressed in 40%.[2] The level of class I MHC expression in epithelial ovarian cancer cells has correlated with the degree of T-cell infiltration in vivo and the ability to expand T cells in vitro in the presence of low levels of IL-2. Low class I MHC expression is a poor prognostic factor in aneuploid ovarian cancers. Antibodies reactive with autologous tumor cells have also been identified.

Ascites contains widely varying fractions of lymphocytes, macrophages, mesothelial cells, and cancer cells. In one study, an average of 51% CD8 T cells, 10% CD4 T cells, and 27% CD14 macrophages were encountered.[2] A variety of chemokines—CCL-2, 3, 4, 5, 8, and 22—and their receptors—CCR1, 2a, 2b, 3, 4, 5, and 8—were detected, and a direct correlation was found between CCL5 and the CD3 T-cell infiltration. Chemokine CXCL12 and its unique receptor CXCR4 have been implicated in metastasis of several different cancers. CXCL12 was found in 91% of ovarian cancers and CXCR4 in 59%.[2] Expression of CXCR4 was associated with decreased disease-free and overall survival. CXCL12 and VEGF are both induced in ovarian cancer cells by hypoxia and synergize to induce tumor vessels.[2] CXCL12 also attracts plasmacytoid dendritic cells into ascites that further enhance angiogenesis by secreting IL-8 and TNF-α.[2]

Among the cells that infiltrate solid ovarian cancers, T cells are most prevalent, B cells are rare, and macrophages vary in number. In addition to the specific cytotoxic effects of T cells, the interferons produced by activated T cells can inhibit tumor growth, inhibit IL-8 secretion, block angiogenesis, upregulate MHC, and augment mucin expression. Intratumoral T cells have been found in 55% of ovarian cancers and are associated with a 5-year survival rate of 38%, compared with 4.5% for patients whose tumors lack T-cell infiltrates.[2] Both CD4 and CD8 cells can be found at tumor sites. The presence of CD8 T cells and a high CD8/CD4 ratio has correlated with the most favorable prognosis, related to the adverse effect of $CD4^+CD25^+FOXP3^+$ regulatory T cells within the $CD4^+$ population.[2] Ovarian cancer cells can secrete M-CSF and MCP1 that exert potent chemotactic activity for macrophages. Cytokines and factors released from activated macrophages can stimulate (IL-1, IL-6, TNF) or inhibit (nitric oxide, TNF) tumor growth. Tumor-associated macrophages have impaired phagocytic activity and effector function for ADCC. Cytotoxic NK cells have been detected in ascites fluid and in solid ovarian cancers. Despite these many potential immune effector mechanisms, most ovarian cancers grow progressively.

Based on the immunobiology of ovarian cancer, a number of strategies have been evaluated for the treatment of the disease.[64] Cancer vaccines have included idiotype anti-MUC16 (CA125),[65] MUC1, CEA, and NY-ESO-1. An alternative approach has used autologous ovarian cancer extracts, viral oncolysates or primed dendritic cells with or without depletion of T_{REGS} using metronomic daily cyclophosphamide. Adoptive immunotherapy has been performed using tumor infiltrating lymphocytes (TILs) expanded ex vivo with IL-2. In an early nonrandomized trial, consolidation of primary therapy with TILs and IL-2 improved progression-free and overall survival in a small group of ovarian cancer patients. Substantial effort has been directed in the laboratory toward developing methods for optimal expansion and antigen-specific stimulation of TILs, as well as to introducing T-cell receptors or chimeric antigen receptors (CARs) into T cells. Monoclonal antibodies have been used to regulate T-cell activity. Ipilimumab, an anti-CTLA4 that inactivates a T-cell checkpoint, has produced anecdotal responses in ovarian cancer patients.

Conclusion

Despite major progress over the past decade, many critical questions remain to be answered if we are to develop therapeutic approaches that will optimally benefit patients. An understanding of the pathogenesis of epithelial ovarian cancer should permit earlier detection and more effective, potentially less toxic, therapy. We will need to embrace the concept that ovarian cancer consists of multiple independent diseases with two major subgroups of Type I and Type II, with the corollary that clinical trials and translational studies must be

performed independently on each disease type. Biomarkers in addition to CA125 and imaging techniques with higher resolution than TVS must be identified to improve the ability to detect small volumes of disease in the ovary or fallopian tube for both early diagnosis and patient monitoring. Autoantibodies against overexpressed wild-type proteins and mutant TP53 provide attractive biomarker candidates, and SQUID imaging with targeted magnetic nanoparticles poses a potentially transformative technology. Low-grade Type I cancers are driven by Ras mutations, PI3K activation, and paracrine IGF signaling, in the context of wild-type TP53 and expression of ER and PR. Combinations of drugs that inhibit MEK, the PI3K pathway, and IGFR need to be tested in Type I ovarian cancers. Hormonal therapy, particularly in the context of targeted therapy, should be explored, especially considering the recent outcomes of trials of hormonal manipulation and mTOR targeting in breast cancers. High-grade Type II ovarian cancers are driven by copy number abnormalities that affect PI3K, NOTCH, and other pathways with loss of TP53 and/or BRCA1/2 function. Dual inhibition of PI3Kness and BRCAness should be evaluated in Type II ovarian cancers based on synergistic activity seen animal models. A variety of drugs targeting the PI3K pathway are in trials in ovarian cancer, and PAPR inhibitors that act as synthetic lethal with defects in BRCA1/2 or homologous recombination have shown activity in selected patients—providing an opportunity for combination trials, which indeed have just been initiated. Development of strategies that target mutant TP53 or act as a "synthetic lethal" with mutant TP53 constitutes a significant knowledge gap that needs to be filled. A number of compounds that can bind and potentially normalize function of TP53 with specific hotspot mutations have been developed and are entering clinical trials. Relevant genetically engineered murine models are needed that are driven by copy number abnormalities. Robust biomarkers for stem cell–like cells must be identified and strategies devised to eliminate dormant cancer cells. Predictive biomarkers are also needed to identify patients most likely to benefit from bevacizumab. Several other angiogenic targets must be evaluated, including FAK, Dll4, EZH2, and EphA2. Finally, therapy with vaccines, adoptive therapy, and checkpoint and other immunoregulatory antibodies must be combined strategically with targeted agents.

Molecular Basis of Prostate Cancer

Prostate cancer is the most common noncutaneous malignancy and the second leading cause of cancer death in men in the United States.[1] Prostate-specific antigen (PSA) screening began in the late 1980s and dramatically increased the diagnosis of this disease. An almost-simultaneous decrease in disease-specific mortality has been noted.[2] Whether this is a result of early and enhanced screening, early treatment of localized disease, early and aggressive treatment of micrometastatic disease, or other unknown reasons is a matter of considerable debate. Screening remains widespread but controversial because of conflicting evidence demonstrating overall survival benefit.[3,4] Prostate cancer has a very heterogeneous natural history, and screening has resulted in overdetection and overtreatment of men with indolent prostate cancer.[3,4] Prostate cancer is not, as yet, curable once it has metastasized; however, differentiation of early-stage disease that ultimately will progress from disease destined to remain indolent is a major research priority. The molecular genetics of prostate cancer hold promise for the development of new screening and diagnostic tests to resolve this issue.

Several risk factors have been associated with prostate cancer, including age, race, family history, and obesity. Subsequently, tumor suppressors, oncogenes, and polymorphisms have been analyzed to help explain these risk factors. Epigenetic alterations have been observed in prostate cancer affecting the expression and function of a large array of genes involved in tumorigenesis, tumor progression, and metastasis. The search for new and more specific biomarkers of disease continues with increased emphasis on epigenetic and genomic alterations predictive of metastasis and aggressiveness in this heterogeneous malignancy.

Pathology

Gleason Grade

The Gleason grading system is the most commonly used pathologic grading system for adenocarcinoma of the prostate. Tissue samples are examined under low magnification, and the two most common gland architectural patterns are assigned a grade from 1 to 5 and reported as a Gleason score. Figure 38-1 demonstrates the three most common Gleason scores. Gleason 1 and 2 are rarely seen in contemporary series of patients. Pathologic Gleason grade is the most important prognostic variable to the clinical risk assessment of newly diagnosed prostate cancer, followed by tumor volume. The importance of Gleason pattern 4 and 5 volume has been correlated with subsequent pathologic stage, metastasis, and outcome. Despite the decrease in prostate cancer–specific mortality seen in contemporary series, there has been a paradoxical increase in the diagnosis of patients with higher Gleason grade disease. This may be due in part to changes in pathologic criteria for diagnosing Gleason 4 disease, rather than a true increase in the incidence of higher grade disease as a result of the International Society of Uropathologists (ISUP) modifying their recommendations on histological grading of prostate cancer by expanding criteria of grade 4 disease. After this recommendation was published, it was projected that many patients previously classified as 3+3 would be subsequently upgraded to Gleason 3+4.

Prostate cancer is often multifocal, meaning that usually, multiple, distinct areas of malignancy exist within the prostate gland.[5] The largest focus of disease is often called the index tumor, and the size of this tumor has been used in disease prognostication and prediction of metastasis. An analysis of genetic alterations in tumor foci and metastases found that metastases were usually homologous with at least one tumor focus, but it was not always the index tumor. Several studies have described genetic heterogeneity within dominant tumor nodules and showed chromosomal differences between various areas of the same disease focus. Because of the genetic variability of prostate cancer and its multifocal nature, debate continues regarding the importance of smaller tumors and their impact on tumor progression and patient survival. There is genetic heterogeneity within dominant tumor nodules and chromosomal differences between various areas of the same disease focus. Because of the genetic

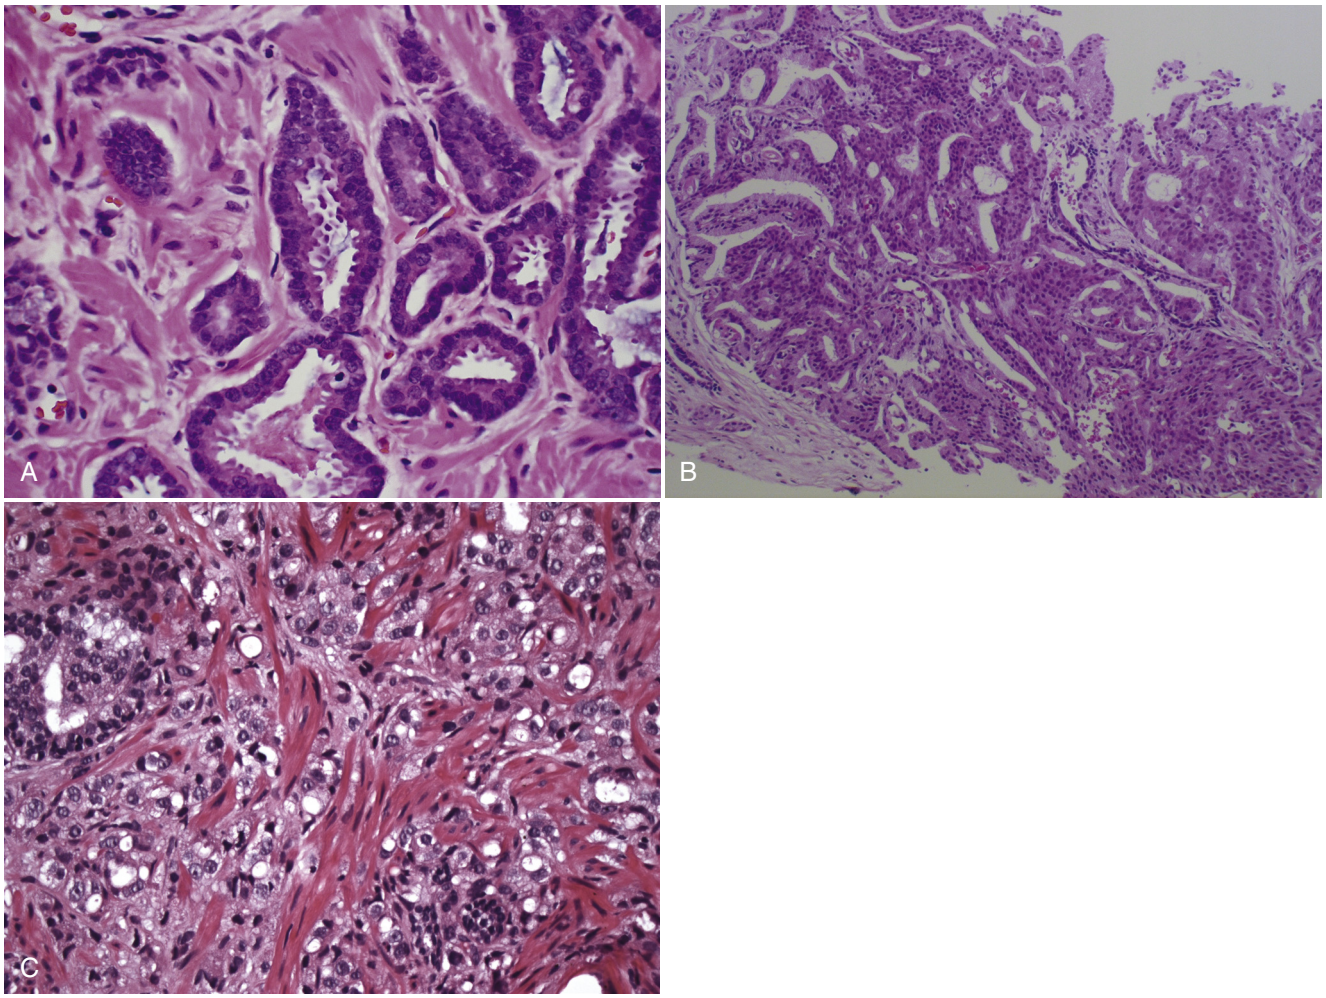

Figure 38-1 Examples of Gleason grade 3, 4, and 5 prostate cancer. Gleason grade 3 shows well-formed, separate glands **(A)**. Gleason grade 4 shows merging or cribriform glands **(B)**. Gleason grade 5 is the most poorly differentiated, and cancer cells no longer form glands but are visible as sheets of cells **(C)**.

variability of prostate cancer as well as its multifocal nature, debate continues regarding the importance of smaller tumors and their impact on tumor progression and patient survival.

Molecular Pathology

Hereditary Prostate Cancer

Family history is one of the strongest risk factors for the development of prostate cancer, with a two- to eightfold higher risk of prostate cancer in men with an affected first-degree relative.[6] Prostate cancer associated with familial clustering and high incidence of cancer among multiple first-degree relatives with a diagnosis before age 60 is considered hereditary and/or familial prostate cancer (HPC/FPC). Approximately 9% of all cases are attributable to hereditary prostate cancer following an autosomal dominant susceptibility pattern. Prostate cancer susceptibility genes have been identified using lineage analysis of affected families. Significant linkage between chromosome 1q24-25, the HPC1 locus, and hereditary prostate cancer has been established. *RNASEL*, which lies within the HPC1 locus, encodes an endoribonuclease that mediates the activities of an interferon-inducible RNA degradation pathway. Polymorphisms of the *RNASEL* gene have been associated with increased prostate cancer risk. However, not all studies have confirmed these findings. Mutations in the RNASEL gene do not occur at a greater frequency in patients with familial prostate cancer compared with patients with sporadic prostate cancer. Recent genome-wide association studies (GWAS) consistently identified that several single-nucleotide polymorphisms (SNPs) in the 8q24 locus are associated with risk of HPC/FPC22. Genetic variants caused by polymorphisms or mutations in other genes, such as *PALB2*, *BRCA2*, the androgen receptor (AR), 5-α-reductase type II (SRD5A2), and *CYP17*, have also been implicated in the development of HPC/FPC.

Table 38-1 Oncogenes and Tumor Suppressors Implicated in Prostate Cancer

Gene	Chromosome/Locus	Function	
PCA3 (DD3)	9q21–22	ncRNA with unknown function	Oncogene
EZH2	7q35	Gene silencing by histone modification	Oncogene
NKX3-1 (NKX3.1)	8p21	Homeobox gene, regulates epithelial growth and differentiation	Tumor suppressor
PTEN	10q23	Dual specificity protein/3-lipid phosphatase	Tumor suppressor
CDKN1B (p27)	12p11–13	Cyclin-dependent kinase inhibitor	Tumor suppressor
KLF6	10p15	Zinc finger transcription factor	Tumor suppressor
ERG/ETV1 (*ETS* family *TMPRSS2-ERG*)	21q22.3/7p21.2	Androgen-responsive fusion protein	Fusion oncogene
RB1 (RB)	13Q14–1-14–2	Suppress cell division	Tumor suppressor
TP53 (p53)	17p13	Cell cycle control	Tumor suppressor
CSMD1	8p23 loss	CUB and Sushi multiple domains 1	Tumor suppressor
MAP4K2	11q13.1 gain	Mitogen-activated protein kinase 2	Oncogene
MEN1	11q13.1 gain	Multiple endocrine neoplasia	Oncogene
SF1	11q13.1 gain	Splicing factor 1	Oncogene
PPP2R5B	11q13.1 gain	Protein phosphatase2, regulatory subunit B isoform	Oncogene
NAALADASEL	11q13.1 gain	*N*-acetylated α-linked acidic dipeptidase-like	Oncogene
EHD1	11q13.1 gain	EH-domain containing 1	Oncogene

Gene Mutation

Early candidate gene approaches have implicated many different genes in prostate cancer. Germline mutations involving *ELAC2* (*HPC2*), *MSR1*, and *RNASEL* genes have been reported in familial prostate cancer. The most common somatic mutations found in sporadic prostate cancer include *TP53*, *PTEN*, and *AR*. Recent whole-genome exon sequencing analyses identified significant mutated genes, including TP53, AR, ZFHX3, RB1, PTEN, APC, MLL2, OR5L1, and CDK12. Of these genes, MLL2, OR5L1, and CDK12 have unknown tumor suppressor functions in prostate cancer.[7] The most commonly affected signaling pathways by genetic alterations are the WNT signaling (TP53, APC, CTNNB1, MYC, and SMAD4) and the PTEN interaction network (PTEN, MAGI3, and HDAC11).[7]

DNA Copy Number Variation

DNA copy number variation (CNV) is DNA structure alteration involving relatively large (at least 1 kb) regions. CNV can manifest as loss or gain of chromosomal regions. Earlier studies using fluorescence in situ hybridization (FISH) and comparative genomic hybridization (CGH) identified common losses at 1p, 6q, 8p, 10q, 13q, 16q, and 18q and gains at 1q, 2p, 7, 8q, 18q, and Xq. For example, *MSR1*, *NKX3.1*, and *N33* are candidate tumor suppressor genes in prostate cancer lying within the most commonly deleted regions on chromosome 8p. *MSR1* encodes a receptor on the macrophage cell surface that induces binding of oxidized low-density lipoprotein and other polyanionic ligands. Mutations, polymorphisms, or loss of the *MSR1* gene may compromise global macrophage function, thereby exposing organs, including the prostate, to oxidative stress and damage. Although this gene does not code for prostatic proteins directly, oxidative stress has been implicated in the initiation of prostate carcinogenesis.

Loss of 8p23, a region that harbors the *CUB* and Sushi multiple domains 1 gene (*CSMD1*), has been associated with advanced prostate cancer. The retinoblastoma (RB1) gene is also a tumor suppressor gene and lies within the 13q locus. It is deleted in early prostate cancer development in animal models, prostate cancer cell lines, and some human prostate cancer specimens. RB1 inactivation in prostate cancer is the result of loss of heterozygosity and mutation. The 10q locus is lost in up to 45% of prostate cancers examined, and *MXI1* and *PTEN* are two putative tumor suppressors in this region.

Regions of chromosome amplification in advanced prostate cancer include 8q containing the *MYC* gene and Xq11-13 encoding the AR gene. Gene amplification at 11q13.1 has been associated with disease recurrence. There are several candidate genes in this location (Table 38-1), but only *MEN1* and *MAP4K2* correlate with disease progression.

Recent prostate cancer genome sequencing studies consistently show that the genes most commonly affected by loss of copy number are CHD1, NTSE, PTEN, RB1, and TP53, and the most gained genes are AR, MYC, PIK3CA, and the HOXA3 cluster. These aberrations are more prominent in castration-resistant prostate cancer compared to localized disease.[7,8]

Gene Fusion

The prostate cancer genome can harbor an average of 90 chromosomal rearrangements involving many genes. One of the most frequent gene fusion events in prostate cancer is the fusion of the *TMPRSS2* and *ERG* genes, which are located 3 Mb apart on chromosome 21q22.2.[9] TMPRSS2 is an androgen-responsive gene, and ERG encodes an erythroblast transformation-specific (ETS) transcription factor. Their fusion is believed to be stimulated by androgens that recruit AR and TOP2B topoisomerase to chromosomal sites where TOP2B introduces double-strand breaks in DNA. TMPRSS2-ERG fusion results in overexpression of *ETS* genes in prostate cancer. *TMPRSS2-ERG* has been identified in 40% to 70% of prostate cancer and correlated with metastasis and disease-specific mortality. Gene fusion events such as *TMPRSS2-ERG* may be used for prostate cancer diagnosis through simple PCR detection of gene fusions in urine sediment.

WNT Signaling and β-Catenin

The Wnt signaling pathway plays a key role in embryonic development and is essential for the maintenance of stem cells. Wnt is an extracellular protein that interacts with the membrane-bound frizzled receptor to initiate its biologic activity. Wnt signaling leads to stabilization of *CTNNB1* and its nuclear accumulation. Nuclear *CTNNB1* converts the TCF/LEF DNA-binding protein complex from a transcriptional repressor into a transcriptional activator. Inappropriate activation of the Wnt pathway is observed in many cancers and is putatively associated with tumor development.

In mice, *CTNNB1* stabilization through targeted excision of *CTNNB1* exon 3 induces prostate intraepithelial neoplasia (PIN)-like lesions that are similar to the early stages of human prostate cancer. In human prostate cancers, high levels of nuclear *CTNNB1* are detectable by immunohistochemistry, whereas their levels are undetectable in normal prostate tissue. High levels of *CTNNB1* expression are associated with the more aggressive prostate tumors. Together, these findings imply that inappropriate activation of the Wnt signaling pathway can contribute to prostate cancer and progression.

There are several mechanisms by which the Wnt pathway may be inappropriately activated in prostate cancer; DNA methylation plays a key role in several of these processes. The adenomatous polyposis coli (APC) gene is hypermethylated in prostate tumors relative to samples of benign prostatic hyperplasia (BPH; 64.1% vs. 8.7%). APC is a key component of the *CTNNB1* degradation complex. Thus, methylation-dependent silencing of APC can lead to *CTNNB1* accumulation and Wnt pathway activation.

E-cadherin (CDH1), a cell membrane protein, interacts with *CTNNB1* and sequesters it at the inside surface of the cellular membrane. However, CDH1 expression is often lost in prostate cancers because of chromosomal loss or promoter hypermethylation. Thus, because CDH1 is no longer present, *CTNNB1* is released into the cytoplasmic and nuclear compartments, leading to Wnt pathway activation. Finally, the secreted-frizzled related proteins (SFRPs) and Wnt inhibitory factor-1 (Wif-1) sequester Wnt and antagonize Wnt signaling. In this manner, loss of *SFRP/Wif-1* expression can lead to Wnt pathway activation. The genes encoding several of the *SFRPs* and *Wif-1* are epigenetically silenced by DNA methylation in colorectal, lung, bladder, and kidney cancers and lymphocytic leukemia. In prostate cancer, *Wif-1* expression is strongly suppressed. The *SFRP1* gene is also aberrantly hypermethylated in prostate tumors relative to BPH tissue and is partially to completely methylated in several human prostate cancer cell lines. These findings suggest that silencing of genes antagonist to *Wnt* may play a role in prostate cancer development.

The Wnt signaling pathway may interact with other signaling pathways such as the AR-CTNNB1, which in turn can upregulate AR transcriptional activity in an androgen-dependent manner. Subsequently, AR enhances nuclear translocation of CTNNB1. In addition, PI3K/Akt can modulate the activity of CTNNB1 by phosphorylation of CTNNB1 by GSK3B, a substrate of Akt.

MicroRNA and Other Noncoding RNA in Prostate Cancer

Only a small fraction of the transcription output in human genome encodes for proteins. Noncoding RNAs (ncRNAs) are arbitrarily classified into two major classes based on their size: small (microRNA) and long ncRNA (lncRNA).

MicroRNA and Prostate Cancer

Small ncRNAs, exemplified by microRNA (miRNA), are known to regulate diverse biological processes in stem cells,

development, differentiation, metabolism, and disease such as cancer. Several hundred miRNAs have been identified in human cells, and these are transcribed from the genome as long, primary miRNAs ranging in size from hundreds to thousands of nucleotides. miRNAs depend on multiple proteins for their biogenesis and function. Aberrations in any of these proteins will affect miRNA-mediated gene regulation. Expression of Dicer, a key gene in the biosynthesis of miRNA, is upregulated in a significant fraction of prostate cancer and is associated with aggressive cancer features. Knockout of Dicer in the mouse prostate impairs prostate stem cell activity and causes prostate atrophy. Some other components of the miRNA machinery (XPO5, Ago1, Ago2, HSPCA, MOV10, and TNRC6B) are also upregulated in prostate cancer.

Processed miRNAs have been found to regulate gene expression by inhibiting protein translation and/or enhancing the degradation of target gene mRNA with which the miRNAs have imperfect sequence complementarity in the 3′UTR region. It has been predicted that each miRNA can target hundreds of genes, and a third of human protein-coding genes are regulated by miRNA. An increasing body of evidence suggests that miRNAs are involved in the initiation and development of different types of cancers, including prostate cancer.

Expression Signature of miRNA in Prostate Cancer

High-throughput miRNA expression profiling studies have found altered miRNA expression in prostate cancer, providing evidence for the involvement of miRNAs in this disease. miRNAs that have increased expression or amplification in cancer can act as oncogenes to enhance cell proliferation and survival by the inhibition of protein-coding tumor suppressor genes. They are thus called *oncomiRs*. Several such oncomiRs have been identified in prostate cancer cell lines including miR-21, miR-291, miR-221, miR-222, and the well-known miR-17-92 cluster, which contains six members: miR-17, miR-18a, miR-19a, miR-20a, miR-19b-1, and miR-92a-1. Some common target genes of these oncomiRs include PTEN, BIM, RB1, p21, and p27. On the other hand, miRNAs that normally target and suppress are regarded as tumor suppressor miRNAs (ts-miRNAs). In prostate cancer, the miR-15a/16-1 cluster that targets BCL2 and CCND1 is downregulated in prostate cancer. Forced expression of these miRNAs can lead to suppression of cell proliferation and induction of apoptosis.[10] Other commonly identified tumor suppressor miRNAs include miR-34a/b/c, miR-145, miR-205, and let-7.

miRNA and the AR Signaling Pathway

The AR signaling pathway and miRNAs are engaged in reciprocal regulation via multiple interaction points. miRNA can suppress AR expression through the canonical miRNA pathway or affect AR transcriptional activity by modulating other AR cofactors such as MYC. A systemic analysis of miRNAs identified a number of miRNAs that could suppress AR expression post-transcriptionally by targeting the AR 3′UTR element. Similar to protein coding genes, miRNA genes are also under the regulation of many transcription factors, including AR, which binds to ARE in the promoter of many miRNAs. As the first example, AR can bind to the ARE of miR-21, a prostate oncomiR, and directly regulate its expression as a downstream signaling effector.[11] Several other miRNAs were later found to be also under the regulation of AR, including miR-101, miR-141, miR-27a , miR-32, and miR-148a.

miRNA as Biomarkers for Prostate Cancer Diagnosis

miRNAs derived from cancer cells can exist as circulating extracellular or cell-free RNA and are remarkably stable in body fluids such as plasma/serum. These extracellular miRNAs can be detected and quantified using either PCR-based methods or other high-throughput approaches, including miRNA microarray and next-generation sequencing. A number of studies have performed miRNA profiling in body fluids including serum, plasma, and urine and have identified several miRNAs whose levels can serve as diagnostic and/or prognostic markers for prostate cancer patients.[12,13] Some of the miRNAs that consistently exist in prostate cancer patients across different studies include miR-141 and miR-375.

lncRNA and Prostate Cancer

The longer class of ncRNAs is known as long intergenic RNA (lncRNA), with sizes ranging from a few hundred to thousands of nucleotides. lncRNAs can regulate protein-encoding genes by affecting transcription and chromatin state by mechanisms distinct from those used by small ncRNAs. Thus genetic alterations and aberrant expression of lncRNAs can be a causal factor in disease. Several lncRNAs pertinent to prostate cancer have been identified. A 3.7-kb lncRNA known as PCA3 (DD3) has been mapped to chromosome 9q21-22 and shown to be highly overexpressed in prostate cancer samples. Genetic variation in lncRNAs has been found to affect prostate cancer risk. Microarray profiling of intronic transcripts identified many

ncRNAs expressed in prostate cancer samples, and the expression levels of some correlate with the extent of prostate tumor cell differentiation.[14] By high-throughput RNA sequencing of 102 prostate tissues and cell lines, Prensner and colleagues identified 121 unannotated prostate cancer–associated ncRNA transcripts (PCATs) and have characterized one of them, PCAT-1, as a prostate cancer–specific ncRNA functionally implicated in disease progression.

Given the regulatory role of lncRNA in prostate cancer, their aberrant expression suggests that they may serve as tumor biomarkers. In this regard, Cui and co-workers identified an lncRNA termed *PlncRNA* that expresses higher in prostate cancer cells compared to normal prostate epithelial cells.[15] Knockdown of PlncRNA has an inhibitory effect on prostate cancer cells, potentially through its regulation of AR activity

Epigenetic Alterations in Prostate Cancer

Epigenetic alterations contribute to the malignant transformation and progression of prostate cancer. Figure 38-2 shows the potential contribution of epigenetic events to the development of prostate cancer and its progression to advanced and castration-resistant cancer. Initially DNA methylation was regarded as a new type of promising biomarker for prostate cancer diagnosis and prognosis, and a therapeutic target. Despite intensive research efforts in the past decade, results from clinical studies evaluating DNA methylation as a biomarker have been disappointing, and so far no biomarker has advanced into the clinical arena.

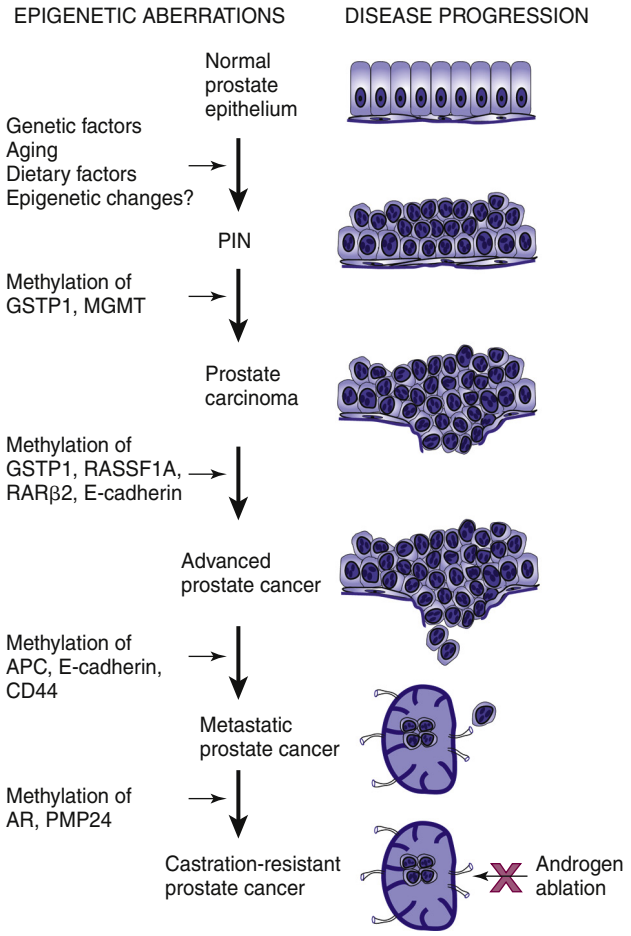

Figure 38-2 Epigenetic alterations in the development of prostate cancer Multiple factors are associated with the development of prostate cancer, including genetic predisposition, environmental factors, diet, ethnicity, and aging. Many of these factors modify the genome through epigenetic effects, and DNA methylation may be an early event causing inactivation of DNA damage repair genes such as *GSTP1* and *MGMT*. Subsequent inactivation of cell-cycle control genes provides a growth advantage leading to locally advanced prostate cancer. Functional loss of genes in the cell adhesion pathway, such as *CD44*, may allow for metastasis. Ultimately, inactivation of AR via DNA hypermethylation allows cancer cells to become androgen insensitive. *From Li LC, Okino ST, Dahiya R. DNA methylation in prostate cancer.* Biochim Biophys Acta. *2004;1704:87-102, with permission.*

Hypermethylation

DNA hypermethylation is one of the most common and best-characterized epigenetic abnormalities in prostate cancer. Genes including classic and putative tumor suppressor genes as well as genes involved in a number of cellular pathways, such as hormonal responses, cancer cell invasion/tumor architecture, cell cycle control, and DNA damage repair, can be hypermethylated in prostate cancer. For many of these genes, promoter hypermethylation is often the mechanism responsible for their functional loss in prostate cancer. Inappropriate silencing of these genes can contribute to cancer initiation, progression, invasion, and metastasis. Some commonly hypermethylated genes in prostate cancer are discussed next (Table 38-2).

DNA Damage-Repair Genes

Antioxidants and DNA repair pathways protect the genome and maintain genome stability during replication or following DNA damage. Hypermethylation of genes important for such processes, such as glutathione *S*-transferase Pi (*GSTP1*) and *O*-6-methylguanine DNA methyltransferase (*MGMT*), has been frequently documented in prostate cancer. *GSTP1*, located at chromosome 11q13, belongs to a supergene family of glutathione *S*-transferases (GSTs) that play an important role in the detoxification of carcinogens and cytotoxic drugs by catalyzing their conjugation to glutathione. *GSTP1* inactivation may lead to increased cell vulnerability to oxidative DNA damage and the accumulation of DNA base adducts, which can precede carcinogenesis.

In prostate cancer, methylation of the *GSTP1* gene promoter is the most frequently detected epigenetic alteration. Elevated CpG methylation has been detected in

Table 38-2 Epigenetic Changes in Prostate Cancer

Gene	Function
Hypermethylation	
GSTP1	Detoxification if electrophilic compounds
RASSF1	Similar to RAS effector proteins
AR	Androgen effects +/–
ESR1, ESR2	Estrogen effects
CCND2, CDKN2A, CDKN1A, SFN	Inhibit cyclin D–associated kinases, other cyclin-dependent kinases
CD44, CDH1, LAMA3, LAMB3	Cell architecture
MGMT	DNA damage repair gene
DAB2IP, EDNRB, RASSF1	Signal transduction
PTGS2	Inflammatory response
Hypomethylation	
CAGE	Novel testis antigen
HPSE	Heparanase
PLAU	Urokinase plasminogen activator
MAGE11	Melanoma antigen gene protein-A11
Histone modification	
VDR	Vitamin D receptor
CPA3	Carboxypeptidase A3
RARB	Retinoic acid receptor β
KLK3	Prostate-specific antigen
DAB2IP	Tumor suppressor

prostate cancer tissues as early as at the stage of atypia and PIN. GSTP1 promoter hypermethylation can also be readily detected in the serum/plasma, urine, and ejaculates of prostate cancer patients with high specificity but unsatisfying sensitivity. Current findings from a large number of studies do not support the feasibility of using GSTP1 as an independent tumor biomarker, but it may complement prostate-specific antigen (PSA) screening for prostate cancer diagnosis.

Hormone Receptors

AR mediates testosterone and dihydrotestosterone activity, which is essential for the development and maturation of the prostate gland and prostate cancer. Most prostate cancer is initially androgen dependent, but eventually becomes androgen independent after androgen-deprivation therapy. Androgen-independent prostate cancers are characterized by a heterogeneous loss of *AR* expression. Genetic alterations that alter the sensitivity of the receptor to androgen, such as *AR* gene mutation and, more commonly, amplification without loss of *AR* expression, are thought to play key roles in the development of androgen-independent prostate cancer. The prostate expresses two types of estrogen receptors (ERs): ERα (ESR1) and ERβ (ESR2), whose functional role in the prostate and prostate cancer remains controversial. Hypermethylation of ERs leading to decreased expression increases with aging and can contribute to tumor progression in prostate cancer patients.

Cell Cycle Control Genes

An important characteristic of tumor cells is unbalanced proliferation due to impaired regulation of the cell cycle. The multiple checkpoints that control the cell cycle include the retinoblastoma protein, cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors (CDKIs). CDKIs are potential tumor suppressor genes that act as molecular brakes on cell cycle progression. Failure of cell cycle arrest due to alterations in CDKI expression has been implicated in prostate cancer. CDKIs are grouped into two families: the INK4 family and the CIP/KIP (kinase inhibitor protein) family. The INK4 family includes CDKN2A (p16), CDKN2B (p15), CDKN2C (p18), and CDKN2D (p19) and inhibits cyclin D–associated kinases (CDK4 and CDK6). The CIP/KIP family, which includes CDKNIA (p21), CDKN1B (p27), and CDKN1C (p57), inhibits most CDKs.

CDKN2A can be inactivated in prostate cancer by a variety of mechanisms, including deletion, point mutation, and hypermethylation. Methylation-mediated inactivation of the *CDKN2A* gene has been reported in prostate cancer cell lines and tissues at a very low frequency (0% to 16%). Inactivation of other cell cycle genes such as CDKN2B, CDKN1A, and CDKN1B by hypermethylation is rare in prostate cancer.

The Ras-association domain family-1 gene (*RASSF1*) is located at 3p21.3 and encodes a protein similar to the RAS effector proteins. A tumor suppressor role has been proposed for *RASSF1*. *RASSF1* promoter methylation is a common event in prostate cancer and high-grade PIN, occurring in 54% to 96% of tumors, and increases with higher Gleason scores.

Tumor Invasion and Tumor Architecture Genes

The cadherin-catenin adhesion system is critical for the preservation of normal tissue architecture and is regulated by a family of proteins collectively termed *cell adhesion molecules* (CAMs). Decreased expression of CDH1 and other CAMs

has been reported to have prognostic significance in various human cancers, including prostate cancer. In prostate cancer, expression of CDH1 is markedly suppressed and its promoter is methylated to varying degrees. In addition, methylation of the CDH1 promoter is increased in advanced prostate cancer, making it a potential biomarker for cancer progression.

CD44 is an integral membrane protein involved in matrix adhesion and signal transduction. Loss of CD44 expression correlates with methylation of its gene promoter in prostate cancer and is associated with stage and prognosis. Other genes involved in the cadherin-catenin adhesion system have also shown methylation-mediated inactivation in prostate cancer, such as H-cadherin, adenomatous polyposis coli (APC), caveolin-1 (CAV1), laminin α-3 (*LAMA3*), laminin β-3 (*LAMB3*), and laminin γ-2 (*LAMC2*).

Other Putative Tumor Suppressor Genes

Other possible tumor suppressor genes that are subject to epigenetic inactivation in prostate cancer include *KAI1* (a prostate-specific tumor metastasis suppressor gene), inhibin-α (a member of the TGF-β family of growth and differentiation factors), and *DAB2IP*, a novel GTPase-activating protein for modulating the Ras-mediated signal pathway.[16] Recent high-throughput DNA methylation profiling in prostate cancer cell lines and tissues unveiled methylated genes such as SLC15A3, KRT7, TACSTD2, GADD45b[17] OXD3 and BMP7[18]PR83, ADCY4, LOC63928, and D4S234E;[19] however, these genome-wide analyses seem not to have yielded consistent information identifying new prostate cancer biomarkers.

Hypomethylation

Both global and gene-specific hypomethylation have been implicated in human malignancy. The *PLAU* gene encodes urokinase plasminogen activator and is highly expressed in most prostate cancer tissues and invasive prostate cancer cell lines. DNA methylation and gene amplification may participate in the regulation of the *PLAU* gene in prostate cancer. Hypomethylation of the PLAU promoter is associated with increased expression in hormone-independent prostate cancer cells, higher invasive capacity in vitro, and increased tumorigenesis in vivo. Other hypomethylated genes in prostate cancer include *CAGE*, a novel cancer/testis antigen gene; heparanase (*HPSE*), *CYP1B1*, and Melanoma antigen gene protein-A11 (MAGE-11). *HPSE*, an endo-β-*D*-glucuronidase, and *CYP1B1* are overexpressed and substantially hypomethylated in prostate cancer compared with benign prostatic hyperplasia samples. Aberrant hypomethylation of repetitive DNA elements such as LINE-1 and ncRNA such as XIST also occurs in prostate cancer.

Histone Modification

DNA is organized into a nucleoprotein complex termed *chromatin*. The basic chromatin unit is the nucleosome, which is composed of 146 bp of DNA wrapped around four pairs of histone proteins. The N-terminal tails of histones are positioned outside the nucleosome core and are thus susceptible to covalent modifications including acetylation and methylation. Acetylation and deacetylation of histone tails are catalyzed by histone acetyltransferase (HATs) and deacetylases (HDACs), respectively. Through histone acetylation, HATs have been shown to increase the activity of several transcription factors, including nuclear hormone receptors, which facilitate promoter access to the transcriptional machinery. Conversely, HDACs cause histone deacetylation, which is associated with transcriptional repression. Histone methylation is facilitated by histone methyltransferases (HMTs), which use *S*-adenosylmethionine as a methyl donor group to the lysine and arginine residues of histone protein pairs H3 and H4. Like histone acetylation, histone methylation is reversible and is facilitated by at least two enzymes: lysine-specific demethylase1 (LSD1) and JmjC domain-containing histone demethylase1 (JHDM1).

The expression of many genes is aberrantly regulated in prostate cancer through histone modification. Tumor-specific alterations in the enzymes that modify histone states can alter global histone modification profiles. For example, MLL2 encodes an H3K4-specific histone methyltransferase that is recurrently mutated in multiple cancers including prostate cancer. Also, the loss of acetylation of H3 and H4 resulting from increased HDAC activity may also be of importance in prostate cancer. Treatment of prostate cancer cells with HDAC inhibitors increased the expression of specific genes such as insulin-like growth factor binding protein-3 and carboxypeptidase A3 (CPA3), thereby suggesting a role for histone acetylation in aberrant gene regulation.

Polycomb Group Transcriptional Repression

The Polycomb group (PcG) proteins are developmental regulators that silence chromatin through H3K27 methylation. Enhancer of Zeste 2 (*EZH2*) and SUZ12 are members of the PcG proteins that are overexpressed in prostate cancer and are highly associated with tumor aggressiveness.

Other studies reveal that *EZH2* is overexpressed and associated with aggressiveness in cutaneous melanoma, endometrial cancer, bladder cancer, and breast cancer. In addition, other PcG proteins, *BMI1* and *RING1*, are also overexpressed in aggressive prostate cancers. The *EZH2* complex silences gene expression by catalyzing H3K27 methylation to generate an inaccessible, heterochromatic chromatin configuration. In addition, *EZH2* was found to control DNA methylation through direct physical contact with DNA methyltransferase. It is unclear how *EZH2* is overexpressed in prostate cancer. EZH2 overexpression in prostate cancer causes the silencing of developmental regulators and tumor suppressor genes such as ADRB2, CDH1, DAB2IP, SNCA, and SOCS via histone methylation, conferring on cancer cells a stem cell–like epigenetic state, because PcG is a stem cell–specific marker including cancer stem cells and plays an important role in maintaining the undifferentiated state of embryonic stem (ES) cells. Pharmacologic disruption of polycomb repressive complex 2 has been shown to inhibit prostate tumorigenicity and tumor progression in animal models of prostate cancer.

PSA

The PSA (KLK3) gene contains an androgen receptor response element in its 5′ regulatory region. Methylation of H3K4 is associated with transcriptional inactivation of the PSA gene in the prostate cancer cell line LNCaP, and transcription of the PSA gene is accompanied by rapid decreases in di- and trimethylated H3 at lysine 4. In addition, a lysine-specific demethylase (LSD1) has been found to interact with the androgen receptor to stimulate the AR-dependent transcription of PSA in LNCaP cells by removing the methyl group at H3K9. An inhibitor of LSD1, pargyline, can block AR-dependent transcription by blocking histone demethylation. The net effect of methylation on the PSA gene needs to be carefully considered, however, because PSA is a marker of disease progression rather than a causal factor.

Aberrant Translational Control in Prostate Cancer Etiology and Progression

In addition to the genomic and transcriptional alterations that drive cancer initiation and progression, there is an emerging appreciation for how altered protein synthesis may have a direct causal role in cancer etiology. The understanding of translational control has undergone a paradigm shift towards a greater appreciation for specificity in this step of gene expression regulation. For example, genes that encode distinct factors involved in translation initiation, the first and most highly regulated step of protein synthesis, are often found aberrantly expressed in human cancers.[19a-19c] Furthermore, translation of mRNA networks involved in tumor suppression and oncogenic transformation is controlled by the presence of regulatory elements in their 5′- and 3′UTRs such as internal ribosome entry sites (IRESes), structured RNA sequences, RNA binding protein domains, and miRNA binding sites. Most importantly, activity of an entire repertoire of translational components is controlled by oncogenic signal transduction pathways such as RAS, PI3K-AKT-mTOR, and MYC, which are master regulators of protein synthesis. These oncogenic signaling pathways are commonly deregulated in human prostate cancer and have been shown to promote cancer initiation and progression.[19d-19h] A striking example is the convergence of RAS, PI3K-AKT-mTOR, and MYC pathways on translation initiation. In this context, these pathways share a common regulatory node: oncogenes[19i] and translational initiation factor eIF4E, which controls global protein synthesis as well as the translation of specific mRNA targets.[19b,19g-19l] eIF4E is the best characterized and rate-limiting factor of the eIF4F translation initiation complex. The activity of eIF4E is negatively regulated by the tumor suppressor eIF4E binding proteins (4EBPs), which are phosphorylated and inhibited by the mTOR kinase.

Deregulation of the 4EBP/eIF4E axis has been linked to prostate cancer initiation and progression. In particular, it has been shown that eIF4E phosphorylation, which directs eIF4E activity, is necessary for tumorigenesis in a mouse model of prostate cancer driven by PI3K-AKT-mTOR hyperactivation.[20] Restraining the oncogenic activity of eIF4E downstream of hyperactive mTOR to normal levels inhibits tumor progression and leads to overall increased survival rates.[21] One of the molecular mechanisms underlying eIF4E's oncogenic activity is its ability to upregulate the translation of pro-survival factors. For example, distinct mRNAs with highly structured 5′UTRs (which is an obstacle for translation initiation), such as the anti-apoptotic protein Mcl-1, are more efficiently translated on eIF4E hyperactivation.[19b] Mechanistically, eIF4E recruits the eIF4A helicase to unwind these 5′UTR structured elements, leading to the translational upregulation of specific mRNAs such as Mcl-1.[22,23] Thus, eIF4E hyperactivation provides a survival advantage for cancer cells.

Genetic and pharmacological inhibition of the 4EBP1/eIF4E axis downstream of oncogenic mTOR also significantly inhibits the invasive and metastatic potential of prostate cancer.[19l] The molecular mechanism by which hyperactive eIF4E exploits specific cellular processes to drive cancer progression is also mediated through the selective translation of distinct nodes of mRNAs. In this context, the translation of a novel signature of metastasis-associated

mRNAs is found to be upregulated during prostate cancer invasion. This cancer cell invasion network includes the intermediate filament protein vimentin,[24] whose expression is increased during cancer progression; CD44, an antigen involved in cell migration that is also associated with cancer metastasis;[25] metastasis associated protein 1 (MTA1), which promotes neoangiogenesis in metastatic forms of cancer;[26,27] and Y-box binding protein 1 (YB-1).[28] The eIF4E-mediated translation of this invasion signature is dependent on a newly identified regulatory element termed a pyrimidine-rich translational element (PRTE) in the 5'UTR of these mRNAs. Importantly, a new and potent class of compounds that blocks mTOR oncogenic activity through inhibition of eIF4E (known as mTOR ATP site inhibitors) decreases the expression of the invasion signature and demonstrates therapeutic efficacy during all stages of prostate cancer progression and metastasis. Additional mRNA targets that direct cell invasion are also controlled by eIF4E including matrix metalloproteinase 9 (MMP9), an enzyme that aids breakdown of extracellular matrix (ECM), and heparanase, which degrades the interior lining of blood vessels. Thus, deregulation of translational control represents a highly specific mechanism for targeting critical nodes of gene expression that can steer prostate epithelial cells towards transformation and cancer progression.[19l,29,30] Interestingly, recent studies have uncovered that YB-1 in turn promotes cap-independent modes of translation for other mRNAs involved in metastasis.

Components of the translational machinery are increasingly being recognized as potential biomarkers of disease progression and attractive therapeutic targets in prostate cancer. eIF4E overexpression is common in multiple cancer types, including malignancies of the prostate, breast, stomach, colon, lung, skin, and the hematopoietic system.[30] In prostate cancer, eIF4E protein and phosphorylation levels as well as 4EBP1 phosphorylation status correlate positively with Gleason grade.[31,32] Furthermore, in postprostatectomy prostate cancer patients, elevated eIF4E expression and increased 4EBP1 phosphorylation are predictive of worse overall survival.[32] Beyond the translational machinery itself, specific downstream mRNA targets of translation initiation factors, including the eIF4E-directed invasion signature described earlier, are also candidate biomarkers for prostate cancer progression. For example, prostate cancer patients exhibit stepwise increases in YB-1 expression at every stage of the disease from normal prostate to castration-resistant prostate cancer.[19l] Furthermore, the matrix metalloproteinase, MMP3, which is a translationally regulated mRNA responsive to eIF4E phosphorylation, is highly expressed in prostate cancer.[31] Other initiation factors are also emerging as biomarkers, including eIF3H, a component of the translation pre-initiation complex that is highly overexpressed at the protein level in human prostate cancer.[33] In addition to the translation initiation machinery, there is evidence suggesting that the abundance of rRNA (ribosomal RNA), a critical component of the ribosome, increases with advanced prostate cancer.[34,35] Moreover, the gene that encodes a key enzyme that modifies specific rRNA nucleotides, known as *DKC1*, is significantly overexpressed in prostate cancers, particularly in patients with aggressive disease. Therefore, multiple components of the translation machinery as well as downstream mRNA targets may have significant predictive power that could help delineate between prostate cancer patients with indolent and those with aggressive forms of the disease. Most importantly, next-generation therapeutics have shown great promise in preclinical and Phase I clinical trials at targeting the oncogenic translation machinery in prostate cancer.[37,38]

Future Directions

The search for new biomarkers is under way to aid in the diagnosis, prognosis, and decision-making process of men with prostate cancer. Because of the multitude of mechanisms of carcinogenesis, many approaches can be taken to accomplish these aims. Because epigenetic events are theoretically reversible, novel therapies that target hyper- or hypomethylated genes or histone acetylation implicated in prostate cancer aggressiveness and progression could bring new hope to patients with metastatic disease. Although the past two decades have been largely dedicated to the use and importance of PSA, the future of prostate cancer detection and treatment will be refined by discoveries in molecular biology.

Molecular Abnormalities in Kidney Cancer

Kidney cancer is one of the 10 most common cancers in the United States in both men and women. A number of subtypes of kidney cancer exist. Historically these subtypes have been recognized based on their histological appearance, but it is also now known that each subtype has characteristic molecular abnormalities as well. Germline and somatic genetic studies have helped identify tumor suppressor genes and proto-oncogenes that play roles in kidney cancer pathogenesis.

The principal objectives of this chapter are to review the following: (1) the epidemiology of kidney cancer, (2) the histopathological subtypes of kidney cancer, (3) the genetic alterations linked to hereditary kidney cancer, (4) the molecular pathogenesis of kidney cancer with a focus on clear cell renal carcinoma, and (5) the potential utility of this information for the early detection and management of kidney cancer.

Epidemiology

Kidney cancer accounts for more than 3% of all malignant diseases. It occurs more frequently in men than in women (M/F ratio = 1.7:3.4), with highest incidence in the sixth and seventh decades. In the United States, incidence rates tend to be higher in African-Americans compared to Caucasians.[1] In the past 65 years, the incidence of kidney cancer has increased steadily at about 2.5% per year. Most kidney cancers (more than 90%) arise in the kidney parenchyma; the remainder originate from the renal pelvis. Renal cell carcinoma (RCC) is the most common form of cancer of the kidney parenchyma that occurs in adults.[1] Most RCCs, in turn, are clear cell renal carcinomas (ccRCC).

There is strong evidence that genetic factors are linked with an increased risk of RCC. Although most renal cancers are sporadic, a small percentage of patients (2% to 5%) have an inherited predisposition to the disease[2] (Table 39-1). In further support of the notion that genetic factors may predispose to renal cancer, a genome-wide association study of RCC recently identified two susceptibility loci, one linked to *EPAS1* on 2p21 that encodes hypoxia inducible factor-2 alpha (HIF2α) and another linked to a HIF-binding site near the *Cyclin D1* locus.[3,4]

Kidney Cancer Histopathology

It is widely accepted that RCC is not a single disease but includes different types of epithelial malignancies of the kidney that are characterized by different histopathologic features and also display different genetic alterations and clinical behavior.[5,6] The current World Health Organization (WHO) classification of kidney tumors is based on both histopathologic and molecular criteria and recognizes 10 major types of RCCs (Table 39-2). Clear cell RCC (ccRCC) is the most common renal cancer type and accounts for 70% to 80% of all cases.

Papillary RCC (pRCC) represents approximately 10% of RCC cases. Chromophobe RCC (chRCC; about 5% of all cases) is grossly a well-circumscribed tumor with a gray to brown cut surface. Microscopically, it consists of tumor cells with pale cytoplasm and prominent cell membrane.

Xp11 translocation RCCs, which bear gene fusions involving the *TFE3* gene at Xp11.2, represent the vast majority of translocation RCCs (tRCCs). Histologically, tRCC usually shows a papillary pattern of growth and the presence of cells with abundant clear or eosinophilic cytoplasm.

Hereditary Kidney Cancer Syndromes and Molecular Pathways of Kidney Carcinogenesis

Studying rare families that are predisposed to cancer because of highly penetrant germline mutations has often led to the

Table 39-1 Inherited Renal Cancer

Syndrome/Disease	Kidney Cancer Type(s)	Extrarenal Manifestations	Gene (Locus)
von Hippel-Lindau (VHL)	Clear cell RCC	CNS and retinal hemangioblastomas, pancreatic cysts and neuroendocrine tumors, phechromocytomas, endolymphatic sac tumors	*VHL (3p25)*
Hereditary papillary renal carcinoma (HPRC)	Papillary RCC, type 1	—	*MET (7q31)*
Hereditary leiomyomatosis and renal cell carcinoma (HLRCC)	Papillary RCC, type 2	Leiomyomas, leiomyosarcomas	*FH (1q42)*
Birt-Hogg-Dubé (BHD)	Chromophobe RCC, oncocytic tumors, clear cell RCC (rare)	Cutaneous lesions (fibrofolliculomas), pulmonary cysts, and spontaneous pneumothorax	*FLCN (17p11)*
Familial clear cell renal cell carcinoma (FCRC)	Clear cell RCC	—	*?*
Tuberous sclerosis (TS)	Angiomyolipoma, clear cell RCC (rare)	Cortical tubers, subependymal giant cell astrocytomas, cutaneous lesions, cardiac rhabdomyomas, pulmonary cysts, retinal hamartomas	*TSC 1 (9q34) TSC 2 (16p13)*
Constitutional chromosome 3 translocation	Clear cell RCC	—	*?*
Hyperparathyroidism–jaw tumor syndrome (HPT-JT)	Mixed epithelial-stromal tumors, Wilms tumor (rare)	Parathyroid adenomas and carcinomas, ossifying fibromas of the jaw	*CDC73 (1q25)*
Familial papillary thyroid carcinoma (fPTC)	Papillary RCC	Papillary thyroid carcinomas, multinodular goiters	*? (1q21)*
Pheochromocytoma/paraganglioma syndrome type 4 (PGL4)	Various histological types have been reported	Pheochromocytomas and paragangliomas, gastrointestinal stromal tumors	*SDHB (1p36)*

Table 39-2 2004 WHO Classification Of RCC

Clear cell renal cell carcinoma
Multilocular clear cell renal cell carcinoma
Papillary renal cell carcinoma
Chromophobe renal cell carcinoma
Carcinoma of the collecting ducts of Bellini
Renal medullary carcinoma
Xp11 translocation carcinomas
Carcinoma associated with neuroblastoma
Mucinous tubular and spindle cell carcinoma
Renal cell carcinoma, unclassified

discoveries of genes and pathways that play much broader roles in human cancer. In particular, the genes linked to these particular syndromes are often somatically mutated in the sporadic counterparts of the tumors that define these syndromes.

Approximately 2% to 5% of kidney cancers are linked to a recognized cancer predisposition syndrome, and there is at least one such syndrome for each of the major histological kidney cancer subtypes (see Table 39-1). Germline *VHL* mutations cause VHL disease, in which ccRCC is a dominant feature, whereas germline *c-Met* and *fumarate hydratase* mutations are linked to hereditary Type 1 and Type 2 pRCC, respectively. Germline *FLCN* mutations cause familial oncocytomas together with an increased risk of renal cell carcinoma (especially chRCC).

von Hippel-Lindau Disease

von Hippel-Lindau disease is an autosomal dominant disorder caused by germline loss-of-function mutations of the von Hippel-Lindau tumor suppressor gene (*VHL*), which is located on chromosome 3p25, and affects about 1 in 35,000 people.[7] Most VHL patients, however, will exhibit some manifestations of their disease by early adulthood. Hemangioblastomas and kidney cancer are the two leading causes of death in this population. All patients with a clinical diagnosis of VHL disease harbor a *VHL* mutation. A number of genotype-phenotype correlations have been described in this setting, however, with respect to the risk of developing specific tumors such as kidney cancer and pheochromocytoma. Type 1 VHL disease is associated with low risk of pheochromocytoma and Type 2 with a high risk of pheochromocytoma. Type 2 disease is subdivided into Type 2A (low risk of kidney cancer), Type 2B (high risk of kidney cancer), and Type 2C (pheochromocytoma only).

Somatic *VHL* Mutations and Hypermethylation in Sporadic Clear Cell Renal Carcinoma

Of sporadic ccRCCs, 40% to 80% have inactivated both *VHL* alleles (maternal and paternal), most often as a result of a

Table 39-3 Somatic Genetic Alterations in Sporadic Renal Carcinomas

Histologic Type	Genetic Alterations	Frequency of Alterations
Clear cell RCC	Mutations	
	VHL	42%-82%
	PBRM1	~40%
	BAP1	~15%
	Copy number alterations	
	3p deletion	86%-98%
	5q gain	40%-69%
	14q deletion	20%-42%
Papillary RCC	Mutations	
	MET	0%-13%
	Copy number alterations	
	Trisomy 7, 17	61%-89%
Chromophobe RCC	Copy number alterations	
	Monosomy 1, 2, 6, 10, 13, 17	68%-100%
Translocation RCC	Translocations	
	Translocations involving Xp11.2 (*TFE3*)	>90%
	t(6;11)(p21;q12) (*Alpha-TFEB*)	Rare
Medullary carcinoma	Translocations	
	t(2;10)(p23;q22) (*VCL-ALK*)	?

somatic intragenic mutation affecting one VHL allele and a large chromosome 3p somatic deletion spanning the other (Table 39-3). In short, the *VHL* tumor suppressor gene, like the *RB1* tumor suppressor gene, conforms to the Knudson two-hit model of carcinogenesis. An additional 10% to 20% of clear cell renal carcinomas have not sustained *VHL* mutations but fail to produce normal levels of the *VHL* mRNA (and hence protein) because the maternal and paternal *VHL* loci are hypermethylated. Some other clear cell carcinomas display a transcriptional signature suggestive of *VHL* inactivation despite an apparent absence of *VHL* mutations or hypermethylation.

VHL Protein Function

The *VHL* gene encodes two proteins by virtue of two alternative, in-frame, translation initiation codons.[8-10] Both protein isoforms behave similarly in most (but not all) assays performed to date, and the *VHL* mutations linked to kidney cancer almost invariably affect both isoforms. pVHL dynamically shuttles between the cytoplasm and the nucleus, although at steady state most of the protein is cytoplasmic. pVHL is a multifunctional protein whose function relates to its role as the substrate recognition module of an E3 ubiquitin ligase complex that also contains elongin B, elongin C, Cul2, and Rbx1[11] (Figure 39-1). The crystal structure of pVHL bound to elongin B and elongin C reveals that pVHL has two subdomains, called the alpha domain and the beta domain, which are hotspots for mutations in VHL disease and which are, directly or indirectly, affected by kidney cancer–associated mutations. A number of putative pVHL substrates have been identified, including members of the HIF transcription factor family.

The HIF Transcription Factor

HIF (hypoxia-inducible factor) is a heterodimeric transcription factor consisting of an alpha subunit and a beta subunit, both of which are members of the basic Helix-Loop-Helix-PAS domain family.[12,13] There are three human HIFα (HIF1α, HIF2α, HIF3α) and three human HIFβ (often referred to as ARNTs for aryl hydrocarbon receptor nuclear translocators) family members.

In the presence of oxygen, HIFα is hydroxylated on one (or both) of two prolyl sites by members of the EglN (also called PHD) prolyl hydroxylase family[14] (see Figure 39-1). Hydroxylation of either of these sites generates a binding site for pVHL, which then directs the polyubiquitylation of the HIFα subunit. Once ubiquitylated, HIFα is then degraded by the proteasome. Under low-oxygen conditions EglN activity is impaired because these enzymes require oxygen, in addition to 2-oxoglutarate and reduced iron, in order to function. This leads to stabilization and accumulation of HIFα, which then binds to HIFβ, translocates to the nucleus, and activates 100 to 200 genes that contain hypoxia-response elements and promote adaptation to hypoxia. In contrast to HIF1α and HIF2α, most of the HIF3α isoforms detected in cells, which arise because of alternative splicing of the HIF3α mRNA, lack transactivation capability and may, in fact, serve to blunt HIF1α and HIF2α activity.

HIF and Kidney Cancer

In pVHL-defective ccRCC, polyubiquitylation of HIFα is impaired, leading to inappropriate activation of HIF target genes under normoxic conditions. HIF activates a number of genes that are believed to play, or suspected of playing, roles in kidney carcinogenesis, including TGFα, Cyclin D1, SDF1, CXCR4, MMP family members, PDGF B, and VEGF. The increased expression of factors such as VEGF likely contributes to the highly angiogenic nature of clear cell renal carcinomas and their responsiveness to VEGF blockade. The overproduction of the canonical HIF target erythropoietin accounts for the association of VHL-associated neoplasms, including renal carcinomas, with paraneoplastic

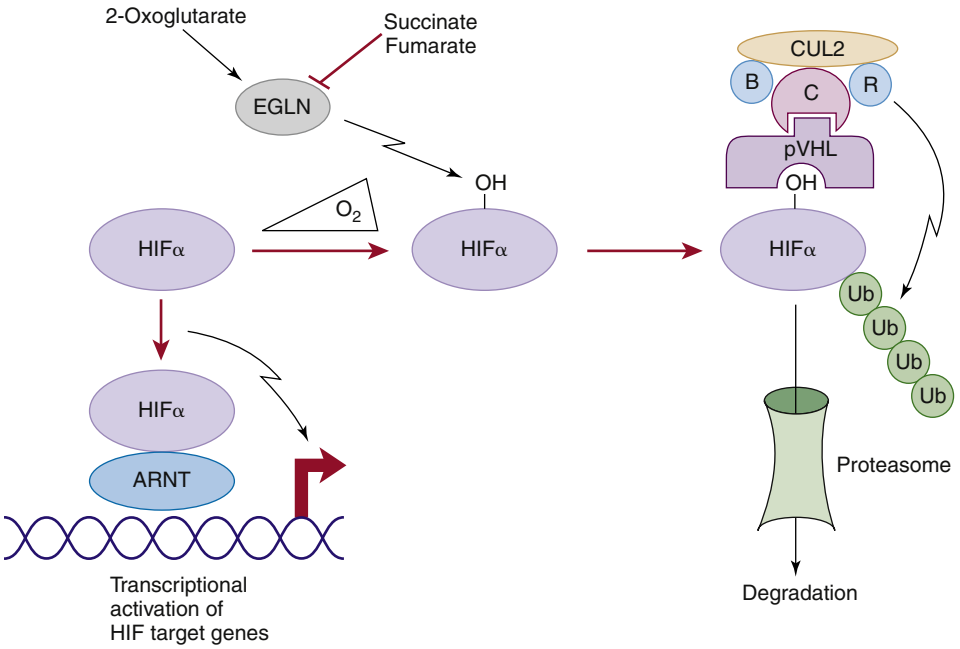

Figure 39-1 Regulation of HIF by pVHL In the presence of oxygen, HIFα is hydroxylated on one (or both) of two conserved prolyl residues by EglN family members. This creates a binding site for pVHL, which is stably bound to elongin B (*B*), elongin C (*C*), Cul2, and Rbx1 (*R*). This complex then polyubiquitylates HIFα, marking it for proteasomal degradation. Under low-oxygen conditions, or in cells lacking pVHL, HIFα binds to ARNT, translocates to the nucleus, and activates HIF target genes such as *VEGF*. EglN family members require 2-oxoglutarate, in addition to oxygen, and are inhibited by succinate and fumarate.

erythrocytosis.[15] HIFα, acting without its partner HIFβ, can also activate Notch signaling, which has been implicated in renal carcinogenesis.

Several lines of evidence suggest that deregulation of HIF, and particularly deregulation of HIF2α, plays a causal role in pVHL-defective renal carcinoma. To date virtually all kidney cancer–associated *VHL* mutations, whether germline or somatic, compromise pVHL's ability to regulate HIF, and the risk of developing kidney cancer in VHL families correlates well with the degree to which their mutant *VHL* alleles deregulate HIF. Close examination of preneoplastic renal lesions in VHL patients reveals that the appearance of HIF2α is associated with histological changes indicative of incipient malignant transformation.

In stark contrast to HIF2α, HIF1α appears to act as a renal cancer suppressor. *HIF1α* resides on chromosome 14q, which is frequently deleted in kidney cancers. *HIF1α* mRNA and protein is decreased in a sizable fraction of clear cell renal tumors, and HIF1α-responsive mRNAs are diminished in 14q-deleted renal tumors. It should be noted, however, that most 14q-deleted clear cell renal tumors, in contrast to cell lines, appear to retain a wild-type *HIF1α* allele. It is therefore possible that haploinsufficiency of *HIF1α* promotes tumor growth in vivo and that reduction to nullizygosity occurs during tumor progression (most cancer lines are derived from metastatic lesions) or establishment and propagation of cell lines. Although rare, intragenic *HIF1α* mutations have been reported in kidney cancers. Collectively, these findings suggest that *HIF1α* is a target of the 14q deletions that are typical of clear cell renal carcinomas.

The differential effects of HIF1α and HIF2α in pVHL-defective tumor growth likely reflect both qualitative and quantitative differences. For example, the genes regulated by HIF1α and HIF2α overlap but are clearly not identical. Perhaps HIF1α preferentially induces the expression of a renal tumor suppressor, or suppressors, whereas HIF2α preferentially induces the expression of one or more downstream oncogenes. Moreover, HIF1α can potentially antagonize HIF2α with respect to the induction of shared targets under normoxic conditions in pVHL-defective cells because transcriptional activation by HIF1α, in contrast to HIF2α, is enfeebled by the oxygen-dependent asparaginyl hydroxylase FIH1.

HIF-Independent pVHL Functions

pVHL has a number of other functions that appear to be at least partially HIF-independent and that might contribute to renal cancer suppression. For example, pVHL promotes fibronectin matrix assembly, maintains microtubule stability and a specialized structure called the primary cilium, suppresses the activating phosphorylation of the NFκB agonist CARD9, suppresses signaling by HGF and c-MET, suppresses Wnt signaling, inhibits atypical PKC activity, promotes the Cbl-independent ubiquitylation of EGFR, and regulates senescence. The ciliary defect in pVHL-defective renal epithelial cells is particularly intriguing because renal cysts are a prominent feature of both VHL disease as well as the other primary ciliopathies.

Mouse Models of VHL Disease

There are currently no genetically engineered mouse models that develop *VHL−/−* clear cell renal carcinomas. *VHL−/−* embryos

die before term, and *VHL*+/– do not develop the usual stigmata of VHL disease. They do, however, develop hepatic blood vessel lesions that are associated with stochastic loss of the remaining wild-type *VHL* allele and HIF activation. *VHL* has also been inactivated using conditional alleles in a variety of mouse tissues, leading to phenotypes such as renal cysts (kidney), hepatosteatosis and hemangiomas (liver), cardiomyopathy (heart), and increased angiogenesis and weight loss (skin). Concurrent inactivation of *PTEN* in the kidney exacerbates the renal cyst phenotype but still does not lead to renal tumor formation. In most of the models tested so far, deregulation of HIF2α appears to be necessary and sufficient for the pathology observed on after pVHL loss in mouse tissues.

Other Hereditary Forms of Cancer

Individuals with germline activating *c-Met* mutations are highly predisposed to Type 1 papillary renal carcinoma, often associated with duplication of the mutant *c-Met* allele located at 7q31[16,17] (see Table 39-1). *c-Met* encodes a receptor tyrosine kinase that influences cellular proliferation, survival, invasion, and metastasis. Somatic *c-Met* mutations are relatively rare in sporadic papillary renal carcinomas (see Table 39-3).

Germline loss-of-function fumarate hydratase (1q42) mutations cause a syndrome characterized by Type 2 papillary renal carcinoma, cutaneous leiomyomata, and uterine fibroids, whereas succinate dehydrogenase subunit mutations cause familial paragangliomas and, rarely, clear cell renal carcinomas (see Table 39-1). Inactivation of fumarate hydratase and succinate dehydrogenase leads to the intracellular accumulation of fumarate and succinate, respectively, which competitively inhibit 2-oxoglutarate-dependent enzymes including the EglN prolyl hydroxylases (see Figure 39-1). Accordingly, HIFα levels are increased in *FH*–/– and *SDH*–/– tumors. It has also been shown that the secondary accumulation of succinate in fumarate hydratase–deficient cells can also, through covalent linkage to a cysteine residue, inactivate the KEAP tumor suppressor protein, leading to deregulation of the NRF2 transcription factor.

Inactivating germline mutations of *FLCN* (17p11.2) cause Birt-Hogg-Dube syndrome, which is characterized by a variety of dermatological lesions, including fibrofolliculomas; renal tumors including oncocytomas and chromophobe tumors and, less commonly, papillary and clear cell carcinomas; and pulmonary cysts (see Table 39-1). The *FLCN* gene product, Folliculin, binds to FNIP1 and FNIP2 and is believed to modulate nutrient sensing by the mTOR signaling pathway. Folliculin also appears to suppress TGFβ

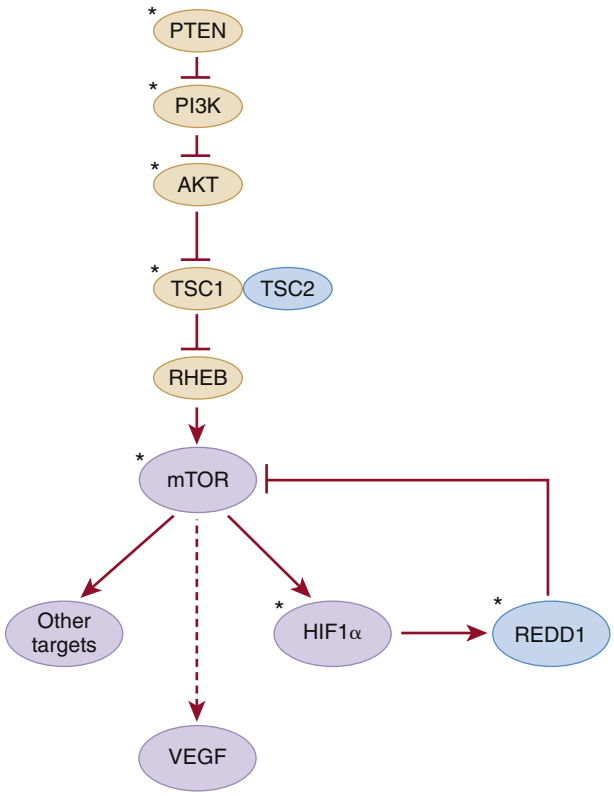

Figure 39-2 Kidney cancer mutations with an impact on mTOR Proteins that have been targets of mutations in kidney cancer are indicated by *asterisks*.

as well as the expression of TFE3, the common partner in kidney cancers linked to Xp11.2 translocations. Inactivating mutations of either *TSC1* (9q34), which encodes hamartin, or *TSC2* (16p13), which encodes tuberin, cause tuberous sclerosis. Tuberous sclerosis is associated with cutaneous, neurological, and renal abnormalities. Renal abnormalities include angiomyolipomata and, less commonly, clear cell renal carcinoma (see Table 39-1). Hamartin and tuberin form a complex that inhibits the mTOR kinase and regulates VEGF via both mTOR-dependent and independent pathways (Figure 39-2). Somatic *TSC1* mutations have been described in sporadic ccRCC, as have mutations in other genes whose products link growth factor signaling, via hamartin and tuberin, to mTOR activity (see later discussion). Inactivation of the hamartin/tuberin complex in mice causes renal cysts, and a germline *TSC2* mutation in the rat (Eker Rat) causes clear cell carcinoma.

Some families predisposed to clear cell carcinoma carry germline translocations involving chromosome 3 and variable partners (see Table 39-1). Loss of the derivative chromosome 3p segment is believed to cause loss of tumor suppressors, such as *VHL*, located between 3p21 and 3p25.

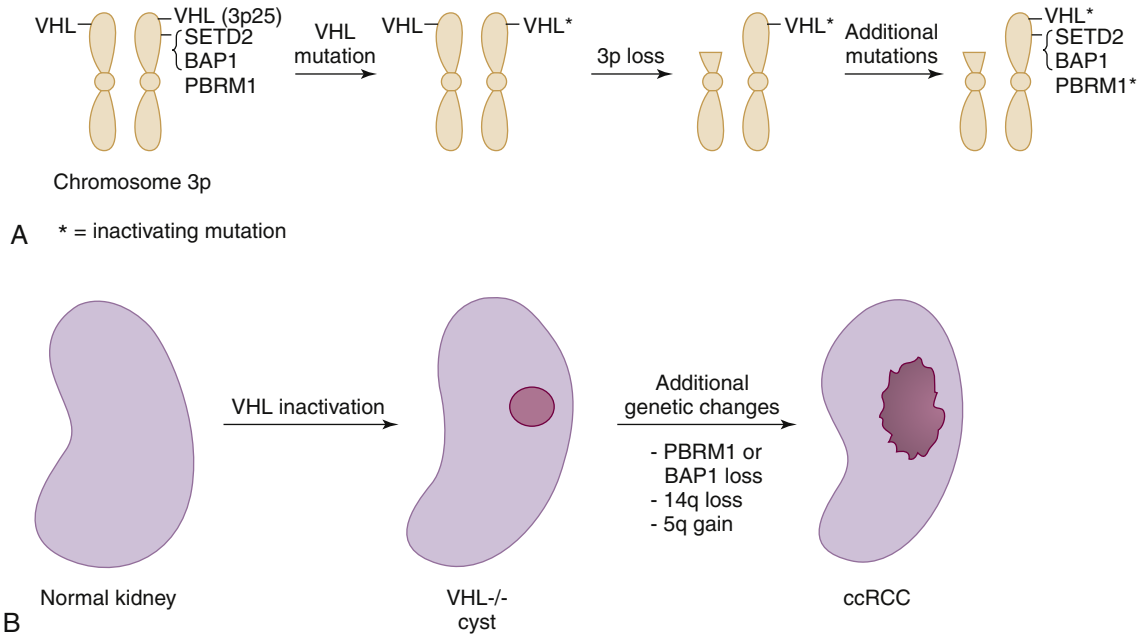

Figure 39-3 Multistep kidney carcinogenesis (A) Multiple renal cancer suppressors are located on chromosome 3p, including *VHL* at 3p25 and *SETD2*, *BAP1*, and *PBRM1* on 3p21. For this reason three genetic "hits" can inactivate two tumor suppressors (and four "hits," three tumor suppressors) provided one of the hits is chromosome 3p loss. In the example shown both *VHL* and *PBRM1* have been inactivated. **(B)** pVHL loss leads to preneoplastic renal lesions, such as *VHL–/–* renal cysts. In VHL disease the kidney is germline *VHL+/–*, whereas in sporadic kidney cancers the kidney is germline *VHL+/+*. Additional genetic changes, such as *PBRM1* or *BAP1* mutations, loss of chromosome 14q, and gain of chromosome 5q, are linked to progression to clear cell renal carcinoma.

Common Somatic Alterations in Clear Cell Renal Carcinoma

Copy Number Changes

The most common copy number changes in clear cell renal carcinoma relate to loss of chromosome 3p, which is observed in more than 90% of these tumors (see Table 39-3). Chromosome 3p harbors several tumor suppressor genes, including the *VHL* gene at 3p25, and *PBRM1*, *BAP1*, and *SETD2* at 3p21 (Figure 39-3, *A*). Other common copy number changes in clear cell renal carcinoma include amplification of chromosome 5q and 7q and loss of chromosome 14q and 6q. Loss of chromosome 3p, gain of 5q, and loss of 14q are seen more commonly in clear cell renal carcinoma than in other cancers.

Inactivation of Tumor Suppressor Genes

PBRM1

PBRM1, located on 3p21 (see Figure 39-3, *A*), is mutationally inactivated in about 40% of ccRCC (see Table 39-3), typically as a result of truncating mutations of one allele coupled with loss of the remaining allele as a consequence of chromosome 3p loss. *PBRM1* mutations are not mutually exclusive with mutations of the neighboring gene *SETD2*, indicating that the two genes are not wholly redundant. *PBRM1* encodes a large protein called BAF180, which contains six bromodomains, 2 bromo-adjacent homology domains, and an HMG DNA-binding domain. BAF180 is a component of the PBAF SWI/SNF nucleosome remodeling complex and is therefore likely to affect transcription by altering chromatin structure so as to alter its accessibility to various transcription factors (Figure 39-4, *A*).

BAP1

BAP1, which is also located on chromosome 3p21 (see Figure 39-3, *A*), is mutationally inactivated in about 15% of clear cell renal carcinomas (see Table 39-3). As is true for *PBRM1*, *BAP1* mutations in kidney cancer are typically truncating mutations that are presumed to be loss of function. Loss-of-function *BAP1* mutations, including germline mutations, have also been linked to other tumors. Interestingly, families with germline *BAP1* mutations may also be predisposed to develop clear cell renal carcinoma. BAP1, which was originally identified as a BRCA1-associated protein, encodes a nuclear deubiquitinase of the C-terminal hydrolase (UCH)-domain family. Suppression of renal proliferation by BAP1 apparently does not require its ability to deubiquitinate its canonical target, histone H2A, but does require that it bind

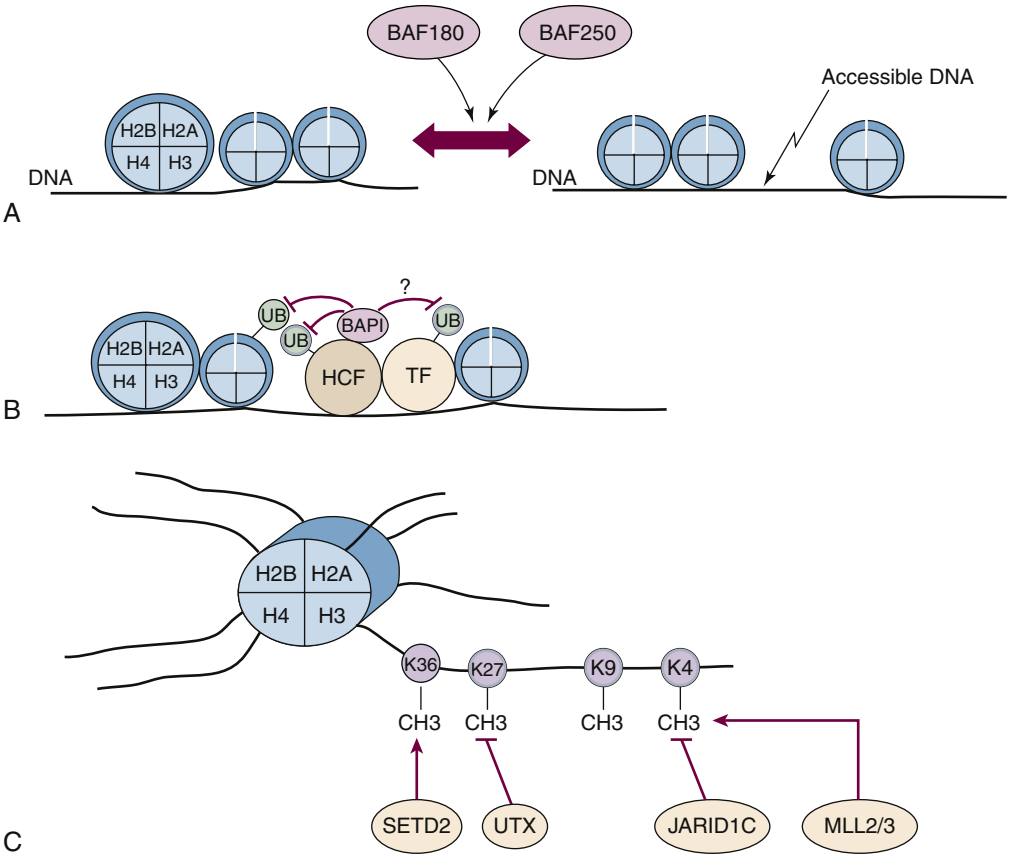

Figure 39-4 Kidney cancer mutations with an impact on chromatin regulation **(A)** The *PBRM1* gene product BAF180 and *ARID1A* gene product BAF250 are components of SWI/SNF complexes that can reposition nucleosomes. **(B)** BAP1 binds to HCF and can potentially deubiquitinate histones, adjacent transcription factors (TF), and HCF itself. **(C)** SETD2, MLL2, and MLL3 methylate specific lysine residues in histone H3, whereas UTX and JARID1 demethylate specific lysine residues. Note that for simplicity, the other components of multiprotein complexes such as the SWI/SNF complexes and MLL complexes are not shown.

to host cell factor-1 (HCF) (see Figure 39-4, *B*). HCF is a transcriptional coactivator that interacts with a number of transcription factors, including E2F family members and histone-modifying enzyme complexes, including histone methyltransferases and acetyltransferases.

SETD2

SETD2, like *PBRM1* and *BAP1*, is located on chromosome 3p21 (see Figure 39-3, *A*). It is mutationally inactivated in about 5% of clear cell renal carcinomas. Loss-of-function *SETD2* mutations have also been found in breast cancers. *SETD2* encodes a SET-domain–containing histone methyltransferase that promotes H3K36 methylation (see Figure 39-4, *C*). H3K36 trimethylation is undetectable in cells lacking wild-type SETD2, suggesting that SETD2 is not redundant with other histone methyltransferases.

UTX/KDM6A

UTX/KDM6A, located on the X chromosome but escaping X inactivation, is mutated in about 2% of clear cell renal carcinomas. *UTX* loss-of-function mutations have been described in a variety of cancers, including hematological malignancies and prostate cancer. *UTX/KDM6A* encodes an H3K27 demethylase (see Figure 39-4, *C*). Interestingly, *EZH2*, which encodes an H3K27 methylase, is overexpressed in renal cancer and promotes renal carcinoma proliferation and survival in cell culture experiments. Moreover, UTX can bind to H3K4 demethylase complexes that contain MLL2 or MLL3, which are mutationally inactivated in a small subset of kidney cancers. Loss of UTX leads to silencing of genes required for pRB-dependent cell-cycle arrest and also leads to activation of the Notch pathway, which has recently been implicated in renal carcinogenesis.

JARID1C

JARID1C/KDM5C, which is also located on the X chromosome as an actively transcribed unit, is mutated in about 3% of clear cell renal carcinomas. JARID1C is an H3K4 demethylase (see Figure 39-4, C). As is true for many other histone demethylases, including JMJD1A and JMJD2B, JARID1C is induced by HIF and hence potentially deregulated in pVHL-defective tumor cells. Increased expression of JARID1C in pVHL-defective tumor cells decreases H3K4 methylation and decreases cell proliferation in vitro and in vivo.

MLL2 and MLL3

MLL2 (12q13) and *MLL3* (7q36) are both mutated at low frequency (1% to 3% each) in clear cell renal carcinoma. As indicated earlier, these genes encode proteins that participate in multiprotein complexes that promote H3K4 methylation and that interact with the UTX tumor suppressor (see Figure 39-4, *C*).

mTOR

Activating mutations of the mTOR kinase gene (1p36) have been described in ccRCC. mTOR plays a critical role in transducing signals related to nutrient and energy availability. Mutations affecting individual components of the mTOR pathway, including mTOR itself, are relatively uncommon in ccRCC but, when viewed in aggregate, support that activation of the mTOR pathway promotes clear cell renal carcinogenesis (see Figure 39-2). Moreover, as described earlier, germline inactivation of the mTOR suppressors hamartin and tuberin has been linked to ccRCC in rodents and people.

Other Genes

Other genes mutated at a low frequency (less than 3%) in clear cell renal carcinoma include the cancer-relevant genes *PTEN*, *PIK3CA*, *AKT1*, *TP53*, *ATM*, *TSC1*, *REDD1*, and *ARID1A*. PTEN, PI3KCA, AKT1, and TSC1 participate in the mTOR pathway (see Figure 39-2). *TP53* mutations, when they occur, have been linked to sarcomatoid changes in ccRCC. *ARID1A* encodes BAF250, which, like BAF180, functions in a chromatin remodeling complex (see Figure 39-4, *A*).

Multistep Genetic Models of Clear Cell Renal Carcinoma

The remaining wild-type *VHL* allele is lost in the numerous preneoplastic renal cysts that develop in patients with von Hippel-Lindau disease.[18] This suggests that additional genetic alterations involving other loci are required to convert these lesions to clear cell renal carcinomas. These alterations presumably involve the copy number changes (such as chromosome 5q amplification and chromosome 14q loss) and intragenic mutations described earlier (such as *PBRM1* or *BAP1* mutations) (see Figure 39-4, *B*). Conceivably one or more of these changes involves circumventing the antiproliferative effects of HIF1α, which in model systems can be accomplished by downregulation of HIF1α itself or by activation of the mTOR pathway. Other changes—for example, mutational inactivation of chromatin modifiers such as BAF180 or JARD1C—might compensate for HIF-driven changes in chromatin structure.

PBRM1 and *BAP1* mutations appear to be largely mutually exclusive, suggesting they affect a common pathway. Arguing against this, however, are the observations that *PBRM1* and *BAP1* mutant tumors have very distinctive transcriptional and signal transduction profiles. It should be noted that kidney cancers do rarely mutate both of these genes, but in these cases the tumors assume rhabdoid features. Deep sequencing of multiple spatially distinct biopsy specimens has recently been used to examine intratumoral heterogeneity within clear cell carcinomas. These studies confirm that clear cell carcinomas evolve over time and can contain multiple subclones that are heterogeneous with respect to their genetic changes subsequent to *VHL* loss.

Common Somatic Alterations in Non–Clear Cell Renal Carcinoma

In contrast to the *VHL* gene, the hereditary kidney cancer genes *c-MET* and *FH* are rarely mutated in sporadic kidney cancers. Somatic *FLCN* mutations have been identified in sporadic chromophobe tumors. Somatic Xp11.2 translocations should be suspected in kidney cancers arising in children and young adults. The usual *TFE3* translocation partners are *ASPL*, *PSF*, *NONO*, *CLTC*, or *PRCC*. Although the mechanism(s) through which Xp11.2 translocations drive kidney tumorigenesis remain largely unknown, it has been recently shown that TFE3 fusion proteins transactivate the *c-MET* promoter and induce autophosphorylation of the MET protein and activation of downstream signaling. Inhibition of MET signaling in cell lines containing endogenous TFE3 fusion proteins causes a decrease in cell growth.

In general, non–clear cell renal carcinomas, because of their rarity relative to clear cell carcinomas, have been less intensively surveyed with respect to intragenic mutations. Each histological type of sporadic kidney cancer does, however, display stereotypical copy number alterations[2] (see Table 39-3). For example, trisomy of chromosome 7 and/or 17 is typical of papillary renal carcinomas, and loss of chromosome 1, 14, and 15 is typical of mucinous tubular and spindle carcinomas. Chromophobe tumors are characterized by loss of genomic material from chromosomes 1, 2, 6, 10, 13, 17, and/or 21.

Clinical Applications of Molecular Insights

Early Detection and Risk Assessment

Kidney cancer can be cured by surgery when it is localized. Therefore screening could, in theory, lower kidney cancer mortality. A major problem for kidney cancer screening, however, is the overall low prevalence of kidney cancer. One study of abdominal ultrasonographic (US) screening of 219,640 persons confirmed RCC in 192 cases (0.09%), and another US study of 60,604 persons found an RCC prevalence of 0.02%. Screening based on computed tomography (CT) has revealed a prevalence of asymptomatic kidney cancer of approximately 0.2%.[19] Moreover, screening for RCC based on anatomical imaging has a high false-positive rate. In one study, 37% of patients with renal tumors smaller than 1 cm detected by screening had benign lesions based on pathological review. Screening with US or CT may be useful in high-risk populations such as patients on dialysis or those with established hereditary kidney cancer syndromes such as VHL disease. In patients with VHL disease, screening for RCC is very important to detect new lesions at an early stage and to monitor the growth of small asymptomatic lesions. There is no standard protocol for screening or surveillance for such patients, but several recommendations exist, such as those adopted by the VHL Family Alliance (www.vhl.org). The treatment approach to kidney cancer in patients with VHL syndrome has shifted from radical nephrectomy to nephron-sparing approaches (surveillance, partial nephrectomy, and thermal ablation). Small tumors are generally observed, as they are at very low risk for metastatic progression as illustrated in a series of 108 patients from the National Cancer Institute, where no metastases were detected in patients with tumors less than 3 cm in diameter.[20]

Therapy (Clear Cell)

Conventional chemotherapy has little role in the management of metastatic kidney cancer. High-dose interleukin 2 remains the only treatment with a small (less than 10%) but measurable probability of inducing durable remissions in this patient population.

VEGF

The knowledge that ccRCC is usually driven by deregulation of HIF, and HIF targets genes such as VEGF, provided a conceptual foundation for testing VEGF antagonists for the treatment of metastatic kidney cancer. In clinical trials about 70% of kidney cancer patients will achieve some degree of tumor shrinkage when treated with such agents. In randomized trials this is associated with an improvement in progression-free survival. Based on such trials, five drugs that either neutralize VEGF or block VEGFR have now been approved by the U.S. Food and Drug Administration (FDA) for the treatment of metastatic kidney cancer (Table 39-4). VEGF inhibitors, although clearly active

Table 39-4 Landmark Phase III Trials of Approved Targeted Agents in Metastatic RCC

Trial	N	Setting	Risk Group(s)	PFS (months)	ORR (%)	OS (months)
Sunitinib vs. IFN-α	750	Treatment naive	Good/intermediate	11 vs. 5	47 vs. 12	26.4 vs. 21.8

BSC, Best supportive care; *ORR*, overall response rate; *OS*, overall survival; *PFS*, progression-free survival.

in kidney cancer, are not curative. Newer, more potent VEGF inhibitors are currently being tested, although there is already an indication that VEGF blockade above a certain threshold will begin to cause on-target side effects such as microangiopathic anemia, cardiomyopathy, and severe hypertension.

mTOR

mTOR regulates both the transcription and translation of HIF and also acts downstream of VEGF in endothelial cells. In addition, mutations affecting the mTOR pathway (*PTEN*, *PIK3CA*, and *mTOR*), although rare, have been documented in ccRCC. Finally, pVHL-defective cells display an increased requirement for mTOR relative to pVHL-proficient cells. Two rapamycin-like mTOR inhibitors (rapalogs), temsirolimus and everolimus, have now also been approved for the treatment of kidney cancer based on favorable randomized trial data (see Table 39-4). As is true for VEGF inhibitors, temsirolimus and everolimus are not curative treatments for kidney cancer. Moreover, rapalogs such as these preferentially inhibit mTOR when it exists in the TORC1 complex relative to the TORC2 complex. This is potentially important because downregulation of HIF2α, which is believed to drive pVHL-defective ccRCC, requires that TORC2 be suppressed. Preclinical data suggest that small molecules that block both TORC1 and TORC2 will be more active than rapalogs for the treatment of kidney cancer.[21]

EGFR

pVHL loss, as described earlier, upregulates EGFR as well as its ligand, TGFα. Moreover, blocking EGFR activity inhibits pVHL-defective ccRCC tumor growth in preclinical models. To date, however, EGFR inhibitors have been disappointing for the treatment of human kidney cancer. This could reflect a failure to achieve sufficient EGFR inhibition or the fact that MET, which becomes activated on pVHL loss, provides collateral survival signals that render cells resistant to EGFR inhibitors, as has been described in other settings.[22]

Therapy (Non–Clear Cell)

Both VEGF inhibitors and mTOR inhibitors have some activity in non-clear cell RCC. Clinical studies with MET inhibitors for pRCC and rapamycin-like drugs for chRCC are anticipated. Rapalogs also appear to be modestly active in the treatment of renal angiomyolipomata.

Prognostic and Predictive Markers

Renal cell carcinoma remains a disease with widely varying clinical outcome. In nonmetastatic RCC, routine prognostic factors are TNM stage, Fuhrman grade, and symptoms at presentation. Gene expression profiling and certain genetic polymorphisms represent some of the promising prognostic biomarkers in localized RCC[23] and may add to established clinical factors.

In metastatic RCC, several host- and tumor-related factors have been identified as important prognostic factors and have been integrated into prognostic models. Of these the most commonly used system is the Memorial Sloan Kettering Cancer Center model. This model stratifies patients with metastatic RCC into poor-, intermediate-, and favorable-risk categories (with distinct survival patterns) based on the number of adverse clinical (performance status, time from diagnosis to systemic therapy) and laboratory (serum hemoglobin, corrected calcium and lactate dehydrogenase [LDH]) parameters present. Unfortunately, there are currently no predictive biomarkers that can help in the selection of systemic therapy in metastatic disease, and most data are retrospective in nature. Single-nucleotide polymorphisms (SNPs) in genes involved in angiogenesis, such as *VEGF* and *IL-8*, or involved in VEGFR inhibitor drug metabolism, may be associated with clinical outcome and with selected toxicities. For mTOR inhibitors, it remains to be determined whether mTOR mutations or mutations affecting the mTOR pathway are predictive biomarkers in this setting. One major challenge for developing personalized therapy in RCC is intratumor heterogeneity manifested by different regions of the same tumor bearing different mutations and having very distinct gene expression profiles.

Summary and Future Directions

Most kidney cancers are renal cell carcinomas, and most renal cell carcinomas are clear cell renal carcinomas. Inactivation of the *VHL* tumor suppressor gene is an early gatekeeper event in clear cell renal carcinoma and leads to deregulation of the HIF transcription factor and HIF target genes. HIF2α acts as a kidney cancer oncoprotein, whereas HIF1α appears to serve as a kidney cancer tumor suppressor. Cooperating mutations in pVHL-defective clear cell renal carcinomas include loss of chromosome 14q, gain

of chromosome 5q, and intragenic mutations affecting a number of genes involved in chromatin regulation, such as *PBRM1* and *BAP1*. The genetic alterations responsible for the other major forms of kidney cancers are beginning to come into view, aided by studies of rare families that are predisposed to specific forms of RCC.

Treatment of metastatic kidney cancer has historically been difficult and restricted largely to immunomodulators. Knowledge of the VHL-HIF-VEGF pathway provided a conceptual foundation for the successful testing of VEGF and mTOR inhibitors for the treatment of clear cell carcinoma. These drugs are not curative, however, as single agents. Deeper understanding of kidney cancer pathogenesis will, it is hoped, yield additional targets that, when inhibited, synergize with existing therapies such as VEGF blockade.

The Biology of Primary Brain Tumors

Malignant primary tumors of the central nervous system (CNS) occur in about 25,500 individuals and account for an estimated 13,700 deaths in the United States annually, a mortality rate of 6.5 per 100,000. Based on most recent reports, benign tumors of the CNS are about twice as common as malignant brain tumors, but with a much lower mortality rate.[1,2] Overall, CNS cancer is estimated to represent about 1% of newly occurring malignant tumors. In children and young adults, brain tumors are a major health problem second only to leukemia as a cause of cancer-related deaths, and they are the third leading cause of cancer-related death between ages 15 and 34. The age-adjusted incidence appears to be similar to that observed in other developed countries.

Brain tumors are a diverse group of neoplasms. The particular combination of somatic genetic alterations found in different brain tumors that are histologically distinguishable can vary considerably among individual examples of a particular tumor type. Similarly, extensive molecular and genetic variation is well documented within tumors that are histologically indistinguishable.[3] Recognition of a number of hereditary and nonfamilial syndromes in which brain tumors play a prominent role or occur with increased frequency provide compelling evidence for the importance of several cell regulatory pathways in brain tumor pathogenesis (Table 40-1). Primary CNS tumors have been classified by surgeons and pathologists on the basis of their location and histologic appearance, providing important information that guides treatment with conventional antineoplastic modalities including surgery, irradiation, and chemotherapy as well as contributing to prognostication. More recently, the drive toward more targeted therapy has focused attention on approaches to classification emphasizing tumor type–specific molecular alterations. Glial tumors account for 50% to 60% of all primary brain tumors, and with the exception of some pilocytic astrocytoma, most are malignant. Astrocytomas account for the great majority of the glial tumors, whereas the second most common type is oligodendroglioma. Exposure to ionizing radiation is the only well-documented environmental risk factor for the development of glioma. Benign CNS tumors consist primarily of meningioma and low-grade glial tumors.

Hereditary Syndromes and Central Nervous System Oncogenesis

In addition to rare families in which there is strong evidence for a hereditary basis for the development of familial meningioma or glioma, a number of well-studied cancer predisposition syndromes include among their associated stigmata the development of CNS tumors (see Table 40-1). These are important clinical observations and have provided insights into the pathogenesis of several different types of primary brain tumors. Typically these syndromes are associated not only with an increased incidence of brain tumors, but also with the occurrence of tumors at an earlier age than those arising spontaneously and with the finding of multicentric tumors. Inherited syndromes associated with brain tumors are inherited as autosomal dominant disorders and arise as the result of the germline mutation of one allele of a tumor suppressor gene whose other copy is typically inactivated in the tumors that arise. The most commonly occurring brain tumor predisposition syndrome is neurofibromatosis type 1 (NF1).[4] NF1 affects approximately 1 in 3000 live births; approximately 15% of these have radiographic evidence of optic glioma early in childhood, although most cases do not become symptomatic. Although peripheral nervous system tumors are common in NF1 patients, these patients are also at increased risk of developing pilocytic astrocytomas and, more rarely, malignant astrocytomas. The protein product of the *NF1* gene, located on the long arm of chromosome 17, is neurofibromin 1 (NF1), which functions to antagonize the proliferative function of p21(ras). Neurofibromatosis type 2 (NF2) is distinct from NF1, affecting approximately one in 50,000 individuals.[5] The *NF2* gene, at 22q12.2, encodes a protein known as neurofibromin 2 or merlin (NF2). NF2 patients frequently present before the third decade of

Table 40-1 Hereditary Syndromes Associated with Brain Tumors

Syndrome	Gene	Chromosomal Location	Associated Central Nervous System Tumors
Neurofibromatosis type 1	*NF1*	17q	Optic glioma
Neurofibromatosis type 2	*NF2*	22q12	Acoustic schwannomas, meningioma, ependymoma, glial tumors
Retinoblastoma	*RB*	13q14	Retinoblastoma, pinealoblastoma
Li-Fraumeni syndrome	*P53*	17p13	Glioma, medulloblastoma
von Hippel-Lindau syndrome	*VHL*	3p	Retinal angioma, cerebellar hemangioblastoma
Tuberous sclerosis	*TSC1* *TSC2*	9q 16p13	Giant cell subependymal astrocytoma, astrocytoma, ependymoma
Turcot syndrome	*APC, hMSH1, hMSH2, hPMS2*	5q21	Astrocytoma, medulloblastoma
Gorlin syndrome	*PTCH1*	9q22.1-q31	Medulloblastoma, astrocytoma
Ollier disease	*IDH1, IDH2*	2q33.3, 15q26.1	Endochondroma, rarely glioma

life with deafness caused by bilateral schwannomas of the eighth cranial nerve. Less commonly NF2 patients develop neuronal schwannoma including tumors of the spinal and cranial nerves, meningioma, low-grade astrocytoma, and ependymoma. The Li-Fraumeni syndrome is observed in patients with germline *TP53* mutations.[6] Although affected family members are predisposed to a number of different tumor types, brain tumors are among the more common and include astrocytomas, medulloblastomas, and choroid plexus tumors. The TP53 protein product, p53, plays an important role in the DNA damage checkpoint of cells and in regulating apoptosis. Its function is commonly inactivated by mutation in a wide variety of human tumors and is thought to play an important role in sporadically occurring astrocytic tumors.

Molecular Biology of the Most Common Primary Central Nervous System Tumors

Brain tumors are thought to arise as the result of genetic and epigenetic alterations that activate oncogenes and inactivate tumor suppressor genes (Figure 40-1, and see Table 40-1). The precise cell of origin in which the most common brain tumors arise is unknown, but emerging evidence suggests that the malignant transformation of different cell types can give rise to high-grade glioma. There is convincing evidence in animal models of glioma that tumors can arise from the malignant transformation of neural stem cells,[7] very early lineage-specific precursor cells,[8] and more differentiated cells that dedifferentiate[9] and take on key characteristics of precursor cells such as proliferative potential, migratory capacity, and multipotentiality. Identifying the cell type in which tumors arise may provide insight into critical pathologic pathways used by tumor cells. Mouse models of glioma provide strong evidence for the possibility of multiple different cells being targets for malignant transformation, resulting in high-grade glioma.

Significant recent progress has also been made in understanding the cell biology of high-grade glial tumors. An emerging body of data indicates that there is a cellular subpopulation in human glioma, typically consisting of very rare cells, that is distinguished from other tumor cells by the ability to grow in vitro in suspension as neurospheres and to recapitulate the tumor of origin when inoculated orthotopically into immunosuppressed mice.[10] This capacity for tumor initiation is typically not shared with the overwhelming majority of tumor cells, and in contrast to other strategies for immortalizing human glioma, tumor cells grown as neurospheres tend to retain a larger number of the genetic alterations present in the tumors from which they are derived. Study of these tumor-initiating cells, sometimes referred to as tumor stem cells, indicates that they exhibit increased resistance to both radiation and chemotherapy, making them a compelling target for the development of future therapeutic interventions.

Astrocytic Tumors

Diffusely infiltrating astrocytomas are so named because they display morphologic and some biochemical evidence of astroglial differentiation. These are the most common tumors of adults and children, occur throughout the CNS, and exhibit a wide range of histopathologic appearances and clinical behaviors. These tumors are organized by the World Health Organization (WHO) according to tumor grade.[11] Histologically, malignancy is manifested as hypercellularity, cellular atypia, endothelial proliferation, necrosis, and

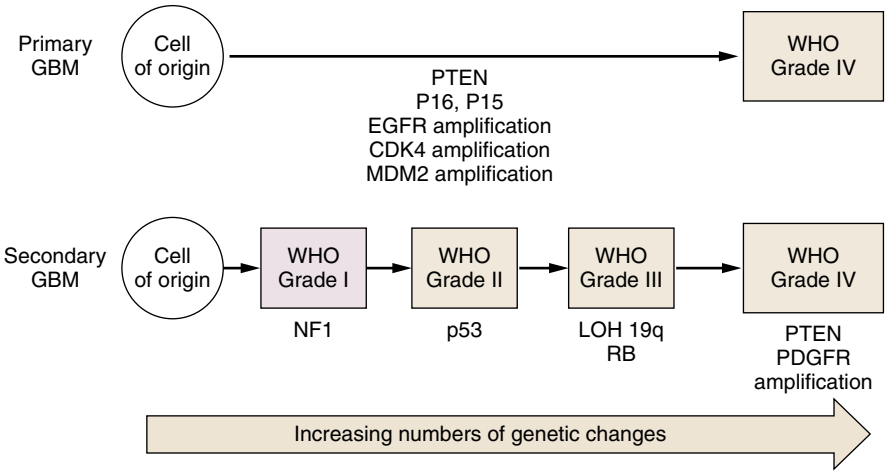

Figure 40-1 Glioblastoma arises in association with the accumulation of multiple genetic alterations. Primary glioblastoma manifests without the presentation of any precursor lesion. Secondary glioblastoma results from the accumulation of additional oncogenic mutations by lower grade astrocytic tumors resulting in increased malignancy. *GBM*, Glioblastoma multiforme; *WHO*, World Health Organization.

invasion of normal adjacent tissue. WHO grade I tumors are variants of astrocytoma that are generally benign, and WHO grade IV, also known as glioblastoma multiforme (GBM), is the most aggressively malignant. Prognosis is closely associated with pathologic grade. WHO grades II and III exhibit intermediate grades of malignancy, but the evidence of increased mitotic activity in grade III tumors is likely to be a key contributor to poor prognosis. Although low-grade tumors can exhibit a circumscribed growth pattern, all pathologic grades of glioma can exhibit invasiveness, and this characteristic compromises the possibility of treating these tumors with surgery alone. The known propensity of some astrocytic tumors that present as low-grade tumors to progress over time to higher grade tumors has provided insight into the pathogenesis of these tumors, suggesting that they are closely related and that progression is associated with the acquisition of sequential genetic alterations (see Figure 40-1; Table 40-2). High-grade astrocytic tumors, GBMs that arise in this manner, are called secondary GBMs. The finding of selected genetic changes (e.g., *TP53* mutation) in lower grade tumors that are also present in higher grade tumors along with additional mutations typically found only in higher grade tumors (e.g., epidermal growth factor receptor [EGFR] amplification) suggests that specific genetic alterations are associated with particular pathologic features characteristic of the corresponding grade. Genetic changes currently thought to be important in this regard are shown in Figure 40-1 and Table 40-2, an adaptation of the pathogenesis model first proposed for colon cancer.[12]

Mutation of the *TP53* gene is likely to be an early event associated with the change of normal cells to low-grade neoplasia. Commonly mutated residues are codons 248 and 273.[13] TP53 has an important role in stabilizing the genome, and the genetic instability resulting from its loss may contribute to the accumulation of multiple mutations in a single cell that are required for the development of highly malignant tumors. Inactivation of *TP53* by mutation or epigenetic mechanisms may occur in up to 75% of astrocytomas. *MDM2*, encoding MDM2, a protein that inhibits the ability of p53 to promote transcription by targeting the protein for degradation, is amplified in approximately 10% of gliomas, and these invariably have a wild-type *TP53* gene. A second gene that is also likely to be mutated early in gliomagenesis is *IDH1*. Mutations of *IDH1* were first identified in studies sequencing glioma cell genomes.[14] Mutations of *IDH1* are found both in lower grade glioma and in GBM. *IDH1* encodes isocitrate dehydrogenase, a Krebs cycle enzyme, and its role in tumorigenesis is an area of intense investigation.

Loss of heterozygosity (LOH) of Ch9p21 at the site of the *CDKN2A* and *CDKN2B* loci leads to homozygous

IDH1, IDH2	2q33.3, 15q26		

deletion of these adjacent genes in approximately 60% of GBM. This deletion results in the loss of the p15 (INK4B), p16 (INK4A), and p14 (ARF) tumor suppressor proteins. *CDKN2A* and *CDKN2B* encode cyclin-dependent kinase inhibitors, p16 (INK4A) and p15 (INK4B), respectively, which bind to the cyclin-dependent protein kinases CDK4 and CDK6 inhibiting the catalytic activity of the cyclin D–CDK complex. p1 (ARF) is expressed from a distinct transcript as the result of alternative splicing of the *CDKN2A* gene and functions to keep MDM2 in the nucleolus so that it cannot degrade p53. Loss of p14 (ARF) results in the enhanced degradation of p53. Other cytogenetic changes including +7p/q, +19q, and −1p/q are widely recognized in high-grade brain tumors, but the best understood is clearly the deletion of chromosome 10, where *PTEN* is located. The *PTEN* protein product, PTEN, is a lipid phosphatase that antagonizes the function of the phosphatidylinositol-3-kinase (PI3K) family of lipid messengers and consequently inhibits downstream signaling through AKT1, a serine/threonine kinase that is a key regulator of critical cell functions including cell proliferation and survival.

Several different receptor tyrosine kinases (RTKs) and their cognate ligands have been implicated in the malignant behavior of astrocytic tumors, and especially GBM. These include PDGF/PDGFR, EGF and TGF-α/EGFR, IGF/IGFR, and others. Although amplification of *EGFR* is found in approximately 50% of GBMs, this change is rarely found in WHO grade III and never in grade I or II tumors. Also, small deletions and rearrangements of the *EGFR* gene are commonly found in GBM.[15] As many as 50% of tumors in which amplification of *EGFR* is detectable also have a rearrangement of *EGFR* in which exons 2 to 7 are deleted.[16] This results in an in-frame deletion that encodes a constitutively active *EGFR* (*EGFRvIII*), which, along with EGFR amplification in tumor cells, predicts a poor outcome. Both antibodies and small-molecule therapeutics have been used to target EGFR in glioma, but resistance to such therapies is rapidly manifested when these treatments are used alone. Although members of the PDGF pathway tend to be overexpressed in all grades of astrocytic tumors, amplification and mutation are rare. Activation of RTKs in glioma leads to autophosphorylation of these receptors, which in turn leads to the docking of a series of proteins on phosphorylated sites of the receptors and downstream activation of various effectors. Activation of RAS by the docking protein SOS1 leads to initiation of the RAF/MEK/MAPK (ERK) pathway that leads to the transcriptional activation of genes important for proliferation. Docking of GAB1 to another phosphorylated site on autophosphorylated RTKs leads to activation of PI3K, which in turn initiates a cascade of phosphorylation leading to PDK1 phosphorylation of AKT1. Activated AKT1 in turn phosphorylates both a number of pro-apoptotic proteins, inactivating them, and a series of transcription factors, activating and leading to transcription of other genes important for cellular proliferation. About 80% of GBMs exhibit activation of AKT1, primarily as a result of RTK activation or deletional inactivation of *PTEN*.[17]

Table 40-3 Glioblastoma Multiforme Subtypes as Suggested by Verhaak et al.

Genes Mutated in Glioblastoma	Glioblastoma Multiforme Subtypes (Frequency of Mutation)			
	Proneural	Neural	Classical	Mesenchymal
TP53	54%	21%	0%	12%
NF1	5%	16%	5%	37%
EGFR	16%	5%	0%	0%
EGFRvIII	3%	0%	23%	3%
IDH1	30%	5%	0%	0%
PDGFRA	11%	0%	0%	0%

Data from Verhaak RG et al. Integrated genomic analysis identifies clinically relevant subtypes of glioblastoma characterized by abnormalities in PDGFRA, IDH1, EGFR, and NF1. *Cancer Cell* 2010;17:98-110.

It is now widely recognized that not all GBMs exhibit the same constellation of genetic alterations, and, interestingly, a second clinical presentation of GBM seems to be associated with a distinctive genetic profile (see Figure 40-1; Table 40-3). Approximately 90% of patients with GBMs present without evidence of a precursor lesion (de novo, primary GBM). Although high levels of *EGFR* expression are frequently found in primary GBM, these are rarely detectable in secondary GBM, which is associated with lower grade precursor lesions. In primary GBM, amplification of *MDM2* is a more common mechanism for inactivation of *TP53* than it is in secondary GBM. The *CDKN2A* and *PTEN* loci are also frequently inactivated by mutation in primary GBM, whereas *IDH1* is more commonly mutated in secondary GBM.

It has not yet been possible to recognize a characteristic pathology or clinical presentation associated with the genetic heterogeneity that is now well documented to accompany the histologic and cytologic variation characteristic of GBM. Current interpretation of the extensive genomic evaluation of glioma gene structure and gene expression suggests that among histologically indistinguishable tumors, there are definable subtypes of glioma characterized by distinctive molecular alterations (see Table 40-3).[18,19] These classifications may be of prognostic significance,[20] although proven targets for therapeutic intervention have not yet been identified.

Oligodendroglioma

Oligodendrogliomas account for about 20% of primary intracranial tumors and are the second most common glial neoplasm.[1] Most frequently these tumors occur in the cerebral hemispheres, typically within the white matter. They are characterized by various histologic criteria of malignancy, which determine their grade. These tumors can have a highly variable spectrum of differentiation, and their cellular origins are not understood, although it is likely that some high-grade gliomas arise from oligodendrocytic precursor cells (OPCs) that are present in the adult nervous system.[21] There is frequent confusion over the proper diagnostic classification for tumors that do not display prototypical characteristics of cells arising in the oligodendroglial lineage or contain multiple populations of cells, one of which will correspond to the oligodendroglial lineage and the other to the astrocytic lineage. Histopathologically, tumors of the oligodendroglial lineage exhibit round, homogeneous, compact cells with a dense central nucleus and clear cytoplasm, sometimes referred to as a "fried egg" appearance. There is rarely identifiable evidence of mitosis. When tumors are highly anaplastic with obvious necrosis and mitotic figures, they are indistinguishable from GBM and are designated as such. Different histologic grades of oligodendroglioma have been associated with specific patterns of gene expression[22] and genetic alterations.[23]

The cytogenetic and molecular biologic profiles of oligodendroglioma are not well characterized but are quite distinct from those of astrocytoma.[23,24] Cytogenetic studies of oligodendroglioma may reveal loss of chromosomes 9p and 22 or gain of chromosome 7, but the most characteristic cytogenetic findings in oligodendroglioma are loss of chromosomes 1p36 and 19q13.3. The presence of these alterations is associated with an enhanced responsiveness to cytotoxic therapies and an improved prognosis.[25] LOH for chromosome 9p, observed in some oligodendrogliomas, corresponds to deletions at the *CDKN2A* locus, and these have been associated with a poor prognosis for patients with this tumor type. Studies looking for mutations that are frequently found in astrocytic tumors have not detected commonly occurring changes in the *TP53* locus. Similarly, Ch10 losses and *EGFR* amplification have been detected only rarely in these tumors. These distinguishing molecular genetic differences are consistent with more recent genomic scale expression analyses that reveal clear differences between astrocytoma and oligodendroglioma.

Meningioma

Meningiomas account for approximately 20% of primary intracranial malignancies[1] and are derived from mesoderm, probably from cells giving rise to the arachnoid granulations. These tumors are usually benign and attached to the dura mater. They infrequently invade the brain parenchyma. Meningiomas may be found incidentally on a computed tomography (CT) or magnetic resonance imaging (MRI) scan, or they may present with a focal seizure, a slowly progressive neurologic deficit, or symptoms of raised intracranial pressure. Total surgical resection of benign meningioma is curative, and when tumor persists, external beam radiotherapy or stereotaxic radiosurgery reduces the recurrence rate to less than 10%. No effective chemotherapy for the treatment of benign meningioma is known, and there is no curative therapy for anaplastic, highly invasive meningioma that cannot be treated locally.

Meningiomas are an important manifestation of neurofibromatosis type 2 (NF2), which occurs as the result of inactivating mutations of the NF2 gene at 22q12. NF2 functions as part of a molecular complex linking the cellular plasma membrane to the cytoskeleton, where it has been implicated in the regulation of cellular proliferation. About half of NF2 patients develop meningioma, and portions of the NF2 gene are lost in approximately half of sporadic meningioma. The frequency of *NF2* mutation does vary somewhat in different histologic types of meningioma.[26,27] *NF2* mutations occur in only about 25% of meningothelial meningiomas, whereas more than 75% of fibroblastic and transitional meningiomas have been found to have evidence of *NF2* inactivation. Other karyotypic abnormalities are also seen in grade II (atypical meningioma) and grade III (anaplastic meningioma). In anaplastic meningioma, the most frequent cytogenetic abnormalities are deletion of Ch1p, partial or complete loss of Ch10q, and loss of Ch14. Unstable chromosome alterations including rings, dicentrics, and telomeric associations also have been observed.

Medulloblastoma

Among children with cancer, only leukemia is more common than primary brain tumors. Medulloblastoma accounts for approximately 15% to 20% of all pediatric brain tumors and for about 80% of childhood primitive neuroectodermal tumors (PNETs) of the CNS. Only gliomas are more common in children. In contrast to other PNET, these tumors are found in the cerebellum, where they are thought to arise from neural progenitor cells (NPCs) of the fetal external granular layer.[28] The 2007 WHO classification of CNS tumors recognized several histologic subtypes of medulloblastoma,[11] and preliminary studies suggest that these are of prognostic significance. Atypical teratoid/rhabdoid tumors of the CNS identified by somatic mutations of the *INI1*

gene often occur in the posterior fossa and can be difficult to distinguish from medulloblastoma. In contrast, medulloblastoma is readily distinguishable from childhood glioma in that it appears as a highly cellular, small, round-cell tumor with frequent mitoses and pseudorosettes. Also, medulloblastoma is more responsive to treatment than glioma, as evidenced by the importance of therapeutic response as a prognostic factor in this disease.[29] The 5-year disease-free survival rate approximates 50% to 70%.[30]

As noted in Table 40-1, the occurrence of medulloblastoma in three inherited cancer syndromes—Turcot syndrome, Li-Fraumeni syndrome, and Gorlin syndrome—has called attention to the possibility that the genes responsible for these syndromes, *APC*, *TP53*, and *PTCH1*, respectively, or the pathways in which they are active might play a role in sporadic medulloblastoma. Although evidence for APC inactivation in sporadic medulloblastoma has not been identified, *TP53* mutations and mutations of *PTCH1* and genes in the *PTCH1*-mediated sonic hedgehog (SHH) pathway are found in sporadically occurring medulloblastoma.[31] Deletions of Ch6q and Ch16q have also been noted in medulloblastoma tumor tissues, and infrequent amplification of *MYC* and *MYCN* has been detected. *NTRK3* neurotrophin receptor expression in medulloblastoma has been reported to be associated with a favorable outcome,[32] a finding consistent with emerging evidence that medulloblastoma tumor tissue expresses a number of genes associated with the neuronal lineage and that expression profiling of these genes may provide a particularly effective approach to devising clinically useful prognostic biomarkers.[33,34]

Molecular Pathophysiology of Primary Brain Tumors

Brain tumors present therapeutic challenges that reflect their occurrence within the closed space of the skull and within a tissue that is particularly sensitive to disruption of its normal function. As a result, simple growth as a space-occupying lesion is particularly problematic in the development of brain tumors as is the invasion of normal tissue, which can occur early in the pathogenesis of some tumor types such as primary GBM and much later in others. The proliferation of brain tumors is thought to be the result of the deregulation of oncogenes and tumor suppressor genes as described previously, and many of the growth-stimulatory pathways that contribute to tumorigenesis in the CNS have been extensively examined. In addition to the oncogenetic alterations described for individual tumors, important regulatory roles in the proliferation of brain tumors include those mediated by EGF and PDGF, which are widely expressed in the normal brain as well.

Glioma and medulloblastoma are typically highly invasive. This characteristic is thought to play an important role in their recurrence after treatment, which tends to occur locally at their original site of presentation. The mechanisms that underlie glial tumor cell invasion are an active area of research.[35-37] Clinicians observed long ago that such malignant tumors have preferred routes of invasion along white matter tracts—although little is known of the manner in which tumor cells recognize white matter tracts and migrate along them. Integrins, especially AvB3 and AvB5, seem to play an important role in this process.[38] Degradation of the extracellular matrix by proteinases produced by tumor cells is now recognized as an important early step in the invasion of normal tissue. Glial tumor cells express urokinase-type plasminogen receptor (UPAR) on their surface,[39] which binds to urokinase plasminogen activators (UPAs) that are also highly expressed in the most malignant gliomas.[39] UPAR presents activated UPA to the extracellular matrix (ECM), where plasminogen is cleaved to active plasmin. This degrades ECM constituents including fibronectin, laminin, and proteoglycans that are especially prominent in the ECM surrounding blood vessels. Matrix metallopeptidases, especially MMP2 and MMP9, also seem to play important roles in ECM degradation.[40] Interestingly, some brain tumors produce inhibitors of various plasminogen activators, thereby inhibiting ECM degradation. The extracellular milieu of the CNS also contains high concentrations of glycosaminoglycan, hyaluronan, and chondroitin sulfate, which are detected in only low amounts in other tissues. How brain tumor cells move through a matrix of such molecules is not known.

The development of a tumor vasculature is a central aspect of tumorigenesis and tumor progression.[41] Although low-grade brain tumors tend to have a vasculature similar to that observed in normal brain, high-grade tumors are heavily vascularized and disrupt the established blood-brain barrier. Such a barrier is not present in the new tumor vessels that are formed.[42] Glial tumor vessel formation is regulated by the endothelial cell RTKs for VEGF, including FLT-1 (VEGFR1) and KDR (VEGFR2).[43] VEGF is a critical mediator of tumor angiogenesis in several different types of brain tumors, and its expression is inducible by hypoxia, a finding consistent with cellular hypoxia being a key stimulant for angiogenesis during glioma formation. VEGF is expressed at very high levels in high-grade gliomas.[44] FLT-1 is not expressed in normal brain tissue but is expressed in a tumor-stage–dependent manner in the vasculature of astrocytoma, and *KDR* is expressed only in high-grade glioma.[43] VEGF is also known to enhance the vascular permeability of normal brain vasculature and may be responsible for the peritumoral edema found frequently in malignant gliomas. Blood vessel formation during tumorigenesis and tumor

progression requires both proliferation and recruitment of smooth muscle pericytes, which is regulated by TGFB1, PDGFRB, and TEK (TIE-2). The TEK receptor and its agonist, ANGPT1, are constitutively expressed in gliomas, suggesting an important role in the development of tumor vasculature for this pathway as well. Bevacizumab, an antibody against VEGF, is widely used in the management of brain tumor patients, though the degree of impact on survival and quality of life remains unclear.[45]

Therapeutic Resistance of Primary Central Nervous System Tumors

Primary brain tumors are widely regarded as being particularly resistant to the most commonly used antineoplastic strategies. Although surgery plays a major role in removing some brain tumors and debulking others, the challenges of working within the skull in a tissue so exquisitely sensitive to anatomic disruption means that tumors that either arise in or invade regions of the brain that are required for vital functions cannot be effectively removed. Also, aggressive brain tumors, especially high-grade astrocytomas, tend to invade as numerous projections from the surface of the tumor and as rare cells that move to very distant regions of the brain, making complete removal impossible. Similarly, the use of radiation therapy is challenged by the compactness of normal tissues in the vicinity of the tumor and by the invasion of tumor into normal tissue. These characteristics of brain tumors mean that delivering effective doses of radiation to the tumor without damaging critical normal tissue is particularly difficult. This is especially important in the developing brains of pediatric patients and compromises our ability to use the highest doses of radiation therapy in children.

Both radiation therapy and chemotherapy are compromised because many glial-derived tumors seem to be particularly resistant to apoptosis following DNA damage.[46] Although the precise contribution of apoptosis to curative therapy in solid tumors is not yet known, it is clear that tumors that are highly resistant to apoptosis do not respond well to cytotoxic therapies. Also, the blood-brain barrier presents a unique challenge for the administration of chemotherapy. Although the barrier is largely destroyed at sites of primary tumor growth, migrating, invasive tumor cells are thought to remain behind the blood-brain barrier until they begin to establish millimeter-size masses, and this finding may account for the apparent resistance to therapy of some tumor types. The use of combination therapy consisting of procarbazine, lomustine (CCNU), and vincristine (PCV) has been found to be quite active in a subgroup of patients with oligodendroglioma, which is characterized by the loss of Ch1p and Ch19q.[47] Also, the combination of temozolomide with radiation has resulted in a slight increase in median survival of patients with GBM, a disease in which surgery and radiation alone result in survival of approximately 1 year.[48] These results indicate that cytotoxic approaches can contribute to the treatment of brain tumors and, it is hoped, will provide insights into how multimodality therapy might be more effective in the future.

Future Directions/Perspective

Recent advances in understanding the genetic underpinnings of primary brain tumors have provided evidence for the involvement of genes and pathways not previously known to be important for the pathobiology of glioma, and in some cases for any cancer. These studies have provided a remarkable picture of the molecular heterogeneity that previous work suggested, and many expected, but is now irrefutable and clearly of great importance in thinking about the development of future therapies. Beyond the mutational heterogeneity important for tumor progression and recurrence, the documentation of epigenetic, biological, and molecular heterogeneity in different parts of high-grade glioma[3]—an observation consistent with the histologic appearance of GBM—raises important questions regarding the design and evaluation of current therapeutic strategies. Characterizations of these genetic and epigenetic changes associated with malignancy have highlighted pathways likely to be the "drivers" of tumor pathology and tumor progression. Although the failure of targeted therapies has to date been focused on target-specific mutations contributing to therapeutic resistance,[49] we will now have to contend with large populations of cells within tumors at presentation and relapse that may require quite different therapeutic approaches[3] and tumor stem cell populations that are intrinsically chemoresistant.[50] Importantly, the need for combinations of targeted therapy is further highlighted by these observations, and that clearly should be an important line of clinical investigation for the immediate future.

Epithelial Skin Cancer

Skin Cancer Research Has Helped Define the Biology of Cancer Pathogenesis

Epithelial nonmelanoma skin cancer (NMSC, primarily basal cell and squamous cell carcinoma) is the most frequent cancer among white populations, with incidence rates matching all other cancers combined in these groups. Although not frequently lethal, epithelial skin cancers are the cause of considerable morbidity, cosmetic defects, and extreme medical expense. Exposure to mutagenic ultraviolet (UV) light is the major skin carcinogenetic stimulus, but sun avoidance has often been superseded by lifestyle choices, and changing atmospheric conditions favor increased intensity of exposure. Thus, considerable attention has been directed to understanding the molecular pathogenesis of epithelial cutaneous cancer, and much progress has been achieved. Consequently, effective therapeutic approaches are evolving that have the potential to sharply reduce the morbidity and expense associated with these lesions. Skin cancer research has also provided significant insight into the mechanisms of understanding cancer pathogenesis in general. Centuries ago, astute clinicians and basic scientists first observed that chemical and physical exposures could cause skin cancer in humans and animals. Modern analysis of skin cancer induction demonstrated that cancers evolve from multiple, clonal, precancerous stages (initiation, promotion, premalignant progression, malignant conversion), and that genetic (e.g., mutation), epigenetic (e.g., gene expression or protein modification), and microenvironmental changes (e.g., inflammation, wounding) contribute to tumor formation. Skin studies first revealed that chemical carcinogens bind covalently to DNA, causing specific mutations in oncogenes and suppressor genes, and that DNA repair protects against cancer risk. In addition, cutaneous cancer research has indicated that viruses can cause human tumors; that immunosuppressed patients are susceptible to cancer; that genetic background can modify cancer rates; that diet, UV exposure, and cigarette smoke are cancer risk factors; and that signaling pathways initially associated with familial basal cell carcinoma (BCC) contribute to the pathogenesis of a variety of epithelial cancers of internal organs.[1] Thus, epithelial skin cancer research has been a major contributor to defining cancer biology and biochemistry in general.

The Molecular Origin of Skin Tumors Is Revealed by Hereditary Syndromes

Cutaneous cancers are the manifestation of germline mutations in a number of hereditary syndromes (Table 41-1). Identifying the mutant genes has revealed pathways relevant to the pathogenesis of cancers in skin and internal organs as well as revealing targets for somatic mutations in spontaneous versions of the same tumor type. The most broadly relevant are the DNA repair genes that comprise the complementation groups of skin cancer–prone xeroderma pigmentosum families.[2] Germline mutations in individual genes at distinct chromosomal loci define proteins that collectively ensure proper global and transcription-coupled nucleotide excision repair. Among these are proteins that recognize and bind to sites of DNA damage (XPA, XPC, XPE),[1] helicases (XPB, XPD), and endonuclease components (XPG, XPF)—defects in any of which can give a skin cancer—prone or defective neurological phenotype.[2] The discovery of germline mutations in the *PTCH1* gene among patients with the basal cell nevus syndrome first revealed the involvement of the Sonic hedgehog pathway in human cancer.[3] Subsequent studies confirmed that most sporadic basal cell cancers had somatic mutations in *PTCH1* or its downstream effector *SMO*. The mapping of the dysplastic nevus syndrome to the *INK4a* locus and identification of mutations in the p16*(INK4a)* gene revealed an important pathway in the etiology of heredity-prone and sporadic melanoma. As important, this discovery pointed to defects in structure or expression of p16 *(INK4a)* and other components of the cyclin-CDK signaling pathway in melanoma and

Table 41-1 Gene Targets for Mutations in Hereditary and Sporadic Cutaneous Cancers

Gene	Function	Locus	Tumor Type	Syndrome	Spontaneous
p53	DNA repair, apoptosis, cell cycle regulation	17 p13.1	BCC, SCC	Li-Fraumeni (but no increase in skin cancers)	Yes
XPA, XPB XPC, XPD, XPE XPF, XPG	DNA repair	9p34.1, 2q21 3p25.1, 19q13.3, 11p11.12 16p13.3, 13q32	BCC, SCC, melanoma	Xeroderma pigmentosum	Possible
PTCH1	Sonic hedgehog receptor	9q22.3	BCC, trichoepithelioma	Nevoid basal cell carcinoma	Yes
SMO	Sonic hedgehog effector	7q31-32	BCC	Not identified	Yes
$p16^{INK4a}$	Cyclin inhibitor	9p21	Melanoma, SCC, trichoepithelioma	Dysplastic nevus	Yes
CTNNB (β-catenin)	Cell-cell adhesion, transcription factor	3p22-p21.3	Pilomatricoma	Not identified	Yes
CYLD1	NFκB inhibitor	16q12-13	Cylindroma Trichoepithelioma	Multiple cylindroma	Yes
PTEN	Phosphatase	10q23.3	Trichilemmoma	Cowden's	Unknown
MSH2 MLH1	Mismatch repair	2p22-p21 3p21.3	Sebaceous gland carcinoma	Muir-Torre	Unknown
Folliculin	Regulates mTor	17p11.2	Fibrofolliculoma	Birt-Hogg-Dube	Unknown
CYLD1	NFκB inhibitor	16q12-13	Trichoepithelioma	Multiple trichoepithelioma	Unknown
?	?	Xq24-q27	BCC	Bazex	Unknown
TGFβR1	Growth inhibitor	9q22.3	Keratoacanthoma	Ferguson-Smith	Iatrogenic
DKC1, TERC, others	Telomere maintenance	X, 3q, others	SCC	Dyskeratosis congenita	No
COL7A1	Anchoring fibrils	3p21.1	SCC	Recessive dystrophic epidermolysis bullosa	No

nonmelanoma skin cancer. Ferguson-Smith disease (FSD), characterized by multiple squamous-carcinoma–like locally invasive skin tumors that grow rapidly for a few weeks and then spontaneously regress, is due to inactivating mutations in *TGFβR1*. Recessive dystrophic epidermolysis bullosa is a blistering skin disorder caused by mutations in *COL7A1*, a critical component of the basement membrane secreted by keratinocytes. DEBS patients suffer from early-onset, highly invasive and metastatic squamous cell carcinoma (SCC), often leading to death. Tumorigenesis is linked to a specific fragment of type VII collagen that promotes tumor cell invasion and constitutively active dermal fibroblasts that enhance tumor aggressiveness. Specific mutations in Cowden syndrome (*PTEN*), Muir-Torre syndrome (*MSH2, MLH1*), pilomatricoma (*CTNNB [β-catenin]*), Birt-Hogg-Dube syndrome (*FLCN*), cylindromatosis (*CYLD1*), and trichoepithelioma (*PTCH1*, p16 (*INK4aA*)) that cause adnexal tumors have revealed much about the pathways important in the development of cutaneous adnexal tissues. In addition to skin tumors, folliculin defects are strongly linked to renal cancer, Pten to breast cancer, and Msh2 to colon cancer. Dyskeratosis congenita is a complex genetic syndrome resulting from defects in any one of related genes involved in the maintenance of telomeres. The association with both cutaneous and head and neck SCC recapitulates mouse models of telomerase deficiency.

In addition to these highly penetrant hereditary syndromes, genome-wide association studies are identifying new loci that confer increased risk for either BCC or SCC, although the mechanistic details remain. Single-nucleotide polymorphisms (SNPs) within several well-characterized pigmentation loci—including *MC1R* (melanocortin 1 receptor) and *OCA2* (oculocutaneous albinism II)—and a potential pigmentation locus *IRF4* (interferon regulatory factor 4) show linkage to increased risk for both BCC and SCC NMSC.[4-6] Other SNPs on 6p25 and 13q32 near the *EXOC2* and *UBAC2* genes also show linkage with increased risk of SCC,[6] whereas two functional SNPs in the nucleotide excision repair gene *ERCC6* are significantly associated with increased risk of BCC. A history of NMSC is also associated with increased risk for subsequent noncutaneous malignancies, and a previous SCC is associated with poor prognosis for cancers of the lung, colon, rectum, and breast and for non-Hodgkin lymphoma. Although the genetic basis of this is currently unknown, GWAS studies of patients

with NMSC and a noncutaneous malignancy will likely reveal additional loci conferring risk for cancer for which the appearance of NMSC may be a signal.

Basal Cell Carcinoma

BCC is a very common, slow-growing, locally invasive tumor that typically presents as a pink or pearly papule with superficial telangiectasia and occasional ulceration. BCC precursor lesions have not been identified, there is no evidence of neoplastic progression, phenotypic diversity even within the same tumor is common, and metastases are exceedingly rare. Chromosomal losses involving 9q mark both sporadic and inherited BCCs, leading to the discovery of mutations in *PTCH1*,[3] a homologue of the *Drosophila ptc* gene involved in embryonic development.

Ptch1 is a 12-pass transmembrane receptor for Sonic hedgehog (Shh), a secreted ligand involved in the proliferation and patterning of multiple tissues and organs during embryogenesis. Shh binds to Ptch and alleviates Ptch-mediated repression of Smo on responding cells (reviewed in Reference 1). Active Smo enters the primary cilium, where it functions to modify the expression and structure of a family of Gli transcription factors to alter the expression of Shh target genes. The complexity of the pathway is enhanced by the presence of additional vertebrate homologues of *Drosophila* proteins, fused (a serine-threonine kinase), suppressor of fused (SuFu) that binds to Gli proteins, Cos 2 (Kif7), and Iguana (Dzip1), with SuFu, Cos2, and Iguana serving as inhibitors of Gli signaling.[1] Activation of the Shh pathway upregulates *Gli1* and *Ptch1*, and these serve as markers for physiologic and pathologic Shh signaling. In human BCCs, inactivating mutation or deletion of PTCH1 results in constitutive signaling independent of SHH. In addition to loss-of-function *PTCH1* mutations, gain-of-function (oncogenic) *SMO* mutations have been found in some BCCs where PTCH1 appears to be normal. *PTCH1* or *SMO* mutations are implicated in about 80% of BCCs, whereas hedgehog signaling is active in all BCCs. Thus, additional mechanisms must exist for uncontrolled activation of this pathway. Rare mutations in SuFu have been reported in BCCs, and other syndromes are known to predispose to BCC, but the genetic bases for these have not been delineated. Although mutations in *p53* have been found in up to 50% of BCCs , most lesions fail to exhibit the genomic instability associated with other cancers where p53 function is compromised,[7] and the presence or absence of p53 mutations does not alter the histological phenotype, although loss of p53 function facilitates the eruption of BCC in animal models.

Gli activation is the driving force for tumor development in the setting of constitutive Hedgehog signaling. The three mammalian Gli proteins are zinc finger proteins that bind to a 9bp canonical binding site in the promoters of target genes following activation of hedgehog signaling (reviewed in Reference 1). The regulation of Gli activity by hedgehog signaling is complex; Gli2 and Gli3 proteins have both transcriptional repressor and activating domains, whereas Gli1 is strictly a transcriptional activator. Much of the regulation of Gli proteins is post-translational. Gli3 processing primarily generates a transcriptional repressor, whereas processed (phosphorylated) Gli2 is ubiquitinated and degraded. Shh signaling suppresses processing and degradation of Gli2 and stabilizes its transcriptional activation function. Genetic ablation studies in mice have displayed the consequences of Gli activity in vivo. Gli1-null mice are without a phenotype, whereas the developmental defects and impaired hair follicle growth caused by ablation of Gli2 indicate that Gli2 is the downstream effector of the Hh pathway.[8] Disruption of Gli3 produces a phenotype consistent with hedgehog activation, validating its action as a repressor of the pathway.

Genetically altered mouse models provide experimental evidence linking the hedgehog pathway to human BCC.[9] Targeting SHH or an activated SMO mutant to the epidermis and hair follicles upregulates Shh target genes and produces basal cell–like proliferations in newborn mouse skin. Overexpression of SHH in human keratinocytes followed by grafting onto severe combined immunodeficiency (SCID) mice produced BCC-like changes as well. Mouse models in which *Ptch* gene function has been disrupted develop microscopic hair follicle–derived proliferations, with the appearance of a variety of macroscopic skin tumors, including BCCs, following exposure to ionizing or UV radiation.[10] Mice with skin targeted overexpression of human GLI1 or mouse Gli2 develop multiple BCCs or other tumors arising from hair follicles. The Hh pathway is regulated through primary cilia, present on most mammalian cells, which acts as an organizing structure for signaling and is essential for proteolytic processing of Gli proteins to activator and repressor forms. Inactivation of Kif3a, an essential component of the anterograde intraflagellar transport motor, blocks formation of BCC in mice expressing the activated form of SMO, but accelerates tumor formation driven by activated Gli2. Thus cilia play a dual role in both activating and inhibiting Shh signaling and tumorigenesis.

Taken together, these findings strongly support the concept that deregulated Shh signaling is central for BCC development. When Gli2 is targeted to mouse epidermis and hair follicles conditionally, BCCs develop from overexpression and regress when expression is discontinued. On reexpression of Gli2 in this model, tumors reemerge from a small residual population of precursor cells. What remains unclear is the identification of the hedgehog target genes

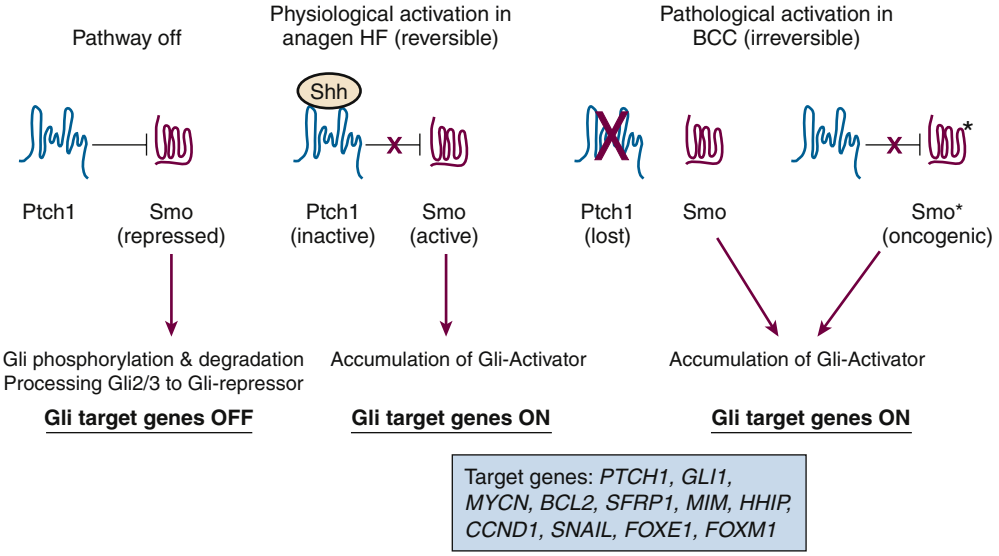

Figure 41-1 Simplified model depicting hedgehog signaling in skin physiology and BCC pathogenesis. The major site of action for sonic hedgehog (SHH) is the hair follicle (HF). In resting hair follicles, SHH is not expressed, and PTCH1 dampens SMO activity. Under these conditions, Gli transcription factors are unstable and degraded. In addition, posttranslational processing of GLI2 and GLI3 processing yields a transcriptional repressor that suppresses SHH target gene expression. When SHH expression increases during HF growth (anagen), PTCH1 is inactivated, SMO is phosphorylated by casein kinase 1 and protein kinase A, and active SMO upregulates Gli proteins by posttranslational mechanisms, leading to accumulation of Gli transcriptional activators. One target of Gli transcription is PTCH1, which serves as a negative feedback on this reversible pathway. In BCC initiation, PTCH1 is genetically deleted (or SMO is mutationally activated to SMO*), and the pathway is irreversibly activated. Gli2 appears to be the major driving factor to upregulate a number of effectors responsible for the neoplastic phenotype, including GLI1, MYCN, BCL2, SFRP1, MIM, HHIP, CCND1, SNAIL, FOXE1, and FOXM1.

downstream from Gli that are essential for BCC formation. A number of candidates have been reported, including several cyclins, E2f1, N-Myc, Pdgfr, Bcl2, BEG4, FOXM1, and FOXE1, Mim, Hhip, Snail, Ptch1, and Gli1 (Figure 41-1), but definitive studies on these genes are lacking. In both human and mouse BCC the Wnt pathway appears dysregulated due to elevated expression of β-catenin, and blockade of Wnt signaling in mice blocks hedgehog-driven tumor growth. Crosstalk between hedgehog and EGFR signaling is synergistic for BCC induction in animal models, suggesting that EGFR inhibitors could have a therapeutic role in the clinic. Small-molecule inhibitors of SMO have been developed based on the natural product cyclopamine, which causes BCC regression in animal models. In recent Phase III clinical trials, the SMO inhibitor vismodegib has caused significant tumor regression in patients with advanced sporadic BCC[11] and regression of preexisting lesions and prevention of new lesions in Gorlin syndrome patients.[12] Vismodegib was approved by the U.S. Food and Drug Administration (FDA) in January 2012 for adult patients with recurrent locally advanced or metastatic BCCs or who are not candidates for surgery or radiation. Other inhibitors are likely to follow, although target-based side effects may be an inherent limitation for long-term treatment. Because the Hedgehog pathway is aberrantly activated in malignancies arising in several internal organs,[1] these inhibitors are likely to have a significant impact on the treatment of a broad range of human neoplasms.

Cutaneous Squamous Cell Carcinoma

Cutaneous SCC frequently presents as a firm, pink papule or nodule, with a conspicuous hyperkeratotic surface. Although SCCs represent only about 20% of nonmelanoma skin cancers, they are invasive and occasionally metastasize (1% to 2%). SCC is more frequent with higher cumulative sunlight exposure and as cancers associated with specific occupational exposures (coke oven and petroleum oil workers). There is roughly a 25- to 200-fold increase in SCC incidence in immunosuppressed organ transplant recipients, with a reversal of the BCC-to-SCC ratio; these tumors are more aggressive, occur in multiple locations within one patient, and are associated with increased morbidity and mortality. Conversely, a drug that activates local innate and adaptive immune responses through TLR-7 (imiquimod (1-(2-methylpropyl)-1*H*-imidazo[4,5-C]quinolin-4-amine) is highly effective in treating BCC, SCC, and its precursor lesion, actinic keratosis (AK).[13] Cutaneous SCC is usually preceded by a benign hyperproliferative-hyperkeratotic AK (Figure 41-2, *A*). These are sunlight-induced clonal lesions that frequently harbor *p53* mutations, particularly at codon 278 or other codons of the DNA binding domain of p53 that contain dipyrimidine sites. AKs often exhibit chromosomal changes, particularly loss of heterozygosity (LOH) at 3p, 13q, 17p, 17q, 9p, and 9q. Such changes are less frequent in SCC, clouding the direct relation of AK to SCC.

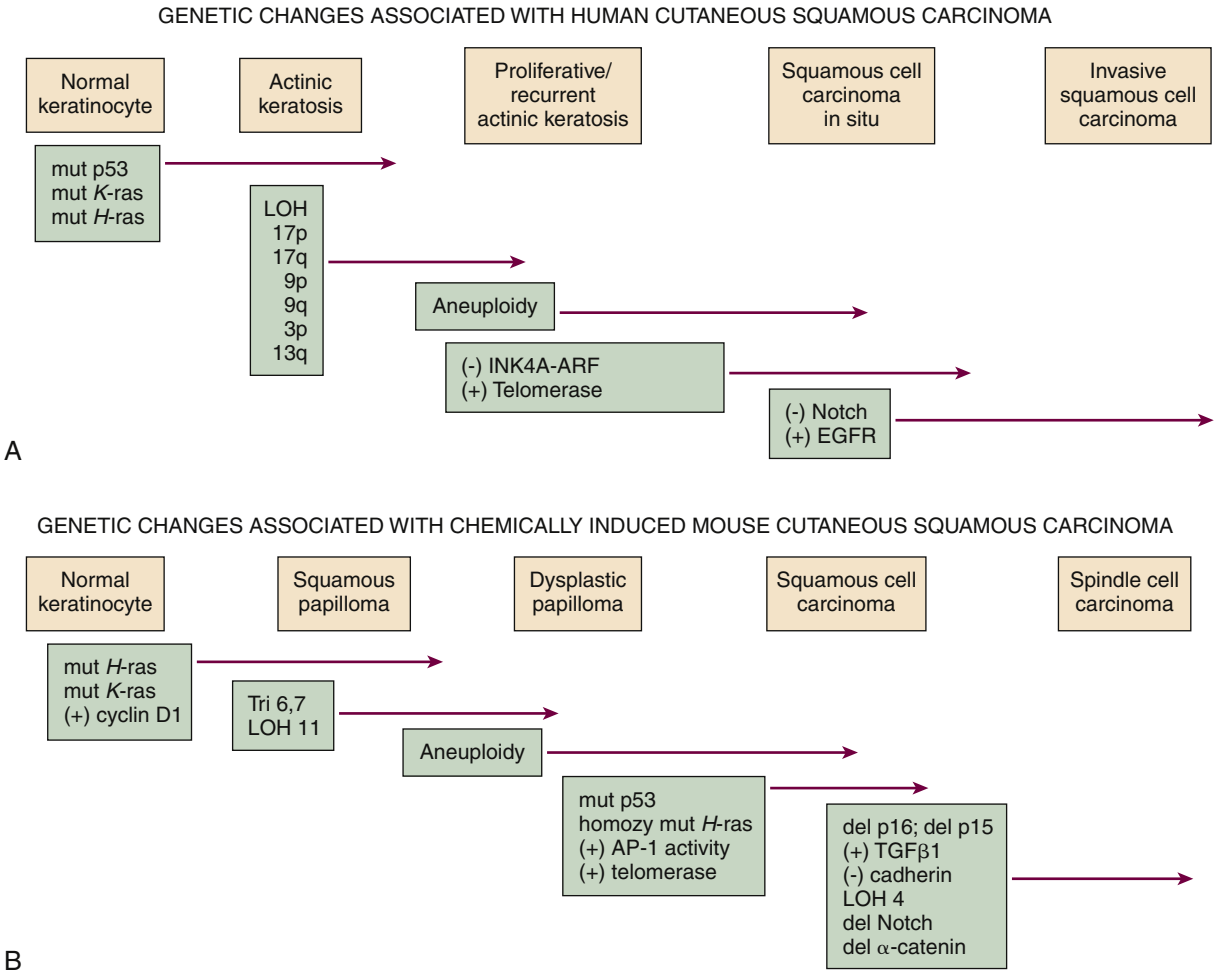

Figure 41-2 Genetic changes associated with (A) human cutaneous squamous carcinoma and (B) experimental mouse skin squamous carcinoma. The multistage evolution of invasive squamous cell cancer is depicted schematically with frequently associated genetic changes detailed here. Although many common pathways exist in the two species, current understanding places p53 mutations early in human SCC development and ultraviolet light–induced mouse skin SCC (not shown), but p53 mutations occur late in chemically induced mouse skin SCC associated with malignant conversion. Increased activity of telomerase (deletion of inhibitor) or EGFR tyrosine kinase (gene amplification) and decreased signaling in the Notch pathway (mutation) may also result from epigenetic changes, as in the case of upregulation of EGFR ligand expression in mouse SCC development. *This figure is modified from Dlugosz A, Merlino G, Yuspa SH. Progress in cutaneous cancer research.* J Invest Dermatol Symp Proc *7:17-26, 2002, with permission of the* Journal of Investigative Dermatology.

However, the frequency of evolution of AK to SCC is very low (0.1% to 10%), suggesting there may be a high-risk AK group with relevant genetic changes not yet documented. Activating mutations in the K-*RAS* or Ha-*RAS* gene are detected in approximately 10% of AK and SCC, and the RAS pathway is activated by non-mutational mechanisms in a much larger fraction of SCCs. Inactivating mutations or epigenetic silencing of p16*(INK4a)* and activation of telomerase are other pathways associated with SCC development. Constitutive activation of the EGF receptor (EGFR) by amplification or increased expression of ligands with the formation of an autocrine loop is a frequent finding in SCC. Gene expression arrays have revealed several other genes whose expression is characteristic of SCC, but experimental validation of a causal relation remains to be determined.

Constitutive activation of NFκB signaling is common in SCC,[14,15] and this is associated with upregulation of specific NFκB target genes associated with altered proliferation, invasion, angiogenesis, and inflammation. NFκB hyperactivation is a known inducer of cylindromatous skin tumors, because homozygous deletions of the CYLD gene, encoding a deubiquitinase that negatively regulates the NFκB pathway through targets such as TRAF2 and BCL-3, has been identified as the basis for familial cylindromatosis (see Table 41-1). Homozygous deletion of CYLD in mice increases susceptibility to squamous skin tumors. However, studies with genetically modified human keratinocytes grafted to nude mice suggest that inhibition of NFκB together with activation of the *RAS* oncogene is sufficient to convert normal keratinocytes into SCC, and a similar result has been obtained in the skin of transgenic mice. This controversy is unsettled at this time.

To prove causal relations among the various associations made by studying human SCC, model systems using

human and mouse keratinocytes in culture and animal models in vivo have been developed. The classical carcinogenesis model to induce SCC on mouse skin involves a limited application of a mutagenic agent such as a chemical carcinogen or UV light that "initiates" the cancer process in a subset of cells, followed by repeated applications of a nonmutagenic agent such as a phorbol ester that provides a microenvironment favorable for the clonal outgrowth of the initiated population. Tumor development proceeds through predictable stages, with the early emergence of benign squamous papillomas, the murine equivalent of AK, some of which progress to invasive SCC, mimicking human SCC with a low metastatic rate (see Figure 41-2, *B*). In some cases SCC will evolve into a more aggressive spindle cell cancer. This model has illuminated the genetic and biochemical changes that are permissive for SCC development under controlled experimental conditions. Heterozygous activating *Ras* gene mutations are sufficient to "initiate" the target cells and produce squamous papillomas, and this is coupled to constitutive activation of the EGFR through overexpression of EGFR ligands (see Figure 41-2, *B*). Papillomas form spontaneously in transgenic mice overexpressing ErbB2 and TGFα in epidermis, and papilloma formation is reduced in mice where EGFR or SOS is ablated. Furthermore, tumor formation is completely inhibited in mice lacking the *Stat3* gene, a downstream target of the EGFR. The clinical relevance of this pathway is highlighted by the effectiveness of anti-EGFR drugs in head and neck SCC patients. The relevance of the RAS pathway in human skin cancer is emphasized by the development of multiple cutaneous SCC and keratoacanthoma expressing *Ha-RAS* mutations in melanoma patients treated with the BRAF V600E inhibitor vemurafenib.[16] This drug also enhanced chemical carcinogenesis on mouse skin through stimulation of MAPK activity. Inactivation of PKCδ is also essential for papilloma development in mouse skin. PKCδ is inactivated by c-Src–mediated tyrosine phosphorylation in initiated mouse keratinocytes, whereas in human skin tumors the expression of PKCδ transcripts is greatly reduced. Transgenic mice overexpressing PKCδ in the skin do not form skin tumors. TGFβ plays a dual role in experimental SCC development, suppressing premalignant progression to SCC while enhancing phenotypic progression from SCC to a spindle cell phenotype.[17] However, topical inhibitors of the TGFβ type I receptor suppress papilloma formation, suggesting that TGFβ signaling is important in tumor outgrowth. Inactivation of p53 enhances malignant conversion of papillomas to SCC in chemical carcinogenesis but is an earlier event in UV light–induced skin carcinogenesis in both mice and humans. Members of the AP-1 transcription factor family also play a dual role in experimental skin tumor development, where c-Jun is essential for papilloma and c-Fos is essential for SCC development. Inhibition of AP-1 activity after the formation of benign papillomas prevents malignant conversion.

In contrast to murine models for BCC, the development of techniques to genetically alter mice greatly expanded the array of genes and pathways that influence SCC development on the skin (Table 41-2), indicating a much more complex pathogenesis. Pathways and genes that can influence SCC development and progression to spindle cell tumors in mice include cyclin D1, ornithine decarboxylase, p16(ink4A), p15(ink4A), p63, E-cadherin, and TGFβ1, and these are frequently altered in human SCC. In several model systems, genetic alterations have resulted in the spontaneous development of SCC in the absence of a precursor lesion. For example, mice ablated for *Notch* or *β-Catenin* rapidly form SCCs even in the absence of carcinogenic exposure, and ablation of *Notch* in epidermis promotes tumor formation by creating a barrier defect and promoting inflammation.[18] In fact, loss of function *Notch* mutations is frequently found in cutaneous SCC.[19] Furthermore, clinical trials of γ-secretase inhibitors for the treatment of Alzheimer's disease have been discontinued because of emergence of NMSC.[20] γ-Secretase is required for the activation of intracellular Notch action.

Defining the Cell of Origin for Cutaneous Cancers

Genetic profiling of both SCC and BCC indicate a monoclonal origin. However, the multiplicity of epithelial tumor phenotypes in skin (see Table 41-1) and the divergent phenotypes within each suggest that either multiple target cells exist within the complex compartmentalization of the integument or that specific genetic lesions or tumor microenvironments acting on a multipotential target cell determine tumor phenotype and malignant potential.[21,22] Both human and murine skin contains several types of stem cells within different locations in the epidermis and hair follicle that maintain discrete epidermal compartments, with stem cells within the bulge region of the hair follicle the best characterized.[22] Gene expression analysis of isolated murine hair follicle stem cells and analysis of genetically altered mice has revealed specific gene expression patterns and signaling pathways that define stemness, and Lgr6+ cells residing above the follicle bulge may mark stem cells capable of generating all three self-renewing compartments of the epidermis.[23]

Lineage tracing studies in mice and targeted activation of Hh signaling in different cells of the hair follicle have revealed that only cells originating in the interfollicular epidermis and upper infundibulum are capable of generating BCC in the absence of other factors, such as wounding hair growth cycle, irradiation, or supraphysiological expression of

Table 41-2 Genetically Modified Mouse Models for Cutaneous Squamous Cell Cancer

Modification	Enhancers	Comments
Tg.AC (ζ globin-v-ras^{Ha})	Promoters, drugs	Enhancers upregulate transgene
Tg.AC	UVB	p53 mutations are absent
K1-ras, K10-ras	Promoters	Predominantly papillomas
ΔK5-ras	None	Papillomas, KA, SCC
K6-ras	Promoters	SCC
K1-TGFα, K14-TGFα, MT-TGFα	Promoters	Predominantly papillomas that regress
Inv-c-MycER	None	Papilloma
K1-v-fos	Promoters	Papilloma
K5-E2F1	p53 deficiency	Papilloma, SCC, BCC
K5-Igf1	Promoters	Papilloma, SCC
K5-ErbB2	Promoters	Papilloma, SCC
K5-SOS-F	None	Tumors inhibited by Egfr deficiency
K14-HPV16	FVB/N mouse strain	Tumors inhibited by difluoromethylornithine
K6-ODC	DMBA	SCC, K-ras mutations
XP mutant models (A, C, D)	Initiation/promotion/UVR	Enhanced sensitivity
Egfr null mutant	v-*ras*^{Ha}	Reduced tumor size
p53 null mutant	DMBA/TPA	Enhanced malignant conversion
p21^{waf1} null mutant	DMBA/TPA	Enhanced papilloma formation
c-fos null mutant	Cross with Tg.AC	Papilloma but no SCC
K14-PKCε	DMBA/TPA	Enhanced SCC, metastases
K14-PKCδ	DMBA/TPA	Reduced papilloma development
K5-src	None or DMBA/TPA	Enhanced spontaneous or induced SCC
K5-IκB mutant	None	Spontaneous SCC/NFκB inhibition
Notch null	None	Spontaneous SCC/nuclear β-catenin
α-catenin null	None	Spontaneous SCC/NFκB activation
Cyld null	None or DMBA/TPA	Enhanced papilloma/NFκB activation

pathway components. Targeting high levels of oncogenic Ras to basal and stem cell keratinocytes gives rise to squamous tumors with a high risk for malignant conversion, whereas targeting suprabasal keratinocytes produces only benign tumors. Lineage tracing with genetically altered mice shows that keratin 15 expressing cells of the hair follicle bulge region contribute to chemically induced squamous papillomas.[24] However, expression of physiological levels of oncogenic Ras in hair follicle bulge stem cells, hair germ, and outer root sheath or interfollicular keratinocytes only gives rise to benign papilloma, but SCC can develop in all cells when combined with p53 deletion. More committed hair matrix keratinocytes were unable to form tumors with Ras or Ras + p53 loss.[25,26] Although the cell of origin has not been identified for human cutaneous SCC, tumor-initiating or cancer stem cells (CSCs) have been isolated from cutaneous SCC based on expression of CD133 (prominin), which can regenerate tumors with similar histology and grade as the original in serial xenotransplants on immunocompromised mice.[27] In murine cutaneous SCC, 2 CSC populations have been identified differing in the expression of the hair follicle bulge marker CD34, and responsiveness to TGFβ1 signaling and FAK-mediated integrin signaling. Other studies have demonstrated dependence of CSC on β-catenin signaling and autocrine VEGF responses requiring the neuropilin receptor. Together these mouse models show that SCC can arise from multiple cells within the hair follicle and interfollicular epidermis, that distinct CSC populations exist within the same tumor, and that they have gene expression patterns distinct from normal hair follicle stem cells and require specific

microenvironmental stimuli and gene expression pathways to maintain the CSC phenotype.

Importance of the Microenvironment in Cutaneous Cancer

Although much cutaneous cancer research has focused on cell-autonomous alterations in keratinocytes that contribute to cancer development, it is now clear that alterations in the cutaneous tissue environment are also critical. Changes in integrin distribution and expression occur during progression of human and chemically induced mouse SCC, and targeted changes in specific integrin complex expression can enhance or suppress malignant conversion. Similarly, mutations in the anchoring molecule collagen VII that block the interaction of collagen VII with laminin 5 predispose dystrophic epidermolysis bullosa to SCC.

Changes in the cutaneous immune microenvironment are also critical for tumor development. Inflammation and immunosuppression caused by UV irradiation are intimately linked to UV-induced skin cancer. Similarly, inflammation within the tumor microenvironment is associated with the progression of AK to SCC. Genetically altered mice lacking skin-resident γδ T cells have increased frequency of chemically induced papillomas and malignant conversion, suggesting that this resident T cell population is important in antitumor immunosurveillance. Surprisingly, Langerhans cells, the other epidermal resident immune cell, mediate chemical carcinogenesis through effects on carcinogen metabolism allowing DNA damage and mutation in keratinocytes. In contrast, mice with a TCRβ deletion (lacking all αβ T cells) have a significantly reduced carcinoma yield, and this may be due to a subset of tumor-promoting $CD8^+$ T cells.[28,29] Humoral immunity and B cells also play a tumor-promoting role in skin carcinogenesis through cutaneous deposition of IgG that enhances recruitment of proinflammatory myeloid cells. Factors that mediate inflammation such as prostaglandins, TNFα, and IFNγ enhance experimental cutaneous carcinogenesis. Likewise, chronic inflammatory skin conditions such as discoid lupus erythematosus, dystrophic epidermolysis bullosa, and chronic wounds are associated with increased susceptibility to human skin cancer.

Perspective

Advances in understanding the molecular basis of cutaneous cancer have reinforced the paradigm that particular genetic and epigenetic changes and the pathways they regulate contribute to skin cancer formation in a stage-specific manner. What benefit may come from these current insights? This is most clear in the case of BCC, where the molecular mechanism of pathogenesis is so precisely defined (perhaps better than in any other human cancer) that curative therapeutic targets are identified, and precise animal models have been developed for testing new therapeutics. Currently cyclopamine and derivatives with better therapeutic index are in clinical trials to block SMO, with remarkable results in advanced patients,[11] and tazarotene, a retinoid used successfully to treat BCC lesions in mouse models, is an inhibitor of GLI function.[30] Although BCC is generally not life threatening, the high frequency of these lesions on exposed skin favors a medical rather than the traditional surgical approach, an advance that is being achieved by translation of basic research. Recent advances in tools for large-scale expression and genomic analysis have been applied to SCC lesions and their precursor AK. Animal models and human tissue analyses have suggested that premalignant precursor lesions vary in risk for progression, and it is anticipated that molecular profiling will reveal markers to identify high-risk lesions for closer clinical scrutiny. Similarly, profiling of SCC will undoubtedly reveal signature markers associated with lesions at risk for metastatic spread. Currently two molecular therapeutic targets derived from basic research on SCC pathogenesis show promise for medical therapy of SCC. Inhibitors of the EGFR, in clinical use for several internal malignancies, show promise in animal models for the prevention of UV-induced mouse skin SCC. Ingenol-3-angelate (Picato), recently approved for treatment of AK, BCC, and SCC in situ, targets protein kinase C to induce an innate immune response and damage tumor vasculature.[31] Stimulation of innate immunity to destroy skin tumors is another paradigm for cancer therapy, first introduced into the clinic with the drug imiquimod (Aldara) that targets Toll-like receptor-7. Other targets identified from experimental studies that offer therapeutic potential are telomerase, TGFβ, Notch, and p53, because drugs targeting these molecules are in clinical trials for treating a number of epithelial cancers.

A developing concept anticipated from molecular analyses is that common gene or protein expression profiles would reveal similar pathogenic mechanisms for skin SCC and squamous tumors of the lung, head, and neck and other sites that pose a threat to life. Similarly, data already exist indicating that the hedgehog pathway is involved in internal malignancies such as pancreatic cancer. If such mechanisms are shared, then new drugs could be tested on skin tumors for therapeutic efficacy. The high frequency of skin cancers, their superficial location, and the capacity for topical testing suggest that the skin provides an excellent surrogate site for evaluating drug development for a variety of internal tumor sites. The skin is also a site that often predicts the presence of

internal tumors with such lesions as acanthosis nigricans, dermatomyositis, paraneoplastic pemphigus, and other dermatoses. Little is known of the pathogenesis of these premonitory lesions, but undoubtedly such knowledge would reveal important aspects of the host response to cancer. Thus, progress in skin cancer research will continue to provide important translational opportunities not just for these very prevalent lesions, but for the advancement of cancer treatment in general.

Acknowledgments

Because of the breadth of this review, we apologize for the unavoidable exclusion of references to work done by many outstanding investigators working in these areas. We acknowledge Professor Andrzej Dlugosz for advice on BCC pathogenesis.

Molecular Basis for Treating Cutaneous Molecular

Introduction

The mapping of the human genome, and more recently the unraveling of human cancer–specific genomes, has led to more detailed understanding of carcinogenesis, cancer growth, progression, and metastasis. With this understanding, new treatment paradigms for cancer have been developed, generating novel agents that have been successfully introduced into the clinic.

Like normal tissues, tumor tissue exploits growth-receptor signal pathways for its maintenance and progression. Disruption of critical pathways can lead to cancer cell death, translating into clinical response, palliation of cancer-related symptoms, and improvement of overall survival for cancer patients. On the other hand, mutations in the growth receptor signal transduction pathway can lead to "addiction" of the tumor to this pathway, resulting in uncontrolled growth. Effective blockade of the mutated protein or its downstream signaling events leads to inhibition of cancer growth and cancer cell death.

The story behind the development of the first targeted therapy, imatinib, illustrates the course of the paradigm shift now gripping the cancer therapeutic world. Since 1960 we have known about the Philadelphia chromosome's association with chronic myelogenous leukemia (CML).[1] Yet the translocation between chromosome 9 and 22 was not described until 1973, and over the subsequent years the translocation was linked to the Abelson oncogenic virus and its human counterpart.[2-6] In the late 1990s Nicholas Lydon and Brian Druker developed imatinib, a compound that blocks BCR-Abl.[7] Because BCR-Abl transcript is constitutively expressed in CML, blocking this path led to remarkable responses in patients with the disease. Imatinib received approval by the U.S. Food and Drug Administration (FDA) for the treatment of CML in 2001, and the paradigm shift in cancer therapeutics took hold.

The implications of this paradigm shift have subsequently led to the identification of many growth-receptor signal transcription kinase–mediated pathways that are either upregulated or mutated and thus targetable for drug development. As experience grows with these new targeted agents, we are discovering the importance of crosstalk with other pathways of cancer destruction, including host-mediated factors attributable to the immune system or to stroma. In this chapter we review the areas of targetable therapy related to melanoma.

Melanoma Background

Melanoma incidence in the U.S. population continues to rise and is associated with a modest increase in mortality rates, primarily in men.[8,9] Nearly 50% of skin melanomas are diagnosed before the age of 55, thus having a significant impact on a population of individuals in the prime of their working lives.[9] Understanding carcinogenesis, predicting clinical course, and developing new treatments is a high priority as melanoma continues to exasperate biomedical scientists and clinicians, with devastating consequences for patients. When diagnosed in its earliest stages, surgical excision can cure many but not all.[10,11] Our current knowledge about the risk for primary melanoma to metastasize uses simple tumor characteristics that can be seen by microscopic evaluation and include the depth of invasion from the surface of the skin, whether the tumor is ulcerated, and the number of mitoses in the vertical growth phase.[11] Unfortunately, even shallow primary melanomas with a good prognosis metastasize and cause death, suggesting that the process of invasion into tissue and spread through the blood or lymphatic systems is much more complex.

Melanoma Pathology

Melanoma is a tumor that arises from melanocytes, the pigment-producing cells of the body (Figure 42-1). Melanocytes arise from the neural crest and primarily populate the skin and eye, although they can be found in various other organs. The overwhelming majority of melanomas arise from the skin and more rarely the uveal tract of the eye. Cutaneous melanocytes are located at the junction between the epidermis and dermis, at the base of the rete ridges. Melanocytes are dendritic-type cells that communicate and provide pigmentation (melanin) to keratinocytes of the skin. They increase pigmentation production in response to UV exposure. Interestingly, melanin pigmentation migrates to the UV-exposed side of the nucleus, providing shielding to DNA-damaging UV light.[12]

Melanocytes will transform into nevus cells that are able to form theques or nests at the junction of the skin layers (see Figure 42-1). These pigmented lesions are called *junctional nevi* and are flat, homogeneous, brown or tan macules that are well defined. Nevic cells have the ability to invade or migrate into the dermis, forming a macular-papular lesion or compound nevus or a dermal nevus if all the nests are in the dermis.[13] Dermal nevi tend to lose their pigmentation, frequently presenting as a flesh-colored papule. Nevi are acquired lesions and slowly change over time. Newborn infants rarely have nevi, and older individuals, although they have numerous pigmented skin lesions, also have few true nevi. A variation of nevi termed *atypical nevi* or *dysplastic nevi* has been recognized and has a different growth pattern, variable amounts of cytological atypia, and a host response identified by lamellar fibroplasia, neovascularization, and lymphocytic infiltration.[14] The number of nevi and atypical nevi are known to be individual risk factors for the development of melanomas.[15] Pathologic series can identify a preexisting nevus in up to 50% of melanomas, suggesting that a precursor lesion exists.[16]

Melanoma typically appears on the sun-exposed areas of the skin, and the amount of sunlight exposure over life is a risk factor. Melanomas arising in sun-damaged skin differ in their molecular pathway expression compared to melanomas from non–sun-damaged skin.[17]

Cutaneous melanomas appear in four major distinct clinical and histologic variants: nodular, superficial spreading, lentigo maligna, and acral lentiginous melanomas. Although molecular pathways may differ between these variants, the risk for metastasis remains linked to the depth of invasion into the skin. Superficial spreading melanoma (SSM) is the most common form of the disease and is typically present for years on the skin. It has the hallmark of the classic ABCDE characteristics popularly known as *a*symmetry, irregular *b*orders, variegated *c*olor, larger *d*iameter (greater than 6 mm), and *e*volving over time.[18] SSM has radial growth and nodular or vertical growth. Nodular melanoma has a vertical growth phase without any evidence of horizontal growth. Nodular melanomas usually appear rapidly and invade the dermis quickly. Acral lentiginous melanoma is seen on the palms, soles, and nail beds and is the most frequent melanoma in dark-skinned people. Lentigo maligna melanoma is the invasive form of lentigo maligna (LM), which is a melanoma in situ arising in sun-damaged skin. LMs are typically noted on the skin for many years.

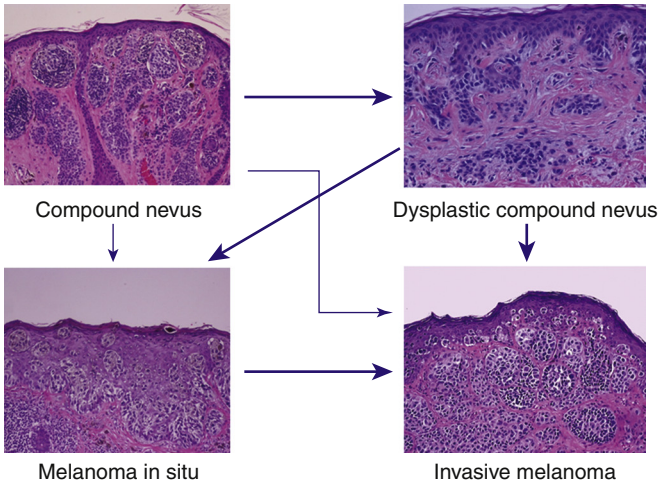

Figure 42-1 Development of melanoma Although melanomas can develop from melanocytes at the epidermal-dermal junction directly or in a preexisting nevus, an orderly progression from melanocyte to neoplasm (benign nevus) to dysplasia to noninvasive (in situ) cancer to overt invasive malignancy can also be seen in clinical material. This figure shows the histopathologic features of a compound nevus, dysplastic nevus, melanoma in situ, and invasive melanoma.

Melanoma Therapy and Molecular Targets

Historically, melanoma has been one of the most unresponsive cancers to traditional chemotherapy approaches. Dacarbazine, an agent that methylates the 7-position of guanine on DNA, crosslinks DNA strands, leading to inhibition of DNA, RNA, and protein synthesis. Treatment with this agent demonstrates an 8% objective response rate in metastatic melanoma.[19] Studies in the 1980s suggested that multiagent chemotherapy could enhance the activity of dacarbazine in patients with metastatic melanoma, but a subsequent randomized study failed to show improvement in overall survival with multiagent chemotherapy compared to dacarbazine alone.[19] The first modern-era immune therapies for melanoma, interferon alpha and interleukin-2, introduced in the 1980s, showed tantalizing results and are still considered part of the therapeutic armamentarium despite recent advances.[20,21]

As molecular pathways related to melanoma carcinogenesis and progression have been discovered, novel targets and agents specific for these targets have also been identified. In addition, the molecular pathways mediating immune response to melanoma may also provide novel strategies for treatment. The most relevant new approaches for melanoma in 2012 target BRAF, c-Kit, and CTLA4.[22-24] We review these approaches first and explore other pathways that will likely be relevant for the future discovery of additional therapeutic agents.

Mapk-Braf and Intersection of Other Pathways

The mitogen-activated protein kinase pathway (MAPK) is an oncogenic pathway that mediates growth and progression (Figure 42-2). Growth factor receptor tyrosine kinases (RTK) associated with RAS initiate this pathway, among others, leading to activation of BRAF, MEK, and ERK in the cytoplasm. Phosphorylated ERK migrates to the nucleus and causes cell proliferation. The three members of the RAS proto-oncogene family include HRAS, NRAS, and KRAS, all with GTPase activity. NRAS is the most frequently mutated gene of this family and is seen in 25% to 35% of melanomas.[25,26] The most frequent mutation in NRAS is arginine (R) substituted for a glutamine (Q) at position 61 (Q61R). Downstream from NRAS is RAF. There are three human isoforms of RAF (ARAF, BRAF, and CRAF), which have different cellular locations and different activation sequences. BRAF has constitutive phosphorylation of the N terminus, which is different than for ARAF and CRAF and thus can be activated directly by RAS.[27] The most common RAF mutation is in BRAF, which has been identified in as many as 66% of melanomas.[28] BRAF mutation is also seen in a high percentage of benign nevi, suggesting that mutation of BRAF is seen early in the transformation of melanocytes at the basal layer of the dermal-epidermal junction into tumor (benign and malignant).[28,29] The highest frequency mutation of BRAF occurs at the 600 position with a substitution of a glutamic acid (E) for valine (V) (BRAF[V600E]). This mutation constitutively maintains activation of a downstream event on MEK and ERK, a process referred to as *addiction to an oncogenic pathway*.

Cancers addicted to an oncogenic pathway are susceptible to inhibition by blockade of that pathway. RAS activation through a number of RTKs, including epidermal (EGFR), platelet-derived (PDGFR), and vascular endothelial (VEGFR) growth factor receptors, mediate not only tumor growth but also tumor-associated angiogenesis. Sorafenib (Bay 43-9006) is a biaryl urea developed as a RAF inhibitor and was the first of its kind to enter clinical trials. It had demonstrable activity against RAF targets, including the mutant BRAF (BRAF[V600E], BRAF[V600K], and BRAF[V600M]).[30] In a Phase II melanoma study, 19% of 37 patients had stable disease, but there was no relationship of response to BRAF(V600E) status.[31] Subsequent studies with combined chemotherapy and sorafenib failed to demonstrate significant activity.[32,33]

Using a structure-guided approach to drug discovery, PLX4720 (vemurafenib) was developed as a selective BRAF(V600E) inhibitor.[34,35] PLX4720 binds to the ATP binding site on active BRAF but not BRAF in its inactive conformation. Inhibitors that bind in and around the region occupied by the adenine ring of ATP are referred to as type I inhibitors, whereas sorafenib is a type II inhibitor that instead occupies a hydrophobic site directly adjacent to the ATP pocket.[35] The first Phase I study of PLX4720 or vemurafenib demonstrated significant activity in metastatic melanoma patients, and subsequent randomized studies confirmed the activity, which led to FDA approval for its use in the treatment of metastatic melanoma.[22,36]

In the Phase III study, 675 eligible patients with metastatic melanoma stage IIIC, M1a, M1b, and M1c were randomized in a 1:1 ratio to receive oral vemurafenib (960 mg twice daily) or dacarbazine (1000 mg/m^2 IV every 3 weeks). At the time of analysis, the hazard ratio for death was 0.37 (95% confidence interval 0.26 to 0.55; $P < .0001$) and for progression-free survival 0.26 (95% confidence interval 0.20 to 0.33; $P < .0001$) favoring the vemurafenib treatment. Two complete responses and 104 partial responses were reported in the 219 evaluable subjects who received vemurafenib. Although the toxicity profile for vemurafenib was mild, with cutaneous toxicity being most significant, dose interruption and modification were required in 38% of subjects. The paradoxical activation of CRAF leads to the development of squamous cell cancers and keratoacanthomas.[37] Subsequent studies have demonstrated a median duration of response to BRAF blockade of approximately 7 months.[38] Other BRAF-targeted molecules are under development.[39]

Although targeting mutant BRAF has had significant impact on the therapeutic paradigm, development of resistance continues to be a barrier for prolonged responses in the majority of patients. Development of resistance to BRAF-targeted agents is complex and multifaceted but appears to be driven by reactivation of the MAPK pathway. One mechanism that has been identified is a 61-kDa splice variant of BRAF(V600E) that lacks the RAS-binding domain at exon 4-8 (p61BRAF[V600E]).[40] p61-BRAF(V600E) shows enhanced dimerization and is resistant to known RAF inhibitors. Increased expression of serine/threonine kinases on BRAF, CRAF, or COT1 may also be involved.[40-42] The activating mutations Q61K/R on N-RAS and C212S on MEK1 have also been implicated in BRAF inhibitor resistance by phosphorylation of ERK.[43,44]

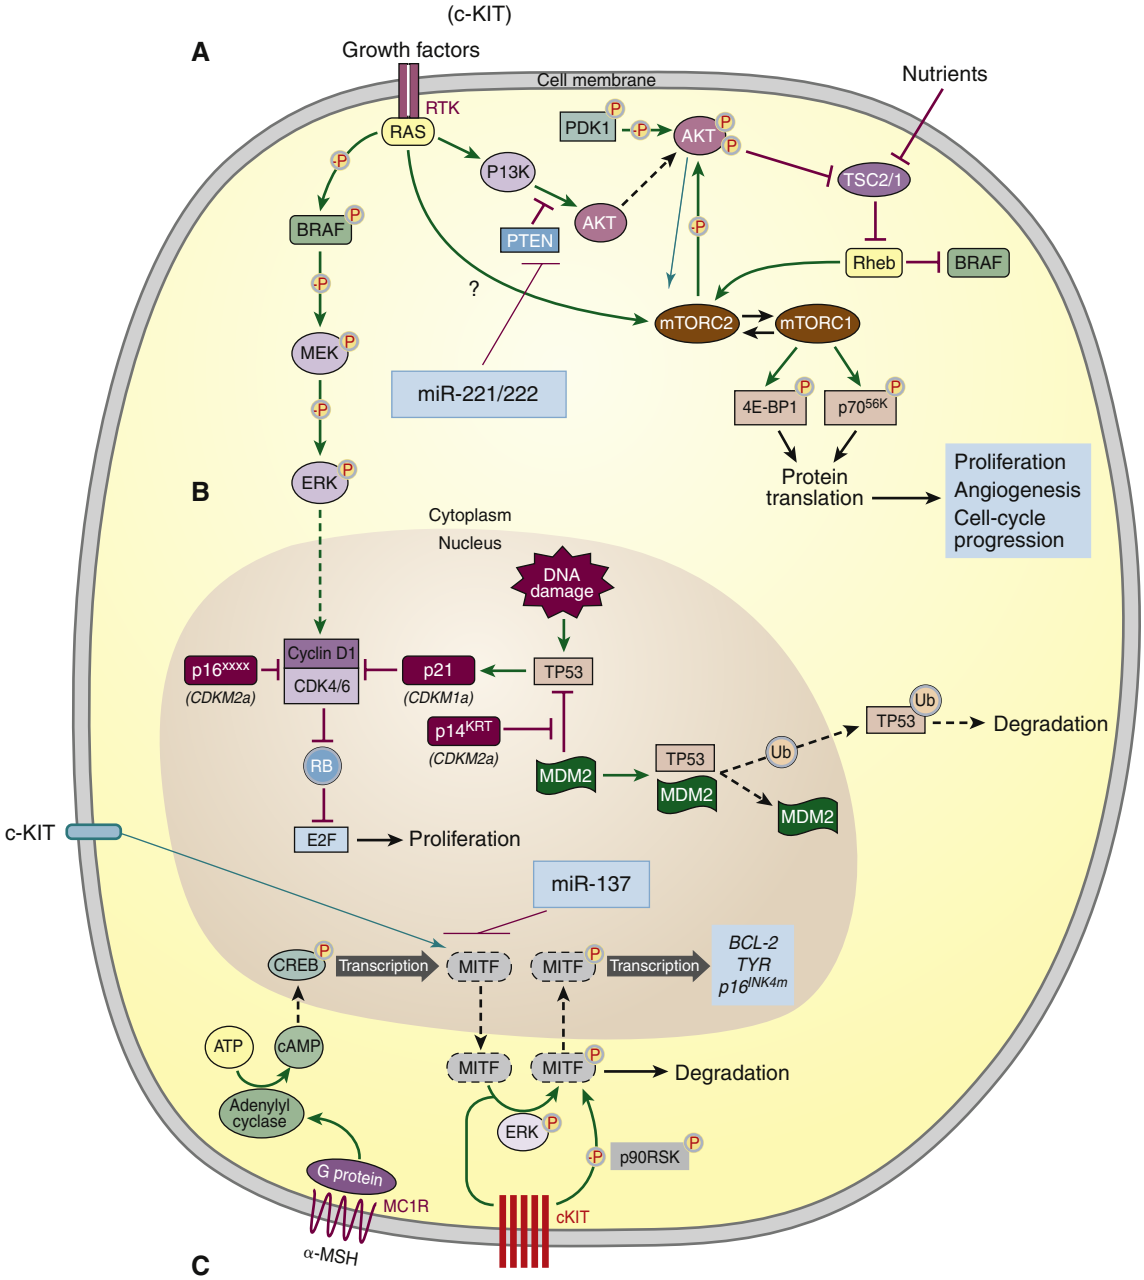

Figure 42-2 (A, B) RTK-RAS activation of MAPK and AKT pathways. *Arrows* represent activation pathways and T (⊥) represents inhibition. In the AKT pathway, PTEN (phosphatase and tensin homologue) dephosphorylates PIP_2 (phosphatidylinositol bisphosphate) and acts in an inhibitory manner. miRNA 221/222 can modulate this pathway by inhibiting PTEN. Activation of AKT is associated with a conformational change and translocates close to the cell membrane where it is phosphorylated by PDK1 (3-phosphoinositide-dependent kinase 1) and then can inhibit TSC2 (tuberous sclerosis protein 2) and activate mTORC2 (mammalian target of rapamycin C2). The MAPK pathway is triggered through RAS activation, ultimately leading to phosphorylated ERK translocating to the nucleus, leading in turn to cellular proliferation through cyclin D1 complex. DNA damage activates TP53 (tumor protein 53), which in turn activates CDKN1a (cyclin-dependent kinase inhibitor 1a), suppresses cyclin D1-$CDK_4/_6$ complex, and inhibits transcription via RB (retinoblastoma). MDM2 (mouse double minute-2) inhibits TP53 by binding it and making available for degradation through the ubiquitin pathway. p14(ARF) sequesters MDM2 and thus inhibits TP53 degradation. **(C)** α-MSH (melanocyte-stimulating hormone) binds to MC1R (melanocortin-1 receptor), stimulating a cascade that transcribes MITF (microphthalmia transcription factor) gene. miR-137 can modulate the MITF pathway by exerting its effects on transcription of MITF. *(Adapted with permission from Ibrahim N, Haluska FG. Molecular pathogenesis of cutaneous melanocytic neoplasms.* Annu Rev Pathol Mech Dis. *2009;4:551-579.)*

The development of multiple pathways of resistance to BRAF inhibition has also been demonstrated from cloning melanoma BRAF mutated resistant cell lines, suggesting that overcoming clinical resistance will be a formidable barrier going forward.[45]

Another mechanism of resistance is signaling through an alternative pathway, PI3K/AKT.[46] PI3K/AKT can be activated through persistence of tyrosine kinase activity of platelet-derived growth factor receptor or insulin growth factor 1 receptor, RAS signaling, RAS independent signaling, or

loss of PTEN activity, as well as other mechanisms. PI3K/AKT and MAPK pathways are co-activated in many melanomas.[47] Resistance to mutant BRAF(V600) inhibitors develops through co-option of the PI3K/AKT pathway and RAF isoform switching.[48] These mechanisms provide the foundation for combining BRAF blockade with inhibition downstream in the MAPK pathway at MEK and inhibition of the PI3K/AKT pathway at AKT or mTOR. Another interconnection between the MAPK pathway and mTOR pathway is through phosphor-ERK (pERK) activation of RSK and TORC1, and inhibition of AMPK. AMP-activated protein kinase is activated during metabolic stress and inhibits protein and fatty acid synthesis.

The AMPK-TORC pathway can be explored using metformin, a drug that activates AMPK and is used to treat type 2 diabetes. Metformin inhibits the growth of NRAS-mutant melanoma but not BRAF-mutant melanoma cells in culture.[49] BRAF-mutant melanoma drives activation of RSK and TORC1, thus overcoming the effects of metformin on AMPK and inhibition of TORC1. Metformin, through activation of AMPK, increases degradation of dual-specificity protein phosphatase (DUSP6), thereby increasing pERK, then VEGF-A, and stimulating BRAF-mutant melanoma growth in a mouse xenograft model. Blockade of VEGF-A with an antibody (bevacizumab) and combination with metformin inhibits tumor growth. These laboratory observations may have significant implications in the choice of agents to control type 2 diabetes in melanoma patients on BRAF targeted therapy and have further implications for multiagent targeted therapy.

Notch protein, so named because it controls notch formation in the wings of fruit flies, has also been implicated in melanoma formation.[50] Notch signaling has been shown to suppress both MAPK and PI3K/AKT pathways indirectly.[51] Inhibition of one of these two pathways reverses the effects of Notch on melanoma progression.[52] A better understanding of the interaction between these pathways may also provide novel strategies for therapy.

Translocation of pERK to the nucleus leads to cell proliferation through CyclinD1. P16 or cyclin-dependent kinase inhibitor 2a (CDKN2A), located at chromosome 9p21, has been associated with familial melanoma syndromes.[53] Alterations in p16 have been seen in benign and dysplastic nevi, suggesting a role in early melanoma development and progression.[54] Thus, independent activation of proliferative pathways in melanoma may also occur significantly downstream of MAPK and theoretically lead to autonomous growth resistant to BRAF targeted therapy. Activating mutations in cyclin-dependent kinase 4 (CDK4) have also been shown to predispose to melanoma and represent yet another checkpoint that may be involved with developing resistance to BRAF targeted therapy.[55]

Melanocortin receptors are G-protein–coupled receptors and comprise a family of five different receptors. When melanocyte-stimulating hormone (α-MSH) binds to MC1R, cyclic adenosine monophosphate is generated and leads to transcription of the microphthalmia transcription factor (MITF), leading to pigment production. Low levels of MITF in melanoma cells signal proliferation and survival.[56] MC1R polymorphisms have been associated with increased risk for melanoma and nonmelanoma skin cancer. Phospho-ERK phosphorylates MITF, and pMITF is degraded through the ubiquitin pathway. Constitutive activation of pERK through mutated BRAF subsequently leads to low expression of MITF and enhances melanoma cell proliferation and survival, most likely through interaction with CDKN2a and BCL-2.[57] This pathway as a role in development of BRAF targeted therapy is not yet well elucidated, but has at least theoretical implications. MITF is also controlled by c-Kit, which is discussed later.

Heat shock protein 90 (HSP90) cooperates with its co-chaperone Cdc37 in supporting a variety of protein kinases involved with cancer progression, including BRAF. HSP90 inhibitors have had little single-agent activity in clinical trials. HSP activity across the spectrum of resistant pathways involved with BRAF inhibitors suggests a role for the combination of these agents. In cell culture experiments as well as in mouse xenograft models, HSP90 inhibitor XL888 was demonstrated to reverse vemurafenib resistance and was associated with degradation of other secondary receptor tyrosine kinases and their downstream constituents.[58]

c-Kit

c-Kit mutations are rare in melanoma and are seen most commonly in tumors derived from mucosal and acral areas or in melanomas associated with sun-damaged skin. c-Kit is involved with the melanocyte pigmentary pathway through activation of MITF. As noted previously, imatinib is a protein tyrosine kinase inhibitor that blocks protein phosphorylation by the fusion protein BCR-abl in chronic myelogenous leukemia and blocks downstream c-KIT signaling in gastrointestinal stromal tumors. Thus, there is a rationale for using imatinib in the subset of patients whose melanoma overexpresses or has mutations in c-Kit. In a Phase II study of imatinib in 43 patients with metastatic melanoma and aberrations in c-KIT, 23% had objective partial responses, and the median progression-free survival was 3.5 months.[23] Of interest is the association of benefit with mutations in exon 11 or exon 13 of c-Kit, with 9 of the 10 responding patients having these mutations. Sunitinib, another agent that inhibits mutant c-Kit, has shown similar results, with response seen in melanomas expressing mutant c-Kit and much less

so in tumors with overexpression of c-Kit.[59] Resistance to c-Kit targeted therapy has been associated with the development of NRAS mutations.[59]

Epigenetic Pathways: MicroRNA

MicroRNAs (miRNAs) are single-stranded noncoding nucleotide sequences about 22 bases long. MiRNAs are generated through a double-stranded precursor that undergoes cleavage by Drosha (RNase type III endonuclease) to an approximately 70-nucleotide unit.[60] Drosha and the associated dsRNA binding protein DGCR8 complex are transported to the nucleus and cleaved by Dicer (RNase type III endonuclease) to the approximately 22-nucleotide double-stranded miRNA. One strand of the miRNA binds to the 3′-untranslated region of messenger (m) RNA, thereby blocking translation and causing cleavage and destruction of the mRNA.[61,62]

MiRNAs are involved with regulation of a number of melanoma-related growth and proliferation pathways and are thus potential targets for therapy. Although the gain or loss of many miRNAs is shared across tumor types, a number of miRNAs are more specifically associated with melanoma.[63,64] MiR-137, located on chromosome region 1p22, and miR-182 (7q31-34) are putative negative regulators of MITF.[65,66] MITF, in turn, regulates the transcription of miR-221 and miR-222.[67] MiR-221/222 are located on chromosome X and function to inhibit expression of c-Kit receptor. Suppression of miR-221/222 with anti-mRNAs in melanoma cell lines resulted in decreasing melanoma cell proliferation and migration.[67]

MiRNAs can be obtained from archival tissues such as blood and serum, allowing them to be considered as biomarkers and potential targets for new therapeutics.[68,69] For example, high expression of miR-15b was found to correlate with poor survival in melanoma patients.[70] The soybean isoflavone genistein inhibits human uveal melanoma cell growth in culture and in a murine model and is associated with alteration of miR-27a, again suggesting that targeting of miRs may have therapeutic importance.[71] MiR-193b is downregulated in human melanoma cell lines.[72] When miR-193b was transfected back into these cells, proliferation was suppressed because of miR-193b directly downregulating cyclin D1.

Paratumoral Pathways

The tumor microenvironment is composed of vascular, stromal, and immune cells that have an intimate spatial relationship with the cancer cell and influence cancer development and progression. As we gain more understanding of these interactions, these paratumoral pathways become targets for therapy.

It is well recognized that fibroblasts are associated with many tumors and that these cells can play a contributing role in cancer progression. Tumor-infiltrating fibroblasts (TIF) are typically spindle-like and express α-smooth muscle actin, resembling myofibroblasts. These cells can express transforming growth factor-β (TGFβ), VEGF, and provide extracellular matrix, all of which support tumor growth. In a 3D coculture model, fibroblasts migrate to and infiltrate human melanoma spheroids within 7 days through melanoma-derived motility factors.[73] These fibroblasts are active and produce extracellular matrix. Following targeted therapy, for example, with an EGFR inhibitor for lung cancer, a flare phenomenon has been observed with rapid progression of cancer. Similar observations have also been noted in vemurafenib-treated melanoma patients. TIFs have been proposed as one component contributing to this phenomenon. The role of these TIFs in producing a niche for melanoma stem survival is unexplored to date, but may provide a mechanism for establishment of a resistant phenotype.

Neoangiogenesis is another paratumoral event required for the establishment and progression of cancer. The pioneering work in this area was led by the late Judah Folkman. Following anecdotal reports of alpha interferon causing regression of benign hemangiomas in infants, a study of 20 subjects demonstrated the significant activity of interferon as an anti-angiogenesis therapy.[74] The role of anti-angiogenesis therapy is now well established in a number of tumor types, although its role in melanoma is not yet definitively demonstrated. The BEAM trial in melanoma evaluated the role of adding bevacizumab (blocking anti-VEGF antibody) to carboplatin and paclitaxel in a randomized Phase II study.[75] Outcomes for the 214 treated patients demonstrate a trend toward improvement in response and median progression-free survival (PFS) (16.4% response and 4.2 months PFS for chemotherapy vs. 25.5% response and 5.6 months for chemotherapy + bevacizumab). A trial of sorafenib with either temsirolimus (an mTOR inhibitor) or tipifarnib (a farnesyl transferase inhibitor required for RAS activation) also failed to show a difference between the arms or improved response or PFS compared to historical controls.[76] Although angiogenesis is an important component of melanoma and VEGF has been implicated, studies to date have failed to show that modification of this pathway results in significant clinical benefit.

Regulation of the immune system is another area of great expectation in melanoma. IFN alfa-2b and peg-IFN alfa-2b are the only agents thus far that have shown clinical benefit in the surgical adjuvant setting of melanoma

patients with high risk for recurrence.[20,77] High-dose IL-2 has an established role in patients with good performance status who have metastatic melanoma, with a small percentage of patients (approximately 5%) reaching complete and durable remissions.[21,78] The understanding of immune regulatory checkpoints has provided a deeper understanding of immune response in cancer and therapeutic targets. Cytotoxic T lymphocyte antigen 4 (CTLA-4), a member of the immunoglobulin superfamily, has been identified as a co-stimulatory molecule involved with negative control.[79,80] Anti-CTLA-4 blocking antibodies have been developed that led to clinical trials assessing their role in the treatment of melanoma.[81,82]

Preliminary data suggested benefit of CTLA-4 blockade, and subsequent randomized trials confirmed the activity of ipilimumab in the treatment of patients with metastatic melanoma.[24,83,84] The first study randomized patients between ipilimumab at 3 mg/kg combined with gp100 vaccine, ipilimumab alone, or gp100 vaccine alone.[24,] Six hundred seventy-six previously treated patients with metastatic melanoma who expressed HLA-A*201 were assigned to ipilimumab and gp100 peptide vaccine, ipilimumab alone or gp100 vaccine alone in a 3:1:1 ratio.[24] Ipilimumab was given at 3 mg/kg every 3 weeks for up to four cycles. The ipilimumab arms had a median survival of 10 to 10.1 months compared to 6.4 months for the arm given gp100 vaccine alone. There was a 2.1% study-related mortality rate. Three patients (0.6%) on the ipilimumab arms entered a complete remission (CR). The second randomized study evaluated ipilimumab 10 mg/kg every 3 weeks with dacarbazine versus dacarbazine alone with placebo.[84] Ipilimumab or placebo was continued every 12 weeks for stable or responding patients. Five hundred two previously untreated patients were randomized in a 1:1 ratio. Median overall survival showed an improvement in the ipilimumab-dacarbazine arm from 9.1 to 11.2 months. Survival was improved in the combination arm at 1 year (47.3% vs. 36.3%), 2 years (28.5% vs. 17.9%), and 3 years (20.8% vs. 12.2%). Four patients (0.4%) had a CR in the combination arm compared to two in the dacarbazine-placebo arm, and no treatment-related deaths were reported.

It has been generally believed that immune therapy is not effective for the treatment of brain metastasis. Nevertheless, 72 patients with melanoma brain metastases were treated with ipilimumab at 10 mg/kg every 3 weeks for 24 weeks with responding patients eligible for maintenance in a Phase II study.[85] In asymptomatic patients, 12 of 51 patients obtained control of their brain metastases and 8 had objective responses. In this cohort of patients, the median overall survival was 7 months with 26% of patients alive at 24 months. This study provides the first evidence of immune therapy benefit for melanoma brain metastasis.

Engagement by antigen of the T-cell receptor (TCR)-CD3 complex provides the first signal to the T cell but is not sufficient for activation. The necessary second signal is provided by CD28 binding to its ligand B7 (1 and 2 or CD80 and CD86, respectively) on antigen-presenting cells such as dendritic cells.[86] The formation of TCR-CD3 complex and CD28 in combination with co-receptors CD4 or CD8 forms the immunological synapse.[87] Once engaged, the co-receptors that are associated with the protein tyrosine kinase LCK, phosphorylates the immune receptor tyrosine-based activation motifs (ITAMS) in the TCRζ chain initiating a cascade. This cascade includes ζ-chain–associated protein kinase (ZAP), SYK (spleen tyrosine kinase), LAT (linker for activation of T cells), and SLP76 (SRC homology 2 (CH2)-domain-containing leukocyte protein of 76 Da), which phosphorylates phospholipase Cγ1, activating the TEC family of kinases. This increases intracellular Ca^{2+}, which leads to activation of transcription factors. CTLA-4 is expressed on activated or memory T cells and has a 50- to 100-fold higher binding avidity to B7 than CD28, most likely because CTLA-4 dimer binds two bivalent B7 molecules, whereas CD28 binds to a single B7 domain.[88,89] Engagement of CTLA-4 leads to termination of the T-cell response. A number of different models have been proposed to explain the mechanism by which CTLA-4 controls regulation. Both CD28 and CTLA-4 bind PI3K at a motif that closely resembles a similar motif on growth factor receptors. CTLA-4 does not have binding domains for LCK or growth-factor receptor 2 (GRB2) whereas CD28 does. This may be one explanation of CTLA-4 activation.

It has long been the practice for oncologists to combine multiple approaches to treat patients with cancer. Thus, the use of cytoreductive surgery followed by radiation and drug therapy has become commonplace. Combining drug therapy using non–cross-resistant multiagent combinations with different mechanisms of action has also become a standard approach for many cancers. This concept is supported by mathematical modeling and observations of clinical benefit.[90-93] There is good rationale for combining targeted and immune therapies in patients with melanoma, based on the recent success. The magnitude and speed of response seen with targeted therapy may affect immune pathways, including reducing tumor-associated immune suppression and enhancing antigen availability to dendritic cells for processing and activation.[94]

The expanding list of agents available for regulating immune and signaling pathways provides tools for exploring this complex cross talk. A mutant BRAF melanoma cell line treated with a BRAF target blocker upregulates melanoma differentiation antigens and can be better recognized and killed by melanoma-specific cytotoxic T cells.[95] Although MEK inhibition also upregulates melanoma differentiation antigens in this model, blocking MEK also inhibits T-cell killing whereas BRAF blockade does not. An increase in

tumor-infiltrating T cells (TILs) has been observed in tumors from patients treated with vemurafenib.[96] We have observed a similar TIL infiltration in a mouse model of BRAF mutant melanoma treated with BRAF blockade (Turk MJ, personal communication). Targeted agents can have both a negative and positive interaction with immune regulation.[97] In addition to the BRAF(V600E) targeted agents, other melanoma-relevant agents that can be considered for combination with immune therapy include imatinib, which blocks c-kit and can also decrease indoleamine dioxygenase (IDO), a negative regulator of immune function, as well as promote dendritic and natural killer cell communication; bevacizumab, a VEGF-neutralizing antibody, which increases DC maturation; bortezomib, a proteasome inhibitor, which can sensitize tumor to immune-mediated killing; PI3K-AKT inhibitors that also enhance tumor cell sensitivity to immune-mediated killing; and HSP90 inhibitors, which can decrease immune suppression and increase NK cell targets on the tumor.[97] As discussed earlier, understanding the molecular pathways of immune cells in the context of cancer will also lead to new strategies of targeted therapy directed at enhancing immune activation and inhibiting regulation.[98,99]

Conclusions

Recent updates of ongoing clinical trials provided with BRAF inhibitors and ipilimumab demonstrate the promise of these new therapeutic tools as well as their limitations. High response rates to vemurafenib and dabrafenib are met with the development of early clinical resistance.[100,101] Although both progression-free survival and overall survival are now extended in patients with metastatic melanoma with BRAF(V600E) mutation, the median overall survival in the BRIM3 trial of 13.2 months is short and demonstrates the need for strategies to convert the initial response to long-term survivorship in a higher percentage of patients.[101,102] The challenge may be met with the identification of resistant pathways and the development of additional agents targeted to these pathways, such as the combination of MEK and BRAF inhibitors. The pipeline in the pharmaceutical industry is full of agents that target MEK, ERK, and others. MiRNA inhibitors are also being developed. Our knowledge of how these signals intersect with the molecular pathway and how miRNAs are regulated should provide additional therapeutic strategies that will need to be tested in the clinical setting.

Another approach is to use pathway inhibitors early in the setting of high-risk stage II and III disease. The questions of which pathway, which agent, and for what duration of therapy can only be answered through the experience gained in clinical trials. The early development of heterogeneity of molecular profiles within cancer[103] may ultimately allow for aggressive and resistant clones to threaten patients' lives and prove to be a barrier that will require combination of therapeutic strategies.

The low objective response rate noted with anti-CTLA4 antibody is counterbalanced by the observation of long complete remissions seen in a small percentage of patients no longer needing additional therapy. This improvement of the tail of the curve is an important concept and should not be underestimated as we seek to enhance the long-term goal of cure of metastatic melanoma.[104] Our understanding of the complex inflammatory and regulatory networks of immune pathways has led to the development of new therapeutic tools that are being and will need to be explored through clinical trials with correlative biological studies. Our recognition of the molecular pathways activated in immune cells from patients with cancer[98,99] will provide new strategies to regulate those pathways.

There is a long history of recognizing that the inflammatory responses in cancers treated with chemotherapy contribute to benefit. We have now identified inflammatory responses in tumors treated with the new targeted therapies, providing an additional rationale for combining these therapeutic strategies.

We have begun to unravel the molecular mysteries of melanoma carcinogenesis, progression, and metastasis, as well as the molecular pathways regulating the host response to this disease. Through judicious and thoughtful manipulation of these pathways, melanoma will likely be tamed to a chronic illness that does not cause death or can be cured outright.

43 Thyroid Cancer

Cancer of the thyroid is the ninth most common malignancy diagnosed worldwide in women and 18th in both genders.[1] In the United States, the incidence has been rising faster than that of any other malignancy; in 2012, overall incidence is projected to be 56,460 persons, ranked fifth among all newly diagnosed malignancies in women.[2] Although only 1780 deaths from thyroid cancer are expected in the United States in 2012, the average age-adjusted mortality increased 0.6% per year between 1998 and 2007, most notably among men, who experienced a striking 1.6% increase per year.[3]

Derived from follicular epithelial cells, differentiated thyroid carcinomas (DTC) include papillary thyroid carcinoma (PTC) and follicular thyroid carcinoma (FTC). These cells generally retain many of the differentiated functions of normal follicular cells, including the ability to respond to stimulation from thyrotropin (TSH) and to concentrate and organify iodine. More aggressive follicular cell-derived histologies include poorly differentiated (PDTC) and anaplastic carcinomas (ATC), which are generally thought to derive from progressive dedifferentiation of DTC although they may also arise de novo. Medullary thyroid carcinoma (MTC), on the other hand, is derived from neuroendocrine C cells present typically in the upper two thirds of each thyroid lobe that lack any of the differentiated functions associated with thyroid follicular epithelial cells.

Characteristic oncogenic mutations have been identified that appear to give rise to the majority of DTC and MTC, affecting tyrosine kinase receptors and downstream signaling intermediates in the mitogen-activated protein kinase (MAPK) and phosphatidylinositol 3-kinase (PI3K)-Akt pathways (Figures 43-1 and 43-2). Their importance is underscored by the virtual absence of overlap among the three most common mutations that all yield activation of MAPK signaling: *BRAF*, *RAS*, and *RET/PTC*. Less common mutations may be involved in the dedifferentiation steps, including loss of tumor suppressors. Further abnormalities that may contribute to tumor proliferation, invasion, and dedifferentiation may include DNA epigenetic alterations, gene amplifications, and other mechanisms that contribute to select gene overexpression. With understanding of these molecular abnormalities that underlie thyroid malignancies, appropriate targeted therapies have been introduced in the past several years and have become a new standard of therapy for advanced metastatic disease. This review focuses on those molecular abnormalities that have been most strongly associated with mechanisms of disease, clinical prognosis, and therapies.

Differentiated Thyroid Carcinoma

Receptor Tyrosine Kinases (RTKs)

Physiologically, RET is a transmembrane RTK with expression typically restricted to certain neuronal and neuroendocrine cells, the collecting duct of the kidneys, and spermatogonial stem cells, but is not normally expressed in thyroid follicular cells. In cooperation with co-receptors, RET binds ligands of the glial cell-derived neurotrophic growth factor (GDNF) family, which leads to receptor dimerization and autophosphorylation of key intracellular tyrosine residues that subsequently activate downstream signaling in multiple pathways.

Somatic chromosomal rearrangements of the *RET* gene were identified in papillary thyroid carcinomas more than 20 years ago that cause constitutive expression and activation of a RET fusion protein denoted RET/PTC.[6] To date, more than a dozen *RET/PTC* translocations have been reported, although *RET/PTC1* and *RET/PTC3* account for more than 90% of the tumors associated with the mutation. In each case, the promoter and N-terminal domain of a heterologous gene fuse with a C-terminal domain of the *RET* gene containing the tyrosine kinase functions, permitting inappropriate expression of RET kinase in thyroid follicular cells under control of the heterologous promoter. The resultant fusion protein resides in the cytosol rather than the

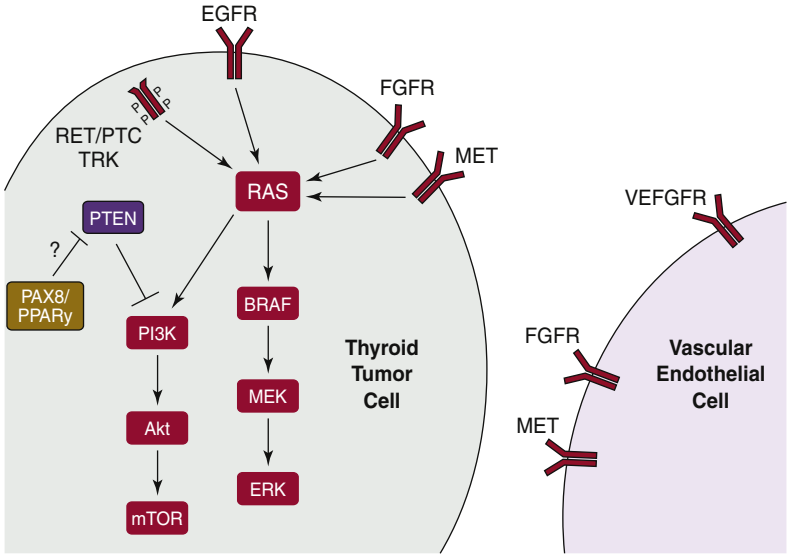

Figure 43-1 Schematic illustration of the key intracellular signaling pathways involved in the pathogenesis of differentiated thyroid carcinoma.

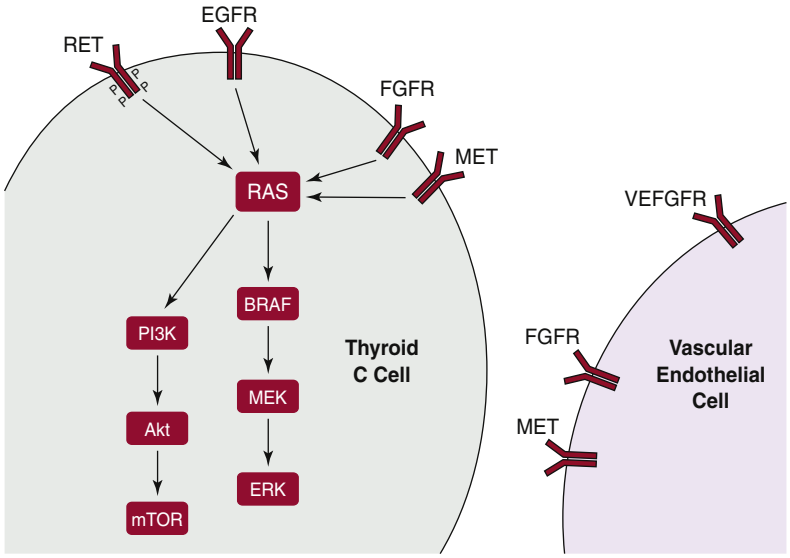

Figure 43-2 Schematic illustration of the key intracellular signaling pathways involved in the pathogenesis of medullary thyroid carcinoma.

cell membrane and is capable of ligand-independent homodimerization, thus triggering downstream signaling activation. A further mechanism to promote tumorigenesis is through cooperation between RET/PTC and another RTK, the epidermal growth factor receptor (EGFR), which is found to colocate with RET/PTC and jointly signal downstream through RAS.[7] *RET/PTC* mutations are commonly seen in about 10% to 20% of PTC (particularly the classic, solid, and almost all oxyphilic variants but less commonly in follicular and tall cell variants), and rarely in PDTC or FTC. The oncogenic role of *RET/PTC* mutations is supported by a high rate of papillary carcinomas in transgenic mice expressing either *RET/PTC1* or *RET/PTC3*, and the mutation is frequently found in occult microcarcinomas.[8]

A second group of chromosomal translocations associated with PTC comprise mutations in the *NTRK* gene that lead to formation of various *TRK* oncogenes. Similar to RET/PTC, these fusion TRK proteins combine the N terminus of one of several genes normally expressed in thyroid follicular cells with the tyrosine kinase domain of the receptor for nerve growth factor.[9] These mutations are seen in about 5% of PTC.

These chromosomal rearrangements involving tyrosine receptor genes are commonly seen following exposure to ionizing radiation and may be the leading mechanism of thyroid oncogenesis in this setting. This has been particularly true following the unfortunate experiences of the Chernobyl nuclear power plant accident as well as atomic bomb explosions in Japan.[10,11] Spatial proximity of *RET* or *NTRK* genes to the heterologous donors of the N-terminal promoter regions specific to chromosomal folding in thyroid follicular cells may permit a single radiation event to cause double-strand breaks in each gene, thus permitting the recombination event.

Other RTKs have been found to be overexpressed in DTC cells and may be relevant to disease biology. In addition to EGFR, these include platelet-derived growth factor receptor (PDGFR) α and β; vascular endothelial growth factor receptors (VEGFR) 1 and 2; fibroblast growth factor receptors (FGFR); and hepatocyte growth factor receptor (MET). Genetic abnormalities are rarely observed, and epigenetic alterations may be contributory; however, the exact mechanisms leading to overexpression are generally not known.

BRAF

Mutations of the serine-threonine kinase BRAF are the most common oncogenic abnormality reported in PTC.[13] Activated frequently in other cancers as well, BRAF has high affinity for binding and phosphorylating MEK isoforms in the MAPK pathway. Although point mutations in multiple codons have been reported to cause constitutive activation of BRAF, the most studied and most frequent is a valine-to-glutamine substitution at amino acid residue 600 (denoted V600E mutation). By destabilizing the inactive conformation of the kinase, the V600E *BRAF* mutation causes the protein to remain in a catalytically competent conformation that allows continuous phosphorylation of MEK. *BRAF* mutations are virtually never seen in benign thyroid lesions, and thus the presence of a *BRAF* mutation can be pathognomonic of a malignancy if detected in a cytologically suspicious biopsy specimen.[15] Of note, a rare translocation mutation of *BRAF* (causing fusion of the *AKAp9* gene with BRAF) has been reported to cause PTC after radiation exposure.

BRAF mutations occur in 40% to 50% of cases of PTC (especially the classical and tall-cell variants) and are also frequent in PDTC and ATC. Multiple studies describe a more aggressive phenotype associated with these mutations, including higher rates of lymph node metastases, extrathyroidal extension, poor radioiodine uptake and response to therapy, and advanced stage at presentation. Prognostically, *BRAF* mutations are associated with higher rates of recurrence and worse survival.[13,16] In a model of conditional activation of the V600E *BRAF* mutant in thyroid follicular cells, mice develop rapidly growing poorly differentiated tumors with negligible expression of thyroid-specific genes such as the sodium-iodide symporter as well as loss of iodine incorporation; these changes are reversible on inhibition of BRAF or MEK kinase functions.[17] Other downstream effects of mutant BRAF include alterations in DNA methylation and increased expression of genes associated with invasive and metastatic disease such as matrix metalloproteinases.[18]

RAS

Point mutations in *RAS* genes are among the most common oncogenic abnormalities in all cancers, and DTC is no different. Mutations in the RAS protein lead to constitutive activation through alterations in the binding affinity of the kinase for GTP or through inactivation of its intrinsic GTPase activity. Thus, mutant RAS can signal downstream through both the MAPK and PI3K/Akt pathways without upstream activation derived from ligand-bound RTK. All three *RAS* genes (*H-RAS*, *K-RAS*, and *N-RAS*) are implicated in thyroid tumor formation from follicular cells, including 20% to 40% of benign follicular adenomas, 40% to 50% of FTC (including 15% to 20% of oxyphilic variants), 10% to 20% of PTC (almost exclusively follicular variants of PTC), and 25% of PDTC.[19-22] The presence of a *RAS* mutation may portend more aggressive disease with worse outcomes, but this has not been extensively examined.[19,23] Each of these histologies has also been observed in transgenic mice expressing *RAS* mutations, although the presence of mutant RAS proteins alone is likely insufficient to cause tumor formation.[24,25]

PI3K/Akt Pathway

Inactivating germline mutations of the tumor suppressor gene *PTEN* cause Cowden syndrome, which carries a 50- to 70-fold increased risk for the development of DTC, especially FTC.[26,27] Loss of this tumor suppressor function leads to activation of PI3K, Akt, and mTOR, thus contributing to enhanced cell cycle progression, decreased apoptosis, and increased tumor proliferation. However, mutations in individual genes in this pathway are otherwise uncommonly reported as early oncogenic events. Instead, somatic mutations and/or overexpression of *PIK3CA* (which encodes the class I p110α catalytic subunit of PI3K), *AKT*, and *PTEN* are observed as frequent later events, especially in FTC, PDTC, and ATC.[20,28,29] Gene amplification as well as activating point mutations are observed in 10% to 20% of PDTC and 40% of ATC and can be found in tumors also bearing either *BRAF* or *RAS* mutations. *AKT* activation is also characteristic of the invasive fronts of aggressive DTC and has been reported to trigger increased cellular motility.[30]

PAX8/PPARγ

A chromosomal translocation, t(2:3) (q13;p25), results in the *PAX8/PPARγ* mutation, which couples the DNA binding domains of the thyroid transcription factor PAX8 with the entire coding sequence of the nuclear peroxisome

proliferator-activated receptor subtype γ1.[31] The actual mechanisms by which the encoded fusion protein contributes to thyroid tumorigenesis remain unclear. However, several critical pathways may be affected, including reduced expression of PTEN leading to increased activation of Akt, and a dominant-negative effect on the normal PPARγ transcription factor permitting enhanced cellular proliferation and reduction of apoptosis.[30,32] This mutation may be preferentially seen in younger patients with smaller tumors, which are generally better prognostic signs, but conversely are also seen in tumors with solid or nested histologies as well as with vascular invasion.[33]

Medullary Thyroid Carcinoma

RET

About 20% of MTC occurs in one of several familial syndromes: multiple endocrine neoplasia (MEN) 2A (which also includes parathyroid tumors and pheochromocytomas); MEN 2B (which also includes pheochromocytomas, intestinal ganglioneuromatosis, neuromas of the tongue and subconjunctiva, and Marfanoid habitus); and familial MTC (FMTC, which lacks the other clinical features of MEN 2A). Additional variants of MEN 2A have been reported that include cutaneous lichen amyloidosis and with Hirschsprung disease. Germline mutations in *RET* were identified as causative of these hereditary forms of MTC in two landmark 1993 studies.[34,35] Today, more than 99% of all cases of hereditary MTC can be attributed to one of numerous point mutations in *RET* that cause activation of the tyrosine kinase function of the RTK (Table 43-1). Given the ubiquitous nature of the mutation, it is not surprising that the disease begins with diffuse hyperplasia of all of the C cells, with eventual development of one or more malignant foci.

The most common germline mutation, a cysteine-to-arginine substitution at codon 634 (denoted C634R), accounts for at least half of all cases of MEN 2A and has also been extensively studied in vitro in the well-characterized TT cell line.[36] This mutation is found in the cysteine-rich extracellular domain of RET, a region responsible for ligand-dependent dimerization. However, in the setting of the C634R mutation, RET is capable of ligand-independent dimerization, leading to autophosphorylation of the intracellular tyrosine residues that are responsible for interaction with downstream signaling pathways. In contrast, a methionine-to-threonine substitution at codon 918 (denoted M918T) is associated with the more aggressive phenotype of MEN 2B. The M918T mutation occurs in the intracellular domain of RET, changing the conformation of the tyrosine kinase domain and allowing marked enhancement of autophosphorylation in the absence of dimerization. In addition, allelic imbalance, due to either increased copy number of the mutant *RET* allele or deletion of part or all of the wild-type allele, has been reported in several cases of MEN 2A as well as the TT cell line itself.

Table 43-1 Most Common Mutations of the *RET* Gene Causing Hereditary Medullary Thyroid Carcinoma

Exon	Codon	Clinical Syndrome	Approximate Frequency
10	609	MEN 2A, FMTC, HD	≤1%
10	611	MEN 2A	2-3%
10	618	MEN 2A, FMTC, HD	3-5%
10	620	MEN 2A, FMTC, HD	6-8%
11	630	MEN 2A, FMTC	≤0.1%
11	634	MEN 2A (±CLA)	80%-90%
13	768	FMTC	≤1%
13	790	MEN 2A, FMTC	≤0.1%
13	791	FMTC	≤0.1%
14	804	FMTC	≤0.1%
15	891	MEN 2A, FMTC	≤1%
16	918	MEN 2B	10%-20%

CLA, Cutaneous lichen amyloidosis; *FMTC*, familial medullary thyroid carcinoma; *HD*, Hirschsprung disease; *MEN 2A*, multiple endocrine neoplasia type 2A; *MEN 2B*, multiple endocrine neoplasia type 2B.

Sporadic MTC, on the other hand, is not associated with germline changes in *RET*, but nonetheless, somatic *RET* mutations have been commonly reported in 25% to 50% of sporadic MTC cases. In this instance, the most frequent somatic mutation is the M918T alteration, but numerous other codon changes have also been observed, including selected deletions as well as point mutations. Of note, about 6% to 7% of patients with clinically sporadic MTC are found to carry germline mutations diagnostic of hereditary forms of the disease despite the absence of a positive family history, thus leading to the consensus recommendation to recommend *RET* germline testing for all newly diagnosed cases of apparently sporadic MTC.[37,38]

Extensive genotype:phenotype correlations have been established in the two decades since *RET* was identified as causing MTC. In addition to identifying specific clinical syndromes associated with each mutation, these analyses have also demonstrated that disease penetrance, typical age of development of C-cell hyperplasia and malignancy, and the aggressiveness of the malignancy vary in a manner that is based to a large degree on the individual mutation. Thus, the intracellular domain mutations, which tend to be associated

with the aggressive MTC characteristic of MEN 2B, are also found to cause aggressive sporadic MTC when they occur as somatic mutations. Patients who present with sporadic MTC associated with a somatic M918T mutation of *RET* have worse outcomes, including overall survival.[39] These genotype:phenotype correlations are also useful in determining the role and outcomes of genetic screening in hereditary disease. Recently published guidelines from the American Thyroid Association divide known *RET* germline mutations into four risk categories that guide earliest age for *RET* testing of potential familial carriers, earliest age for recommended first thyroid ultrasound and serum calcitonin testing to detect early presymptomatic evidence of disease, and role for potentially curative prophylactic thyroidectomy.[38] Using this type of approach, most young patients identified by prospective genetic screening as carriers for FMTC or MEN 2A can be cured with prophylactic thyroidectomy, although a small percentage remain with biochemical evidence of residual disease.[40]

RAS

Mutations of *RAS* have recently been recognized as common in sporadic MTC in the absence of documented *RET* mutations.[41,42] A wide range of frequency has been reported, however, between 10% and 80% of all *RET*–wild-type sporadic cases, using differing techniques for identifying *RAS* mutations. In the largest study, tumor samples from 108 sporadic disease patients without somatic *RET* mutations were subjected to *RAS* sequencing, yielding a frequency of 17% in that setting.[42] Of the three potential genotype combinations, patients who were (mutant)*RAS* (wt)*RET* were more likely to be disease free after a median follow-up of 5 years than those who were (wt)*RAS* (wt)*RET* or (wt)*RAS* (mutant)*RET*.

Other Molecular Mechanisms Active in Thyroid Carcinoma

As described earlier, tumor cells in DTC often express or overexpress cell surface RTKs for a variety of circulating growth factors, including VEGFR, FGFR, EGFR, PDGFRβ, IGFR, and MET. In addition, MTC cells also can contain similar cell surface RTKs for growth factors, including EGFR, MET, and FGFR. Overall, their roles appear to enhance the proliferative effects of mutated RTKs and intracellular signaling kinases, but in certain settings they may have critical functions. For example, studies of cancer stem cells, such as those derived from the MTC cell line MZ-CRC-1 that contains the M918T *RET* mutation, demonstrate the dependence on FGFR in the presence of RET knockdown for continued sphere formation and stem-cell proliferation.[43]

Of clear importance, however, is the role of growth factors secreted by thyroid tumor cells that interact with the neighboring stromal cells. This is particularly relevant for angiogenesis, by which tumor cells stimulate growth of vascular structures for supply of nutrition and oxygen as well as a conduit for distant metastasis. Cells from both DTC and MTC actively secrete various VEGF isoforms under conditions of limited oxygen, particularly VEGF-A, which interacts with VEGFR on neighboring vascular endothelial cells.[44-47] Similarly, cells from both DTC and MTC generate hepatocyte growth factor and FGF to stimulate MET and FGF receptors, respectively, on neighboring cells, an important pathway for stimulating angiogenesis in the absence of VEGFR activity.[48-50]

The TSH receptor has an indispensable role to stimulate thyrocyte proliferation normally. In neoplastic cells, the receptor is generally expressed and functional in DTC and PDTC, but usually absent in ATC. Short-term increases in the level of TSH can stimulate malignant cells with a functioning receptor, as evidenced by increases in differentiated functions such as thyroglobulin production and radioiodine incorporation, and tumor proliferation is similarly observed from chronic exposure to high levels of TSH.[51] There has also been recent evidence to suggest that TSH is necessary for BRAF-induced thyroid carcinogenesis.[52]

The tumor suppressor gene *TP53* is frequently mutated in advanced thyroid cancers. Point mutations that inactivate the suppressor protein are often seen in PDTC and ATC but are not seen in DTC.[53,54] Reexpression of normal p53 protein restores differentiated function in vivo.[55] Combining *TP53* mutation with other genetic lesions in animal models can reproduce the phenotype of ATC.[56,57]

The Wnt/β-catenin signaling pathway is often activated in advanced thyroid cancers, but recent data suggest a possible early role as well. Mutations in the scaffold proteins APC and Axin, along with β-catenin itself, have been reported in a majority of PDTC and ATC tumors, associated with increased tumor proliferation and loss of tumor differentiation.[58] In RET/PTC-mutant PTC, increased β-catenin localized to the nucleus has been observed as a result of posttranslational modification and protein stabilization.[59] Patients with familial adenomatosis and Gardner's syndrome, associated with mutations in the *APC* gene, have high risk for development of PTC, particularly an aggressive cribriform-morular variant.[60] In cases that have been examined, the presence of a germline *APC* mutation is associated with very high expression of β-catenin in the PTC cells along with frequent mutations in the gene as well as in *RET/PTC*.[61]

Therapeutic Targeting

The development of tyrosine kinase inhibitors (TKIs) that target many of the key oncogenes and other molecular abnormalities in thyroid cancer has led to the investigation of many agents in treatment of patients with advanced and metastatic disease.[62] Initial efforts focused on drugs that could inhibit activated RET kinase, such as vandetanib.[63] In this early study, a tyrosine kinase inhibitor that primarily inhibited VEGFR and EGFR was shown to block autophosphorylation of M918T and RET/PTC3, to prevent growth of cell lines with *RET/PTC1* mutations, and to inhibit growth of tumors after injection of fibroblasts transformed with the *RET/PTC3* gene. Based on findings like these, numerous multitargeted TKIs that can inhibit both RET and VEGFR (as well as other kinases) have been studied in the laboratory and in clinical trials. For example, vandetanib and cabozantinib (which also inhibits MET) significantly improve progression-free survival in patients with metastatic MTC.[64,65] Both drugs appear to be slightly more effective in patients whose tumors have *RET* mutations, but remain beneficial even in the absence of the targeted mutation. It remains to be determined whether these agents primarily work by targeting mutant RET kinase, through inhibition of angiogenesis through VEGFR (and MET for cabozantinib), or other mechanisms such as inhibiting the normal function of wild-type RET.

In DTC, initial interest in RET inhibitors waned when it was recognized that *RET/PTC* mutations are uncommon in advanced and metastatic disease. Instead, focus has been placed on targeting VEGFR-mediated angiogenesis with multikinase inhibitors such as motesanib, sorafenib, and sunitinib.[66-69] More recently, the availability of highly selective inhibitors of individual kinases in the MAPK pathway such as vemurafenib, dabrafenib, and selumetinib, has enabled trials evaluating oncogene targeting. Phase I experience with the two BRAF inhibitors, vemurafenib and dabrafenib, suggests that about one third of patients with BRAF-mutant PTC may respond to therapy[70,71]; phase II studies are under way. Selumetinib, an MEK inhibitor, has been studied in a fascinating pilot trial of 20 patients with progressive, radioiodine-refractory PTC, in which a 5-week course of selumetinib therapy followed immediately by radioiodine scanning induced restoration of enough radioiodine uptake and retention to permit high-dose radioiodine therapy to be subsequently administered to 7 of the patients; partial responses were observed in 5 patients who received the radioiodine therapy.[72]

Moving beyond inhibitors that target single pathways or kinases, studies are now under way to evaluate rational combinations of agents. For example, preclinical studies suggest that simultaneous inhibition of both MAPK and PI3K pathway signaling in DTC and MTC may be more effective than inhibiting either pathway individually, providing the rationale for combining drugs such as sorafenib and everolimus. Similarly, inhibition of both BRAF and MEK in melanoma yielded a potentially more effective regimen with fewer side effects than use of a BRAF inhibitor alone, and this approach is also being tested in BRAF-mutant PTC.[73]

Future Directions

The molecular abnormalities described here represent a broad effort during the past 20 years to understand the fundamental pathophysiology of thyroid cancer. Whereas early oncogenic events have been identified that probably account for the majority of these tumors, further study is needed to identify the incipient events in the remaining tumors. Just as critical is the need for a more comprehensive understanding of the steps that lead to progression, invasion, metastasis, and occasional dedifferentiation. An integrated framework will be required that merges knowledge of DNA mutations with understanding of the role of epigenetic alterations, changes in miRNA regulation of gene expression, and other fundamental processes that contribute to the malignant phenotype. Clinical trials of therapies to reverse genetic changes and alter complex signaling abnormalities will need to be informed by comprehensive, individualized tumor profiling that will facilitate the selection of the correct combination of therapies for each individual patient, including the identification of patients with sufficiently indolent tumors that no therapy will ever be required.

Soft Tissue Sarcomas

Introduction

Soft tissue sarcomas are a heterogeneous group of neoplasms arising in mesenchymal tissue. There are more than 35 histologic subtypes, often associated with distinctive clinicopathologic features. Based on advances in our knowledge of the molecular pathogenesis of these tumors over the past decade, sarcomas can be subdivided into those with recurrent, usually quite simple genetic alterations (approximately one third of sarcomas; Table 44-1), and those with nonrecurrent genetic alterations.[1,2] Examples of the latter group include leiomyosarcomas, malignant peripheral nerve sheath tumors, and unclassified high-grade pleomorphic and spindle-cell sarcomas (often formerly known as "malignant fibrous histiocytomas"), all of which lack specific recurrent genetic aberrations and instead exhibit complex karyotypes including multiple chromosomal deletions, losses, and gains. These last sarcomas frequently have alterations in the *p53* tumor suppressor pathway and a clinically aggressive course.[3] Recurrent translocations in the former group are typically the only cytogenetic alteration present and often involve transcription factors (e.g., *FOXO1A*, *WT1*, *PAX3*, *TFE3*, *FLI1*). This chapter focuses on three tumors with well-characterized genetic alterations—synovial sarcoma, well-differentiated liposarcoma, and gastrointestinal stromal tumor—as prototypical examples of translocation-associated, gene amplification–associated, and oncogenic mutation–associated sarcomas, respectively. The identification of specific genomic alterations in these and other sarcomas is leading to both enhanced prognostication as well as identification of potential therapeutic targets.

Synovial Sarcoma

Clinical Description and Pathology

Synovial sarcoma (SS) accounts for approximately 8% to 10% of all sarcomas; it is the most common sarcoma of young adults.[4] The peak incidence is between ages 15 and 40, and the majority occurs before age 50,[5] with males slightly more affected than females. SS most commonly arises in the extremities (90%), although almost any other site can be affected. It typically presents as a slowly growing, painful mass, with calcifications often being present radiologically.[6] It is an aggressive sarcoma, with a 5-year mortality rate ranging from 25% to 76%.[7-9] Up to 50% of SS recur, usually within 2 years of initial diagnosis. The most common location for metastases is the lungs, and the most important predictor of metastasis is tumor size, with size greater than 5 cm correlating with a significantly increased metastatic risk.[8] Advanced age and advanced stage at presentation, as well as poorly differentiated histology, also correlate with a worse outcome.

Histologically, SS is a mesenchymal neoplasm displaying varying degrees of epithelial differentiation and bearing no biologic relationship to synovial tissue. The tumor was originally designated SS because its tendency to occur near articular surfaces and the frequent presence of an epithelioid component initially suggested origin from synovial tissue. However, ultrastructural, immunohistochemical, and genetic analyses have demonstrated true epithelial and mesenchymal (but not synovial) differentiation.[4,10] Moreover, a mouse model for SS implicates skeletal muscle (particularly myoblasts) as a potential tumor source.[10] In this mouse model, tumors occurred only within a background of myoblasts expressing myogenic regulatory factor myf5 and not in more differentiated myoid lineages.[10]

SS is divided into two principal morphologic subtypes, biphasic and monophasic, based on the presence or absence of glandular epithelial differentiation. The biphasic variant is characterized by spindle-cell areas intermingled with an epithelial component, often forming glands, tubules or nests (Figure 44-1, *A*). The epithelial cells are usually larger, with paler nuclei and more abundant cytoplasm than the spindle-cell component. The epithelial component can be very focal, making it difficult to detect unless highlighted by keratin stains. The spindle-cell areas are composed of closely packed cells with hyperchromatic nuclei and scant cytoplasm,

Table 44-1 Soft Tissue Sarcomas with Recurrent Genetic Alterations

Tumor	Recurrent Genetic Abnormality	Genes Involved

imparting an overlapping appearance, growing in sheets and/or fascicles. Keratins and other epithelial immunohistochemical markers are more abundant in the epithelial component; however, they (especially epithelial membrane antigen) are also expressed, albeit to a lesser extent, in the spindle-cell areas. The monophasic variant is composed entirely of the spindle-cell component and is the more common subtype (see Figure 44-1, *B*). Another characteristic hallmark of both biphasic and monophasic variants is the presence of branching vessels, termed *hemangiopericytoma-like*, as well as wiry stromal collagen. SS with areas of densely packed small round to spindled cells and a high mitotic rate (with or without necrosis) are designated poorly differentiated and, as mentioned earlier, have a worse prognosis.

Genetics and Molecular Pathogenesis

SS contain a specific translocation between chromosomes X and 18 [t(X;18);(p11.2;q11.2)].[4] This translocation results in fusion of the *SYT* gene on chromosome 18 with either *SSX1* or *SSX2* (or rarely *SSX4*) on chromosome X. The resulting fusion gene contains *SYT* gene minus the final 8 C-terminal amino acids and the C terminus of the *SSX* gene (see Figure 44-1, *C*).

In the literature to date, it appears that biphasic SS much more commonly carries the *SYT-SSX1* fusion, whereas monophasic SS shows either *SYT-SSX1* or *SYT-SSX2*.[11-13] This trend between fusion gene product and histologic type suggests the possibility that the *SYT-SSX1* fusion gene is more efficient at promoting epithelial differentiation than the *SYT-SSX2* fusion gene. However, some biphasic SS carry the *SYT-SSX2* rather than the *SYT-SSX1* transcript, so this reported association is by no means consistent.

Attempts have also been made to correlate fusion type with prognosis, although the results are conflicting. Several studies suggested that patients with the *SYT-SSX2* translocation have a better prognosis than those with the *SYT-SSX1* transcript;[13,14] others have found no statistically significant correlation between fusion type and prognosis.[12] All of these studies were retrospective, and none could control for differences in treatment or selection bias in follow-up data.[15] The proposed correlation of fusion gene type with prognosis therefore remains unconfirmed.

SYT is widely expressed during early murine embryogenesis and in the adult.[11] The gene encodes a protein with three possible SH2- and one possible SH3-binding domains (likely protein-protein interaction domains), a novel N-terminal domain (termed an *SNH domain*), and a C-terminal domain rich in glutamine, proline, glycine, and tyrosine (QPGY domain) similar to those found in the *EWSR1* gene and other transcriptional activators (see Figure 44-1, *C*). There is in vitro evidence that *SYT* can act as a transcriptional activator and *SYT* has been shown to bind to the *SWI/SNF* chromatin remodeling complex.[16] *SYT* also interacts with the p300 nuclear pore protein, and this interaction appears to promote cell-cell adhesion.[17] An *SYT* deletion mutant lacking the eight C-terminal amino acids (the most common *SYT* mutant found in the *SYT/SSX* fusion gene product) acts in a dominant negative fashion, preventing cell adhesion to an extracellular matrix.[17]

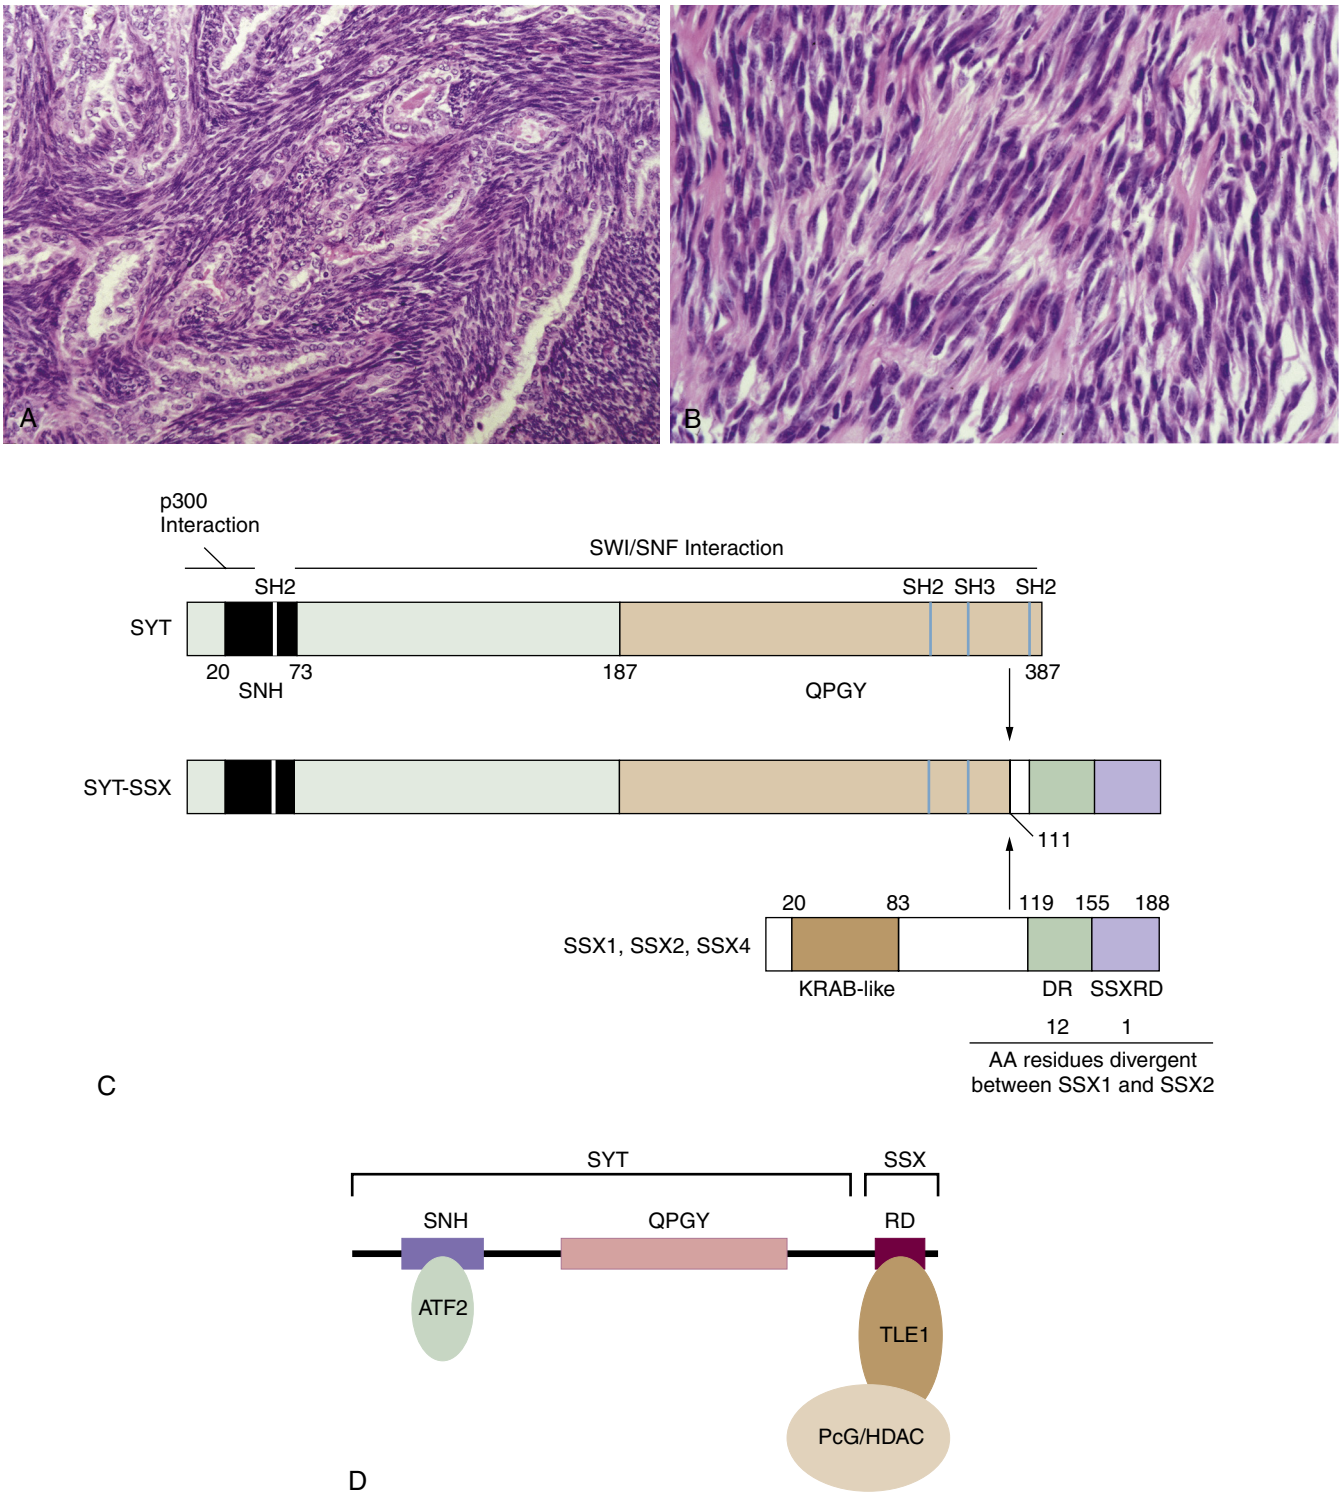

Figure 44-1 Synovial sarcoma **(A)** Biphasic synovial sarcoma, with glandular differentiation within a spindle cell background. **(B)** Monophasic synovial sarcoma, demonstrating the typical densely packed spindle cells growing in a fascicular pattern within a background of wiry stromal collagen. **(C)** Diagram of SYT, SSX, and the SYT-SSX fusion proteins. **(D)** Interaction of SYT-SSX with ATF2 and TLE1 leads recruitment of PcG/HDAC via TLE1. *AA,* Amino acids; *DR,* SSX divergent region; *KRAB,* Kruppel-associated box; *QPGY,* SYT glutamine, proline, glycine, and tyrosine-rich domain; *SNH,* SYT N-terminal domain; *SSXRD,* SSX repressor domain.

SSX1 and *SSX2* share significant homology (81% identity) to each other and belong to a gene family whose expression is predominantly restricted to germ cells and tumors.[11] The *SSX* protein contains an N-terminal domain similar to the Kruppel-associated box (KRAB) domain found in several transcriptional repressors, and an acidic C-terminal region (SSX-RD) that appears to be a novel transcriptional repressor domain[18] required for colocalization with polycomb group (PcG) proteins, which are important for maintaining transcriptional repression from one cell cycle to the next.[19]

The transforming capability of the *SYT-SSX1* fusion gene product has been demonstrated in vitro and in vivo.[20] The N-terminal region of *SYT* (which binds to the *SWI/SNF* chromatin remodeling complex) is required for the transforming properties of *SYT-SSX1*, suggesting a role for transcriptional regulation by *SYT-SSX1* via the *SWI/SNF* complex in SS tumorigenesis. Recently, proteins involved in the transcriptional regulatory activity of SYT-SSX have been identified, including activating transcription factor 2 (ATF2; a transcriptional activator), TLE1 (a transcriptional repressor), and histone deacetylases (HDAC).[21] TLE1 is strongly expressed in SS and is a sensitive diagnostic marker for SS.[22-24] Knockdown of both ATF2 and TLE1 in both human and mouse SS cell lines via small interfering RNA (siRNA) prevented tumor cell colony formation and inhibited cell growth,[21] supporting a role for these proteins in the oncogenic activity of SYT-SSX in SS. The association of SYT-SSX with ATF2 and TLE1 results in repression of ATF2 target genes via recruitment of HDAC/PcG by TLE1 (see Figure 44-1, *D*).

The role of the HDAC/PcG complex in the oncogenic effects of SYT-SSX provides a clinically relevant therapeutic target, namely, HDAC inhibitor targeted therapy. In preclinical studies, HDAC inhibitors have shown early success in SS growth inhibition and remain an area of significant interest in SS treatment.[21,25,26]

In addition to a potential role for HDAC inhibitors in SS targeted therapy, recent data have implicated a role for the phosphatidylinositol-3′-kinase (PI3K)/AKT signaling pathway in SS tumorigenesis,[27] as this signaling is frequently activated in SS. Inhibition of PI3K also decreased SS growth in vitro.[27] These data point to a potential role for PI3K inhibitors in SS therapeutic strategies.

Atypical Lipomatous Tumor/ Well-Differentiated Liposarcoma

Clinical Description and Pathology

Liposarcoma as a class is the most common malignant soft tissue neoplasm. Of the several distinct subtypes, atypical lipomatous tumor/well-differentiated liposarcoma (ALT/WDL), a sarcoma of intermediate (locally aggressive) malignancy, is the most common.[28] It is a tumor of older adults, most often presenting in the sixth or seventh decades. Males and females are equally affected. ALT/WDL occurs most frequently in the extremities or retroperitoneum, followed by the paratesticular region, mediastinum, and head and neck. They tend to be deep-seated, slowly growing masses, and thus are often quite large before coming to clinical attention.

Anatomic location is the most important prognostic factor, because ALT/WDL does not metastasize unless dedifferentiation has occurred (see later discussion). Indeed, although the terms *ALT* and *WDL* are synonymous, tumors in surgically resectable locations in the limbs and trunk are labeled *ALT* because wide excision is curative. In contrast, those located in the retroperitoneum and mediastinum, where wide excision is difficult, are referred to as *WDL*, because repeated and uncontrolled local recurrences are very common, and mortality is high even in the absence of dedifferentiation.

Histologically, ALT/WDL is divided into four subtypes (without prognostic implications): adipocytic (lipoma-like), sclerosing, inflammatory, and spindle cell, of which the first two are the most common.[28] In general, ALT/WDL is composed of relatively mature adipose tissue with significant variation in cell size and varying degrees of nuclear atypia in adipocytes and stromal cells, particularly within fibrous septa. Lipoblasts are often present; however, they are frequently rare and are not required for the diagnosis. Sclerosing ALT/WDL is characterized by collagenous stroma containing pleomorphic hyperchromatic stromal cells and is most common in the retroperitoneum and paratesticular region. Inflammatory ALT/WDL is rare but is important to recognize in that it can be misdiagnosed as Hodgkin's lymphoma, as other sarcomas, or even as a nonneoplastic process, because of the very extensive chronic inflammation present. Spindle-cell ALT/WDL is composed of only mildly atypical spindle cells admixed with adipocytes and lipoblasts (in many cases), in a fibrous or myxoid stroma.

Dedifferentiation, defined by progression to nonlipogenic, often morphologically high-grade sarcoma, occurs in approximately 10% of ALT/WDL. It most commonly occurs in the retroperitoneum, because dedifferentiation appears to be a time-dependent (or size-dependent) phenomenon, and retroperitoneal ALT/WDL often remains asymptomatic until it reaches a large size and tends to have a protracted clinical course because of its relative unresectability. Histologically, dedifferentiated liposarcoma (DDLPS) is characterized in most cases by an abrupt transition from ALT/WDL areas to variably pleomorphic spindle cell sarcomatous areas. DDLPS has a 40% to 50% local recurrence rate, a 15% metastatic rate, and a 30% 5-year mortality rate.[29]

Genetics and Molecular Pathogenesis

Giant marker and supernumerary ring chromosomes are the hallmark of ALT/WDL and are also present in DDLPS.[30] These giant ring and marker chromosomes contain massive amplification of the 12q13-15 chromosomal region.[31] A number of other chromosomal regions, including 12q21-22 and 1q21-25, have also been shown to be co-amplified. The *p53* regulator *MDM2*, located in 12q14-15, is consistently amplified in ALT/WDL, typically in association with neighboring genes, including *CDK4*, *SAS*, and *HMGA2*. Expression of both MDM2 and CDK4 has been shown to be a sensitive and specific marker to distinguish ALT/WDL from benign lipoma (which can be a challenge, especially if there is coexistent fat necrosis).[32] *MDM2* negatively regulates the tumor suppressor *p53* by targeting it for ubiquitin-mediated destruction.[33] Approximately 30% to 40% of sarcomas in general display *MDM2* overamplification, and 38% of tumors in mice overexpressing *MDM2* are sarcomas.[34] Nutlins, a class of small-molecule inhibitors of *MDM2*,[35] have been shown to have growth inhibitory effects on ALT/WDL cell lines, raising their consideration as a new potential therapeutic option.[36]

Although not fully elucidated, recent data have begun to unravel the molecular pathogenesis of tumor progression from ALT/WDL to DDLPS. DDLPS differ cytogenetically from ALT/WDL in that they often show additional complex karyotypic changes, including involvement of 1p32 and 6q23.[37] DDLPS also have been shown to possess a greater degree of 12q amplification than ALT/WDL. Chibon and colleagues[38] identified a role for amplification of *ASK1 (MAP3K5)* a mitogen-activated protein *(MAP)* kinase kinase on 6q23 that is upstream of JNK kinase and *JUN*, in dedifferentiation via inhibition of adipocyte differentiation. More recently, a role for *JUN* oncogene amplification on 1p32 in dedifferentiation has been shown.[39,40] Overexpression of *JUN* results in downregulation of genes involved in adipocytic differentiation, possibly via its direct interaction with CCAAT-enhancer-binding protein beta *(C/EBPβ)*, a transcription factor involved in adipogenesis.[39] Interestingly, *JUN* amplification has been found in the WDL component (separate from the DDLPS component) of a number of DDLS, suggesting that JUN amplification occurs before dedifferentiation in at least a subset of WDL.[37,40] Inhibition of JUN expression in DDLPS with amplified *JUN* results in a reduction in proliferation and tumor growth, both in vitro and in vivo, suggesting a key role for *JUN* upregulation in DDLPS.[40] These in vivo data, however, suggest that *JUN* amplification is likely not to be sufficient to promote dedifferentiation, as inhibition of JUN expression does not promote adipocyte differentiation in DDLPS tumors.[40]

Despite its histology, DDLPS has a less aggressive clinical course than most high-grade pleomorphic sarcomas in adults. The latter tumors typically display both *MDM2* and *p53* alterations that correlate with a poor prognosis.[41] In contrast, although there are conflicting data regarding the frequency of *p53* mutation in DDLPS,[42-44] it is likely mutated in only a minority of these tumors.

Gastrointestinal Stromal Tumor

Clinical Description and Pathology

Gastrointestinal stromal tumors (GISTs) are the most common sarcomas of the gastrointestinal tract.[45] The overall age range at presentation is very broad; however, the majority of tumors are diagnosed in patients older than 50. GISTs occur with equal incidence in both males and females and can occur at any location in the gastrointestinal tract. The most common site is the stomach (50%), followed by the small intestine (25%), large intestine (10%), esophagus (5%), and, rarely, the gallbladder, appendix, or pancreas. GISTs can also arise at sites outside the tubular gastrointestinal tract, including the retroperitoneum, pelvis, mesentery, and omentum, although these extragastrointestinal GISTs account for only about 10% of all GISTs. Clinical presentation may include anemia secondary to gastrointestinal bleeding, early satiety, and intestinal obstruction; however, smaller GISTs are also quite often identified as incidental findings.

The most common metastatic sites for GISTs are intra-abdominal, namely the liver, peritoneum, omentum, and mesentery. GISTs rarely spread to lymph nodes (other than in the pediatric subtype) or to extra-abdominal sites, and when they do, it tends to be late in the course of disease. The most important predictors of metastasis are tumor size and mitotic index, with a size less than 5 cm and a mitotic index less than 5 per 50 high power fields (hpf) conferring a low risk of aggressive behavior and a size greater than 10 cm and/or a mitotic index greater than 10 per 50 hpf conferring a high risk of aggressive behavior.[46] Very occasionally, however, even small GISTs (less than 2 cm) with a low proliferative rate can behave aggressively; thus follow-up is recommended even for lesions with a low relative risk of metastasis.

Based on cytomorphology, GISTs can be divided histologically into three categories: spindle cell, epithelioid, and mixed epithelioid and spindle-cell type. Epithelioid areas are composed of cells growing in sheets or nests, with round nuclei and fairly abundant eosinophilic cytoplasm (Figure 44-2, *A*). The spindled cells are typically monomorphic, with vesicular chromatin and palely eosinophilic, almost syncytial cytoplasm, growing in short fascicles (see Figure 44-2, *B*). Pleomorphism is rare. Additional characteristic features of both spindle-cell and epithelioid GISTs are the presence of

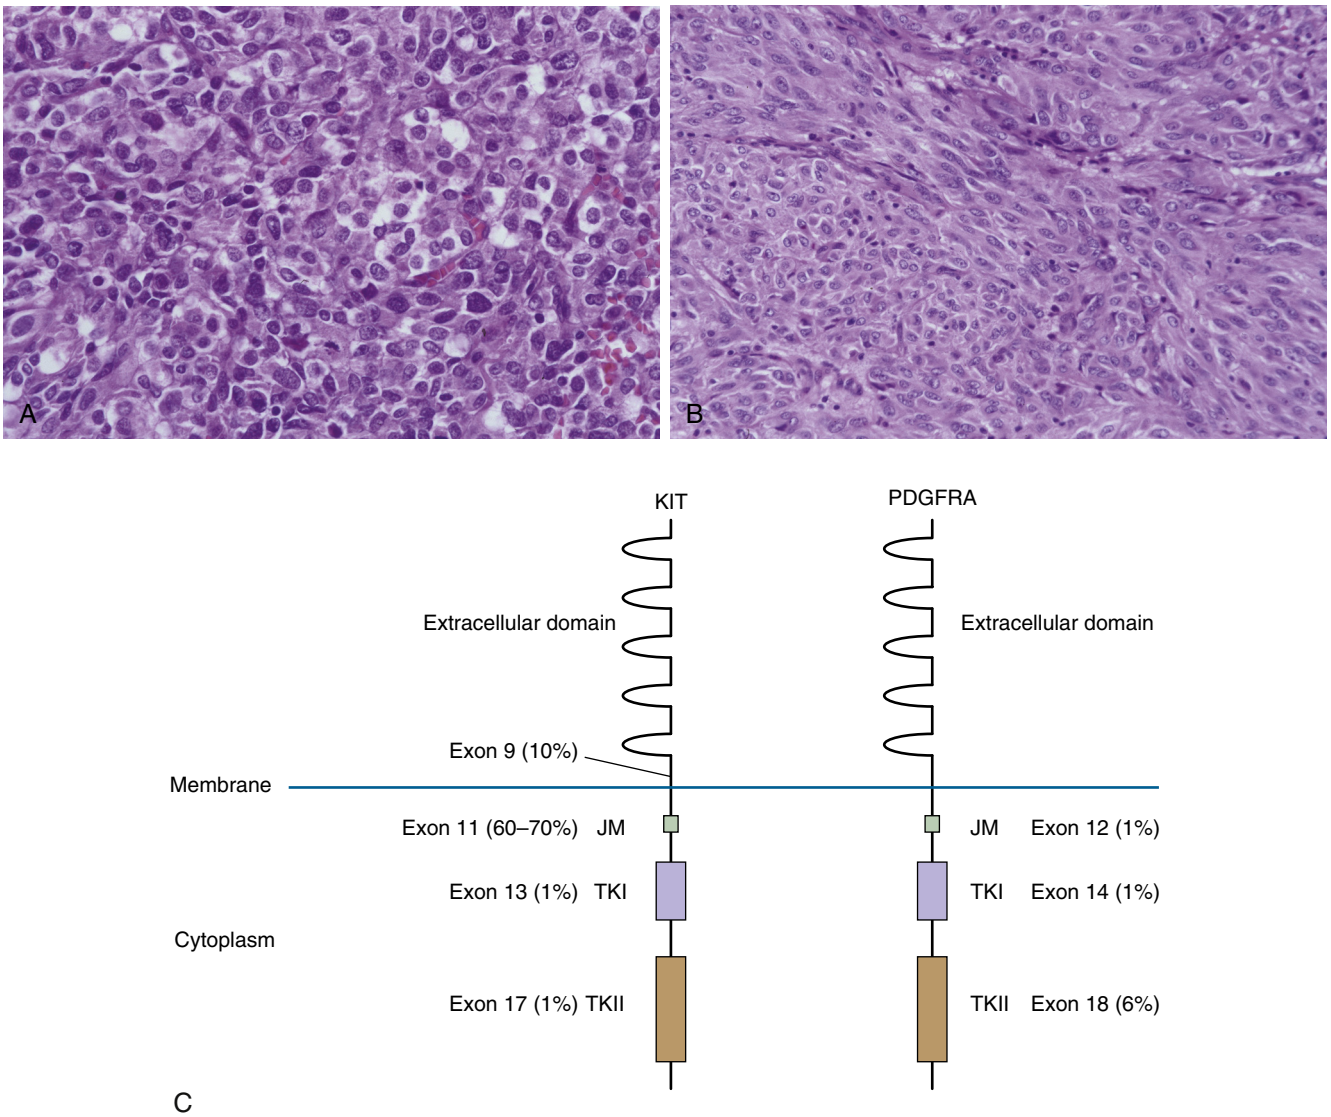

Figure 44-2 Gastrointestinal stromal tumor (GIST) **(A)** Epithelioid GIST, showing cells with round nuclei and fairly abundant eosinophilic cytoplasm, perinuclear vacuoles, and fibrillary eosinophilic cytoplasm. **(B)** Spindle-cell GIST, demonstrating the typical monomorphic cells with vesicular chromatin and palely eosinophilic syncytial-appearing cytoplasm, growing in short fascicles. **(C)** Diagram of c-Kit and PDGFRA, demonstrating localization and frequency of mutations occurring in sporadic GIST. Approximately 5%-10% of GIST lack either c-Kit or PDGFRA mutations. *JM,* Juxtamembrane domain; *TKI,* tyrosine kinase domain I; *TKII,* tyrosine kinase domain II; *TM,* transmembrane domain.

perinuclear vacuoles (especially in gastric lesions) and the fibrillary nature of the cytoplasm.

GISTs frequently stain positively for smooth muscle markers (at least 30% to 40% are positive for smooth muscle actin or caldesmon). In the past, this finding, combined with the eosinophilic quality of the cytoplasm, caused these tumors to often be mistaken for smooth muscle tumors. GISTs were also not uncommonly mistaken for neural tumors because they can exhibit prominent nuclear palisading, mimicking a nerve sheath tumor, and can occasionally (approximately 5%) stain positively for *S100* protein, a marker common to neural tumors. However, unlike other mesenchymal tumors of the gastrointestinal tract, the vast majority (95%) of GISTs are positive for the tyrosine kinase receptor *c-kit* (KIT) (also known as *CD117*), typically in a diffuse cytoplasmic, dotlike, or membranous pattern.[45] This KIT immunopositivity reflects the effect of activating mutations in KIT (see later discussion) and has greatly improved the reproducibility of GIST diagnosis. More recently, antibodies to DOG-1, a protein highly expressed in GISTs, have been shown to be highly specific, and more sensitive than KIT, in the diagnosis of GIST.[47,48]

In the gastrointestinal tract, KIT is also expressed in interstitial cells of Cajal (ICC), gut pacemaker cells exhibiting both smooth muscle and neuronal differentiation ultrastructurally and immunohistochemically, which are important for intestinal peristalsis.[49] Given the similarities between ICC and GISTs both ultrastructurally and

immunohistochemically, it is believed that most GISTs show differentiation toward ICC.

Genetics and Molecular Pathogenesis

Approximately 85% to 90% of GISTs harbor activating *KIT* or *PDGFRA* mutations[45] (including in familial GIST syndrome, in which patients have germline activating mutations in *KIT* or *PDGFRA*, which are inherited in an autosomal dominant fashion).[50] In addition to GISTs, patients with familial GIST syndrome also have ICC hyperplasia, and those with specific mutations in exon 11 of *KIT* have abnormal skin pigmentation and mastocytosis. The proto-oncogene KIT is a type III receptor tyrosine kinase related to platelet-derived growth factor receptor (PDGFR) and is required for melanogenesis, myelopoiesis, fertility, and ICC and mast-cell development.[51,52] It is a transmembrane protein whose ligand is stem-cell factor (SCF). Binding of SCF to KIT results in KIT activation via autophosphorylation, leading to downstream phosphorylation of key signal transduction proteins and regulation of a number of cell processes, including proliferation, survival, cell adhesion, and differentiation.[53] In GISTs, *KIT* mutations cluster mainly in four exons: exon 9 (extracellular transmembrane domain), exon 11 (intracellular juxtamembrane domain, exon 13 (initial portion of the kinase domain), and exon 17 (kinase activation loop) (see Figure 44-2, C). Current data suggest that exon 11 mutations are the most frequent (60% to 70% of GISTs).[45] Mutations in exons 13 and 17 are rare.

Platelet-derived growth factor receptor A *(PDGFRA)* is mutated in approximately 5% of GISTs, resulting in constitutive activation and downstream activation of signal transduction molecules similar to those affected by KIT activating mutations.[54] *KIT* and *PDGFRA* mutations are mutually exclusive and the mutations found in *PDGFRA* map to similar domains on the protein to those found in *KIT* (see Figure 44-2, C). GISTs with *PDGFRA* mutations tend to exhibit epithelioid rather than spindle-cell morphology and tend to be more common in the stomach.

A mouse knockin model expressing constitutively active KIT has demonstrated that this constitutive activation is necessary and sufficient for GIST tumorigenesis;[55,56] thus mutation in either KIT or *PDGFRA* is likely an early step in GIST pathogenesis. However, other recurrent genetic changes have been shown to occur. These include loss of chromosomes 14q, followed by loss of 22, 11p, 9p, or 1p.[45] Loss of 9p, on which the tumor suppressor *p16(Ink4a)* is located, appears to be associated with a worse prognosis. Gains of chromosome 5p, 20q, 17q, or 8q are also associated with a more aggressive clinical behavior; however, correlation of tumor progression with specific genes in those regions has yet to be demonstrated.

Approximately 5% to 10% of GISTs lack either *KIT* or *PDGFRA* mutations (wild-type [WT] GIST). These *KIT*/*PDGFR*-intact GISTs tend to occur in the pediatric population, as well as in the setting of specific genetic syndromes, namely, neurofibromatosis type I/Von Recklinghausen's neurofibromatosis (NFI); Carney triad (CT); and Carney-Stratakis syndrome (CSS). CT, for which a clear genetic inheritance pattern or germline mutation has not been found to date,[57] consists of extra-adrenal paragangliomas, pulmonary chondromas, and multifocal epithelioid GISTs of the stomach.[58] The CSS is characterized by paragangliomas and GISTs and is due to germline mutations in succinate dehydrogenase subunits B, C, or D *(SDHB*, *SDHC*, *SDHD)*, inherited in an autosomal dominant fashion.[59,60] *SDH* is a mitochondrial enzyme complex that functions in the Krebs cycle. Recent data have also identified *SDHB* or *SDHC* germline mutations in patients with WT GISTs without a personal or family history to suggest CT or CSS,[61] as well as somatic mutation of *SDHA*.[62] In addition, loss of *SDHB* protein expression and decreased *SDH* complex activity have been demonstrated in WT GISTs in patients without germline or tumoral *SDH* mutation, further supporting a role for the *SDH* complex in tumorigenesis in these genetically distinct GISTs.[61] Although the majority of *SDHB*-deficient GISTs occurs in young patients (hence being designated *pediatric-type*), comparable lesions with distinctive clinicopathologic features occur more rarely in adults.[63,64]

GISTs are not responsive to conventional chemotherapy or radiation, and thus, before the identification of *KIT* mutations in GISTs and the development of targeted therapy, the outlook for patients with clinically aggressive GISTs was grim. Imatinib mesylate, also known as Gleevec, binds to and inhibits the ATP-binding pocket of both KIT and PDGFRA and is approved to treat patients with metastatic and/or unresectable GISTs. Mutational status appears to be important in predicting response to imatinib, in that patients with exon 11 *KIT* mutations have a significantly better response than patients with exon 9 *KIT* mutations or without *KIT* or *PDGFRA* mutations.[65] Interestingly, GISTs with either exon 9 *KIT* mutations or without *KIT* or *PDGFRA* mutations are more likely to be responsive to sunitinib, a second-line tyrosine kinase inhibitor approved as therapy for imatinib-resistant GISTs.[66] Given the role of *SDH* mutation and/or deficiency in a significant subset of WT GISTs, protein expression of *SDHB* has been proposed as a means to initially triage GISTs into those that likely harbor *KIT* or *PDGFRA* mutations (type 1; intact *SDHB* expression), and those with likely *SDH* complex deficiency (type 2; absent *SDHB* expression[67,68]). This subclassification has important clinical implications, as the type 2

GISTs (WT GISTs) usually do not respond to imatinib. It remains important, however, to consider *SDHB* expression alone with caution, because of potential difficulties in staining interpretation, and because some tumors classified as type 1 via *SDHB* positivity (namely, GISTs occurring in the setting of NF1) do not contain *KIT* or *PDGFRA* mutations and do not typically respond to imatinib.[69]

Unfortunately, a significant number of patients eventually develop secondary resistance to imatinib as well as to sunitinib, primarily via secondary mutations in the KIT kinase domain or through KIT amplification.[66,70,71] KIT has been shown to activate a number of key signal transduction pathways, including the mitogen-activated protein kinase *(MAPK)*, Janus kinase/signal transducers and activators of transcription *(JAK/STAT)*, Src family of tyrosine kinases *(SFK)*, Ras/extracellular regulated kinase *(Ras/Raf/Erk)*, and *PI3* kinase signaling pathways.[53,72] Of these pathways, in vitro and in vivo data demonstrate that the *PI3* kinase, *MAPK*, and *SFK* pathways are activated in GISTs.[72,73] In contrast, phosphorylation of the *JAK/STAT* kinases *STAT1* and *STAT3* was not dependent on oncogenic KIT signaling, and *STAT5* phosphorylation was not detected in either primary GISTs or GIST cell lines. In addition, inhibition of the JAK/STAT pathway did not inhibit proliferation in GIST cell lines, arguing against a significant role for this pathway in GIST oncogenesis.[74] Elucidation of the comparable importance of downstream targets of KIT in GIST tumorigenesis has important therapeutic implications, particularly for the development of treatment strategies in imatinib-resistant tumors. For example, a secondary mutation in BRAF kinase (a kinase mutated in several cancers, particularly melanoma, papillary thyroid carcinoma, and a subset of colorectal cancers) has been identified in an imatinib-resistant GIST, suggesting a possible role for the potent BRAF inhibitor vemurafenib as second-line therapy.[75] Interestingly, *BRAF* somatic mutation has also been identified as a rare event in WT GIST.[75]

Conclusion

The identification of specific chromosomal aberrations in a significant subset of sarcomas has improved our ability both to diagnose and to develop novel treatment strategies for these tumors. Just as the elucidation of specific translocations in another category of mesodermally derived neoplasms—leukemias—allowed the development of directed chemotherapeutics (e.g., chronic myelogenous leukemia and imatinib), so, too, the discovery of specific recurrent genetic mutations in sarcomas provides opportunities for intelligent design of targeted therapies. This is in contrast to the two thirds of sarcomas that lack recurrent genetic abnormalities and which often possess complex karyotypes, which unfortunately include most pleomorphic/spindle-cell sarcomas of older adults. Application of comprehensive genomic analysis over the past several years to these and other sarcomas, however, has provided new insight into novel oncogenic drivers of these tumors, as well as an enhancement in our ability to predict clinical behavior.[76,77] This improved understanding of sarcoma genetics is providing new potential therapeutic targets as well as diagnostic and prognostic biomarkers.[2,78]

45 From Bench to Bedside with Targeted Therapies

Targeted therapy of human disease celebrated its 100th birthday in 2011. A century ago Paul Ehrlich, a German pathologist, produced the first "rationally designed" drug, which selectively targeted the microorganism *Treponema pallidum*, the cause of syphilis. The project was the outcome of a thoughtful hypothesis based on the observation that certain organic dyes were selectively taken up by some cells and infectious agents, and not by others. Ehrlich postulated the presence of specific receptors on cells and bacteria to which the dyes bound and were internalized. He then proposed to attach a toxic molecule (in this case, arsenic) to a dye molecule that was selective for a receptor on the bacterium, with the goal of producing selective cytotoxicity against the bacterium[1] (Figure 45-1).

To carry out this work in an efficient and systematic way, he invented an array-like approach to his research. A series of large organic molecules were attached to arsenic by his colleague, Sahachiro Hata, a synthetic chemist, and then were tested by Ehrlich for selective toxicity. Number 606—actually, a modification of the original number 606—was effective and became arsphenamine (Salvarsan). To demonstrate efficacy and lack of toxicity, Ehrlich first performed experiments with rabbit models of syphilis (mice resist the infection), followed by what we would call Phase I and II clinical trials with patients—keeping careful records. Finally, after obtaining positive results, he scaled up production and marketed the first synthetic "blockbuster" chemotherapeutic agent in 1911, a mere decade after initiating the project. It remained the standard of care until antibiotics were discovered.

The subsequent production of numerous chemical agents that can cure disease or prolong life is a magnificent story of moving discoveries from the research bench to the patient's bedside, and from the patient back to the research bench. In the history of chemotherapy for cancer, progress developed in two phases. During the first phase, from 1946 to the mid-1980s, the drugs produced were screened for efficacy primarily by assaying cytotoxicity against cancer cells in culture and in animal models, and then in patients. Most of the drugs acted by interfering with DNA replication or cell division. It is remarkable that until the1970s, medical students were taught that the biochemical and molecular abnormalities in cancer cells were quantitative (altered amounts) rather than qualitative (altered chemical composition and structure). During the second phase, which began in the mid-1980s, the targets for drug development became products of the aberrantly functioning genes that produce cancer. This progression was made possible by new knowledge about oncogenes and suppressor genes, and by new technologies for accurately detecting abnormalities in DNA and proteins.

Drug Development

The First Phase

Chemotherapy for cancer began in the 1940s, with the development of agents that target and eliminate malignant cells. The observed toxicity of mustard gas against blood leukocytes led Louis Goodman and Alfred Gillman to produce a form of this DNA alkylating agent, which could be delivered intravenously.[2] This chemotherapy, named nitrogen mustard, produced objective clinical responses in patients with lymphoma. Another novel therapy that targeted DNA synthesis was developed by Sidney Farber. Knowing that folic acid was required for DNA synthesis, he worked with a synthetic chemist to produce folate antagonists. Amethopterin and later Aminopterin (methotrexate) produced dramatic but short-lived responses in children with acute lymphoblastic leukemia.[3] With these two reports, the pharmacological therapy of cancer was born.

Although the title of this chapter is "From Bench to Bedside," it is important to emphasize that the movement of

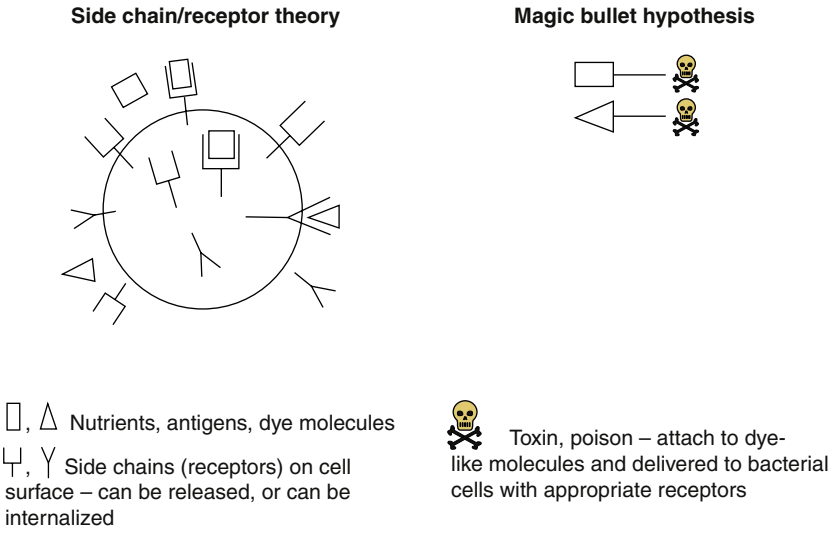

Figure 45-1 Paul Ehrlich: birth of targeted therapy, 1911.

ideas is invariably in both directions, back and forth between clinical researchers and the laboratory researchers. Nitrogen mustard was developed because physicians observed destruction of leukocytes and lymphocytes in soldiers gassed during World War I. The antifolate, Aminopterin, was developed because Sidney Farber tried treating leukemic children with folic acid (reasoning that their malignant cells appeared similar to cells observed with folate deficiency), and the acuteness of their disease became worse, not better. These observations, in turn, stimulated and informed laboratory research.

For the next 40 years, great progress was made in developing additional chemotherapeutic anticancer agents. Two approaches were used. The first approach involved synthesis of specific targeted agents—as with methotrexate. The next success was 6-mercaptopurine, another inhibitor of DNA synthesis, produced by George Hitchings and Gertrude Elion and shown by Joseph Burchenal to be effective in acute leukemia.[4] The synthesis of new therapeutic molecules has been greatly enhanced by the development of three-dimensional models of target molecules, enabling chemists to design small lead molecules and test them using in silico computer-based screening.

The second approach involved screening of large numbers of natural products and led to the discovery of taxanes and camptothecin. These successes were followed by discovery of the anticancer properties of vinca alkaloids, platinum-based agents, nitrosoureas, and anthracyclines, all of which remain in use today.

The pharmaceutical industry has used these two general approaches—synthesis of new compounds and broad screening of natural products—to develop many therapies against cancer and bring them to the clinic for investigation in therapeutic clinical trials[5] (Figure 45-2). The successful chemotherapeutic agents that have been developed are summarized in Chapter 46. Today new methods of targeting and screening are being used to find therapies that counteract the function, or loss of function, of the products of aberrant genes that cause cancer (see later discussion).

Two other major breakthroughs in the development of cancer therapies during this first phase deserve emphasis. The first is the development of combinations of therapies administered simultaneously. This was applied to leukemia by Emil Freireich, Emil Frei, and James Holland in 1956, soon after combinations of antibiotics were found to produce enhanced efficacy against bacterial infections such as tuberculosis. The principle is to use two or more agents that provide additive killing capacities against a target, but with different toxic side effects that are not additive. In the late 1950s and early 1960s, this principle was first applied successfully in a series of clinical trials by these investigators and others for the treatment of childhood leukemia,[6] and it was first used for the successful treatment of a solid tumor, testicular cancer, by M. C. Li and colleagues.[7]

Leukemia researchers also pioneered the idea that treatment must continue beyond the time that the cancer is clinically detectable, in order to prevent recurrence due to the persistence of subclinical disease. Today this is standard practice for the care of many types of cancer. As with the combination therapy studies, the results of leukemia research in murine models provided the rationale for these studies.

A second major breakthrough in cancer therapy and the treatment of many diseases took advantage of a new technology invented by Kohler and Milstein, which enabled production of large quantities of a monoclonal antibody raised against a specific antigen.[8] This technique was rapidly applied to the production of antibodies targeting molecules on the surface of cancer cells. Major clinical responses in lymphoma patients were reported by Ronald Levy and colleagues in 1982, with an anti-idiotype antibody against the specific immunoglobulin molecule expressed on the surface

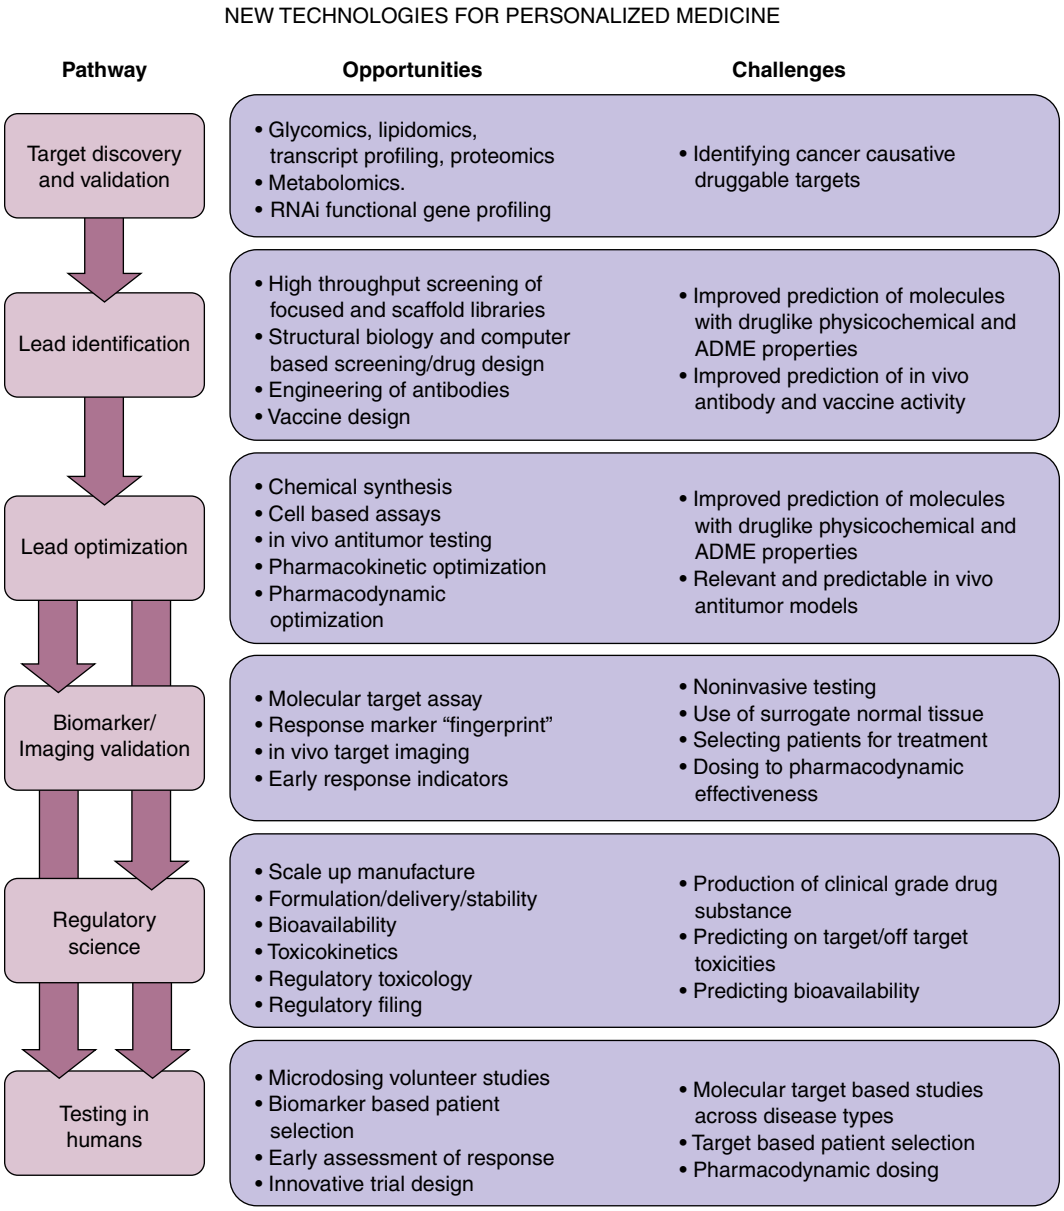

Figure 45-2 New approaches and challenges for personalized cancer medicine Therapy development is shown as linear process, whereas in reality it is iterative in all its stages.

of the patients' malignant B cells.[9] Today, nearly half of the agents that are approved by the U.S. Food and Drug Administration (FDA) for the treatment of cancer are monoclonal antibodies, a revolution in targeted cancer therapy that has occurred in the past three decades.

The Second Phase

Why not produce an anticancer therapy that targets a molecule that is known to cause cancer? A preliminary to this approach dates back to the 1940s and 1950s, when Charles Huggins discovered that depriving prostate cancer patients of androgen and breast cancer patients of estrogen can result in remission of their disease.[10] Both approaches are used in the clinic to this day, but the method has evolved from surgical removal of organs producing these hormones to targeted drugs that act on hormone receptors or hormone production.

The target for therapy switched from cytoplasmic hormone receptors to growth factor receptors on the cell surface in the early 1980s. Our group first hypothesized that inhibition of a receptor function might inhibit tumor cell growth (Table 45-1). We produced a monoclonal antibody, cetuximab, which binds to the EGF receptor, blocks activation of the receptor's tyrosine kinase by its ligands, EGF and TGFα, and inhibits proliferation of cancer cells in culture and in human tumor xenografts.[11-13] This was followed by reports on trastuzumab, a monoclonal antibody that binds to the closely related HER-2 receptor.[14] It was during this period that the term *oncogene* was first used, and these were the first

Table 45-1 Rationale for Targeting EGF Receptors, 1980

- EGF characterized 1962. EGF receptor characterized 1975-80. (Cohen)
- Autocrine hypothesis 1980. (Todaro and Sporn)
- Tyrosine kinase first identified in three molecules: src oncogene, EGF receptor and PDGF receptor (Hunter, Erickson, Cohen).
- EGF receptor commonly overexpression in cancers (Ozanne, others)
- Preferential addiction of cancer cells to essential nutrients and growth factors
- Receptor inhibition by circulating autoantibodies can produce stable physiologic change (disease) in humans: myasthenia gravis, hyperthyroidism, insulin resistance

experimental cancer therapies that targeted the products of an oncogene—in these cases a receptor tyrosine kinase. Since the mid-1980s, many oral chemotherapeutic agents have been developed that target these two tyrosine kinases and many other kinases, located both in receptors and free in the cytoplasm.

Trastuzumab received regulatory approval for the treatment of breast cancer expressing high levels of HER-2 in 1998.[15] This was followed by imatinib against the product of the BCR-ABL gene translocation, another tyrosine kinase, in patients with chronic myelocytic leukemia in 2001.[16] Cetuximab entered clinical trials in 1990 and was approved for colorectal cancer in 2004[17,18] and for head and neck cancer in 2006. These approaches to experimental therapeutics created a new paradigm for the development of therapies against cancer.

Three breakthroughs in knowledge and technology converged to greatly accelerate this change in therapeutic research on cancer:

(1) We have learned that accumulated genetic aberrations are the cause of cancer. This dates from observations by Bishop and Varmus in experiments exploring viral carcinogenesis with the SRC oncogene, published in 1976, showing that the genetic abnormality was intrinsic to human cells, not the Rous sarcoma virus.[19] Today, hundreds of genes are known to be altered in human cancers.

(2) There are more than 800 new drugs under development at pharmaceutical and biotechnology companies and universities, which are designed to target the products of the aberrantly functioning genes that cause cancer.

(3) New instruments and analytic techniques have reduced sequencing of a human genome from a 10-year, $3 billion project to a 10-day, $5000 project, which allows us to interrogate an individual patient's cancer to detect genetic aberrations in the patient's tumor. The speed and cost continue to improve dramatically.

As a result of this confluence of discoveries, there is pressure from all stakeholders in cancer care for development of new approaches to the treatment of cancer—using the genomic and molecular analysis of an individual patient's cancer to select the targeted therapy that is most likely to provide clinical benefit. Although earlier approaches provided many successful chemotherapeutic agents and continue to be important, the new targeted approach to developing new cancer therapies dominates the field today. These new therapies are designed to target a particular gene product that has been shown to contribute to the malignant phenotype of cancer cells in correlative studies of molecular pathological data and clinical data and in laboratory experiments with cultured cells and animal models.[20,21]

There have been some spectacular successes in clinical trials with experimental targeted therapies that enrolled only patients whose cancer was known to harbor an aberrancy in the target of that experimental drug or antibody. These successes have resulted in substantial prolongation of patients' lives for many months or years.

The first example of this approach to reach the clinic involved trastuzumab, the monoclonal antibody against the HER-2 receptor. It is overexpressed on 20% to 25% of breast cancers and was found to be a biomarker predicting a worse prognosis in these patients. Clinical activity of trastuzumab was demonstrated in early studies only among patients whose cancers expressed high levels of HER-2. Genentech adopted a new paradigm for designing a randomized Phase III clinical trial, investigating standard chemotherapy with or without trastuzumab for treatment of patients with advanced, metastatic breast cancer. Only patients with high expression of HER-2 in their tumors were eligible to enroll. This enriched the trial with patients more likely to respond, and converted what would otherwise have been a negative study (too few responders) into a positive study, leading to FDA approval in 2002.[15] The optimal clinical situations for the use of trastuzumab have been refined continuously, as a result of dozens of clinical trials over the ensuing decade (see Chapters 36 and 50).

A second and most dramatic example involves the development of the ABL tyrosine kinase inhibitor imatinib for the treatment of patients with chronic myelocytic leukemia (CML), whose leukocytes nearly always carry a BCR/ABL gene rearrangement. Before this treatment, the median survival of patients with this disease was 3½ years. Today most patients on this and follow-up drugs live in remission more than 5 years, and some may reach a normal lifespan.[16] The incidence of CML is only 4000 cases per year. A drug against this disease was not considered to be a potential "blockbuster" compared with a treatment for lung cancer (over 200,000 cases/year). Movement from the research laboratory in a pharmaceutical company to clinical trials was encouraged by the persistent efforts of an academic clinician scientist, Brian Druker, who performed preclinical studies in his laboratory demonstrating efficacy against CML cells and

then led the first clinical trials. The premise, which turned out to be prescient, was that blocking the abnormally active ABL tyrosine kinase—a product of the BCR-ABL rearrangement in patients with early CML—might produce especially effective responses, because this was the only known genetic abnormality in these patients. In contrast, most cancers have many genetic aberrations that contribute to their malignant activities at the time they are first detected.

A third example involves oral inhibitors of the EGF receptor tyrosine kinase, gefitinib and erlotinib (TKIs). In a series of very large and expensive randomized trials of chemotherapy plus or minus one or the other of these TKIs in patients with advanced lung cancer, the results showed no significant overall benefit from adding the TKI. However, a few patients had a substantial prolongation of survival. When it was discovered that mutations were present in the gene encoding the EGF receptor in the lung cancers of many of the patients who responded well,[22-24] clinical trials were repeated with the requirement of an EGF receptor mutation for enrollment. The positive response rates for advanced lung cancer patients with a mutated EGF receptor were confirmed.[25] This time, in the selected patient population, the results were positive in the majority of patients. Thus, a "failed" new targeted therapy was converted into a successful treatment for the 10% of lung cancer patients with mutated EGF receptor genes in their tumors, and the median duration of survival for those patients has doubled. In fact, for these patients the TKI therapy was more effective than chemotherapy, whereas for patients without the mutation, chemotherapy gave better outcomes than treatment with a TKI.[25] This "resurrection of a cancer drug" brought clinical benefits to selected patients and economic benefits to the pharmaceutical companies, which were now able to market their new targeted drugs. This was a wake-up call to the industry, strongly suggesting the value of a new, selective approach to clinical trials with new targeted cancer treatments.

Among the lessons from these examples is the observation that for each case the circumstances were different, and an understanding of both the molecular biology and the clinical disease was critical in the development of a novel therapy that targeted a molecular abnormality in these patients' cancers.

Von Hoff was the first to report on a clinical trial in which patient enrollment was governed by the result of a molecular analysis of tumors, using immunohistochemistry, fluorescence in situ hybridization, and, primarily, gene expression arrays. Of 66 patients treated with commercially available drugs that were felt to match the detected molecular markers, 27% had a progression-free survival at least 30% longer compared with the response to the previous drug(s) they had received.[26] In this study, the patients served as their own controls, and gene mutations were not analyzed.

Recent examples have demonstrated the utility of identifying the targeted genetic aberration in the tumors of patients who enroll in clinical trials with experimental targeted therapies at the earliest stages.

The Biomarker-integrated Approaches of Targeted Therapy for Lung Cancer Elimination (BATTLE) trial for patients with advanced, heavily treated non–small-cell lung cancer was the first reported study with a panel of experimental drugs that (1) required a fresh tumor biopsy for genetic and molecular assays to detect particular aberrations that could serve as biomarkers for assigning therapy and (2) introduced an adaptive randomization design to assign a patient to receive one of the four experimental therapies that did, or did not, target an abnormality detected in that patient's cancer. Essentially, this was a panel of four separate Phase II trials, testing the efficacy of "rationally" assigning patients to a particular trial. Importantly, nearly 100% of patients who were offered participation agreed to the biopsy procedure as a condition for receiving access to one of the experimental targeted therapies in a randomized study. The endpoint of the trial was improved duration of progression-free survival, which was subsequently confirmed by improved overall survival. The results showed that there were four situations where the results of the biomarker assays predicted a significant improvement in response, or in one case, a worse response, to an experimental drug targeting that biomarker.[27] This suggested that preselection of patients for a panel of Phase II studies of new therapeutic agents based on biomarkers showing abnormalities in the targets of these agents is useful and may improve clinical outcomes.

Another trial at MD Anderson Cancer Center retrospectively analyzed response rates and survival of patients treated with experimental drugs that matched genetic abnormalities in their cancers. Over a 4-year period, more than 1000 patients with advanced, heavily treated cancers were tested for mutations in hot spots in 11 genes and for loss of expression of PTEN. An experimental drug was often available targeting the detected genetic aberration for most of their genes in ongoing Phase I/II trials. A total of 291 patients with genetic aberrations could be evaluated for response to an experimental targeted therapy. Of these, 175 received a targeted therapy that matched an aberrant gene target in their cancer, and 116 were treated with nonmatched therapy (based on nonavailability of matched therapy at the time). The overall response rate of the first group was 27% (including two complete responses), significantly greater than the second group, which was 5%. Median overall survival was 13.4 months compared to 9.0 months, a 49% increase.[28] In most reports analyzing the results of Phase I trials, the main objective is determination of maximal tolerated dose and

toxicities, and the objective response rate to new therapies is less than 10%. This trial, which achieved a much higher response rate, was a nonrandomized study and involved many types of cancer and many separate clinical trials of new drugs at varying doses. Although the results support the benefit of matching experimental therapy to genetic aberrations, this conclusion now must be confirmed in a randomized study. Today a number of cancer centers are carrying out prospective clinical trials using next-generation sequencing technology to assess cancers and using the results for assigning patients to trials of experimental targeted therapies.

Two recent highly successful Phase II trials of experimental targeted drugs took an approach to testing a new experimental therapy similar to that used in the registration trial of trastuzumab, the trials of TKIs in patients with mutated EGF receptors, and in most of the patients with CML treated with imatinib. Each trial studied a single drug. Large numbers of patients were screened for enrollment, based on the presence of the genetic aberration that the experimental drug was designed to target.

In the first clinical trial, crizotinib, which already was in trials targeting the EML4-ALK rearrangement in lymphoma, was tested for activity against patients with this rearrangement in their lung cancer. This was found to occur in less than 5% of lung cancers. More than 1700 patients were screened at multiple institutions to populate a Phase II trial with 82 preselected patients. The drug was successful, with a response rate of 57%, an additional 35% achieving stable disease, and a median time to progression of greater than 6 months at the time of publication.[29] These results led to successful follow-up trials and FDA approval, within only 5 years of discovering this genetic aberration in small numbers of lung cancer patients (the drug was already available).

Another clinical trial explored the efficacy of vemurafenib which was designed to block the activity of BRAF, a gene that was reported to be mutated in many patients with melanoma. The complete plus partial response rate with advanced melanoma patients whose cancer had the targeted BRAF mutation was over 70%, with a median duration of 7 months.[30] FDA approval followed soon afterward.

These were remarkable results in patients with advanced cancers that were well known to be minimally responsive or resistant to chemotherapy. It is clear that genomic screening can improve response rates with targeted therapies, benefiting patients and shortening the time required for testing an experimental therapy. However, we will not know how generalizable this conclusion is until the results of all such targeted trials—positive and negative—are reported and shared. Negative trials of experimental drugs are not typically reported, although they inform decision making by the pharmaceutical company that is developing them. Meanwhile, the results just described support pursuing this approach to testing targeted experimental therapies in a screened subset of cancer patients.

Next Steps in Drug Development

Progress will be hastened if a number of challenges are addressed—some involving gaps in scientific knowledge and technology, and others involving changes in the clinical trials process.

Scientific Knowledge and Technology

A major scientific challenge is the need to balance the tremendous power of next-generation genomic sequencing and other technologies for interrogating molecular aberrations in a patient's cancer with the mandate to keep down the costs of clinical care. The most sophisticated genomic tests (see Chapter 24) add substantial costs for instrumentation and data analysis, although they may reduce the cost of care in the long run. An added factor is the requirement in the United States that all tests performed to guide clinical care must be carried out in laboratories with Clinical Laboratory Improvement Amendment (CLIA) certification, which ensures high standards, but adds costs. Similar standards are used in Europe. Finally, sophisticated, deep-level next-generation sequencing often identifies hundreds of genetic aberrations in human cancer specimens,[31] and most of these are not actionable because their significance in the tumor's biology and the patient's disease is not known, or drugs that target them are not yet available.

For these reasons, clinical testing for genomic aberrations in most medical centers currently is limited to assays that measure mutations (insertions, deletions, or substitutions of nucleotides) in selected genes, alterations in gene copy number, and structural rearrangements in selected genes[32] (Figure 45-3). Available experimental or approved drugs that target the products of aberrant genes are currently limited to a few dozen genes. At the author's institution, we currently are sequencing 740 hot spots in 46 genes. This detects only the first of the three categories of genomic analysis listed above. To capture all three categories and expand the gene coverage, we are planning to move to the targeted deep sequencing of the exons (open reading frames) of a few hundred genes. Both of these approaches to sequencing enable multiplexed assays on many genes to be run on a single extracted sample of tumor DNA. This is a huge advance over the technology just a few years ago, when selected regions of genes were sequenced in a separate assay for each individual mutation, and the amount of tumor

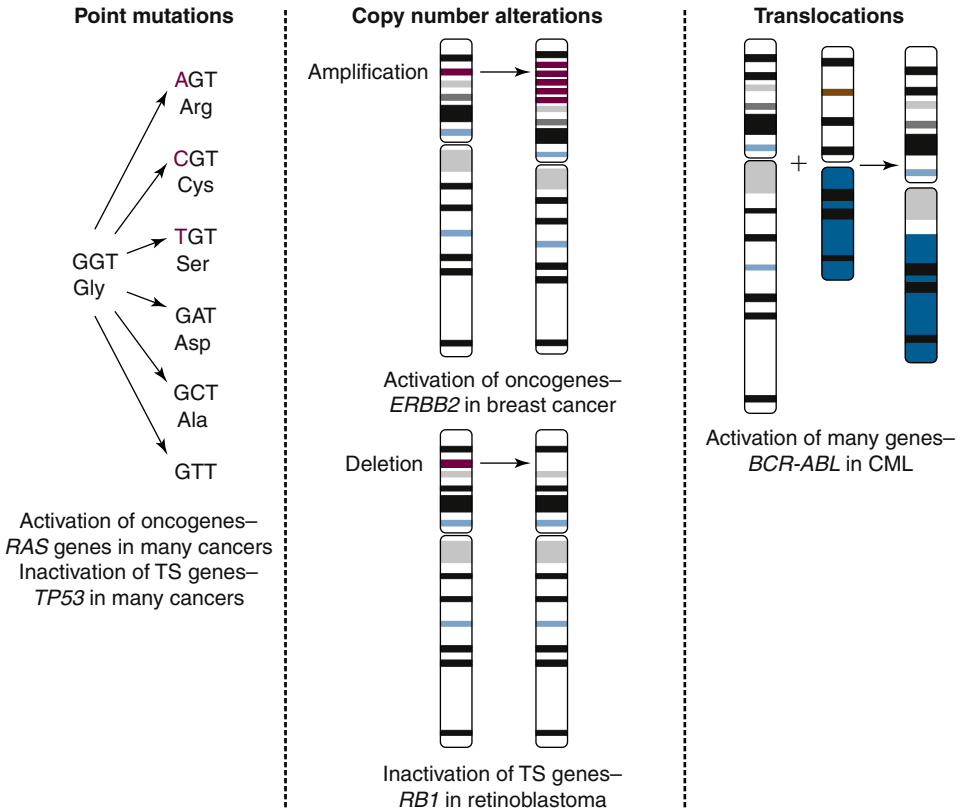

Figure 45-3 The major classes of genomic alterations that give rise to cancer. *CML*, Chronic myelogenous leukemia; *TS*, tumor suppressor.[32]

tissue available rapidly became a limiting constraint. A number of cancer centers have started programs assaying DNA in patient's cancers to guide therapy (e.g., Refs. 33, 34).

With 800 experimental targeted drugs in the clinical pipeline and a few dozen already approved, current second-generation sequencing of advanced solid tumors yields a match between a genetic aberration and a targeted drug about 40% of the time. The yield is higher in reported cases of deep sequencing with more complete genomic analysis. The ingenuity of companies developing new technologies for detecting genetic aberrations guarantees that advancements will continue to enable more rapid and complete analysis for less cost. The limiting factors have become the need for bioinformatics and computational tools and for trained personnel to use these tools to interpret the sequencing data.

Two key rate-limiting gaps in scientific knowledge were identified recently in a report from the President's Council of Advisors on Science and Technology.[35] These were (1) identifying and validating the protein targets that are critical to the survival of cancer cells and are "druggable," and (2) predicting more effectively the efficacy and toxicity of candidate drugs before high investments of funds and time are made in clinical trials.

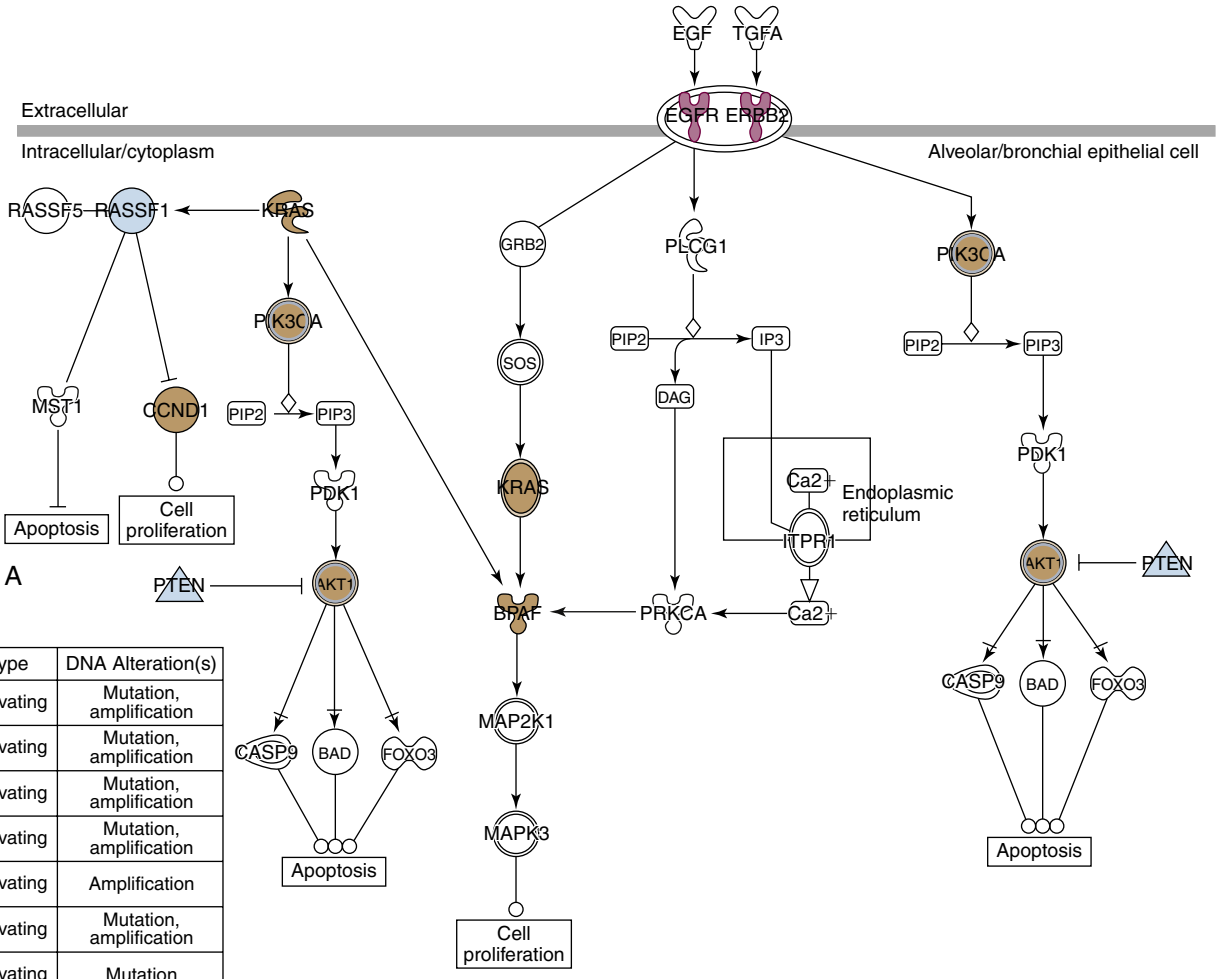
The new fields of systems biology and computational biology have emerged to address the first of these questions. Through extensive computer-based analysis of data from biological studies on the biochemical steps that activate or suppress molecular processes in cells, investigators have been able to draw complex maps of interconnected pathways that regulate the activities of proteins in those cells. Candidate "drivers" that form pivotal controlling nodes in these interconnected pathways are identified in a number of ways: (1) They may connect multiple signaling pathways; (2) they may be recurrently mutated in human cancer specimens; (3) introduction of specific RNAi's can block a signaling pathway that changes major phenotypic functions in the cell (such as maintaining viability); and (4) knockin or knockout of the gene's activity in genetically engineered mouse models (GEMMs) results in molecular alterations, changing the phenotype in significant ways that affect malignant behavior.[36,37] It is important to note that up to now, most targeted therapies discussed in this chapter were developed with earlier approaches that involved identification of abnormal functioning of a target in biological experiments with cancer cells, not because of detection of aberrant genes in broad screens of human cancers.

The Human Cancer Genome Atlas and additional data collected from genomic testing of cancers in multiple centers will identify more genetic aberrations that are cancer drivers and potential targets for new drugs. These new approaches will also enable identification of driver genes that are present at low frequencies—for example, less than 5%—in few types or only one type of cancer. It must be cautioned that a mutation in a known oncogene does not necessarily mean that it

is a driver in a particular cancer, and a gene could have "driver" status in a cancer without a genetic aberration, working instead through amplification or an epigenetic mechanism, or through changes in expression of message or posttranslational modification of the protein it encodes. It also must be emphasized that a driver molecule may be activated by a variety of mechanisms related to its situation in one or more activated regulatory pathways[38] (Figure 45-4).

The ultimate driver gene is one which is so critical to a cancer cell's survival that when its function is blocked, the cell dies, typically by apoptosis. The observation of this phenomenon led to the "addiction hypothesis" of Weinstein, who postulated that in cancer cells that are driven by a mutation in a critical regulatory pathway, alternative pathways that could promote or bypass the driving gene's activity may be downregulated to the point where, unlike the situation in normal cells, they may be irretrievably damaged when the driving, addicting gene is suddenly blocked by a targeted therapy.[39]

The identification of a driver gene does not invariably lead to creation of a drug effective against the gene's product. The tyrosine kinase oncogenes have turned out to be "druggable" targets, and a few dozen new agents against these targets are in clinical use or in clinical trials—both antibodies against receptors on the cell surface and their ligands, and low



Gene	Type	DNA Alteration(s)

Figure 45-4 Activation of EGFR signaling in non–small-cell lung cancer (NSCLC) can occur via disruption of several different components at multiple levels of the pathway. (A) Different proteins in the EGFR pathway can be activated (*red*) or inactivated (*blue*) by underlying genetic or epigenetic changes at the DNA level, leading to aberrant pathway activity and oncogenic signaling in NSCLC. Examples of key oncogenes affected include *EGFR*, *RAS*, *PIK3CA*, and *AKT*. Conversely, examples of tumor suppressors that are inactivated include *PTEN* and *RASSF1*. **(B)** Genetic and epigenetic mechanisms responsible for the disruption of genes in the EGFR signaling pathway in NSCLC include DNA copy number alterations (amplification or deletion), point mutations, and DNA methylation changes. Thus, it is important to consider multiple aspects of the genome and epigenome simultaneously to elucidate the mechanisms driving pathway deregulation. *(This illustration was generated using Ingenuity Pathway Analysis software).*[38]

molecular-weight drugs that act intracellularly. Suppressor genes such as p53, genes controlling transcription factors such as MYC, and genes whose products have more challenging molecular characteristics such as RAS have turned out to be less "druggable." However, by knowing the upstream molecules that interact with these gene products, or the downstream molecules that they activate, targets may be identified that counteract the activity of these genes and are more "druggable."[40]

It was initially hoped that a drug which successfully targeted the product of an aberrant gene in one type of cancer would be effective in other types of cancer with the same genetic abnormality. However, this has not always turned out to be the case, because different types of cells can express pathways that may bypass the drug's target. An example is found with vemurafenib, which, as noted, is effective against the majority of melanomas expressing a mutated BRAF gene at V600E, but is not effective against colon cancers with the same genetic aberration.[41] This has been investigated by screening a panel of colon carcinoma cell lines bearing V600E RAF mutations with a short-hairpin RNA (shRNA) library representing the full complement of 518 human kinases, in the presence or absence of the BRAF inhibitor PLX4032. It was found that shRNA vectors targeting and eliminating EGF receptors converted resistant cells into becoming sensitive to inhibition by the BRAF inhibitor.[42] This effect was duplicated by treating cells with a drug or antibody against the EGF receptor. Thus inhibition of the EGF receptor tyrosine kinase appears to be required to permit sensitivity to this BRAF inhibitor in colorectal cancer cells. Most melanoma cells do not have the active EGF receptors that are seen in typical epithelial cells, and therefore are sensitive to the drug inhibiting BRAF. Clinical trials are testing this important experimental observation in patients with colorectal cancer bearing the V600E BRAF mutation, by adding an EGF receptor inhibitor to a BRAF inhibitor.

The above experiment is one example of many biological studies with cell lines and tumor biopsies that provide explanations for resistance to targeted drugs, involving activation of bypass pathways. For example, MET amplification can lead to resistance against the EGF receptor inhibitor gefitinib by activating ERB-B3.[43] Likewise, the efficacy of MEK inhibitors in basal-subtype breast cancer cells is limited by a feedback loop involving activation of the PI3K pathway by activation of the EGF receptor tyrosine kinase.[44] This suggests that a combination of inhibitors of MEK plus inhibitors of EGF receptors or the PI3K pathway may be effective in this situation.

In summary, combination treatments with agents against two different targets, in order to attack a driver gene and a bypass pathway concurrently, may provide a way to overcome resistance. Many clinical trials are testing this hypothesis.

With the technologies available today, an attractive way to investigate the mechanisms of failure (resistance) after initial response to an experimental targeted agent in a clinical trial is to biopsy the recurrent tumor and use genomic and expression array analysis—in comparison with the original tumor—to determine what new event or events have conferred resistance.

The bypass mechanisms that explain resistance to a targeted drug in a primary tumor may be discovered by direct comparison of genomic aberrations in primary tumor specimens from patients who are sensitive, or resistant, to a drug targeting a genetic aberration that they share. For example, clinical responses occur only in a minority of the colon cancer patients treated with the EGF receptor inhibitors cetuximab or panitumumab. It was found that colon cancers with a mutation in K-RAS were not responsive to these EGF receptor inhibitors.[45] Furthermore, when resistance to these anti-EGF receptor antibodies developed in colon cancer patients who were initially responsive, biopsy of the recurrence showed that a mutation in RAS (either from outgrowth of a minor subpopulation below the limits of detection in the primary tumor, or occurring de novo) accounted for resistance in the majority of patients.[46,47] Unfortunately, an effective inhibitor of K-RAS is not available to administer with the EGF receptor inhibitor. Because nearly 50% of colon cancers have mutations in K-RAS, screening for these mutations provides benefits to the patient by *avoiding* a therapy that will not be beneficial, and to controlling the costs of medical care by avoiding the use of these expensive agents in this clinical situation. Testing for this biomarker is now standard of care for treatment of colon cancer patients.

The complexity of the challenge in identifying genes that can modulate sensitivity and resistance to targeted therapies is exemplified by the many mechanisms of resistance that have been discovered in patients with malignant melanoma who were initially responsive to therapy with vemurafenib against V600E B-RAF, and subsequently relapsed. Six different mechanisms identified in tumor biopsies from these patients are listed in Table 45-2.[48-54] In all cases, confirmatory studies were carried out with cell lines containing the V600E B-RAF mutation, to demonstrate that the proposed

Table 45-2 Mechanisms of Resistance to Vemurafenib Treatment in Patients with V600E B-RAF Malignant Melanoma

Mechanism of Resistance	Reference
1. Mutation in MEK, downstream of B-RAF	48, 49
2. Increased copy number of V600E B-RAF	50
3. Aberrantly spliced, truncated v600E B-RAF	51
4. Upregulation of PDGF receptor B, or N-RAS mutation	52
5. PTEN loss reduces BIM-mediated apoptosis	53
6. Increased IGF-1R levels and activity	54

mechanism was able to confer resistance to the inhibitor. The common theme in this series of observations and in studies of resistance to other targeted therapies is that there are two predominant resistance mechanisms—new aberrations of the targeted gene and activation of bypass pathways.

These data naturally stimulate the formation of hypotheses on how to overcome resistance to drugs that target B-RAF. One approach that was tested recently was the addition of an inhibitor of MEK, administered concurrently with an inhibitor of mutated B-RAF. The rate of complete or partial response with the combination was 76%, as compared with 54% with monotherapy (P = 0.03).[55] Of course the hope is that these responses will be more durable, resulting in substantial prolongation of life—but the results will not be available for a few years.

Although driver genes and genes to which cancer cells are addicted are obvious targets for drug development, there are other genes and pathways that do not cause cancer but are important for the survival and growth of cancer cells. This has generated the concept of "non-oncogene addiction."[56] Examples include gene products involved in DNA damage repair, protein chaperones and heat shock proteins, histone modification, and buffering of reactive oxygen species. Attacking these pathways that support the malignant phenotype, in addition to targeting critical oncogenes, may be a fruitful approach to combination therapy of cancer.

The series of experiments just discussed demonstrate the appropriateness of the term *precision medicine*. This term describes the situation in which a more precise understanding of the various genetic aberrations in a particular patient's cancer, and their interactions with each other and with the surrounding microenvironment, can provide decision support to the treating oncologist—enabling selection of a targeted drug or drugs that are appropriate for that patient's illness. In this chapter, the emphasis has been on genomics as the basis of precision medicine. This is because at the present time, genomic biomarkers are the most useful for drug development and for making clinical decisions. In the future, it is anticipated that biomarkers from at least four other sources will contribute more and more to precision medicine:

- *Expression of genes*. Data are being reported suggesting that a considerable fraction of mutated genes are not expressed. In the case of suppression genes, this is expected, because this is the basis for their impact on the cell's phenotype. For potential oncogenes, however, this prevents the genetic aberrancy from having an impact. Furthermore, the level of expression of a gene—unrelated to the presence of a mutation—may alter cell behavior and phenotype. Again, the EGF receptor provides an example. This receptor is overexpressed (10- to 1000-fold) on a large fraction of epithelial cancers and is likely to create a "non-oncogene addiction" in these cells.[56] Thus an important area of cancer research will involve closely examining the expression of RNA and proteins coded for by aberrantly functioning genes, to assess the importance of their expression levels in identifying a biomarker signature useful for precision cancer care.
- *Epigenetics*. Current technologies and computational methods in this area are not adequate to inform clinical decisions. Many investigators believe that epigenetic changes play a major role in oncogenesis and the malignant phenotype.[57] This is a topic that will likely need to be visited more thoroughly in the future, as advancements are made in knowledge and assay techniques.
- *Immunologic profile*. As discussed in Chapters 50-52, immunological interventions are beginning to affect cancer therapy, leveraging recent gains in understanding the functioning of the human immune system. The patient's immune system is likely to play an important role in controlling malignancy, as was postulated five decades ago. With increased understanding of the role of cytokines derived from the patient's lymphocytes and leukocytes in promoting or inhibiting cancer cell growth, a profile of the patient's immune functions is likely to become a component of the biomarker profile informing precision cancer care.[58]
- *Proteomics*. Evaluation of the functional status of proteins in a patient's cancer (e.g., phosphorylation status) and detection of circulating protein markers derived from cancers (e.g., HCG levels) are promising areas for the clinic and should expand in value as biomarkers, as mass spectrometry techniques and the use of reverse phase protein arrays are developed into more useful clinical tests.[59]

Predicting Drug Efficacy and Toxicity

The other major scientific gap identified in the Report from the President's Council of Advisors on Science and Technology underscored the need for improved ways of predicting at the earliest possible stage of development the efficacy and toxicity of candidate drugs. This requires continued efforts at developing improved models of human cancer in cell culture and animal models.

At the level of cell culture, screening on arrays containing hundreds of human cancer cell lines is providing new data on mechanisms of drug action, on potential synthetic-lethal targets which predict pairs of targeted drugs that may be effective when either alone is not,[60] and on patterns of gene aberrations and gene expression that predict sensitivity or resistance to specific targeted experimental drugs.

At the level of drug-testing systems in animal models, progress has been made on two fronts:

- Growth of primary human tumor specimens in direct xenografts, without an intermediate step of culture on plastic surfaces, has produced models of human cancer in mice that are more closely comparable to primary human cancers.[61]
- GEMMs with inducible promoters on mutated genes permit activation of the aberrant gene in specific organ sites and at specific time points, creating murine models that can more closely mimic human cancers.[21]

Mouse models are discussed in Chapters 8 and 9.

Clinical Trials

The sequencing of clinical trials that is currently used to study new cancer drugs is presented in Chapter 48. There are two advances that may improve the efficiency and effectiveness of trials with experimental cancer therapies. The first is the increased use of adaptive randomization of patients to receive one of two drugs, or one from a panel of drugs. Initially, patients are assigned randomly to receive one or another of the drugs. As results accumulate, patients are assigned preferentially (but not invariably) to drugs that are producing more benefit. Eventually, with accrual of data on additional patients, poorly performing drugs are eliminated and new drugs can be added.[62] This method depends on powerful preset biostatistical tools that track and calculate probabilities of benefit sequentially, as results on each patient are added continuously to the database. The BATTLE Trial in advanced lung cancer, discussed earlier, was one of the first with targeted experimental therapies to use adaptive randomization, and the I-Spy 2 Trial for breast cancer is one of many current examples that is ongoing. This approach[63] is quite different from the standard randomization protocol, in which the number of patients to be studied is predetermined by a calculation of the number needed for statistical significance of the results. Patients are then assigned randomly to one of two or more arms of the trial, and results remain undisclosed until the trial reaches a predetermined point for evaluation. The advantage of adaptive randomization is the capacity to study more experimental agents and reach yes-or-no decisions with fewer patients, which speeds up the process and reduces the number of patients who are receiving a drug that is not going to be beneficial. However, there is concern about the possibility of moving too swiftly and discarding an experimental drug inappropriately because decisions are made on a small number of patients, which bypasses the value of randomizing large numbers in order to stratify for unknown variables that might affect responses.

The other major advance in clinical trial design involves more stringent criteria for selecting patients in the earliest Phase II setting, once the dose and toxicity issues are settled in Phase I. A number of the successful trials described in this chapter enrolled only patients whose cancers had been shown to bear the genetic aberration that the experimental drug was designed to target. It is possible that off-target effects of an experimental drug may make an important contribution to its efficacy. However, the logic of this approach to testing drugs that target the products of a specific aberrant gene is obvious, provided that the experimental drug does indeed work primarily by acting on that target. With this approach, fewer patients will have to be studied to reach statistically valid conclusions, drug approval by the FDA will be achieved in shorter time frames, and patients will receive treatment with a drug that is more likely to be effective. A positive result in a clinical trial performed in this manner validates the genetic aberration tested for in patients' cancers as a useful biomarker. The successes with this approach have led to Phase I/II trials, where biomarker-based enrollment in Phase II on a fixed dose and schedule is a seamless transition from Phase I.

As noted, most cancers are likely to have a number of driver genetic aberrations—a typical estimate is five—and it is not clear which or how many need to be targeted to eliminate the malignant cells. Because most drugs given at maximal tolerated doses only partially block their targets, and because of the redundancies in most signaling and regulatory pathways, it is likely that there are few occasions when a cancer cell is so totally addicted to a particular aberrant gene that a single drug targeting the product of that gene will cause death of the cancer cell. This reasoning, combined with knowledge of reported clinical outcomes data, suggest that optimal anticancer treatment is likely to require administration of drugs in combinations. In the past, combinations were selected based on the efficacy of individual drugs with nonoverlapping toxicities, whereas today a more rational selection of combinations of targeted drugs is based on knowledge of intersecting signaling and regulatory pathways and data on the genomic aberrations in more than one driver gene in a particular cancer.[64,65]

Bringing two or more investigational drugs into clinical trials for use in combinations has been a challenging task, because the FDA required demonstration of the efficacy and safety of each drug alone before a combination could be tested. The FDA has released a new Guidance Document that provides guidelines for exploring combinations more efficiently, in situations where one or both new drugs are unlikely to provide benefit to patients when administered alone.[66]

With the proliferation of data on the genomic and molecular aberrations in many thousands of patients' cancers and data on their responses to both targeted and conventional therapies, we will have new opportunities to learn by retrospectively correlating genomic and clinical data and comparing effectiveness of all available treatment options. The growing fields of health information technology and medical informatics should make this possible.[67,68] Examples of insights that can be gained include discovery of a rare toxicity of a cancer therapy and discovery of an unanticipated association between responsiveness to a drug and a particular signature of genomic aberrations. However, many issues remain to be solved. Perhaps the most daunting is the need for standardized nomenclature and formats for electronic reporting of data, and interoperability between multiple clinical databases from multiple sources. Large health care providers such as Kaiser Permanente have solved many of these problems with sophisticated information systems that process and analyze large amounts of clinical data. There should be a federated system of access to data that protects patient confidentiality, but allows wide access for data mining and analysis as well as hypothesis testing. Another factor that prevents data sharing is the desire of academic institutions, clinical researchers, and pharmaceutical companies to sequester data that they can control because of concerns about protection of intellectual property.

Once analysis of databases and results of research projects on genomic-based cancer treatments have produced results, this information must be gathered and organized in a way that supports clinical decision making. Doctors and patients need analytical tools that enable them to make decisions about cancer therapy that are informed and evidence-based. Only a learning system which gathers and organizes information in ways that are accessible, reliable, and rapid will be useful to the practicing oncologist.[60] This is a challenge for the future.

The implementation of genomics-based personalized cancer care raises a number of ethical issues: confidentiality of information; clarity on the level of certainty about clinical inferences that can be made from the results of tests for biomarkers; and the level of patient counseling appropriate for proper understanding of genomic data. Interpretation of genomic data is rendered difficult by intrinsic errors in the methodology, the high number of apparent aberrations observed in DNA from most cancer cells, the challenge of determining which genetic abnormality is a relevant driver of a patient's cancer, and the heterogeneity within each human cancer that can invalidate predictions based on data from only a single sampling of the tumor. Genomic data are not perfectly predictive, and both physicians and patients must understand and accept this in order to use the data appropriately to improve decisions about cancer therapy.

Table 45-3 Challenges for Personalized Cancer Therapy

1. Unresolved biological and molecular questions:
   - Tumor heterogeneity within a site and between sites
   - Identification of genetic aberrations that "drive" a cancer
   - Influence of tumor microenvironment
2. Complexity of clinical trial design and computational analysis of data
3. Requirement of an integrated process involving many clinical and research disciplines
4. A risk-averse "one at a time" clinical trial environment
5. Need for regulatory harmonization: FDA, CMS, CLIA, etc.
6. Need for decision support tools that supply actionable information to treating oncologists and their patients
7. Ethical concerns, especially related to privacy and control of data
8. Need for proof of value (benefit/costs) in order to justify reimbursements

CLIA, Clinical Laboratory Improvement Amendment; *CMS*, Centers for Medicare and Medicaid Services; *FDA*, U.S. Food and Drug Administration.

Many advances have been made, but many challenges remain to be addressed before personalized, precision treatment based on a more complete knowledge of a patient's cancer at the molecular level becomes the standard of practice. Table 45-3 lists some of these challenges.

Although much can be learned by sampling a patient's cancer for performance of genomic analysis, the procedure of obtaining a biopsy presents risks that must be taken into consideration, and biopsies cannot be performed repeatedly. Noninvasive ways of obtaining actionable information about a patient's cancer are desirable, and two that are being explored are promising. The most advanced noninvasive test for assessing molecular and metabolic properties of cancers involves medical imaging, especially positron emission tomographic (PET) scanning and magnetic resonance imaging (MRI).[69] The measurement of fluorodeoxyglucose (FDG) uptake with PET scanning to detect changes in glucose metabolism and measurement of deoxyfluorothymidine (FLT) uptake to estimate the rate of proliferation can help in the differential diagnosis of an abnormal mass and can provide a rapid demonstration of the effect of a therapy on cancer in a patient. Some very promising progress has been demonstrated in the imaging of gene products and molecular abnormalities in animal cancer models, and this work is in early stages of evaluation in the clinical setting.

The second noninvasive test that holds great promise is the evaluation of circulating cancer cells and circulating fragments of cancer cell DNA that are released into the blood.[70,71] The presence of circulating cancer cells and changes in their number have been shown to be predictive of prognosis and response to therapy in selected situations. DNA fragments are released into the circulation as a natural result of cell death in the body, and cancer cell DNA can be identified by the presence of genomic aberrations known to exist on the basis of prior assays of the patient's tumor. This may enable tracking of a patient's tumor burden by periodic sampling of DNA in the blood, as well as screening for a cancer recurrence or documenting a response to therapy.

It is hoped that these technologies will develop to the point where they can be advanced into standard practice during the next 5 to 10 years.

Conclusion

A striking lesson relevant to clinical oncology that comes from the expansion of research on human cancer during the past decade is the value of genetic and molecular biomarkers for identifying the most useful targets for new drug development, and for screening patients to identify those most likely to bear cancers that will respond to particular targeted therapies.

In parallel, advancements in understanding signaling and regulatory pathways in cells and their interactions in complex systems have enabled identification of targets for therapy that are most likely to be driving the behavior of cancer cells.

What is especially exciting is that knowledge and technology are enabling sophisticated laboratory research and diagnostic molecular assays to be performed on specimens of primary human cancers. The knowledge gained from those studies is more likely to be relevant to development and selection of effective therapies than the data from cell lines and xenografts, which we were forced to depend on for so many years.

Information that guides selection of therapy will continue to expand as the status of critical RNA and protein molecules is assayed on primary tumor specimens and metastases, and further understanding leads to measures of the patient's immune/inflammatory system as well as the influence of the microenvironment around the tumor.

The confluence of these approaches will lead to increasingly effective personalized care and precision medicine, moving us forward toward the ultimate goal of understanding how to give the right therapy to the right patient at the right time.

46 Cancer Therapeutics

Cancer is characterized by the transformation of normal cells to ones characterized by abnormal cellular differentiation, proliferation, invasion, and metastases. The molecular and biochemical bases underlying the transformation process are becoming increasingly clear and provide critically important information for identifying new drug targets.

Normal cell division results from the interaction of growth factors with specific receptors (plasma membrane, cytoplasmic, nuclear). This initiates a signal transduction cascade through receptor tyrosine kinases and downstream serine, threonine kinases that culminates in uncoiling of DNA by the action of histone acetylases and topoisomerases and activation of nuclear transcription factors that produce cell-proliferation and cell-viability molecules. It should not, therefore, be surprising that cancer cells usurp these normal pathways and that our most effective drugs target many of these processes (Figure 46-1).

Malignant cells acquire the ability to replicate indefinitely, invade, and metastasize. This process includes activation of telomerase, detachment from the primary site, anchorage-independent growth, invasion through the basement membrane, and access to the blood or lymphatic vessels, as well as entry to distant organs through adherence to visceral capillaries and the ability to grow in a foreign site, thereby escaping a variety of immunological mechanisms designed to protect the host from "foreign invasion." An understanding of the interactions between cancer cells and the surrounding stroma (malignant tissue) helped identify new targets to interfere with this characteristic of malignancy.

Recent attention has been turned to the existence and role of cancer stem cells. Dick and colleagues first identified cells from acute myeloid leukemia that had stem-cell characteristics[1] based on the identification of a subpopulation of cells with a $CD34^+/CD38^-$ phenotype that possessed the ability to recapitulate the phenotypic heterogeneity of the original leukemia. Subsequently, cancer stem cells (CSCs) or tumor-initiating cells have been found in other leukemias and in most solid tumors.[2] The therapeutic importance of the stem cell model is that it posits that our inability to cure most tumors is due to resistance of CSCs to current chemotherapy and radiation therapy.

In this chapter, we attempt to place cancer chemotherapeutic drugs in a molecular biological context as summarized in Tables 46-1, 46-2, and 46-3.*

Molecular Basis of the Therapeutic Index

Therapeutic index is defined as follows: LD_{50}, or *median lethal dose*, is the dose of drug that causes death in 50% of experimental animals, and ED_{50}, or *median effective dose*, is the dose that produces a specified effect ("response") in 50% of the population under study. The therapeutic index in the clinic compares the dose of a drug that causes untoward toxicities to the dose that produces the desired therapeutic effect.

All drugs have targets, but it is the unique relationship of the target to the disease that can ultimately affect a drug's therapeutic index. Traditional drug targets included DNA (nucleotide bases, enzymes of DNA synthesis, degradation, and repair), microtubules, and growth factor receptors. New targets include mutated, overexpressed, or fused growth factor/oncogene products (EGFR [Her-1], Her-2/neu, ras, bRaf, bcr:abl), immune checkpoint modulators (CTLA4, PD-1), cell surface antigens (CD33, CD22, CD20), anti-apoptotic proteins (bcl-2), cell-cycle regulators (cyclin-dependent kinases), epigenetic targets (histone deacetylases and methyltransferases), metabolic pathways (mTOR, PI3K, AKT) , stem-cell pathways (notch, wnt), and the machinery

*We focus primarily on drugs that have achieved approval from the U.S. Food and Drug Administration (FDA); numerous drugs against new targets are in development, but a comprehensive description is beyond the scope of this chapter.

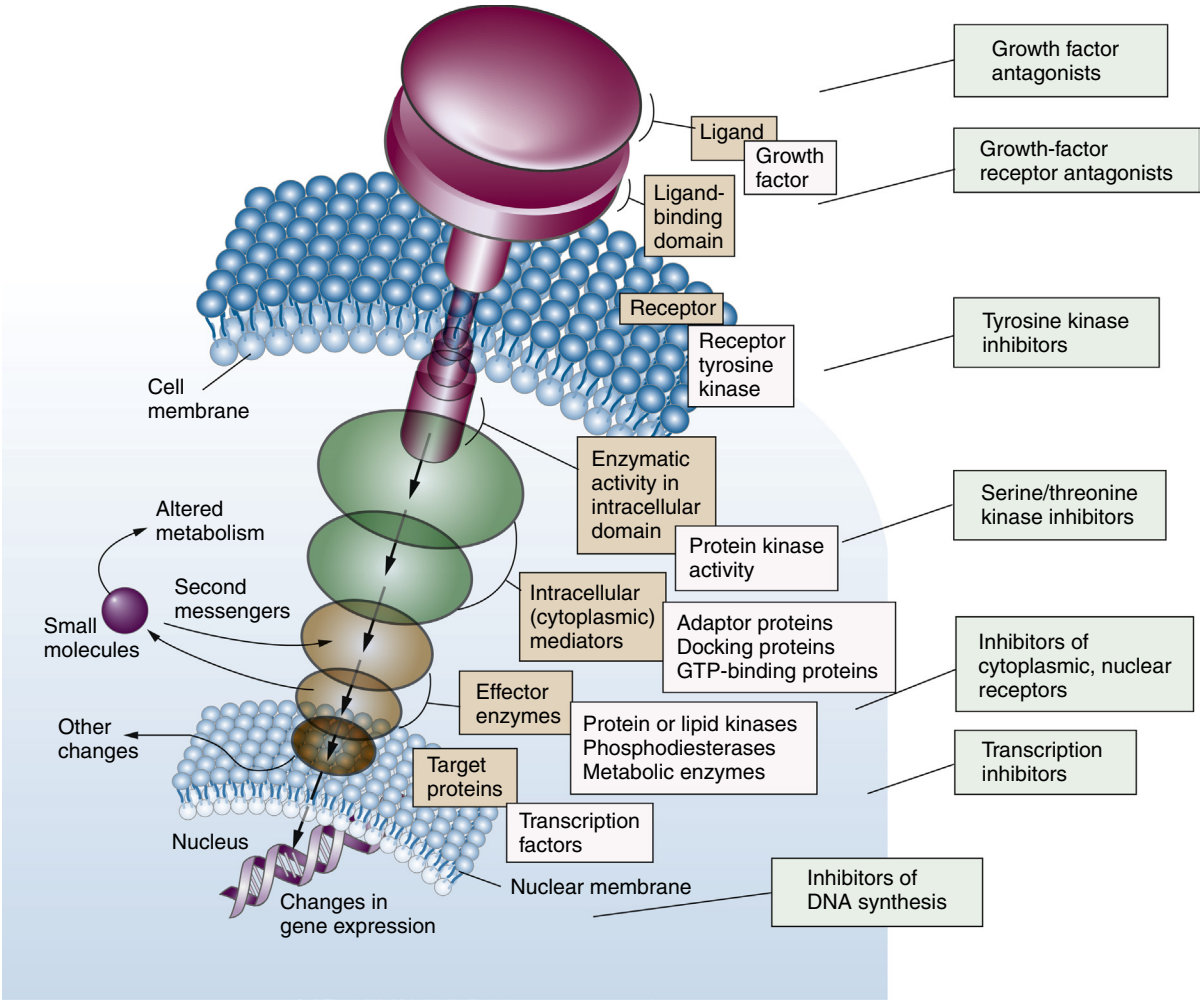

Figure 46-1 Targets for anticancer drugs Anticancer drugs work by interfering with the processes underlying normal cellular physiology. These include receptor-activated signal transduction pathways culminating in transcriptional activation, DNA replication, protein synthesis, and cell division. *(Modified by permission from Macmillan Publishers Ltd: Downward J. The ins and outs of signaling.* Nature. *2001;411:759).*

of protein synthesis (L-asparaginase) and degradation (proteasome). Drugs that affect these newer targets are often referred to as *targeted therapies*, creating the false impression that classic chemotherapeutics do not have targets.

The specificity/selectivity of a drug for a particular target is, in general, proportional to the affinity constant, K_a, more accurately defined for competitive drug target interactions as the K_i, which is the reciprocal of the concentration of drug required to inhibit 50% of the target's activity when controlled for all possible ligand or substrate concentrations. The activity of a drug refers to its effectiveness independent of dose or concentration.

There are several factors that help explain why cancer cells are more sensitive to cancer therapeutic drugs than normal tissues. For any drug, the therapeutic index is related to absorption, uptake, distribution, and metabolism. Differences in tumor vasculature, intratumoral pressure, and drug binding may alter drug uptake in a favorable or unfavorable way. Classically, the therapeutic index of intravenously administered cancer chemotherapy has been thought to be due primarily to cell-cycle kinetics. Many chemotherapeutic agents are more effective against cycling than noncycling cells and are tested under cell culture conditions where cancer cells rapidly proliferate ("log phase"); this a posteriori conclusion was derived from these observations. However, many solid tumors have a relatively long doubling time, yet a therapeutic index remains. Therefore, alternative explanations must exist. One includes differences in energy requirements between normal and malignant cells. For example, whereas normal tissues use oxidative phosphorylation to metabolize glucose, malignant tissues are often dependent on aerobic glycolysis. This is thought to reflect the selection pressure placed on tumor cells to cope with relatively hypoxic and nutrient-deprived conditions. Rather than using the electron transfer chain within the mitochondria to yield 36 mol ATP per mol glucose, cancer cells metabolize glucose via glycolysis, generating a net 2 mol ATP per mol glucose metabolized

Table 46-1 Chemotherapeutic Drug Overview

Target	Examples	Use
Nuclear Receptors		
Estrogen receptor	Tamoxifen, toremifene, raloxifene, fulvestrant	Treatment and prevention of breast cancer
Progesterone receptor	Megestrol acetate	Breast cancer
Retinoid receptor	Retinoic acid	Promyelocytic leukemia
Androgen receptor	Bicalutamide, flutamide, nilutamide, enzalutamide	Prostate cancer
Plasma Membrane Receptors and Tyrosine Kinases		
Her-1 (EGFR)	Gefitinib, erlotinib, cetuximab, panitumumab	Non–small-cell lung; pancreas
Her-2/neu	Trastuzumab, pertuzumab	Breast
Bcr:abl	Imatinib, dasatinib, nilotinib	Chronic myelogenous leukemia
VEGF receptor	Sorafenib, sunitinib	Renal cell
cKit	Imatinib, sorafenib, sunitinib	Gastrointestinal stromal tumor (GIST)
Flt-3	Sorafenib, sunitinib	
Fms	Sunitinib	
Gonadotropin receptors	Abarelix, leuprolide, goserelin	
Growth factors		
Aromatase inhibitors Cyp17A1	Letrozole, anastrozole, exemestane Abiraterone acetate	Breast cancer Prostate cancer
Vascular endothelial growth factor (VEGF)	Bevacizumab	Colorectal cancer
Multiple Kinases		
VEGFR, PDGFR, cKIT, Flt-3, FMS, bRAF, Ret	Sunitinib	Renal; GIST
VEGFR, PDGFR, cRAF, bRAF, Flt-3, Fms	Sorafenib	Renal
Miscellaneous		
CD20 CD25	Rituximab, ibritumomab tiuxetan (Zevalin), tositumomab (Bexxar), ofatumumab Denileukin diftitox	Lymphoid malignancies Cutaneous T-cell lymphoma
CD52 CD30	Alemtuzumab Brentuximab vedotin	Chronic lymphocytic leukemia (CLL) Hodgkin's disease
DNA Synthesis		
Dihydrofolate reductase	Methotrexate, trimetrexate	Breast, lymphocytic leukemia, choriocarcinoma, lymphoma
Thymidylate synthase	5-Fluorouracil, capecitabine, pemetrexed	Colon, breast, mesothelioma
Adenosine deaminase	Pentostatin, cladribine (2CDA)	Hairy-cell leukemia, lymphomas, CLL
DNA Replication		
Nucleic acid bases		
Alkylating agents	Nitrogen mustards (e.g., mechlorethamine, cyclophosphamide, bendamustine)	Leukemia, lymphoma, breast, brain, melanoma, etc.
	Nitrosoureas (e.g., BCNU, temozolomide)	Glioblastoma, anaplastic astrocytoma
	Ethyleneimines (e.g., thiotepa)	Bone marrow transplantation
	Alkyl sulfonates (e.g., busulfan)	Leukemia
	Triazenes (e.g., dacarbazine)	Melanoma
Platinating agents	Cis-, carbo-, oxaliplatin	Lung, head and neck, bladder, germ cell, colorectal

Continued

Table 46-1 Chemotherapeutic Drug Overview—cont'd

Target	Examples	Use
Transcription inhibitors	Actinomycin-D	Wilms' tumor
DNA methylation	5′-Azacytidine, decitabine	Myelodysplastic syndrome
Topoisomerases		
Topoisomerase I	Topotecan, irinotecan	Colorectal, ovary, lung, cervical
Topoisomerase II	Doxorubicin, epirubicin, etoposide, mitoxantrone	Breast, lymphoma, leukemia, lung, ovary, testicular, etc.
Microtubules		
Vinca alkaloids	Vincristine, vinblastine, vinorelbine	Breast, lung, acute lymphocytic leukemia (ALL), bladder, lymphoma, etc.
Taxanes Epothilones	Paclitaxel, docetaxel Ixabepilone	Breast, lung, bladder, ovarian, etc. Breast cancer
Protein Synthesis		
	L-Asparaginase	Childhood ALL, T-cell lymphoma
Protein Degradation		
60S proteasome	Bortezomib, carfilzomib	Multiple myeloma, mantle-cell lymphoma

Table 46-2 Drugs That Alter Nucleic Acid Synthesis and Function

Target	Examples	Use
DNA Synthesis		
Dihydrofolate reductase	Methotrexate, trimetrexate, pemetrexed, pralatrexate	Breast, lymphocytic leukemia, choriocarcinoma, lymphoma, etc.
Thymidylate synthase	5-Fluorouracil, capecitabine, pemetrexed	Colon, breast, mesothelioma, etc.
Adenosine deaminase	Pentostatin, cladribine (2CDA)	Hairy-cell leukemia, lymphomas, CLL
DNA Replication		
Nucleic acid bases		
Alkylating agents	Nitrogen mustards (e.g., mechlorethamine, cyclophosphamide)	Leukemia, lymphoma, breast, brain, melanoma, etc.
	Nitrosoureas (e.g., BCNU)	
	Ethyleneimines (e.g., thiotepa)	
	Alkyl sulfonates (e.g., Busulfan)	
	Triazenes (e.g., dacarbazine, temozolomide)	
Platinating agents	Cis, carbo-, oxaliplatin	Lung, head and neck, bladder, germ cell, colorectal
Transcription inhibitors	Actinomycin-D	Wilms' tumor
DNA methylation	5′-Azacytidine	Myelodysplastic syndrome
Topoisomerases		
Topoisomerase 1	Topotecan, irinotecan	Colorectal, ovary, lung, cervical
Topoisomerase II	Doxorubicin, epirubicin, etoposide, mitoxantrone	Lymphoma, leukemia, lung, ovary, testicular

(the Warburg effect). As a result, cancer cells are metabolically fragile and are unable to cope as readily with cellular damage. This may be particularly relevant for drugs that block the effects of growth factors, because growth factor depletion produces rapid downregulation of nutrient transporters, which would lead to metabolic crisis in cancer cells more rapidly than in normal cellular counterparts.

Another concept is that tumor cells exhibit "oncogene addiction" and that inhibition of one or more of these oncogene products rapidly results in apoptotic cell death in

Table 46-3 Drugs with Other Mechanisms

Target	Examples	Use
Microtubules		
Vinca alkaloids	Vincristine, vinblastine, vinorelbine	Breast, lung, ALL, bladder, lymphoma
Taxanes	Paclitaxel, docetaxel	Breast, lung, bladder, ovarian
Protein Synthesis		
	L-Asparaginase	Childhood ALL, T-cell lymphoma
Protein Degradation		
60S proteasome	Bortezomib	Multiple myeloma, mantle-cell lymphoma

"addicted" cancer cells but not in normal counterparts. Thus, tumor cells that depend on their survival by overexpression of a growth factor receptor (e.g., EGFR) would be more susceptible to inhibitors than are normal cells.

Drugs Affecting Growth Factors and Growth Factor Receptors

Cancer cells usurp the mechanisms of normal cell division, which results from the interaction of growth factors with specific receptors (plasma membrane, cytoplasmic, or nuclear). This initiates a signal transduction cascade culminating in activation of nuclear transcription factors that produce cell-proliferation and cell-viability molecules. Thus, it stands to reason that some of our most effective drugs target growth factors or their receptors (see Table 46-1) and the downstream consequences of this interaction that include activation of protein kinases, replication of DNA, transcription of mRNA, synthesis of new proteins, formation of the mitotic spindle through microtubule polymerization, and creation of interphase daughter cells via microtubule depolymerization (see Table 46-2). In addition, the nutrient requirements of cancer cells create an increased dependence on the uptake of glucose (the basis for positron emission tomography or PET scan) and the ability to sustain energy requirements through frequent alterations in the PI3K/AKT/mTOR pathway and activation of autophagic cell survival (Figure 46-2).

Drugs Affecting Growth Factors

Sex Hormones

Aromatase is an enzyme complex made up of two proteins, aromatase cytochrome P450 (CYP19) and NADPH-cytochrome P450 reductase. Inhibition of aromatase blocks the conversion of androgens (androstenedione) to estrone in peripheral tissues including fat, liver, muscle, and breast without detectable effects on adrenal synthesis of corticosteroids or aldosterone. Following the reports by Santen and colleagues that aminoglutethimide could inhibit the conversion of androstenedione to estradiol,[3] aromatase became an attractive target for new drug development. Three aromatase inhibitors are used in the clinic, including letrozole (Femara), anastrozole (Arimidex), and exemestane (Aromasin). Whereas letrozole and anastrozole are reversible, nonsteroidal inhibitors of aromatase, exemestane is a steroidal derivative of androstenedione that binds irreversibly to the enzyme and targets the protein for degradation. Aromatase inhibitors further deplete circulating estradiol in postmenopausal women and are highly effective in the treatment of breast cancer in the adjuvant and metastatic settings. These well-tolerated medications can produce osteopenia and are often prescribed with a bisphosphonate, calcium, and vitamin D to prevent this complication.

Cyp17A1 is a cytochrome P450 enzyme complex that has both hydroxylase and lyase activity. It catalyzes the hydroxylation of pregnenolone and progesterone to their 17-OH derivatives and the conversion of 17-hydroxyprogesterone and 17-hydroxypregnenolone to DHEA and androstenedione via its lyase activity, leading to the synthesis of androgenic steroids in the gonads, adrenals, fat, and tumor stroma. Abiraterone acetate (Zytiga) is a prodrug of abiraterone, a potent and selective Cyp17 inhibitor shown to increase overall survival in patients with castration-resistant prostate cancer.[4]

Gonadotropin-Releasing Hormones

Drugs that target receptors for gonadotropin-releasing hormones (GnRHs) decrease the production of ovarian or testicular hormones. The most widely used agents (leuprolide, goserelin) are agonists of GnRH receptors that cause an immediate increase in gonadotropins and eventually produce castration levels of sex hormones by the desensitization of GnRH receptors. A newer agent, abarelix (Plenaxis), is a GnRH receptor antagonist that immediately decreases GnRHs without the disadvantage of an initial hormone surge.

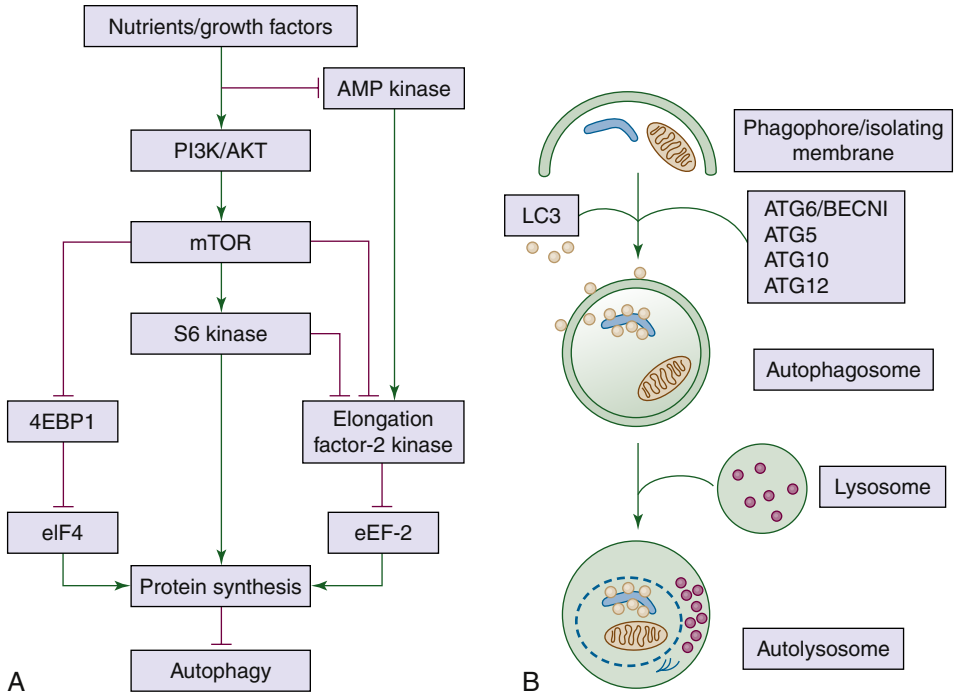

Figure 46-2 Energy regulation through PI3 kinase signaling Cancer cells require exquisite control of energy utilization because of a dependence on aerobic glycolysis to generate ATP. The PI3 kinase pathway serves as an energy sensor with links to self-preservation through autophagic cell survival. **(A)** When there are adequate nutrients, the pathway is activated, protein synthesis is increased, and autophagy is inhibited. In contrast, in the case of nutrient deprivation, protein synthesis is suppressed and autophagy is activated. **(B)** The process of forming the autophagosome in response to nutrient deprivation. *(From Moreau P, Pylypenko H, Grosicki S. Subcutaneous versus intravenous administration of bortezomib in patients with relapsed multiple myeloma: a randomised, phase 3, non-inferiority study.* Lancet Oncol. *2011;12:431-440).*

Vascular Endothelial Growth Factor

The observation by Folkman and colleagues that tumors stimulate blood vessel formation, coupled with the knowledge that angiogenesis is required for tumor growth and metastasis, led to a search for effective inhibitors of this process.[5] Vascular endothelial growth factor (VEGF) is produced by normal and neoplastic cells and regulates angiogenesis. The demonstration by Kim and colleagues[6] that a murine monoclonal antibody against VEGF had preclinical activity led to the development of *bevacizumab*, a human monoclonal antibody that binds to and inhibits VEGF, preventing its interaction with VEGF receptors (Flt-1 and KDR) that are present on the surface of endothelial cells,[7] thus inhibiting endothelial cell proliferation.

Bevacizumab (Avastin) was first approved for first-line treatment of metastatic colorectal cancer in combination with 5-fluorouracil–based chemotherapy and now has several other indications. Its most common side effects include hypertension, thrombosis, and proteinuria, but asthenia, gastrointestinal perforation, wound dehiscence, hemorrhage, and nephrotic syndrome have been reported, as has been a possible increase in congestive heart failure. Recently, a recombinant fusion protein, *ziv-aflibercept* (Zaltrap), referred to as a "VEGF trap," has been developed and approved in combination with FOLFIRI for refractory colorectal cancer. The VEGF trap fuses the extracellular domain of VEGF receptors 1 and 2 with an Fc domain of human IgG1, thereby acting as a soluble receptor for VEGFs.[8]

Drugs Affecting Growth Factor Receptors

Steroid Hormone Receptors

The interaction between steroid hormones and intracellular receptors recruits co-activators and co-repressors to the nuclear transcription complex, leading to transcriptional activation of genes containing specific steroid response elements.

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators (SERMs) bind with high affinity to cytoplasmic and nuclear estrogen receptors, then recruit transcriptional co-activators and co-repressors to the transcription complex, where they bind to estrogen response elements within promoter regions of estrogen-regulated genes. In certain tissues SERMs are antiestrogenic, whereas in others they are estrogenic; this is believed to be due to differential recruitment of co-repressors versus repressors in a specific tissue type. For example, *tamoxifen* (Nolvadex) behaves as an estrogen receptor antagonist in breast tissue, but as an agonist in the uterus, bone, and

liver. As a result, tamoxifen is a highly effective drug for the treatment of breast cancers that express hormone receptors but has the disadvantage of also increasing endometrial proliferation and the risk of uterine cancer. The estrogenic effect of tamoxifen on bone prevents osteopenia, while its estrogenic effects on the liver lower cholesterol and increase the incidence of thrombosis. In contrast, *raloxifene* (Evista) is a SERM that behaves as an antiestrogen in breast, uterus, and liver, but retains estrogenic activity in the bone. Although results with raloxifene were disappointing for the treatment of metastatic breast cancer, it is effective for breast cancer prevention.[9] *Fulvestrant* (Faslodex) is a pure antiestrogen that binds to the estrogen receptor and targets it for ubiquitin-mediated proteasomal degradation.

Enzalutamide (MDV 3100)[1] is a potent and selective androgen receptor antagonist that has recently been shown to increase survival in patients with castration-resistant prostate cancer.[10]

Bexarotene (Targretin) is an analog of vitamin A that binds with high affinity to retinoid "X" receptors. It is approved for use against refractory cutaneous T-cell lymphoma. Its side effects include cheilitis, headache, myalgias, and arthralgias, as well as an increase in liver function tests, hypertriglyceridemia and hypercalcemia, and hypothyroidism.

Drugs that Affect Oncogenic Growth Factor Pathways

Epidermal Growth Factor Receptor Family

Her-2/Neu. The discovery of a transforming element in the DNA of a malignant glial cell line by Weinberg and colleagues led to the identification of HER-2/neu.[11] When Slamon's group observed that HER-2/neu was overexpressed in aggressive breast cancers, a search ensued for a means to inhibit this membrane receptor.[12] The biology of HER-2/neu activation is complex with both putative and proven ligands. Intracellular signaling occurs after receptor activation that leads to hetero- and homodimerization with other members of the EGFR receptor family, including HER-1, HER-3, and HER-4.

Trastuzumab. Trastuzumab (Herceptin) is approved for use alone or in combination with paclitaxel for the treatment of metastatic breast cancers that overexpress HER-2/neu. In the 25% to 30% of patients who respond to treatment, a substantial number survive for long periods of time. Unfortunately, these patients relapse, often in the central nervous system (CNS), probably because of the inability of trastuzumab to cross the blood-brain barrier rather than a predilection of these cells for the CNS. Trastuzumab is also effective in breast cancer patients receiving adjuvant chemotherapy.[13]

Her-1 (*epidermal growth factor receptor [EGFR]*). EGFR is overexpressed in 60% to 80% of colorectal cancers and in many other tumor types. It can be transforming in laboratory models. The demonstration by Mendelsohn and colleagues that antibodies directed against the EGFR extracellular domain inhibited the growth of cancer cells led to the development of several types of EGFR antagonists.[14] Cetuximab (Erbitux) is a humanized mouse monoclonal antibody used in the treatment of *Kras* wild-type colorectal cancer alone or in combination with irinotecan, and more recently in combination with the FOLFOX regimen. Cetuximab has activity in head and neck cancers and is synergistic with radiation in preclinical models. Cetuximab is well tolerated. The major side effects include asthenia and an acneiform rash.

Several drugs have been developed to target the tyrosine kinase domain of the EGFR. For example, gefitinib (Iressa) received accelerated U.S. Food and Drug Administration (FDA) approval for the treatment of refractory non–small-cell lung cancer (NSCLC), but failed to show a survival advantage in larger randomized clinical trials. In contrast, erlotinib (Tarceva), a structurally similar molecule, produced a survival advantage in patients with NSCLC and is approved for use in this group of patients. Two reports demonstrated that gefitinib was particularly active in patients whose tumors harbored activating mutations in the tyrosine kinase catalytic domain of EGFR.[15,16] This alteration was particularly prevalent in nonsmokers, women of Japanese descent, and tumors of bronchoalveolar histology. Erlotinib also received approval in combination with gemcitabine for the treatment of pancreatic cancer. Acneiform rash and diarrhea are the most common side effects of these generally well-tolerated medications.

Bcr:abl. Of all the newer "targeted" therapies, none has been more impressive than imatinib (Gleevec; 4-[(4-methyl-1-piperazinyl)methyl]-*N*-[4-methyl-3-[[4-(3-pyridinyl)-2-pyrimidinyl]amino]-phenyl]benzamide methanesulfonate) for use in chronic myelogenous leukemia, gastrointestinal stromal tumors, and a chronic myeloproliferative disease characterized by eosinophilia.[17] Imatinib targets the tyrosine kinase domain of the fusion protein formed by the reciprocal translocation involving the long arms of chromosomes 9 and 22 [t(9;22)(q34.1;q11.21)], referred to as the *Philadelphia chromosome* (Figure 46-3). Imatinib is also active against the tyrosine kinase activity of c-kit and the platelet-derived growth factor receptor (PDGFR), the former accounting for its activity against GIST and the latter for its activity against the chronic myeloproliferative syndrome. *Denileukin diftitox*, or *DAB389IL-2 (ONTAK)*, is a fusion protein consisting of cytotoxic A and B chain fragments (Met[1]-Thr^{387}-His) of diphtheria toxin fused to interleukin-2 (IL-2).[18] It is approved for the treatment of persistent or recurrent cutaneous T-cell lymphoma expressing the CD25 component of

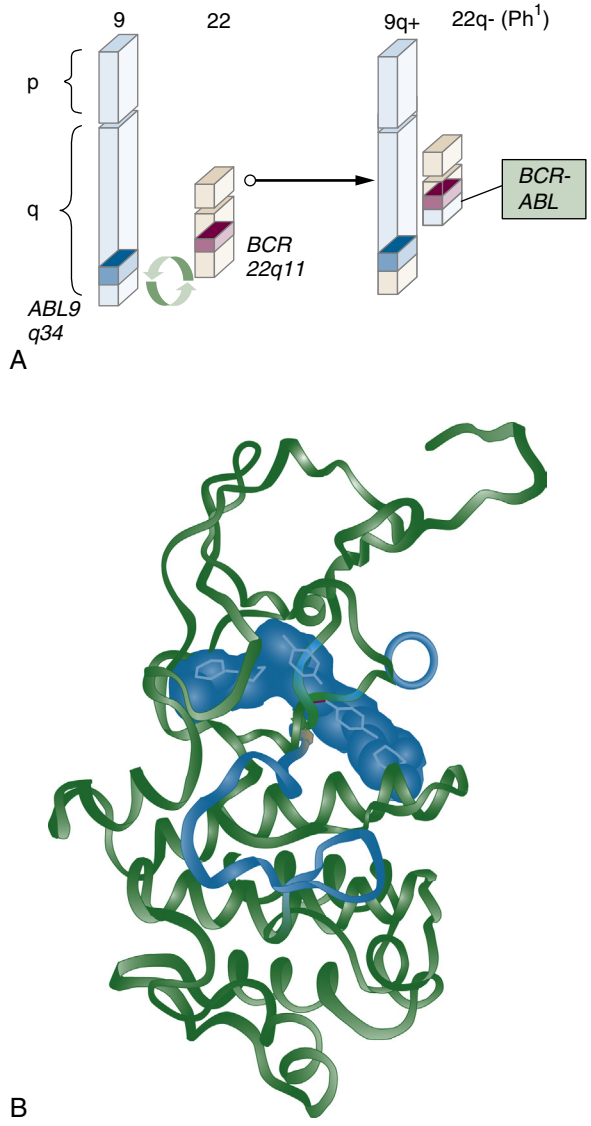

Figure 46-3 Genetic and structural changes underlying the activity of imatinib **(A)** The 9:22 chromosomal translocation that produces the bcr/abl oncogenic tyrosine kinase. **(B)** Ribbon drawing of the structure of the Abl kinase domain *(green)* in complex with imatinib (Gleevec). The activation loops and the van der Waals surfaces corresponding to the inhibitor are colored. Helix α C and the interlobe connector are shown in *dark green.* *(From Kantarjian H, Sawyers C, Hochhaus A, et al. Hematologic and cytogenetic responses to imatinib mesylate in chronic myelogenous leukemia.* N Engl J Med. *2002;346:645-652).*

the IL-2 receptor. Denileukin thereby delivers this potent exotoxin, which ADP ribosylates elongation factor-2 and terminates protein synthesis. Side effects include flulike symptoms, acute hypersensitivity reactions, nausea and vomiting, vascular leak syndrome, infections, and transient elevation of liver function tests.

bRaf. Sequencing of the melanoma genome revealed a *bRaf* mutation in approximately 60% that replaced a valine with a negatively charged glutamic acid, creating constitutive activation of the enzyme. *Vemurafenib* (Zelboraf) selectively inhibits the mutant form of the kinase. In a 55-patient dose escalation trial, Flaherty and co-workers[19] demonstrated that among 32 patients with the bRaf(V600E) mutation, 24 had PRs and 2 had CRs for an 81% objective response rate (ORR). A notable adverse event was the appearance of cutaneous squamous-cell carcinomas, mostly of the low-grade keratoacanthoma variety. Resistance appears to emerge rapidly because of NRAS mutation, PDGFR upregulation, and overexpression of the map kinase COT, which suggests ways of further improving results in the future.

Drugs that target multiple signal transduction enzymes. Signaling in malignant tissues is often complex. Therefore drugs that target a single pathway may not be as effective as those that have multiple targets. Protein kinase inhibitors are rarely completely selective for a given target, given the similarities in the catalytic domains of these enzymes. Two drugs have recently been approved that have relatively permissive activities (i.e., they inhibit multiple kinases including those that phosphorylate tyrosines, serines, or threonines in substrate proteins). For example, *sorafenib* (Nexavar) was approved for the treatment of renal-cell carcinoma and was initially believed to be specific for bRaf kinase, a serine/threonine kinase downstream of Ras that is mutated in melanoma and activated in several other malignancies. However, sorafenib is also a potent inhibitor of the VEGF receptor tyrosine kinases VEGFR-2 and -3, FLT-3, Kit, and PDGFR-β.[20] Similarly, *sunitinib* (Sutent), which was recently approved for treatment of renal-cell carcinoma and for GIST patients who have progressed following treatment with imatinib, can also inhibit multiple kinases including PDGFR-α and -β, VEGFR-1, -2, and -3, Kit, FLT-3, CSF-1, and RET.[21] These drugs possess a different spectrum of untoward side effects from that of classical cytotoxic agents. For example, hypertension, bleeding (including tumor hemorrhage), diarrhea, mucositis, skin rash, and taste abnormalities occur more frequently than for placebo. Sorafenib was associated with hand-foot syndrome (palmer plantar dysesthesia), and both drugs appear to increase cardiac events. Patients receiving sunitinib were more likely to have decreases in their left ventricular ejection fraction (10%) than placebo-treated controls (1%), and those on sorafenib were more likely to experience cardiac ischemic events (2.9%) than controls (0.4%).

Crizotinib (Xalkori). Fewer than 6% of NSCLCs harbor a fusion of EML4 with ALK. Crizotinib, an MTKi originally developed for the inhibition of cMET, also is active against ALK. This led to the rapid demonstration that crizotinib was highly effective for this subset of patients who rarely harbor *ras* or *EGFR* abnormalities.[22] In a disease with a historical response rate of about 10%, they observed a response rate to crizotinib of 57% and a disease control rate of 90%. ALK-positive patients tend to be younger, light or never smokers, and have a histology

characterized by abundant mucin production and the presence of signet ring cells.

Drugs That Target Cancer Stem Cells

Like normal marrow, skin and colon stem cells, CSCs are relatively resistant to chemotherapy and radiation. Mechanisms of resistance include an increase in drug efflux pumps, an increase in DNA repair capacity, and aberrant or overexpression of key signaling pathways such as hedgehog and notch. *Vismodegib* (Erivedge), an inhibitor of hedgehog signaling, has been found useful to treat basal-cell carcinoma, a malignancy characterized by upregulation of this pathway.[23] Inhibitors of the notch pathway are also being tested in the clinic, in particular when upregulation of this pathway can be found, as in T-cell leukemia.

Drugs That Target the Immune System

The observation that melanoma can be immunogenic, as manifested by spontaneous regression and vitiligo, focused attention on directing an immune response against this disease. The pioneering work of Rosenberg and colleagues demonstrating that activation of cytotoxic T cells by interleukin-2 could produce dramatic responses[24] led to the approval of *aldesleukin* (Proleukin) for the treatment of melanoma and renal-cell carcinoma.

CTLA4. Allison and colleagues hypothesized that inhibiting the function of immune inhibitory Treg cells would be an effective treatment for patients with advanced melanoma. Hodi and co-workers randomized 676 patients who were progressing on therapy for metastatic disease to *ipilimumab* (Yervoy), a monoclonal antibody targeting CTLA, alone or in combination with the gp100 protein and measured overall survival (OS) as the primary endpoint. Unlike most other therapies, ipilimumab significantly improved OS and ORR.[25] This result, however, came at the cost of autoimmune reactivity in the skin, gastrointestinal tract, and endocrine system and rare drug-related deaths (7 of 540). As physicians have gained experience with this form of treatment and learned how to manage these untoward effects, the safety profile is improving.

Programmed death 1[2] (PD-1). PD-1 is a cell surface receptor on T cells that functions to dampen immune response to certain antigens. Recent evidence suggests that targeting this receptor with an anti–PD-1 antibody (BMS-936558) can restore immune reactivity, resulting in tumor responses in melanoma, NSCLC, and renal-cell carcinoma.[26] Serious drug-related adverse events occurred in approximately 14% of patients.

Drugs That Alter Nucleic Acid Synthesis and Function

Growth factor/growth factor receptor interactions activate signal transduction cascades that initiate DNA synthesis through transcriptional activation of cell proliferation genes, culminating in DNA replication and cell division. A good example is phosphorylation of the retinoblastoma protein (Rb) by CDK4 and CDK6 followed by CDK2. This releases a family of bound transcription factors, E2F(s), which activate genes critical for progression into S phase and are overexpressed in malignancies (e.g., thymidylate synthase, dihydrofolate reductase). For DNA to then be transcribed, it must be made accessible to transcription factors. This is accomplished by releasing DNA from histone packaging via histone acetylases and unwinding of the double helical structure via the action of helicases and topoisomerases. Therefore, it is not surprising that some of our most effective chemotherapeutic drugs target these downstream events, including DNA synthesis, transcription, topoisomerase, and histone deacetylase and methylase activities.

Inhibitors of Nucleic Acid Synthesis

Dihydrofolate reductase (DHFR), the enzyme that replenishes reduced folate pools, was one of the earliest targets for cancer chemotherapy drugs that included *aminopterin* and *methotrexate*. By inhibiting DHFR, methotrexate and its polyglutamated derivatives deplete reduced folates and thereby block the synthesis of thymidylate and de novo purine synthesis. Similarly, targeting thymidylate synthase (TS) to interfere with DNA synthesis led to the development of 5-fluorouracil and 5-fluorodeoxyridine; these drugs remain critically important in the modern oncologist's armamentarium.

Pralatrexate (Folotyn) is a second-generation antifolate that also targets dihydrofolate reductase.[27] Compared to methotrexate, this compound is transported more efficiently into tumor cells via the reduced folate carrier and has better retention because it is a better substrate for polyglutamate synthetase, the enzyme that adds glutamates to reduced folates and folate analogs. In patients with relapsed or refractory peripheral T-cell lymphoma, a Phase II study showed a 29% response rate and duration of response of 10.1 months. Because patients with this disease have limited treatment options, it was approved by the FDA in 2009. It has subsequently been shown to be effective in patients with refractory

or relapsed cutaneous T-cell lymphoma, with response rates of 30% to 40%. The dose-limiting toxicity to this drug is stomatitis rather than marrow suppression. Pretreatment of patients with folic acid and vitamin B_{12} can ameliorate this toxicity, presumably without affecting antitumor effects.

Pemetrexed (Alimta) is a unique antifol containing a 6-5 fused pyrrolo[2,3,-*d*]pyrimidine nucleus that inhibits thymidylate synthase, glycinamide ribonucleotide formyltransferase (GARFT), and dihydrofolate reductase, folate-dependent enzymes involved in the synthesis of thymidine and purine nucleotides. Like methotrexate, pemetrexed is transported into cells by the reduced folate carrier and membrane folate-binding proteins, where it is metabolized to polyglutamates by folylpoly-gamma-glutamate synthetase. Polyglutamated forms are retained intracellularly and have greater affinity for TS and GARFT than pemetrexed monoglutamate. Pemetrexed also inhibits DHFR. Therefore, this drug interrupts de novo synthesis of thymidine and purine nucleosides.[28] Pemetrexed is approved for the treatment of mesothelioma and NSCLC. Pretreatment with folic acid and vitamin B is now used to ameliorate the most frequent side effects, including bone marrow suppression, fatigue, and skin rash.

Capecitabine (Xeloda) is an orally administered carbamate derivative of 5′-deoxy-5-fluorouridine that acts as a prodrug of 5-FU.[29] It is approved for use as a single agent in metastatic breast cancer that is resistant to anthracyclines and taxanes and in combination with docetaxel for metastatic breast cancer after relapse from anthracyclines. It is also approved as a single agent in the first-line treatment of metastatic colorectal cancer. Capecitabine is converted to 5′-deoxy-5-fluorocytidine (DFCR) by carboxylesterases in the liver. DFCR is then converted to 5′-deoxy-5-fluorouridine (DFUR) by cytidine deaminase in the liver and tumor tissue. DFUR is then converted to 5-FU by thymidine phosphorylase. The therapeutic index of capecitabine may be based on an increased activity of thymidine phosphorylase in tumor compared to normal tissues; therefore, capecitabine may have additional selectivity over 5-FU, although this has not been rigorously demonstrated in the clinic. Its side effects—neutropenia, diarrhea, stomatitis, and palmar-plantar dysesthesia (hand-foot syndrome)—are similar to those seen when 5-FU is given by continuous intravenous infusion.

Gemcitabine (Gemzar) is the 2′-deoxy-2′,2′-difluorocytidine analog of deoxycytidine, which was selected for development because of its activity against murine solid tumors.[30] It is approved for the treatment of recurrent pancreatic cancer and for front-line treatment of inoperable, locally advanced, or recurrent/metastatic NSCLC as well as breast and ovarian cancer.

Gemcitabine inhibits DNA synthesis by intracellular conversion by deoxycytidine kinase to the active diphosphate (dFdCDP) and triphosphate (dFdCTP) nucleosides that lead to competitive inhibition of DNA polymerase. In addition, gemcitabine diphosphate inhibits ribonucleotide reductase, thereby blocking the synthesis of deoxynucleoside triphosphates for DNA synthesis. Gemcitabine triphosphate also competes with dCTP for incorporation into DNA. The reduction in the intracellular concentration of dCTP (by the action of the diphosphate) enhances the incorporation of gemcitabine triphosphate into DNA (self-potentiation). Side effects include myelosuppression, nausea, vomiting, transaminitis, diarrhea, stomatitis, proteinuria, hematuria, fever, maculopapular rash, peripheral edema, and flu-like symptoms.

Clofarabine (Clolar) is a purine nucleoside antimetabolite approved for treating relapsed or refractory acute lymphocytic leukemia (ALL) in children after at least two other types of treatments have failed.[31] Efficacy and safety were demonstrated in a single multicenter trial in patients aged 2 to 19. Six patients (12%) achieved a complete remission (CR), 4 patients (8%) achieved a complete remission without total platelet recovery, and 5 patients (10%) achieved a partial response. Of the 15 responding patients, 6 had post-clofarabine bone marrow transplantation. The principal clofarabine toxicities were nausea, vomiting, and marrow suppression with febrile neutropenia. Clofarabine can produce systemic inflammatory response syndrome/capillary leak syndrome, manifested by the rapid development of tachypnea, tachycardia, hypotension, shock, and multiorgan failure. It can also cause left ventricular systolic dysfunction and tachycardia.

Inhibitors of DNA Topoisomerase

Topoisomerases correct the altered DNA topology that occurs during DNA replication and transcription by inflicting transient single-strand (topoisomerase I) or double-strand (topoisomerase II) breaks in DNA. Several natural-product antineoplastic drugs inhibit topoisomerase I or topoisomerase II. The effect of drugs on topoisomerases is different from that on most other enzyme inhibitors (i.e., they "poison" the enzymes by inhibiting religation of the DNA nicks produced during topoisomerase catalysis, thereby locking the enzyme in the "on" or catalytic conformation).[32]

Topoisomerase activity is increased during S phase, and cancer cells appear to have greater topoisomerase activity than their normal counterparts. Thus topoisomerase-targeting drugs inflict greater drug-induced DNA damage and cell death on cancer cells than on normal cells. Differences in the processing of topoisomerase-mediated DNA damage by malignant versus normal cells may also be important in the therapeutic index of these drugs.

Currently approved topoisomerase II inhibitors such as doxorubicin, daunomycin, mitoxantrone, etoposide, and

teniposide are part of many combination chemotherapy regimens and form the basis for some of our earliest curative regimens (e.g., non-Hodgkin lymphoma [doxorubicin], acute myelogenous leukemia [daunorubicin], and germ-cell malignancies [etoposide]). Additional topoisomerase II formulations include liposomal doxorubicin (Doxil), originally approved in 1995 for Kaposi sarcoma (Doxil is now approved for relapsed ovarian cancer) and *epirubicin* (Ellence), an anthracycline that is approved as a component of adjuvant therapy for node-positive breast cancer.

Currently approved topoisomerase I inhibitors include the camptothecin derivatives topotecan and irinotecan. Camptothecin was identified in the early 1960s by Wani and Wall as a potent anticancer alkaloid present in extracts from *Camptotheca acuminata* (the Chinese yew tree).[33] The sodium salt entered clinical trials in the 1970s but was discontinued because of severe and unpredictable toxicities. The appreciation of its unique mechanism of action by the Liu laboratory[32] and the pH dependence of lactone ring cleavage led to the development of stabler and safer derivatives. *Topotecan* (Hycamtin), a semisynthetic analog of camptothecin produced by adding a basic side chain at the 9-position of the A-ring of 10-hydroxycamptothecin, has increased water solubility without requiring hydrolysis of the lactone (E-ring). Topotecan was the first topoisomerase I inhibitor approved for clinical use and is indicated for refractory ovarian cancer and "sensitive" small-cell lung cancer after first-line chemotherapy. Its major untoward side effects include myelosuppression, fatigue, moderate nausea and vomiting, diarrhea, and alopecia.

Irinotecan (Camptosar; CPT-1) is another semisynthetic analog of camptothecin approved in 1996 for the treatment of colorectal cancer refractory to 5-FU. It is a prodrug that is converted to the active compound (SN-38) by carboxylesterases, which are present at relatively high concentrations in the intestine. Indications now include first-line treatment in combination with 5-FU and leucovorin for metastatic colon or rectal cancer and for colorectal cancer that has progressed or reoccurred following initial treatment with 5-FU. Its myeloid and gastrointestinal toxicities are enhanced when given in combination with 5-FU and leucovorin. Patients with Gilbert's disease or other polymorphisms in the UGT1A1 glucuronyl transferase have an increased risk of toxicity.[34] The combination of irinotecan and 5-FU/LV was approved in combination with bevacizumab for first-line treatment of metastatic colorectal cancer.

Alkylating Agents

DNA replication requires that the bases be accessible for Watson-Crick pairing. This normal biochemistry is interrupted by the alkylating agents.[35] The work of Alfred Gilman and Louis Goodman and their colleagues at Yale University demonstrated that nitrogen mustard could abolish lymphomas in experimental animals and had chemotherapeutic effects in man. These studies, carried out during World War II, were the start of cancer chemotherapy. The classes of alkylating agents include the nitrogen mustards (e.g., mechlorethamine, cyclophosphamide, bendamustine), nitrosoureas (e.g., BCNU), ethyleneimines (e.g., thiotepa), alkyl sulfonates (e.g., busulfan), and the triazines (e.g., dacarbazine, temozolomide).

Temozolomide (Temodar) is the 3-methyl derivative of mitozolomide, which was discovered when screening a series of 1,2,4-triazenes and triazinones synthesized in the 1960s and 1970s.[36] Mitozolomide was the most promising compound, but it had severe and unpredictable side effects. Temozolomide, like DTIC, methylates N-7 and O-6 of guanine to produce the cytotoxic lesion. Temozolomide is approved for the treatment of adult patients with refractory anaplastic astrocytoma (disease progression after nitrosourea or procarbazine) and as adjuvant treatment when given with radiation to patients with glioblastoma multiforme. The most common side effects are lymphocytopenia, transaminitis, nausea and vomiting, hyperglycemia, anemia, and thrombocytopenia.

Bendamustine (Treanda) was used extensively to treat lymphoma in the 1980s in East Germany, but only became available in the United States in 1990.[37] It was approved by the FDA in 2008 for the treatment of CLL and indolent B-cell non-Hodgkin lymphoma that progressed during or within 6 months of treatment with rituximab or a rituximab-containing regimen. It acts as an alkylating agent causing intrastrand and interstrand crosslinks between DNA bases. The role of the purine ring in the molecule is not clear. It is usually used in combination with rituximab for the treatment of CLL and lymphoma. Common adverse reactions include nausea, fatigue, vomiting, diarrhea, fever, constipation, loss of appetite, cough, headache, unintentional weight loss, difficulty breathing, rashes, and stomatitis, as well as immunosuppression, anemia, and low platelet counts.

Platinating Agents

The therapeutic properties of cisplatin were deduced from studies of bacterial motility in electric currents, where bacterial cell death was observed adjacent to platinum electrodes.[38] Platinating agents consist of platinum complexed with ligands that are displaced by nucleophilic attack to produce inter- and intrastrand DNA adducts. Currently approved platinating agents include cisplatin, carboplatin, and oxaliplatin, which differ in their spectrum of activity and untoward side effects. For example, cisplatin is active

against lung cancer, head and neck cancer, and in combination with vinblastine and bleomycin led to the first reliable cures of testicular cancer. Cisplatin is highly emetogenic and is a potent oto- and nephrotoxin. In contrast, carboplatin appears to be less active than cisplatin against tumors of the head and neck and perhaps NSCLC. It is less emetogenic and nephrotoxic than cisplatin, but more myelotoxic. *Oxaliplatin* (Eloxatin; *trans*-l-diaminocyclohexane oxalatoplatinum) is a divalent coordination complex of platinum consisting of an oxalato group and a 1,2-diaminocylohexane (DACH) ligand. This third-generation platinum derivative is more active than cisplatin against colon cancer. Unlike cisplatin or carboplatin, renal dysfunction, ototoxicity, and alopecia are uncommon. The dose-limiting toxicity is peripheral neuropathy, which can be acute (lasting less than 14 days) or persistent (14 days or greater); an acute syndrome of pharyngolaryngeal dysesthesia can be exacerbated by exposure to cold (temperature, objects, or liquids). Oxaliplatin is approved for the treatment of colorectal cancer in either the adjuvant or metastatic settings. The activity of oxaliplatin is dependent on the formation of intrastrand (Pt)-DNA adducts/crosslinks, similar to that of other Pt compounds. DNA crosslinks inhibit replication and transcription and activate apoptosis. Oxaliplatin has been reported to also downregulate TS and increase sensitivity to fluoropyrimidines.[39] Oxaliplatin forms 2- to 10-fold fewer Pt-DNA adducts than cisplatin at equimolar and equitoxic concentrations, suggesting that these adducts may be more cytotoxic or that alternative mechanisms of action exist. DACH-Pt-DNA adducts formed by oxaliplatin are bulkier and more hydrophobic than *cis*-diamine-Pt-DNA adducts and may have greater inhibitory effects on DNA repair. DNA mismatch repair complexes do not recognize DACH-Pt-DNA adducts.

Epigenetic Modulators

The modification of DNA sequences by methylation and acetylation provides a remarkably diverse and powerful control over gene expression. The work of Peter Jones, Steve Baylin, and many others highlighted the types of epigenetic modifications that appear to be part of malignant transformation.[40] Furthermore, drugs that alter these epigenetic "marks" through enzyme inhibition of histone methyltransferases, such as *decitabine* (Dacogen) and *azacitidine* (Vidaza), or histone deacetylases, such as *suberoylanilide hydroxamic acid* (SAHA; vorinostat, Zolinza) and romidepsin, have had some success in the clinic.

Romidepsin. Romidepsin, isolated from a culture of *Chromobacterium violaceum*, was found to have cytotoxic effects against several human cancer cell lines in vitro and against xenografts. It was subsequently found to inhibit histone deacetylase.[41] Romidepsin acts as a prodrug, with the disulfide bond undergoing reduction within the cell to release a zinc-binding thiol. The thiol reversibly interacts with a zinc atom in the binding pocket of Zn-dependent histone deacetylase to block its activity. The FDA approved romidepsin for treatment of peripheral T-cell lymphoma (PTCL) in 2011 based on a Phase II study that showed a 25% response rate with 15% of patients achieving a CR.[40] The median duration of response was 17 months. The most common side effects were nausea and vomiting, fatigue, infection, loss of appetite, and anemia, thrombocytopenia, and leukopenia.

Vorinostat (SAHA, suberoylanilide hydroxamic acid) is a potent histone deacetylase inhibitor approved by the FDA for treatment of refractory cutaneous T-cell lymphoma based on a large Phase II study.[42] Response and duration of responses were similar to romidepsin. Side effects include fatigue, diarrhea, nausea, hyperglycemia, and thrombocytopenia.

Drugs that Affect the Mitotic Apparatus

Vinca Alkaloids, Taxanes, and Epothilones

Microtubules are essential for normal cellular function. They form the mitotic spindle, maintain cell shape, organize the location of organelles, mediate intracellular transport and secretion, and neurotransmission as well as axonemal flow and cell motility. Microtubules are composed of α- and β-tubulin dimers organized in bundles of 13 protofilaments that form hollow cylinders. The protofilaments are aligned with the same polarity. The (+) or fast-growing end moves outward from the nucleus to the plasma membrane, whereas the (−) or slow-growing end marks the site of nucleation of the microtubule, which often begins in the centrosome. Time-lapse microscopy has demonstrated that microtubules grow in spurts or may disappear altogether. This process, termed *dynamic equilibrium*, is an essential feature of microtubule physiology. For microtubules to elongate they require the addition of both α- and β-tubulin bound to GTP. Once bound to GTP, β-tubulin forms a GTP cap at the elongating end. Rapid microtubule growth requires bound GTP to increase the affinity for other tubulin molecules. During depolymerization, GTP is hydrolyzed more rapidly than it can be added, resulting in weakening of the bonds that hold the tubulin molecules together.

Antimitotic drugs act by interfering with the normal dynamic equilibrium of microtubules, thereby disrupting the function of the mitotic apparatus. In addition, by affecting microtubules in interphase cells, these drugs inhibit cell motility and normal subcellular organization.

Drugs Affecting Microtubule Polymerization

Paclitaxel (Taxol) was isolated in 1971 by Wani and Wall as an active moiety from the bark of the pacific yew, *Taxus brevifolius*.[43] The taxanes are large alkaloid esters consisting of a taxane ring linked to a four-member oxetan ring at positions C-4 and C-5. Docetaxel (Taxotere), a semisynthetic derivative produced from 10-deacetylbaccatin III, is more water soluble and more potent in vitro. Initially, the difficulties encountered in formulating this insoluble compound and its toxicities in patients diminished enthusiasm for developing this new agent. However, interest in paclitaxel was renewed when the Horowitz laboratory identified its unique mechanism of action (i.e., stabilization of polymerized microtubules[44]). Paclitaxel and docetaxel share broad-spectrum antitumor activity including breast, lung, ovarian, and bladder cancers. Both have effects against lymphoid malignancies. Nab-paclitaxel (Abraxane) is a derivatized formulation of paclitaxel bound to albumin nanoparticles, allowing the drug to be administered at a higher maximum tolerated dose and without Cremophor-El, thereby eliminating the need for extensive premedication. The albumin moiety may help target this agent to tumors expressing SPARC, the albumin receptor.[45]

Taxanes preferentially bind to the N-terminal 31 amino acids of the β-subunit of tubulin oligomers or polymers and inhibit microtubule depolymerization. At nanomolar concentrations, the taxanes produce a mitotic block without increasing microtubule polymer mass. At stoichiometric concentrations (1 M drug per 1 M tubulin dimer), taxanes polymerize and stabilize microtubules in the absence of GTP or microtubule-associated proteins (MAPs); these microtubules are resistant to depolymerization by calcium or low temperature.

The taxanes have broad-spectrum anticancer activity. They are used predominantly in the treatment of solid tumors (ovarian, breast, lung, bladder, head, and neck). Although docetaxel is more potent than paclitaxel, there is little direct evidence that it is more effective. The combination of docetaxel with estramustine or prednisone prolongs survival of patients with hormone-refractory prostate cancer.[46] Preclinical studies demonstrated that unlike most chemotherapeutic agents, taxanes are more active against cancer cells harboring p53 mutations; this may help explain their widespread activity and therapeutic index.[47] Both paclitaxel and docetaxel produce peripheral neuropathy, dose-limiting bone marrow suppression, and alopecia. Nausea, vomiting, and diarrhea occur with both drugs but are rarely severe. Docetaxel can cause vascular permeability (peripheral edema, pleural effusions, and ascites). Fluid retention occurs at cumulative doses above 400 mg/m^2 and may be decreased by lower single doses (less than 60 to 75 mg/m^2) or premedication with dexamethasone. Docetaxel also produces skin toxicities including an erythematous maculopapular rash of the forearms and hands. Both paclitaxel and docetaxel cause type I hypersensitivity reactions characterized by flushing, bronchospasm, dyspnea, and hypotension.

Ixabepilone (Ixempra) is a member of the epothilone family of natural product macrolides initially discovered as cytotoxic metabolites from the myxobacterium *Sorangium cellulosum*. They have a similar mechanism of action to the taxanes and compete for a binding site on polymerized microtubules.[48]

Drugs Affecting Microtubule Depolymerization

The vinca alkaloids were identified as extracts from the pink periwinkle plant (*Catharanthus roseus* G. Don.) that produced granulocytopenia in rats. This observation led to the isolation of four active alkaloids, of which two, vincristine and vinblastine, became active therapeutic agents. Today, this class also includes vinorelbine and vindesine.

The vinca alkaloids are large symmetrical molecules consisting of a dihydroindole nucleus (vindoline) connected to an indole nucleus (catharanthine) by a methylene bridge. Vincristine and vinblastine differ by a single R1 substituent, whereas vinblastine and vindesine differ in the R2 and R3 positions; vinorelbine has a modification of the catharanthine ring.

The mechanism of action of these drugs is concentration related. At substoichiometric concentrations, they bind to high-affinity sites at the ends of microtubules (K_a 5.3 × 10^{-5} M) and prevent microtubule polymerization. At higher concentrations, vincas bind to low-affinity, high-capacity sites (K_a 3-4 × 10^{-3} M) and lead to the disintegration of formed microtubules.

Despite structural similarities, the spectrum of activity and toxicities of the vinca alkaloids are different. For example, vincristine is highly effective against non-Hodgkin lymphoma, Hodgkin's disease, and pediatric solid tumors, yet vincristine has little activity against adult solid tumors. In contrast, vinorelbine is active against breast and lung cancer. Vinblastine is most frequently used in the treatment of testicular cancer and non-Hodgkin lymphoma and is an active agent in the treatment of breast cancer. Vinca alkaloids are potent inhibitors of angiogenesis, which may contribute to their activity.[49] Major toxicities include dose-limiting myelosuppression and neurotoxicity. Vinblastine and vinorelbine produce far greater neutropenia than vincristine, with nadirs occurring at 4 to 10 days with recovery seen in most patients by 7 to 21 days. All three agents cause mild alopecia and are severe vesicants. Vinorelbine may cause chest pain and other deep-seated pain of unspecified origin. Respiratory reactions include acute bronchospasm and subacute cough;

dyspnea and pulmonary infiltrates have also been reported and appear responsive to steroids. The most frequent neurotoxicities are numbness and tingling of the extremities, loss of deep tendon reflexes, and distal muscle weakness. Although the sensory changes are bothersome, they usually reverse over time and may not require discontinuation of the drug. Loss of motor function is a later and more ominous side effect, requiring discontinuation of the medication and or a search for other contributing factors.

Brentuximab vedotin is a chimeric anti-CD30 antibody conjugated to four molecules of a potent tubulin inhibitor, monomethyl auristatin.[50] This antibody-drug conjugate targets CD 30, a surface protein fairly specific to Reed-Sternberg cells and anaplastic large-cell lymphoma (ALCL). Key to the success of brentuximab vedotin is the cleavable dipeptide linker that is stable in serum, but once internalized is cleaved by lysosomes releasing auristatin. This drug was approved in 2011 for the treatment of relapsed Hodgkin's lymphoma patients and of systemic ALCL after failure of at least one multiagent chemotherapy regimen. The response rate in Hodgkin's patients with refractory disease was 75%, with 34% complete remissions. In ALCL there was an 86% response rate and 53% complete remissions. Similar to other antitubulin agents, brentuximab vedotin causes peripheral neuropathy, with 52% experiencing neuropathy of any grade, and 8% grade 3 or 0% grade 4 neuropathy. The neuropathy, usually sensory, can also be motor and irreversible; patients need to be monitored carefully during treatment. Other side effects include marrow suppression, fatigue, and gastrointestinal effects.

Drugs That Affect Protein Synthesis and Degradation

Few drugs affecting protein synthesis and/or degradation have been used for the treatment of cancer. This is somewhat surprising given that the complexity of the process provided important targets for the development of antibacterial antibiotics. The process of protein synthesis includes initiation, elongation, and termination requiring an array of amino acids, structural proteins, enzymes, and substrates including ribosomes, initiation factors, elongation factors, termination factors, and protein kinases that regulate the function of many of these elements. Historically, L-asparaginase has been the prototype of this class of drug. Recent attention has turned to the factors that control protein degradation. The ansamycins (e.g., geldanamycin) represent a class of agents that interfere with protein chaperones (i.e., proteins that bind to and stabilize newly formed or damaged proteins). Proteins targeted for degradation due to damage, improper folding, or cellular excess may proceed through one of two pathways, lysosomal or proteasomal. Bortezomib (Velcade), a drug that broadly inhibits proteases that are present in the proteasome, has been approved for the treatment of refractory myeloma.[51] It interferes with proteasomal degradation of proteins such as the NFκB inhibitor, IκB. NFκB is a constitutively activated transcription factor in myeloma[52] shown to promote oncogenesis by increasing growth factors (IL-6, VEGF), cellular adhesion molecules (ICAM1, VCAM1), and antiapoptotic proteins (bcl-2, IAP). For a drug that interferes with a fundamental cellular process, bortezomib is relatively well tolerated. Peripheral neuropathy is the most troublesome side effect, which can be ameliorated by subcutaneous administration.[53]

Recent attention has focused on the PI3K/AKT signaling pathway because it is frequently altered during malignant transformation. This pathway provides exquisite control over energy utilization (see earlier discussion and Figure 46-3) by regulating protein synthesis,[54] the most voracious energy consumer. Inhibitors of mTOR such as everolimus (Afinitor) and PI3Kδ are recent examples of this class of agent.

Natural and Acquired Resistance to Cancer Therapies

Chemotherapy of cancers has resulted in some notable successes, such as the cure of the majority of patients with childhood leukemias, testicular carcinomas, and Hodgkin's and non-Hodgkin lymphomas. In other cancer types, such as breast, colorectal, and lung, chemotherapy also cures some patients when used in the adjuvant setting, that is, after debulking of the cancers with surgery and/or radiotherapy. However, for these common epithelial cancers, cure is rarely attained when the cancers have reached the stage of known metastatic disease. In such cases of advanced-stage cancers, chemotherapies may provide clinical benefit in the form of temporary remission of tumors and abatement of symptoms. In most patients, resistance to therapies is manifested as growth of cancers despite administration of drugs or in relapse or regrowth after a remission. In this chapter, we review reasons for failure of systemic cancer therapies (Table 47-1).

Pharmacologic and Physiologic Causes of Treatment Failure

Inadequate Drug Dose

In addition to cellular mechanisms of drug resistance, pharmacologic and physiologic factors may play a role in outcomes of cancer therapy. Pharmacologic factors include inadequate drug dosing or suboptimal scheduling of agents.[1-3] Traditionally, cytotoxic drugs have been administered at the maximum tolerated doses based on toxicities to normal tissues. Increased therapeutic efficacies with increasing doses, up to maximum levels of acceptable toxicity, have been demonstrated for virtually all cytotoxins in preclinical models and are supported by clinical data relating dose to efficacy in many cancers.[3]

For recently developed targeted drugs, such as kinase inhibitors, the optimal dose may not be the maximum tolerated dose in patients. The relationships among antitumor efficacy, side effects, pharmacodynamic endpoints, and dose of these agents are complex and require novel methodologies and study designs.

Suboptimal Schedule of Drug Administration

With regard to schedule, drugs with short half-lives and cell cycle phase–specific mechanisms of action are typically more active with continuous drug exposure schedules, such as repeated dosing and continuous infusions.[1] Examples include the antimetabolites cytarabine and 5-fluorouracil, the antibiotic bleomycin, and topoisomerase I inhibitors.

Drug Sanctuary Sites (Central Nervous System and Testis)

A physiologic cause for drug resistance is inadequate distribution of drugs to the central nervous system (CNS) and testis, because of the blood-brain and blood-testicular barriers. A major component of these barriers is endothelial cell expression of the multidrug transporter P-glycoprotein.[4,5] Thus, relapse in the CNS and testis became evident as major sites of treatment failure after most children with acute lymphoblastic leukemia achieved a clinical complete remission. New treatment strategies such as high-dose methotrexate and intrathecal administration of chemotherapy were devised to circumvent the problem of relapse in these so-called sanctuary sites.

Poor Drug Diffusion into Cancer Tissues

The physiology of abnormal new blood vessel formation (angiogenesis) and areas of poor blood supply may also limit the ability of anticancer drugs to distribute into cancer tissues and thus result in treatment failure.[6,7] Inhibitors of

tumor angiogenesis such as sunitinib and bevacizumab have been shown to normalize tumor vasculature, thus increasing perfusion and distribution of chemotherapeutic drugs and potentially enhancing therapeutic efficacy.[8]

Cellular Mechanisms of Drug Resistance

Intrinsic versus Acquired Resistance

The various types of cellular mechanisms of drug resistance are depicted in Figure 47-1. These mechanisms can be either intrinsic (i.e., constitutively expressed in the tumor tissue from the outset) or acquired (i.e., derived by mutation or induction of gene expression within the tumor cell population), often after exposure to therapies.[9,10] Intrinsic resistance generally refers to the preexisting expression of cellular defense mechanisms, which are also present in the normal tissues from which the cancer is derived.

Table 47-1 Causes for Failure of Systemic Cancer Therapies

A. Pharmacologic and physiologic mechanisms
1. Inadequate drug dosing
2. Suboptimal schedule of drug administration
3. Sanctuary sites (blood-brain and blood-testicular barriers)
4. Poor diffusion and distribution into tumor tissues
B. Cellular mechanisms of drug resistance
1. Drug efflux transporters
2. Impaired drug uptake
3. Mutation or altered expression of molecular targets
4. Intracellular redistribution of drug
5. Detoxification of drug or intermediate drug product
6. Enhanced DNA repair
7. Decreased drug activation
8. Altered pathways for programmed cell death (apoptosis)

Epithelial tissues such as the colon, kidney, and liver express many transporters and detoxifying enzymes for xenobiotics. These defense mechanisms are also usually expressed in carcinomas originated from those organs and confer resistance to many chemotherapeutic drugs. Normal hematolymphoid tissues are less well defended against xenobiotics, with the exception of certain subtypes (natural killer cells, hematopoietic stem cells).[11] Thus, lymphomas and leukemias express fewer resistance mechanisms and are generally more sensitive to chemotherapies than are epithelial cancers.

The distinction between intrinsic and acquired resistance is blurred in the case of oncogenic mechanisms, such as mutations of *p53* and translocations resulting in high activity of the anti-apoptotic protein BCL-2. These oncogenic mutations result in the inhibition of normal apoptotic mechanisms and thus have a dual effect of causing cancer and resistance to anticancer therapies, which require apoptotic c signaling to kill cancer cells.[12-25] The tissue microenvironment of cancers, involving cell-cell and cell-matrix interactions, may also lead to resistance to cancer therapies via pathways that inhibit apoptosis.[26]

Genetics of Drug Resistance

One of the hallmarks of cancer is genetic instability, resulting in a variety of genetic aberrations, including

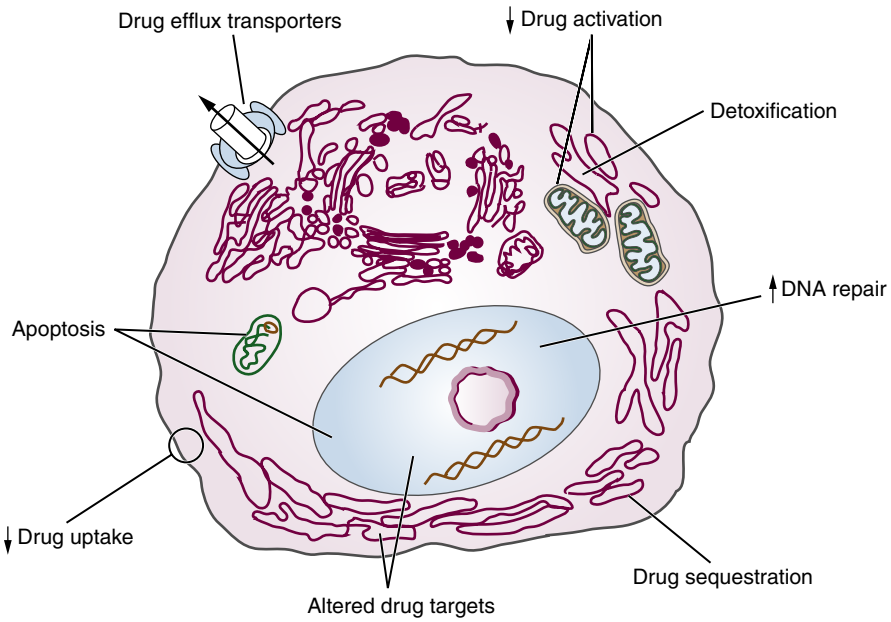

Figure 47-1 Mechanisms of cellular drug resistance.

aneuploidy, point mutations, deletions, gene amplifications, and chromosomal translocations.[27] These result in marked clonal heterogeneity within cancers, resulting in altered gene and protein expression and substantial diversity among cellular populations in primary cancers, metastases, and relapsing tumors after therapies.[28,29] Goldie and Coldman formulated a mathematical model relating rates of generation of drug-resistant mutations to the number of cells in a cancer at diagnosis, the probabilities for cure, and implications for various treatment strategies.[30-32] Studies of human cancer cell lines using Luria-Delbrück fluctuation analysis have demonstrated mutation rates for drug resistance at a frequency of 10^{-6} to 10^{-7} per cell generation.[33-36] Moreover, strategies that suppress one mechanism of resistance (activation of the *MDR1* or *ABCB1* gene) reduce the frequency of acquired resistance and result in the selection of alternative resistance mechanisms.[35]

It is likely that the rate of development of drug-resistant mutants in a cancer varies depending on the nature of the genetic instability of that cancer, the drug mechanism, and the treatment dose and schedule (selection pressure).[30-32,37,38] In general, the concept of selection for acquired resistance implies that mutations either may preexist as small subpopulations within the cancer or may arise during the course of therapy and eventually manifest themselves as regrowth of tumor. The tumor cell population in newly diagnosed metastatic cancers almost always exceeds 1 billion cells (equivalent to 1 g or cubic centimeter of tumor). Thus, it is very likely that cancers that are intrinsically sensitive to any therapeutic agent will also contain one or more drug-resistant clones. This provides a powerful rationale for both combination drug therapies (to lessen the likelihood of doubly resistant clones) and adjuvant therapies of cancers (to cure patients with micrometastatic disease and lower tumor burdens).

Recent genetic studies have provided new insights into clonal populations and the evolution of resistant variants in clinical cancers.[39-41] These studies used DNA sequencing and sampling of multiple tumor sites of primary and metastatic cancers to directly demonstrate heterogeneity within tumors and changes in the distribution of clonal populations after therapies.

Gene amplification, or increase in gene copy number, was first described for the *DHFR* gene as a mechanism for acquired resistance to methotrexate.[42] Amplification of genes is now known to be a prominent feature of the genomic instability of cells and to be a key genetic mechanism involved in oncogenesis (*MYC*, *HER2*, *EGFR*), as well as in drug resistance. It is one of the major mechanisms for increasing the expression of drug-resistance genes, including *MDR1/ABCB1*.[27,43]

Epigenetics and Drug Resistance

In addition to selection of resistant mutants, acquired resistance may develop via epigenetic changes, by induction of resistance gene expression.[44] For example, various cellular stresses, including exposure to ionizing radiation and chemotherapies, have been shown to increase expression of the multidrug transporter gene *MDR1/ABCB1*.[27,45-47] These epigenetic mechanisms such as DNA methylation and histone modifications can contribute to heterogeneity in gene expression and also offer the possibility of reversing drug resistance with drugs such as vorinostat and decitabine that target the epigenome.[48-55] MicroRNAs are a target for epigenetic regulation that can alter drug resistance. Thus, downregulation of the miR-200 family results in epithelial-to-mesenchymal transition (EMT) and upregulation of tubulin beta-3 (TUBB3), which can confer resistance to taxane drugs.[56]

Cancer stem cells (CSCs) represent a subset of cells within a cancer that have the capacity for sustained proliferation and that are thought to be primarily responsible for the growth of cancer. CSCs typically have an EMT phenotype and upregulation of many survival mechanisms, including drug transporters and resistance to apoptosis.[57-60]

Tumor Stroma, Cell-to-Cell Interactions, and Drug Resistance

The tumor microenvironment and, in particular, interactions of stromal cells with cancer cells have been shown to enhance drug resistance.[61-64] The underlying mechanism for this effect is protection from cell death or apoptosis, mediated by both cellular and noncellular components of the tumor microenvironment. These stromal components include cellular adhesion molecules in the extracellular matrix, chemokines such as CSCL12, and integrins. Cross talk between cancer-associated fibroblasts and malignant cells in tumors promotes tumor progression and cell survival in part via cell adhesion to fibronectin.[64]

Drug Efflux Transporters

There are approximately 50 ABC transporters (ATP-binding cassette membrane proteins) in the human genome.[65-67] Defective forms of several of these transporters are causes of human genetic diseases, such as cystic fibrosis and Dubin-Johnson syndrome.[65] Several members of the ABC transporter family have the capacity to efflux small molecules, including anticancer drugs, and thus contribute to drug resistance. The major drug-resistance ABC transporter genes

include *MDR1/ABCB1*, several members of the *MRP/ABCC* subgroup, and *ABCG2*.[65,67,68]

P-glycoprotein (P-gp), the product of the *MDR1/ABCB1* gene, is the most prevalent ABC drug-resistance transporter and has been extensively studied.[69-73] The protein has a molecular mass of 180 kDa, with 12 transmembrane segments and two intracytoplasmic ATP binding domains (Figure 47-2). High-resolution electron microscopy has revealed that the transmembrane segments form a pore, and drug binding sites have been identified within this pore. Access of drugs to the transporter is thought to occur both via the cytoplasm and by diffusion within the membrane. P-gp is a transporter with very broad substrate specificity, including approximately a third of all anticancer drugs, as well as many other drugs used in other areas of medicine. Active efflux of drugs is mediated by conversion of ATP to ADP. Theories regarding the molecular mechanism of drug extrusion include an ATPase-mediated conformational change in the protein producing a "flippase" action, which exposes substrate drugs to the extracellular environment, and a "membrane vacuum cleaner" function in which drugs access the transporter via the bilipid plasma membrane.[70] The direct role of P-gp in conferring multidrug resistance has been confirmed by transfection of the gene in cellular models.[72]

P-gp is expressed in many normal tissues, where it serves as a barrier to drug absorption (small bowel and colon), a barrier to tissue entry (endothelial cells of the CNS, testis, and placenta), and to facilitate drug excretion (biliary tract of the liver and proximal tubule of the kidney.[4,73] It is also highly expressed in cancers derived from these tissues (colorectal, renal) and is one of the constitutive mechanisms of drug resistance in these cancers.

P-gp expression in cancers results in a classical multidrug-resistance phenotype, with high degrees of resistance to the drugs that are transport substrates for the protein. These drug substrates include the anthracyclines (doxorubicin, daunorubicin, idarubicin, and epirubicin), vinca alkaloids (vincristine, vinblastine, vindesine, vinorelbine), taxanes (paclitaxel, docetaxel), epipodophyllotoxins (etoposide, teniposide), mitoxantrone, and dactinomycin.[70] Many

newer, targeted drugs such as imatinib are also transport substrates for P-gp.[74]

The clinical significance of P-gp in drug resistance is supported by evidence that its expression confers an adverse prognosis in many tumor types, including acute myeloid leukemias (AMLs), acute lymphoid leukemias, lymphomas, myeloma, breast and ovarian cancers, and sarcomas.[9,75-81] In AML, P-gp is expressed in more than 70% of specimens from patients older than age 60, versus 30% to 40% of patients up to age 60, and its expression correlates with reduced rates of complete remission and shorter survival.[80] In breast cancers, P-gp expression occurs in 40% to 50% of specimens and is associated with decreased rates of remission to P-gp substrate drugs (taxanes and anthracyclines).[81] Selection of multidrug-resistant (MDR) subclones within cancer populations is suggested by evidence that P-gp expression is more frequent in leukemias and breast cancers after patients have relapsed from prior therapy with MDR-related chemotherapy drugs.[80,81]

The prevalence and adverse prognostic effects of P-gp in many cancers have led to attempts to reverse MDR by combining chemotherapy with inhibitors of P-gp.[80,82-84] These clinical trials to reverse or modulate MDR have used a variety of competitive and noncompetitive inhibitors of P-gp, including verapamil, cyclosporine, quinine, the cyclosporine analog valspodar, and others. In general, these attempts have not resulted in proven clinical benefit. The reasons for these failures are multiple and include the following: inadequate concentrations of MDR-reversing agents because of toxicities to normal tissues, lack of specificity of P-gp inhibition leading to drug interactions and off-target effects, use of an unselected patient population including patients who did not express P-gp, and coexpression of other mechanisms of drug resistance.[80,82-84] A particularly problematic issue is the co-inhibition by cyclosporins and other MDR inhibitors of other ABC transporters as well as the mixed-function oxidase CYP 3A4, resulting in the need to reduce doses of chemotherapeutic drugs while attempting to sensitize P-gp–expressing cancer cells.[84-87] Despite these issues, cyclosporine has been shown to moderately increase complete remission rates and to significantly prolong survival in a randomized clinical trial in AML.[80,88] A more potent and specific inhibitor of P-gp, zosuquidar, has not prolonged survival in AML, although the schedule of administration of the drug in this trial was suboptimal.[89]

Several members of the *MRP* or ABCC gene family also function as drug transporters.[68,90-97] The MDR-associated protein (the *MRP1/ABCC1* gene) confers resistance to anthracyclines, vinca alkaloids, and epipodophyllotoxins and preferentially transports glutathione conjugates of substrate drugs.[90,91,94-97] In general, *MRP1* is not as strongly associated with clinical drug resistance and prognosis as *MDR1*, and clinical strategies for reversing resistance related to *MRP1* have not been developed. The *MRP2/ABCC2* gene encodes the canalicular multiple organic anion transporter, which is expressed at high levels in the biliary tract, and transports glucuronide and glutathione conjugates of drugs, including anthracyclines. It plays a role in hepatic excretion of anticancer drugs, but its role in drug resistance is not clear.[92,95] Its hereditary deficiency results in the Dubin-Johnson syndrome.[68] The transporter encoded by the *MRP3/ABCC3* gene confers low-level resistance to epipodophyllotoxins as well as to methotrexate.[68,93] *MRP4/ABCC4* and *MRP5/ABCC5* confer resistance to anionic purines and other nucleotide analogs and their metabolites.[68,98]

ABCG2 (BCRP) is another member of the ABC family, implicated in clinical resistance to the anthracenedione drug mitoxantrone and the camptothecins.[99,100] This transporter is 72 kDa in size, less than half the size of the ABCB and ABCC subgroups, and is thought to require dimerization for its function. It is variably expressed in AML and is a negative prognostic factor in that disease.[101-103] Together with P-gp, *ABCG2* is constitutively expressed in both normal hematopoietic and leukemic stem cells[104,105] and is a marker of cancer stem cells.[60]

Polymorphisms in the DNA sequence of *ABCB1* and other ABC transporters are being studied for their relationship to drug disposition, efficacy, and toxicities.[66] Single-nucleotide polymorphisms of the *ABCB1* gene (C1236T, G2677T, and C3435T), which have been associated with altered drug absorption or disposition in some studies, were not found to effect complete remission and survival in patients with AML.[106] The function and clinical significance of the ABC transporter family in anticancer drug resistance continue to be investigated.

Two membrane proteins involved in the efflux of copper, ATP7A and ATP7B, have been shown to also transport the platinum drugs and contribute to resistance to cisplatin, carboplatin, and oxaliplatin.[107,108]

Impaired Drug Uptake

Cellular entry of most anticancer agents is via passive diffusion. However, some drugs are also transported into cells by membrane proteins, and the expression and activity of these proteins are determinants of cellular sensitivity or resistance. Methotrexate enters cells by means of the reduced folate carrier, and decreased expression of this protein results in relative resistance to the drug.[109] Reduced drug uptake has also been observed in some cells resistant to platinum drugs.[110] The major copper influx transporter, CTR1, been implicated in the regulation of intracellular accumulation of cisplatin, carboplatin, and oxaliplatin.[107]

Mutation or Altered Expression of Molecular Targets

As previously mentioned, the first description of gene amplification as a genetic phenomenon and as a mechanism for acquired drug resistance was the discovery of amplified dihydrofolate reductase *(DHFR)* genes in a cell line selected by exposure to increasing concentrations of methotrexate.[42] Multiple copies of *DHFR* were identified in extrachromosomal fragments of DNA, termed *double minute chromosomes* (DMs), in the methotrexate-resistant cells. Resistance in these cells was unstable because DMs were not normally replicated in the absence of drug selection.[111] Subsequently, other methotrexate-resistant cells were found to have multiple gene copies of *DHFR* integrated into the genome, in areas of "homogeneously staining regions," or HSRs. HSRs are more stable because they are integrated into the genome and included in the normal process of DNA replication.

Several important classes of anticancer drugs (vincas, taxanes, epothilones) act by binding to β tubulins and altering the dynamic instability of microtubules (Figure 47-3).[112] Alterations in β tubulins, including mutations and changes in the proportion of β-tubulin isoforms, particularly the class III isoform, have been implicated in resistance to taxanes.[112-115] Vinca alkaloids inhibit tubulin polymerization and thus have opposing effects to those of taxanes and epothilones, which stabilize polymerized microtubules. These opposing mechanisms of action may be reflected in reciprocal effects of changes in tubulin content or isotype expression on vinca and taxane sensitivities, with resistance to one class of drugs accompanied by increased sensitivity to the other.[112]

Although mutations in β-tubulin that alter taxane binding have been found to confer resistance in cellular models, such mutations have not been found in various human cancer clinical specimens.[116,117]

The microtubule binding protein, MAP-Tau, binds to a site on β-tubulin overlapping with taxanes and affects microtubule dynamic instability. Its expression has been associated with resistance to the taxane drug paclitaxel in breast cancer specimens.[118,119] Other mechanisms of resistance to antitubulin drugs include the P-gp transporter (for taxanes and vincas),[81] the cell spindle checkpoint control pathway,[120] and regulation of programmed cell death or apoptosis.[112,121]

The epothilones are a new class of antitubulin cytotoxic drugs whose binding site on tubulins overlaps with the taxanes.[122] In contrast to taxanes, epothilones are not transport substrates for P-gp and therefore have potential antitumor efficacy in cancers that are multidrug resistant because of P-gp expression.[122,123] However, they are likely to share some of the target-related mechanisms of resistance to taxanes, such as factors that affect microtubule dynamicity and regulation of apoptosis.

Topoisomerase I and II are drug targets for camptothecin and epipodophyllotoxin drugs, respectively, and mutations or altered expression of these enzymes have been shown to cause cellular resistance to these drugs.[33,124-129] Because drug-induced DNA breakage is proportional to the amount of topoisomerase II enzyme, decreased enzyme content is associated with resistance, and higher enzyme content with drug sensitivity.[33,125,128]

Alteration of drug targets is an important mechanism of resistance for new, targeted drugs, such as the tyrosine

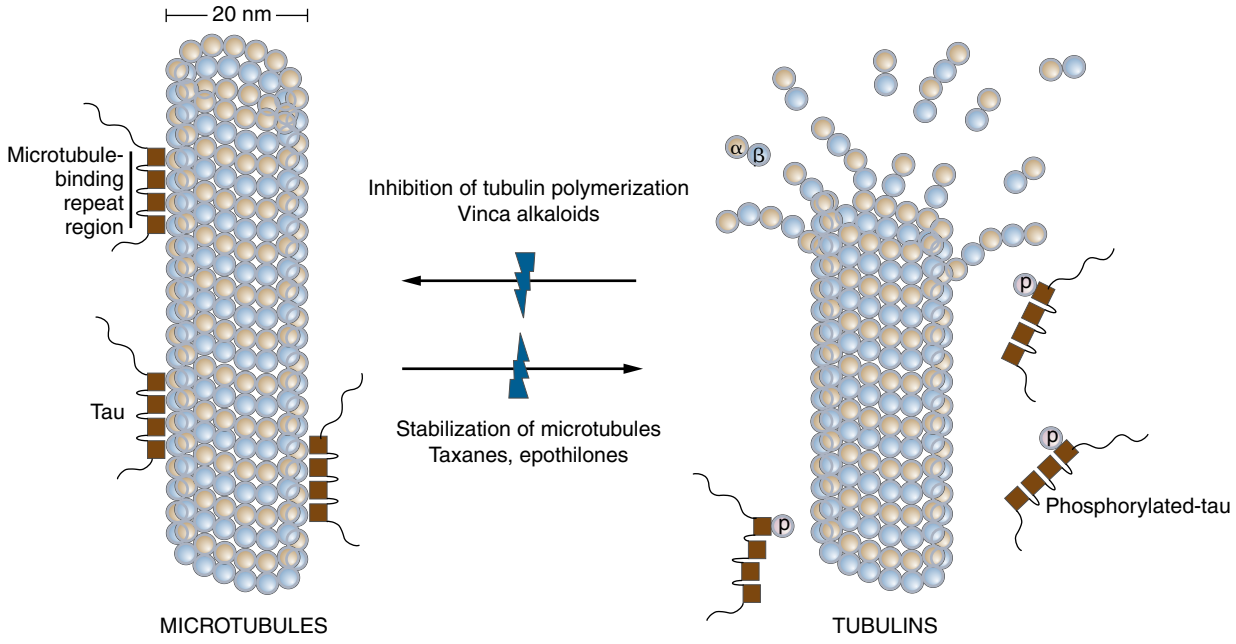

Figure 47-3 Mechanism of action of tubulin polymerizing and microtubule-stabilizing drugs.

kinase inhibitors (Figure 47-4).[74,130] For the drug imatinib, an inhibitor of the fusion oncoprotein gene *BCR/ABL*, point mutations in the kinase domain of its target are a major mechanism of acquired resistance in chronic myeloid leukemias (CMLs).[131] More than 30 such mutations that confer resistance to imatinib have been identified. Because resistance to imatinib occurs at a rate of around 3% of patients per year of drug therapy, such mutations occur relatively infrequently. The drug dasatinib, a potent inhibitor of the *BCR/ABL* kinase, has been shown to inhibit almost all of these mutant kinases and to produce remissions in imatinib-resistant CML.[131] One *BCR/ABL* mutant, T351I, remains resistant to both imatinib and dasatinib, although other new drugs are being developed for this double-resistant mutation. BCR/ABL gene amplification can also result in resistance to the kinase inhibitors in CML.[132]

Intracellular Redistribution of Drug

Intracellular drug sequestration of anthracyclines has been observed in cellular models with high expression of the major vault protein (MVP), also known as *LRP*.[133] Vaults are barrel-like cytoplasmic organelles with a molecular mass of 13 MDa, which are thought to function in intracellular transport. In addition to high expression of MVP in some cellular models of drug resistance, this protein is variably expressed in acute myeloid leukemias and may be a factor in clinical drug resistance in that disease.[134]

Detoxification of Drug or Intermediate Drug Product

Metabolic inactivation of drugs is a mechanism of resistance to many agents. Thus, cytidine deaminase activity can result in resistance to cytarabine.[135] Dihydropyrimidine dehydrogenase catabolism of 5-fluorouracil is a determinant of activity of that agent.[136]

The DNA-binding glycopeptide drug bleomycin is inactivated by an aminopeptidase termed *bleomycin hydrolase*.[137] Most cancers are resistant to bleomycin and have high levels of this enzyme, whereas sensitive tumors (germ cell cancers, lymphomas, squamous carcinomas) have low levels. Similarly, most normal tissues have high levels of bleomycin hydrolase, but the two major sites of toxicity, lung and skin, express low levels.[137]

For electrophilic DNA alkylating agents and platinum drugs, detoxification via nucleophilic sulfur-containing compounds is an important class of resistance pathways.[108] Glutathione reductases are an important class of detoxifying enzymes that can generate resistance to such drugs by conjugation with glutathione.[138-148] Moreover, as previously noted, some members of the MRP family of transporters can efflux glutathione conjugates of cytotoxic drugs, so that

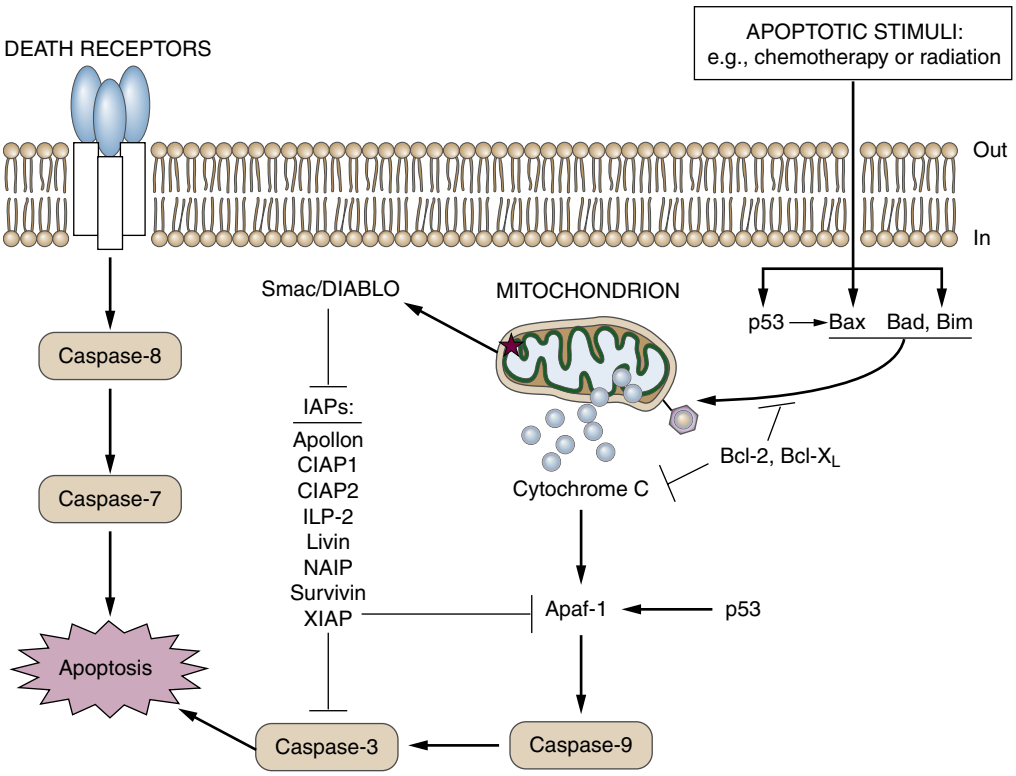

Figure 47-4 Cellular pathways of programmed cell death, or apoptosis.

metabolic detoxification is coupled to outward transport of toxins.[68,95,97]

Enhanced DNA Repair

DNA repair pathways are important determinants of response to alkylating agents and platinum drugs.[108,149-152] Nucleotide excision repair (NER) is a complex, highly regulated process involving more than 30 proteins. Moreover, two general pathways are involved: global genomic NER, which repairs damage in transcriptionally silent areas, and transcription-coupled NER, which repairs damage to the actively transcribed DNA strand. The steps in NER include recognition of the damaged DNA, DNA unwinding, incision, degradation, polymerization, and ligation.[151] Evidence for the role of many DNA repair genes in response to both DNA-damaging drug and ionizing radiation derives in part from studies of genetic defects such as ataxia telangiectasia, xeroderma pigmentosum, and Bloom syndrome, in which hypersensitivity to DNA-damaging agents has been observed.

Among the many genes involved in NER, recent attention has focused on *ERCC1*. High expression of the DNA excision repair gene *ERCC1*, which is involved in repair of DNA adducts from alkylating agents and platinum drugs, has been shown to correlate with adverse outcomes in patients with advanced-stage non–small-cell lung cancers treated with cisplatin-based chemotherapy.[153] In earlier stages of lung cancer, patients whose tumors did not express ERCC1 benefited significantly from cisplatin adjuvant chemotherapy, whereas patients whose tumors expressed *ERCC1* did not benefit from the chemotherapy.[154] Paradoxically, high expression of ERCC1 was found to be a favorable prognostic factor for survival in patients with early stages of lung cancer, in the absence of adjuvant chemotherapy.[154-156]

O6-Methylguanyl-methyl-transferase (MGMT) is particularly important in resistance to the nitrosourea carmustine and the DNA-methylating agent temozolomide.[149,151] MGMT has been identified as a key factor in clinical outcomes in brain tumors, and drugs to deplete MGMT are being developed as potential therapeutic approaches to modulate drug resistance.[149]

Decreased Drug Activation

Most antimetabolite drugs generally require metabolic activation to generate their active nucleoside or nucleotide moiety, via kinases and phosphoribosyl transferases.[157] Thus, for cytarabine, generation of ara-dCTP levels intracellularly is an important determinant of antitumor efficacy.[157] In the case of 5-fluorouracil, activation of the drug requires formation of 5-fluorodeoxyuridine monophosphate (FdUMP).[157] In addition, optimal inhibition of thymidylate synthase by 5-fluorouracil depends in part on intracellular levels of the cofactor 5,10-methylene tetrahydrofolate.[158]

The oxazaphosphorine mustards (cyclophosphamide and ifosfamide) are prodrugs that are activated predominantly in liver tissue by mixed function oxidases (CYP enzymes).[150] Although the major mechanisms of resistance to these drugs are thought to be inactivation of alkylating metabolites by thiol compounds, as well as DNA repair mechanisms, variable levels of mixed function oxidase activity within cancers may also be a determinant of their activity.

Altered Pathways for Programmed Cell Death (Apoptosis)

Pathways for the regulation of programmed cell death or apoptosis are important both in oncogenesis and as determinants of response to cancer therapies (Figure 47-5).[12-25] *BCL2* is oncogenic in many B-cell lymphomas, where its expression is upregulated by chromosomal translocations and other mechanisms. It also functions to protect cells from apoptosis after radiation, glucocorticoids, and chemotherapies.[13,14,25] The *BCLX* gene has long and short forms, encoding the proteins bcl-xL and bcl-xS, which serve to inhibit and promote apoptosis, respectively.[24] Both the BCL-2 and the inhibitor of apoptosis (IAP or BIRC) families of regulators of cell death are currently being explored as targets to sensitize drug-resistant cancer cells to chemotherapies.[159,160]

The relationship between oncogenesis and drug sensitivity or resistance is also exemplified by the p53 pathway, which is mutated in the majority of human cancers. Normal p53 function is essential for the efficient functioning of the mitochondrially mediated apoptotic pathway, particularly in response to DNA-damaging agents, including ionizing radiation and many chemotherapeutic drugs, such as alkylating agents, platinums, anthracyclines, and topoisomerase inhibitors.[12,15,22,23]

Individualization of Therapy Based on Predictive Multigenic Markers

Knowledge about mechanisms of drug resistance, molecular targets of drugs, and signaling pathways related to treatments is enabling more precise predictive molecular testing of drug efficacy.[10] Historically, such approaches were pioneered in the treatment of breast cancer by the use of hormone receptor measurements to guide hormonal therapy

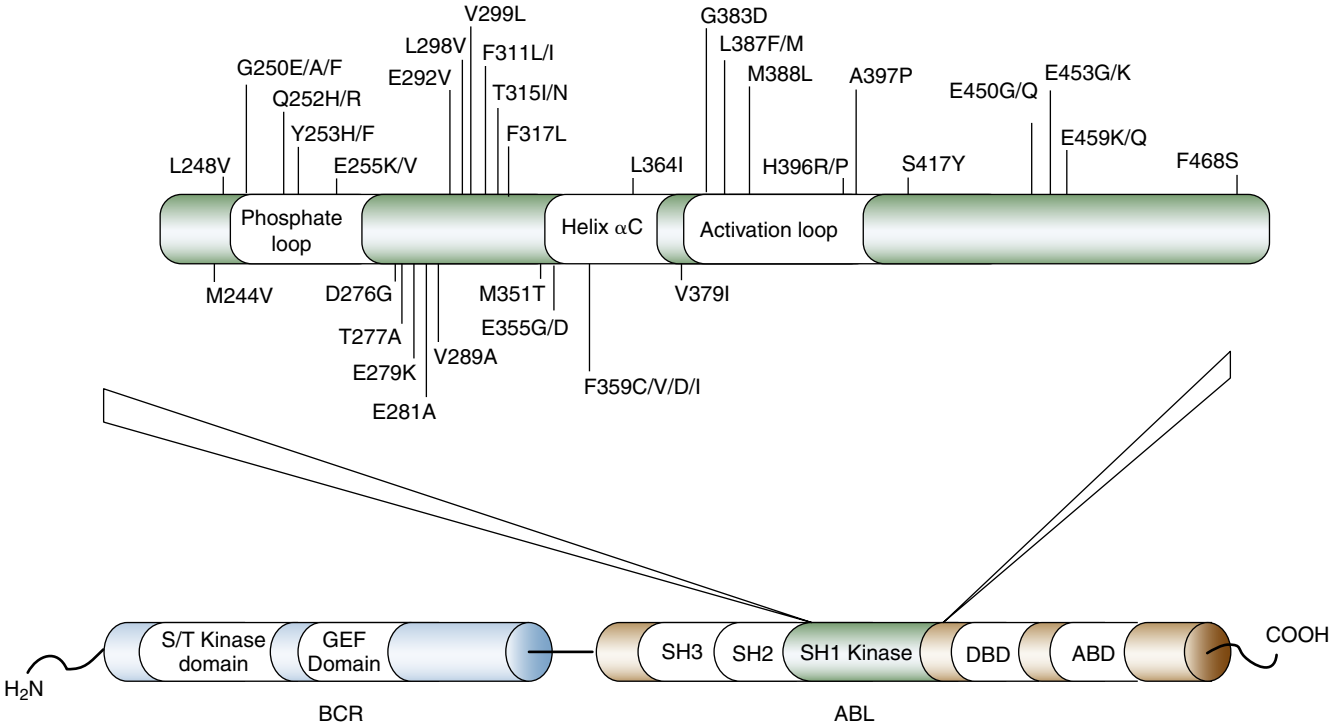

Figure 47-5 Structure of the fusion oncoprotein BCR/ABL, depicting the point mutations that result in resistance to imatinib in chronic myeloid leukemias.

and testing for overexpression or amplification of the *HER2* gene to identify breast cancer patients for trastuzumab therapy. The ability to determine genome-wide expression by microarray analysis has resulted in the identification of candidate gene profiles that are associated with remissions to drugs or drug combinations.[161,162] Such approaches may lead to increasing individualization of therapy with the use of genomic or proteomic panels of predictive markers, but prospective validation of such markers in clinical trials has been difficult.

48 Phase I Trials Today

Introduction

All commercially available anticancer agents must have undergone Phase I investigation as part of their clinical development. As novel anticancer drugs evolved from primarily cytotoxic agents to targeted therapies, clinical investigators have developed novel Phase I trial designs and endpoints. It is estimated that approximately 500 anticancer agents will present to the clinical arena within the next decade. It is a well-known fact that one of the most important components of conducting Phase I trials is eligible patient availability. As the number of commercially available agents for several tumor types has increased, as well as the number of patients treated off-protocol in community settings, the availability of patient resources has become a challenge.

As a result, it is important to conduct efficient and effective trials by maximizing data acquisition while minimizing patient numbers. Previously, standard Phase I trials used large patient numbers and cohorts. Now, it is the norm to utilize well-thought-out trials minimizing patient numbers and cohorts by using alternative designs and carefully selecting the starting dose. Once thought of only as an alternative to hospice with no significant benefit, treatment on a Phase I trial is now viewed as an additional therapeutic option. The overall clinical benefit of Phase I trials is approximately 45%, with highly variable response rates, depending on the type of agent and the Phase I trial under investigation.[1] Ethically, the intent of all clinical studies, for both the patient and physician alike, is therapeutic.[2-4] A better understanding of the compound(s) under investigation and the various types of Phase I clinical trials available will assist the investigator in determining at what point and for which patient specific Phase I clinical trials should be considered.

Types of Phase I Clinical Trials

Phase I clinical trials are the first stage of drug testing in human subjects. These studies play a vital role in the development of novel therapeutics. Phase I studies are typically designed to assess the safety, tolerability, pharmacokinetics, and pharmacodynamics of a novel agent. Novel cancer therapeutics are usually offered to patients with advanced cancer who have had other types of therapies and who have few, if any, remaining treatment options. In addition, because of several tumor types with limited current treatment options that could have a favorable impact on patient survival, it is considered ethical to treat patients with metastatic disease in Phase I trials by utilizing novel agents in combination with standard therapies; this is especially true if the standard therapies demonstrated therapeutic success in previous clinical investigations.

Although the primary stated objective of a typical Phase I study is to determine the optimal dose of a novel therapeutic for use in subsequent studies, several different types of Phase I clinical trials exist to meet specific needs for clinical early drug development.

Single Ascending Dose (SAD)

Single ascending dose (SAD) studies are those in which groups, or cohorts, of up to six patients are given a small dose of the drug and observed for a specific period of time. The initial dose is commonly based on one tenth of the murine equivalent lethal dose in 10% of animals (MELD10) or the human equivalent dose of the no observed adverse effect level (NOAEL, the highest nontoxic dose) achieved in the most sensitive preclinical species multiplied by a safety factor (default is greater than 10-fold). If the cohort does not exhibit any adverse side effects, a new group of patients is then given a higher dose. This continues until intolerable side effects are observed. Once such side effects occur in a patient, the protocol typically explores whether this is sporadic or reproducible, as described later in detail. The highest dose administered to a patient on a Phase I trial is referred to as the *maximum administered dose*. The dose that is as high as possible but still tolerable for patients is said to be the *maximum tolerated dose* (MTD).

Often, SAD clinical trials can be categorized as being first-in-human, first-in-class, or a combination of the two. As the name implies, first-in-human clinical trials are those that are conducted for the first time in a human patient. In order to be tested in humans, a drug typically has to first show promise of activity in the laboratory and in animals. Normally, a small group of patients (approximately 20) will be selected for inclusion into a first-in-human Phase I study. First-in-human studies for noncancer indications are almost always done in a single ascending dose manner. The objective of the first-in-human Phase I trial is to find a suitable safe dose (the MTD) for use in later studies that will more thoroughly examine efficacy. Once the MTD has been determined in a Phase I SAD study, later phase studies can be designed and multiple ascending dose studies can be performed.

First-in-class studies examine novel drugs that are uniquely manufactured or based on a new target or indication. Such therapeutics are typically innovative and novel, and no other pharmaceutical products are currently approved for the same therapeutic indication; hence, they have no pharmaceutical substitute.

Multiple Ascending Dose (MAD)

Multiple ascending dose (MAD) studies are conducted to better understand the pharmacokinetics and pharmacodynamics of a drug and determine the dose that is tolerable for repeated administration in therapeutic intent trials (Phase II). In these studies, a group of patients receives a low dose of the drug and the dose is subsequently escalated to a predetermined level. A single schedule that is judged optimal from preclinical studies or multiple schedules may be tested. Specimens (of blood and/or other fluids) are collected at various time points and analyzed to understand how the drug is processed within the body. In cancer, where MAD studies are commonplace, subjects receive repeated doses at a predetermined schedule, and new cohorts of patients receive progressively higher doses on the same schedule (see later discussion).

Method and Model (MeMo)

MeMo trials are studies that are done in anticipation of a Phase I clinical trial. Typically done for "targeted" agents, these trials help in the development of a pharmacodynamic endpoint. They may help identify either a direct tissue or a surrogate tissue marker. This assists in determining if the marker can be measured within the tissue and also helps to refine the assay needed for pharmacodynamic measurement.

Phase I Trials Using Radiolabeled Tracer Doses

The use of radiolabeled experimental agents has become an increasingly important factor in drug development. In preclinical studies, radiolabeled compounds are frequently used in the laboratory to understand the distribution, metabolic fate, and localization of experimental drugs both in vitro and in vivo. Clinical studies performed as part of Phase I trials, or in support of them, may also involve the administration of small doses of radiolabeled compounds, called *tracers*, to healthy human volunteers or to patients in order to better understand the mechanisms of drug action.

Radiolabeled tracers are synthesized by replacing one or more atoms of an experimental drug agent with a radioisotope. Radioisotopes must have a suitable half-life in order to allow for imaging or detection in biological samples. Examples of commonly used isotopes for detection in tissue or blood samples include carbon (^{14}C), hydrogen (^{3}H), sulfur (^{35}S), and iodine (^{125}I). Isotopes that are commonly used in imaging, specifically in positron emission tomography (PET) scanning, include fluorine (^{18}F), carbon (^{11}C), and oxygen (^{15}O).

Radiolabeled compounds have allowed researchers to study many aspects of a drug's behavior in vivo.[5] Evaluation of the mass balance of a drug can be performed to better understand how much of an applied dose is recovered with respect to time. The metabolism of the drug can be extensively studied to determine if any metabolites might represent a potential toxicological hazard to the patient. Advances in clinical imaging have had great impact on drug discovery and development in recent years.[6] Clinical imaging studies using labeled drug have the potential to facilitate early clinical pharmacokinetic/pharmacodynamic assessments, including target interaction and modulation.[7] This is particularly useful in patients where there are no direct measures of pharmacokinetics/pharmacodynamics throughout the tissues of the body and at the target.

Studies using a method called *microdosing* offer the prospect of taking a drug directly into human studies by administering extremely low doses of radiolabeled agent. Microdosing studies may also be referred to as Phase 0 studies. Using only tiny amounts of radiolabeled drug, researchers employ microdosing to establish the likely pharmacological dose and thereby determine the first dose for a subsequent Phase I study. However, microdosing is not without controversy among researchers in drug development.[5] Concern has been raised that microdosing may not accurately predict the behavior of clinical doses. It has also been suggested that nonlinearities may be induced when binding, metabolizing, or eliminating systems become saturated, thus resulting in differences between low and high doses.

Drug/Food Metabolic Interaction Studies

The U.S. Food and Drug Administration (FDA) has recommended that the metabolism of an investigational new drug be defined during drug development and that interactions with other drugs be explored as part of an adequate assessment of its safety and effectiveness.[8] Medicines are often used concomitantly with other drugs, and some degree of drug-drug interaction often occurs with concomitant use. Concomitant medications can abruptly alter metabolic routes of absorption and elimination. Although only a small proportion of drug interactions are clinically significant, they sometimes cause serious adverse reactions.

Therefore, early on in the drug development process, appropriate efforts should be made to predict the nature and degree of potential interactions so that patients will not be adversely affected. The important cytochrome P450 (CYP450) family of enzymes is found in the liver and plays a large role in metabolizing drugs. Many metabolic routes of elimination, including most of those occurring via the CYPP450 family of enzymes, can be inhibited, activated, or induced by concomitant drug treatment. The FDA has recommended that detailed studies be performed with the major CYP450 enzymes (CYP1A2, 2C9, 2C19, 2D6, 2E1, and 3A4). Typically, preclinical testing is performed to investigate the effects of an agent on metabolic factors, such as CYP450, and of inhibition or induction potential. If in vitro experiments reveal the potential for drug-drug interaction, in vivo experiments usually will follow. Therefore, Phase I clinical trials often include testing for the ability of an experimental agent to affect CYP450 and a determination of whether the agent causes a change in concentration of other drugs as a result. With the combination of in vitro studies and in vivo studies in support of Phase I clinical trials, the potential for drug-drug interactions can be studied early in the development process, with further study of observed interactions assessed later in the process, if necessary.

Organ Dysfunction Studies

The desirable and undesirable effects of a drug arising from its concentrations at the sites of action are usually related either to the amount administered (dose) or to the resulting blood concentrations (accumulation), which are affected by its absorption, distribution, metabolism, and/or excretion. Elimination of a drug or its metabolites occurs either by metabolism, usually by the liver, or by excretion, usually by the kidneys and liver.

Although clinical trials for drug approval are often conducted in patients with normal hepatic and renal function, patients in clinical practice, especially those with cancer, may have compromised organ function because of underlying disease.[8] It has been recommended that organ dysfunction studies be designed in the form of a formal dose-escalation Phase I study, with a complete pharmacokinetic and toxicity profile as endpoints.[8,9] The primary goal of the Phase I study in an organ-impaired population should be to determine if the pharmacokinetics are altered to such an extent that the dosage requires adjustment, based on degree of organ dysfunction, from the dose established in the unimpaired population.

Because of the uniqueness of eligible patients, these studies are typically conducted as multisite studies so that they can be completed in a timely and efficient fashion. In 1999, the National Cancer Institute developed an Organ Dysfunction Working Group (ODWG), comprising approximately 12 to 15 Phase I sites. The ODWG has successfully completed evaluation of oxaliplatin, imatinib, and bortezomib in the renally and hepatically impaired populations.[10-15] In addition, several additional agents are currently undergoing evaluation.

Thorough QT Phase I Studies

Adverse effects on cardiac health have become one of the most common causes of product withdrawal from the market. As a result, regulatory authorities around the world have recently placed greater emphasis on cardiac safety. The FDA's regulatory guidance recommends a thorough QT Phase I study to be conducted irrespective of preclinical cardiac findings.[16] When a thorough QT study is not feasible for other reasons, which may be the case in certain therapeutic areas such as oncology, alternative approaches are recommended, such as expanding the number and timings of electrocardiographic (ECG) recordings in other clinical studies in patients.

Dose-Scheduling Studies

Inefficient dose scheduling can lead to treatment failure and the inadequate development of a potentially promising therapeutic. Unlike the typical Phase I clinical trial designed to determine the MTD, an investigator may be interested in determining how often (i.e., how many administrations of a schedule) an agent could be safely administered to determine the long-term toxicity due to cumulative effects. Dose-scheduling studies are designed to determine the optimal administration schedule for an investigational agent.

Dose-scheduling studies can be combined with dose-finding studies or can be completely separate studies. Pharmacokinetic and safety data obtained during a Phase I

dose-finding study may suggest it is feasible to increase the dose and/or reduce the frequency of administration of an agent, therefore indicating that a dose-scheduling study is warranted.

Combination Studies

The typical Phase I dose-finding study is designed to determine the maximally tolerated dose of a single, novel agent. However, an increasing number of patients, particularly in oncology, are being treated with drug combinations. The goal of a two-agent dose-finding trial is to find the maximally tolerated dose of a dose combination (or combinations). Combination studies can be performed to determine the optimal dose and schedule of experimental drugs combined with standard chemotherapies and also of novel drugs combined together.

At the time that a combination study is designed, the monotherapy MTDs of the individual agents under investigation are usually known. As a result, a minimal number of dose levels are typically needed to achieve the recommended dose of both drugs in combination. In the past, combination studies were routinely performed as single-arm trials. However, recent novel designs, which include targeted and standard therapies, have been designed with several arms with differing standard therapies in combination with the novel agent under investigation.[17] Such a design has been shown to expedite the identification of the combination MTD.

A common design for dose-finding studies with multiple agents is to investigate a single dose, or a small number of doses, of one agent and multiple doses of the second agent. If the study is combining a novel agent with a standard chemotherapy, the dose of the novel agent is usually varied while the standard chemotherapy is held to a single or a few doses.

Phase I Cancer Clinical Trial Designs

Many Phase I clinical trial design methods have been proposed, and there is currently no consensus among the scientific, medical, and statistical communities on how best to perform these studies in humans.

Traditional Design

The most commonly used design, often referred to as the *traditional* or *3+3 design*, begins by assigning three patients in a cohort at a designated dose level, often one-tenth the lethal dose (LD_{10}) in mice or the NOAEL in the most sensitive animal species, scaled to humans.[18] Doses to be assigned are predefined by the investigators, based on preclinical data and clinical experience with similar agents, if it exists. One method of assigning successive dose levels uses a set of "increasing decreasing" Fibonacci dose-level increments, usually 100%, 67%, 50%, 40%, and 33% for each dose level thereafter.[19-21] These increments are added to each dose to get the next dose level. For example, the second dose level is 100% more than the first, the third dose level is 67% more than the second, the fourth dose level is 50% more than the third, and so on.

The decision whether to escalate to the next higher dose, expand a cohort, or de-escalate to a lower dose is made based on the toxicity information received from each three-patient cohort (Figure 48-1). If none of the three patients experiences a dose-limiting toxicity (DLT), the study proceeds to another cohort of three patients at a higher dose level (escalation phase). DLTs are predefined and often include unacceptable drug-related toxicities as defined in grading scales commonly used in oncology, such as the National Cancer Institute's Common Terminology

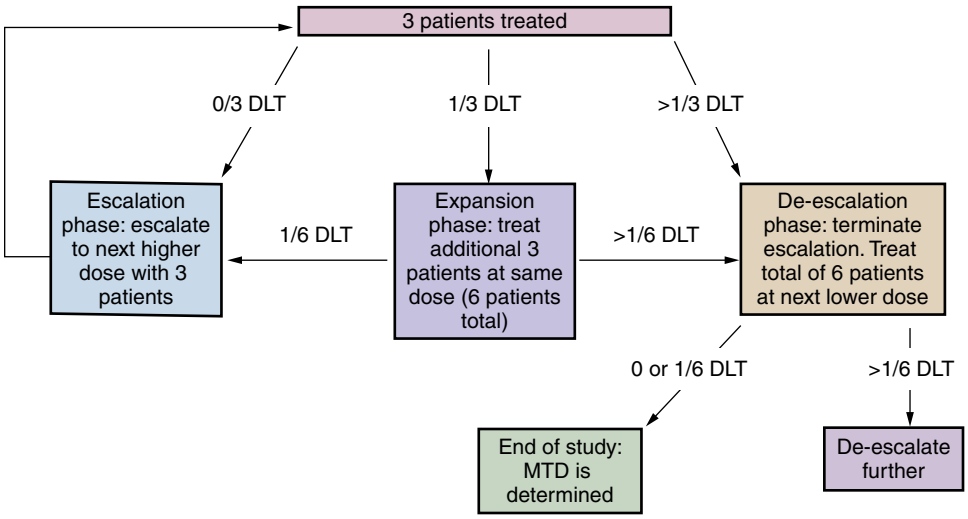

Figure 48-1 The traditional "3 + 3" Phase I clinical trial design. The initial 3-patient cohort begins at a predefined dose. If no DLTs are observed, escalation to the next higher dose will occur. If a single DLT is observed, expansion of the cohort to a total of six patients occurs. If more than 1 DLT is observed, de-escalation to the next lowest dose will occur for a total of six patients treated at that dose. Termination of the study will occur if more than one DLT is observed at the starting dose. The MTD is defined as the highest dose level for which no more than one patient out of six experiences a DLT.

Criteria for Adverse Events (CTCAE). If 1 of the 3 patients treated on a dose-level cohort experiences a DLT, up to an additional 3 patients (for a total of 6) are treated at that dose level (expansion phase). If none of the additional patients experiences a DLT, the dose will escalate. If at least 2 patients experience a DLT, the MTD is said to have been exceeded and the maximum administered dose (MAD) has been defined. An additional 3 patients will be tested at the next lowest dose level if there were only 3 patients previously treated at that level (de-escalation phase). In this particular case, the MTD is therefore defined as the highest dose level for which no more than 1 patient in 6 experiences a DLT. Table 48-1 shows the different dose escalation/deescalation decisions associated with toxicity outcomes at a given dose for an example of the 3+3 design.

The rolling six design (RSD) has been used by the Children's Oncology Group as an alternative design to the 3+3 design.[22,23] Because ethical considerations of informed consent almost always preclude a first-in-human trial in a pediatric population, the RSD is used to reduce trial interruptions and delays where there is prior human experience. The RSD begins like the 3+3 design and enrolls a cohort of 3 subjects on a dose. A fourth subject can be enrolled if at least one of the first 3 patients has not fully completed the initial first-dose evaluation for toxicity and no more than 1 of the previous 3 subjects has experienced a DLT. A fifth (sixth) patient can be enrolled if at least 1 of the first 4 (5) subjects has not completed the initial observation period and no more than 1 DLT has been observed. If not more than 1 fully evaluable patient at a specific dose cohort experiences a DLT, the study enrolls a new cohort of patients on the next highest dose. If at any time, 2 of 2 to 6 patients receiving the same dose experience a DLT, the study enrolls a new cohort of subjects on the next lowest dose. If 6 patients were already entered at the next lowest dose, that next lowest dose is selected as the MTD. The RSD allows for temporal overlap of the two cohorts of 3 subjects used in the 3+3 design. Hence, the probability of trial suspension to further accrual is lower in the RSD design as compared to the 3+3 design.[22]

Table 48-1 Dose Escalation/De-escalation Decisions Associated with Toxicity Outcomes at a Given Dose for a Popular Version of the 3 + 3 Design

No. of Patients with Dose-Limiting Toxicity	Decision
0/3	Escalate one level
1/3	Treat 3 more at same level
1/3 + 0/3*	Escalate one level
1/3 + 1/3*	Stop and choose previous dose as the MTD
1/3 + (2/3 or 3/3)*	Stop and choose previous dose as the MTD
2/3 or 3/3	Stop and choose previous dose as the MTD

*Note that those rows with number of toxicities equal to 1/3 + t/3 (for t = 0, . . . , 3) corresponds to situations in which one toxicity is observed in the first cohort of 3 patients enrolled at the current dose and t toxicities are observed in the second cohort of patients enrolled at that dose.

Modifications to the Traditional Design

A fundamental conflict in Phase I trial design exists between escalating too quickly, resulting in the potential exposure of patients to excessive toxicity, and escalating too slowly, resulting in the treatment of patients at doses too low to be efficacious.[19] A major criticism of the traditional Phase I design is that the potential exists for many patients to be treated at subtherapeutic dose levels. In addition, the length of time these studies often take can inhibit the ability to rapidly bring new agents to subsequent Phase II and Phase III studies. Several variations to the traditional design have been developed in order to reduce the number of patients treated at doses below the biologically active level and to improve on the precision of the MTD definition. Some of the most commonly used types of modified traditional designs include those proposed by Storer[24] and by Simon and colleagues.[18]

The Storer BD design uses a two-stage approach.[24] In the first stage, only a single patient is entered at each dose level. Dose escalation continues with one-patient cohorts until a DLT is observed. Accrual to the second stage then begins at one lower dose level and follows the traditional (three-patient cohort) design. Such a scheme allows fewer patients to be treated at dose levels less likely to be efficacious. Storer also proposed defining the MTD by fitting the first-course toxicity data to a logistic dose-toxicity curve and letting the MTD be defined as the dose level associated with a target DLT rate (e.g., 20% to 30%).[24] This allows for a more precise MTD definition.

Simon described three types of accelerated titration designs that were modifications of the traditional design (referred to by Simon as Design 1).[18] The Simon Design 2 is similar to the Storer design in that it uses single-patient cohorts during the initial stage, but the switch to the second stage (the traditional design) occurs when either the first instance of first course DLT is observed or if two patients exhibit grade 2 toxicity, as defined by the CTCAE, during their first course of treatment.[18] The Simon Design 3 mimics Design 2, except for the incorporation of more rapid dose escalation by using double-dose steps during the single-patient cohort stage. Finally, the Simon Design 4 is similar to Design 3, except switching to the second (three-patient cohort) stage may occur when either the first instance of a DLT occurs or the second instance of grade 2 toxicity is observed in *any* course of treatment. The three Simon

accelerated titration designs also allow for intrapatient dose escalation, permitting escalation for an individual patient if toxicity during their previous course was less than grade 2 as defined by the CTCAE and did not result in a DLT. Accelerated titration designs have become very popular, as they can dramatically reduce the number of patients required, shorten the duration of the trial, and provide a great deal of information about cumulative toxicity, interpatient variability, and steepness of the dose-toxicity curve.[25] Most importantly, they provide all patients a maximum opportunity to be treated at a therapeutic dose. In reviewing several accelerated titration–design Phase I trials, it was identified that the advantages of its use from a prospective perspective were a minimal amount of patients needed to reach the MTD, a lower percentage of patients treated at potentially subtherapeutic doses or with an ineffective agent, and cost containment.[26-30] However, accelerated titration designs did not expedite the speed of completion of studies overall, relative to traditional designs when compared to matching studies done in high-throughput Phase I centers.

Cytotoxic versus Targeted Design

One of the assumptions inherent in the traditional Phase I design is that both toxicity and clinical benefit will increase as the dose of an agent increases. For cytotoxic therapeutic agents, this assumption usually holds true. Recently, however, several agents have been developed that target specific tumor characteristics, such as receptor function, and these agents may not follow the standard efficacy/toxicity model. Specifically, targeted agents may demonstrate a plateau on the dose-efficacy curve, meaning higher doses will not improve clinical benefit. In addition, toxicity occurring with the use of these agents, if it occurs at all, may not necessarily increase as the dose increases. For drugs of this type, determining the MTD may not be feasible or useful. For targeted agents that do not produce immediate or consistent drug-related toxicity, three categories of alternative endpoints have been considered: (1) measuring inhibition of a target, (2) plasma drug levels that are biologically relevant, and (3) surrogate markers of biologic activity in nontumoral tissues.[31]

Several Phase I trial designs have been developed for studies examining targeted, noncytotoxic agents.[32-34] Hunsberger and colleagues proposed several designs based on the assumption that there is a binary (positive or negative) response that is measured in each patient after treatment with an agent; this response indicates whether or not the desired effect has been achieved.[32] The simplest of these designs mimics the traditional 3+3 design but adapts it to examine response rather than toxicity. The goal of this design is to recommend the lowest dose meeting a predefined level of activity (response) for further testing. Dose escalation occurs when a predefined number of responses are not observed. Dose de-escalation will occur if the predefined level of activity has been exceeded.

Pharmacokinetically Guided Dose-Escalation Method (PGDE)

The pharmacokinetically guided dose-escalation (PGDE) method of clinical trial design was proposed by Collins and associates as a more informative and efficient alternative to the traditional design.[19,35] The authors retrospectively analyzed the results of several Phase I studies of chemotherapeutic agents and demonstrated that observed toxicity was not a function of the dose administered to the patient, but rather was a function of the area under the curve (AUC) of plasma drug concentration measured over time of exposure. The PGDE Phase I clinical trial design targets the AUC associated with the mouse LD_{10}. Patients are treated at one-tenth of the mouse LD_{10}, as in the traditional method, but escalation to the next dose and subsequent doses is based on the distance of the observed AUC in humans to the target mouse LD_{10} AUC. The retrospective analysis performed by Collins and colleagues indicated that the sample size of Phase I clinical trials could be reduced by as much as 50% by using the PGDE over the traditional design.[19] Although several studies have reported success with the PGDE design, it is still not widely used in the drug development community.[36] One reason for the lack of use is the presence of large interpatient variability in AUC for the same administered dose.[25] For some drugs (e.g., antimetabolites and vinca alkaloids), toxicity is a function of exposure time above a threshold rather than AUC, and the use of a PGDE design is not justified.[37] Finally, the requirement of real-time pharmacokinetic monitoring inherent in the PGDE design has been considered a limitation to its use.[36,38] Pharmacokinetic correlative studies, however, have become standard measurements in almost all oncology Phase I trials as they help to better understand Phase I trial outcomes.

Continual Reassessment Method (CRM)

O'Quigley and co-workers proposed the Continual Reassessment Method (CRM) as an alternative Phase I study design. This Phase I design uses formal statistical methods of dose-toxicity modeling to guide dose escalation.[39] The CRM is considered superior by many because it allows the use of toxicity information gained at earlier time points of the study to assign subsequent doses. The CRM design is considered less likely to treat patients at toxic doses and more likely to

treat patients at doses considered efficacious.[40] The CRM, as originally designed, works by fitting a dose-toxicity curve to the available toxicity data and assigns subsequent patients to the dose most likely to be associated with a predefined target toxicity level. Therefore, the MTD is defined as the dose estimated to produce a desired predefined toxicity rate. The estimated dose-toxicity curve is refitted after the outcome of each individual patient is determined, and the next patient is assigned the dose estimated to be nearest the MTD based on the new data.[40] Because of its complexity, involvement of a capable statistician is necessary in the design and execution of a CRM-designed clinical trial.

Statistical Considerations of Phase I Studies

There are many designs available to estimate the MTD, as discussed earlier. Two of the main design types used in practice are either algorithmic in nature (e.g., the previously described 3+3 design) or model-based designs (i.e., designs based on a statistical model). The purpose of the 3+3 design is not to produce accurate estimates of the probability of toxicity at a given dose but to quickly identify a dose level that does not exhibit too much toxicity. An alternative to algorithmic approaches such as the 3+3 design, and one more amenable to the goal of precisely estimating (i.e., estimating with more certainty) the MTD, is model-based methods. The conceptual framework for most model-based Phase I designs is Bayesian. Bayesian designs treat the probability that a patient will experience toxicity at a given dose as a quantity about which the investigator has some degree of uncertainty. Moreover, this uncertainty is quantified via probability. The Bayesian framework provides a means by which one can learn about the toxicity rates at the different doses and naturally make decisions based on the data observed in a sequential manner.

Using these model-based designs requires that the investigator *explicitly* specify a target probability of toxicity. The target probability of toxicity represents the rate of toxicity acceptable to the investigator (the 3+3 design has an *implicit* target rate of toxicity of approximately 17%). For compounds associated with very severe life-threatening toxicities, the target probability may be set by the investigator at 0.10 (i.e., 10%), whereas for other compounds with more mild toxicities it may be acceptable to set the target probability of toxicity at 0.35. As with algorithmic designs, patients are sequentially enrolled into the trial in cohorts of patients. After each cohort of patients has been evaluated for toxicity, the decision to escalate, stay, or de-escalate from the current dose is based on the dose that has the expected probability of toxicity closest to the target toxicity.

An important advantage of model-based Phase I designs is that they allow one to combine information from patients treated at different dose levels, that is, to "borrow strength," in order to more reliably predict what may occur at a particular dose given to a future patient. A second advantage is the ability to adjust the target probability of toxicity to match the characteristics of the compound under investigation. A third advantage of model-based methods is that, unlike the 3+3 design, the cohort size is not limited to 3 patients and, more importantly, a variable cohort size may be used. Although one could argue that algorithmic designs can also use alternative cohort sizes, the complication associated with changing the cohort size when using "X+X" algorithmic approaches (e.g., 2+2, 4+4, 5+5) is that the implicit targeted rate toxicity changes with the size of the cohort. We should note that there are other algorithmic designs which do not tie the implicit target toxicity rate to the cohort size but these methods are very rarely used and tend to place too many patients on doses that are too toxic (reviewed in Ivanova and colleagues[41]).

Although model-based designs have been available since the early 1990s, these methods have not gained as wide an audience as biostatisticians would like. This is because it can be difficult to explain these methods to nonstatisticians, and the methods are difficult to implement.[42] These difficulties are being addressed by making computer code available to investigators and by providing innovative designs that target endpoints other than the typical endpoint in a classical implementation of a Phase I oncology design.

Pharmacodynamic Markers in Phase I Studies: Tissue Analysis

Overview of Pharmacodynamic Markers in Tissues

In recent years, there has been significant progress in the development of drug-targeted therapies, particularly those that target receptor tyrosine kinases (RTKs).[43,44] The emergence of molecularly targeted agents against numerous targets offers potentially greater anticancer efficacy with fewer side effects. Despite these recent advances, assessing the effects of these agents individually or in combination, or combined with conventional therapies, has created significant challenges for basic scientists and clinical investigators to effectively integrate molecular targeted therapies into clinical practice.[45] Because the number of possible drug-target combinations is enormous, better strategies are needed to understand the pharmacodynamic effects of

investigational agents in tumors.[46] One of the most informative approaches is to implement correlative tissue-based analyses in clinical studies.[47] This section discusses the development of reliable assays for quantifying pharmacodynamic effects in tissues, the effects of different agents on various markers and their correlation with clinical outcome, and issues that pose challenges for incorporating tumor tissue analysis into clinical trials.

Quantitative Analysis of Pharmacodynamic Markers in Tissues

Investigators typically rely on immunohistochemistry (IHC) assays to measure the pharmacodynamic effects of molecular targeted therapies in tissues. The majority of these studies use chromogenic or immunoperoxidase staining, which are semiquantitative and have other limitations.[48] In contrast, immunofluorescence (IF) detection methods can provide simultaneous labeling of multiple proteins in one sample and a quantitative assessment using a continuous scale.[49] Recent research efforts have focused on the development of IF-based assays to quantify protein expression patterns and apoptosis in tissues for Phase I studies (Figure 48-2).[50,51] Initially, this work focused on developing a method to detect apoptosis in endothelial cells, which requires three fluorochromes to visualize the total cell nuclei, endothelial cells, and terminal deoxynucleotidyl transferase-dUTP nick end labeling (TUNEL)-positive cells.[52] Hence, multiple labeling techniques can facilitate visualization of specific cell types by eye as a result of colocalization of different fluorochromes (see Figure 48-2). However, manual quantification is limited to enumerating "positive" and "negative" cells in random microscopic fields using a categorical score and may not be able to detect subtle but significant changes.[53]

Various platform technologies have been developed to facilitate quantitative in situ assessment of protein expression.[54] Most of these systems are designed for standard IHC assays using chromogenic substrates. Measuring the

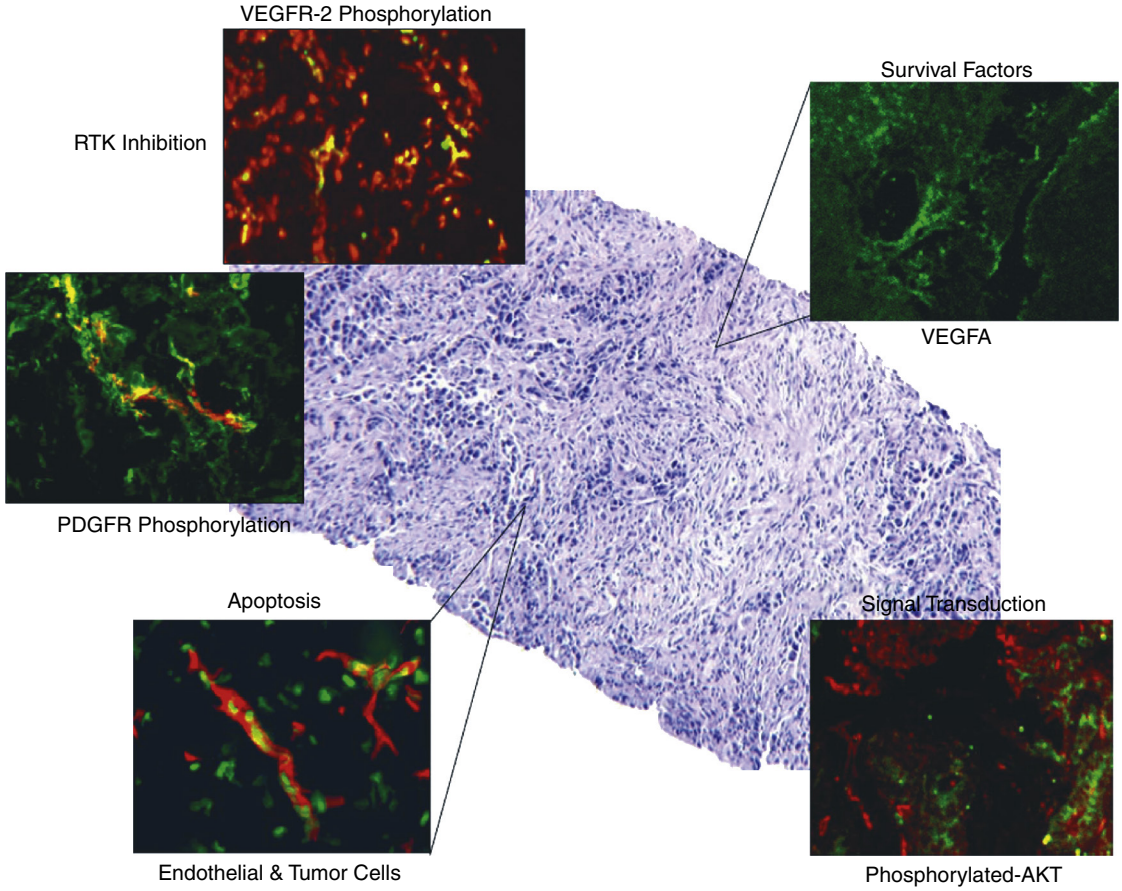

Figure 48-2 Pharmacodynamic analysis of molecular targeted therapies in tumor tissues. Correlative tissue studies may help determine the pharmacodynamic effects of targeted therapies on receptor tyrosine kinase phosphorylation, growth factors, signal transduction, and apoptosis in Phase I studies. Immunofluorescence detection permits the analysis of biomarkers in specific cell types, such as phosphorylation of PDGFR-β in endothelial cells. Measuring endpoints that include target or pathway inhibition linked to apoptosis may provide better evidence of the biological effects of the drug in the tumor and correlation with clinical outcome. (*Red*, endothelium; *green*, protein expression or terminal deoxynucleotidyl transferase-dUTP nick end labeling (TUNEL); *yellow*, colocalization of endothelium and protein or TUNEL.)

pharmacodynamic effects of molecular targeted therapies requires the ability to detect specific cell types, such as endothelial cells, and quantify their protein expression patterns. One platform technology capable of quantifying multiple fluorochromes in fixed tissue specimens is the laser scanning cytometer (LSC). The LSC platform is an automated analysis system described as a cross between a flow and a static image cytometer. Lasers are used to simultaneously excite different fluorochromes in cellular specimens that emit discrete wavelengths detected by a set of photomultiplier tubes. Together these features permit the ability to generate high-content stoichiometric data on heterogeneous populations of large numbers of cells. Thus, the LSC is used much like a flow cytometer to obtain multicolor immunofluorescence intensity information on fixed specimens.

Several Phase I studies have incorporated LSC-mediated analysis to determine drug-target interactions, effects on downstream signaling pathways, and rates of apoptosis in skin and tumor tissues.[49-51,55] Because the LSC is a platform technology, many different applications can be developed to exploit its inherent capabilities. Research efforts have been focused on developing specific tissue-based applications using LSC technology in an attempt to standardize the methodology for consistent data generation that can be compared between different tissue specimens and molecular targeted therapies. Although LSC-mediated data acquisition is automated, the process requires a systematic interactive approach to maintain high quality-control standards and ensure consistent data generation (Figure 48-3). Pharmacodynamic data generated using a process to analyze markers in entire tumor tissue cross sections has consistently provided biological evidence of the effects of targeted therapies and correlation with clinical outcome.[49,56,57]

Pharmacodynamic Analysis of Receptor Tyrosine Kinase Targeted Therapies

Aberrant expression of cell-surface RTKs, such as epidermal growth factor receptor (EGFR), plays a pivotal role in the progression of cancer.[58] Drugs that target RTKs are designed to block the intrinsic enzymatic activity that catalyzes the transfer of the gamma-phosphate of ATP to tyrosine residues in protein substrates.[59] Inhibiting phosphorylation of these tyrosine residues prevents downstream signaling events, which affect cellular function (e.g., proliferation, differentiation, migration, or apoptosis).[60] Thus, the ability to measure phosphorylation status and signal-transduction pathways has become an important pharmacodynamic endpoint in clinical studies.

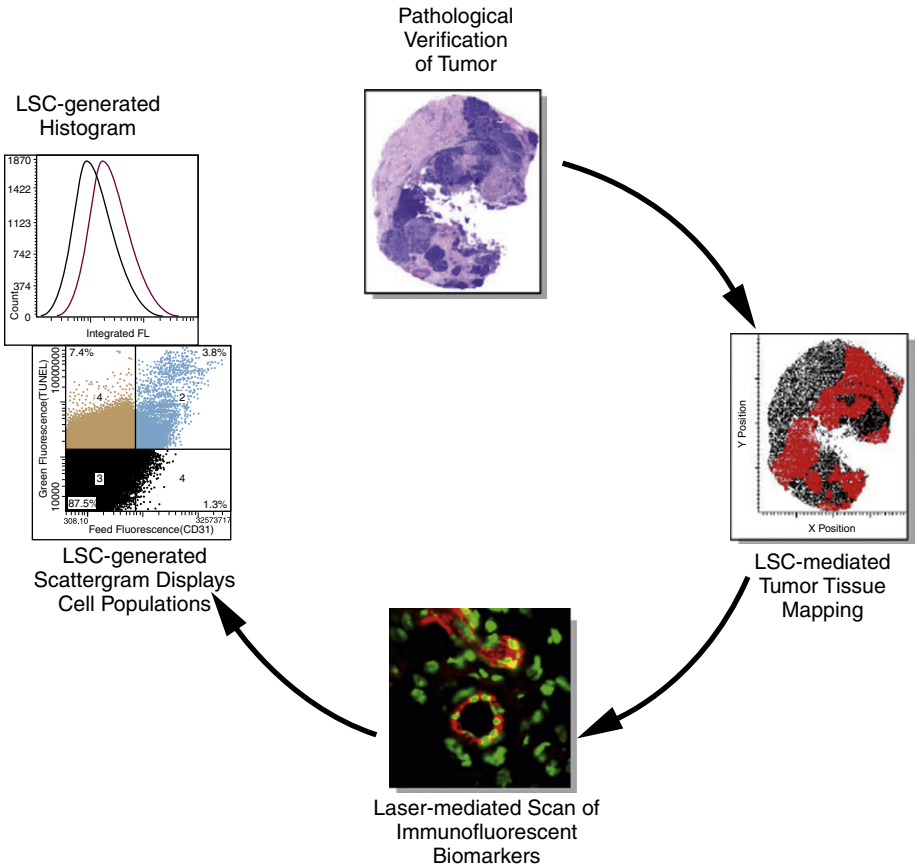

Figure 48-3 Quantitative analysis of pharmacodynamic effects in tissues using LSC technology. Pathological verification of biopsy samples is essential for mapping tumor regions and excluding normal and necrotic regions from the analysis. Lasers detect individual cells within the mapped region of interest based on immunofluorescence staining. LSC-generated scattergrams display the percentage of cell populations based on user-defined gating using controls, e.g., apoptotic endothelial cells. Alternatively, protein expression levels, such as phosphorylated VEGF receptor-2, measured by mean fluorescent intensity may be determined as shown in the histogram. *(Immunofluorescent image appears with permission of Eaton Publishing, Westborough, MA 01581, USA; Cover,* BioTechniques, *Vol. 28, No. 6 (June 2000)).*

Table 48-2 Recent Successful Phase I Trials

Drug	Patients	Response Rate	Stable Disease	Disease Control
Erivedge[65]	33	55%	33%	88%
Vemurafenib[66]	16	69%	19%	88%
Crizotinib[67]	10	30%	40%	70%

Gefitinib

Gefitinib (Iressa, ZD1839) was the first in a new class of small, molecular targeted therapies against EGFR to gain market approval (based on two Phase II studies) for non–small-cell lung cancer.[61,62] Although the Phase II studies did not incorporate correlative tissue studies, it was demonstrated in two different Phase I studies of gefitinib that pharmacodynamic endpoints can be measured in both tumor and skin tissues. In a metastatic colorectal cancer trial, total EGFR levels; phosphorylation of EGFR, AKT, and ERK; p27 levels; beta-catenin expression; and apoptosis were assayed before and after treatment in tumor biopsies, with interesting results in only a small number of patients. In another Phase I study of gefitinib in metastatic breast cancer, comparison of pre- and posttreatment ERBB2 and EGFR values was not statistically significant between the subgroups of patients regarding responsiveness to treatment.[63]

Serial skin biopsies have been analyzed as potential surrogate tissues for monitoring the biologic effects of molecular targeted therapies. A Phase I study of gefitinib in advanced solid malignancies incorporated skin, but not tumor, biopsies to determine the effects on EGFR signaling.[64] Levels of phosphorylated-EGFR expression were completely inhibited; however, no changes in total EGFR expression were observed after treatment. Other downstream markers in the EGFR network were affected by ZD1839, including phosphorylated-Ras-mitogen-activated protein kinase (MAPK) and STAT3, Ki67, p27(kip1), and apoptosis (Table 48-2).[65-67] Although significant changes were observed in almost all of the markers when comparing pre- and posttreatment skin biopsies in small numbers of patients, none of the changes correlated with dose or clinical response.

Pharmacodynamic Analysis of Signal Transduction Inhibitors and Other Targets

Vemurafenib

Vemurafenib (PLX4032, Zalboraf) is an ATP-dependent serine/threonine kinase inhibitor approved for use in patients with stage IV melanoma with BRAF(V600E) mutations. Forty percent to 60% of melanomas, and 7% to 8% of all cancers, carry an activating mutation in *B-RAF*. Ninety percent of reported *BRAF* mutations result in a substitution of glutamic acid for valine at amino acid 600—the V^{600} mutation. This BRAF mutation constitutively activates BRAF and downstream signal transduction in the MAP kinase pathway. Preclinical studies showed that vemurafenib inhibits the kinase activity of BRAF with the V^{600} mutation at low nanomolar concentrations, abrogates signaling through the MAP kinase pathway, and blocks proliferation of cells carrying BRAF with the V^{600} mutation in vitro at high nanomolar concentrations.

In the Phase I clinical trial, the extent of pathway inhibition and tumor responses correlated with higher plasma drug exposures. Patients with vemurafenib plasma exposures (AUC_{0-24}) less than 300 mM hr experienced no measurable tumor responses, whereas 24 of 32 patients treated at the MTD/RP2D of 960 mg BID had PRs or CRs, where the AUC_{0-24} was 1741 μM hr. Paired biopsies were taken from selected patients, at baseline and after 14 days of exposure. Decreases in cytoplasmic, though not nuclear, pERK correlated well with tumor response. Greater than 80% inhibition of cytoplasmic ERK phosphorylation was observed in responding patients, which suggests that near-total inhibition of BRAF signaling is required for clinical benefit.[68]

Aflibercept (VEGF-trap, Eylea) is a recombinant protein consisting of segments of the extracellular domains of human vascular endothelial growth factor receptors 1 (VEGFR1) and 2 (VEGFR2) fused to the constant region (Fc) of human IgG1. Aflibercept functions as a soluble decoy receptor, binding to blood vascular endothelial growth factors (VEGFs) and preventing VEGFs binding to the VEGFR-1, -2 receptors. Aflibercept is approved for use in age-related macular degeneration and in combination with chemotherapy for colorectal cancer. In Phase I clinical trials in cancer patients, the saturation of aflibercept by circulating VEGF was used to determine the appropriate dose for Phase II/III trials. Preclinical studies demonstrated a requirement for free aflibercept to exceed the VEGF-aflibercept complexes for antitumor activity. At doses of 2 mg/kg[69] and 800 mg,[70] there was no further increase in complex formation, and free drug levels remained in excess of bound aflibercept levels. These concentrations correlated with DCE-MRI effects on tumor perfusion (see later discussion), immunologic evidence of VEGF binding, and clinical outcome, thus allowing selection of a biologically active dose on a rational basis.

Recent Therapeutic Successes with Phase I Trials

Although the traditional role for Phase I studies has been the evaluation of toxicity of the MTD and RP2D, with

efficacy evaluated in expansion cohorts and Phase II trials, recent studies with enriched populations for specific targets have shown significant responses, followed by successful randomized Phase III trials and FDA approval, although the approval occasionally occurred even before or in the absence of the Phase III trial (see Table 48-2). Erivedge (GDC0449) received FDA approval after remarkable results from the Phase I trial, where responses were seen in 18 (55%) of 33 patients with locally advanced or metastatic basal cell carcinomas, with an additional 11 (33%) patients achieving stable disease; progression was seen in only 4 patients.[65] In the Phase I trial of vemurafenib (PLX4032), in patients with melanoma harboring the BRAF V600E mutation, complete or partial responses were observed in 11 (69%) of the 16 patients treated in the dose-escalation phase and 26 (81%) of the 32 patients treated at the extension phase with the recommended Phase II doses.[66] Vemurafenib was subsequently approved after the results of a randomized Phase III trial showing improved overall survival compared to dacarbazine in patients with BRAF V600E mutated in previously untreated patients with metastatic melanoma.[71] In the Phase I trial of crizotinib (PF-20341066), there were 3 responders and 4 patients with stable disease, including 3 patients with tumor reduction of 20% and one with stable disease for 28 weeks, among the 10 patients with ALK rearranged non–small-cell lung cancer.[67] The promising results were confirmed in the Phase II study, where 47 (57%) of 82 patients with ALK rearrangement achieved partial response, and 27 (33%) had stable disease, mostly by tumor shrinkage that did not meet criteria for partial response.[72] These highly successful drugs may change the paradigm in Phase I studies, bypassing Phase II studies to move directly into randomized Phase III studies in an attempt to allow rapid access to drugs with the potential to significantly improve survival in selected patient populations.

Challenges and Perspectives

There are many challenges involved in successfully incorporating tissue analysis in the design of a clinical study. Acquiring the tissue alone requires the commitment of the sponsor, scientists, oncologists, interventional radiologists, committees, and patients. Standardization of tumor sampling, tissue procurement, and storage procedures is critical to ensure that quality tumor tissue is being evaluated. A lack of quantitative standardization among different assays may lead to unintentional interpretation and variability among laboratories. Other issues that may affect interpretation of pharmacodynamic data are intra- and intertumor heterogeneity, tissue microenvironment (skin versus tumor), compensatory mechanisms, and timing of biopsies after initiation of therapy and after the last dose. It is worth emphasizing that few studies have attempted to link target or pathway inhibition with tumor-cell apoptosis. It is possible that some agents may demonstrate transient target inhibition, but fail to induce apoptosis.[49] Thus, measuring pharmacodynamic endpoints that include target or pathway inhibition linked to cellular fate, such as apoptosis, may provide better evidence of the biological effects of the drug in the tumor.

Pharmacodynamic analysis of tumor tissues can provide direct proof of whether an investigational agent affected its intended target and downstream consequences on signal transduction and apoptosis; however, such studies are limited. Recent studies have demonstrated that skin may serve as a surrogate tissue to confirm drug-target inhibition, signal transduction, and kinetics in clinical studies. However, analysis of biomarkers in tumor tissues may better represent the biological effects of a targeted therapy, as tumor cells often respond differently compared to normal cells. More quantitative studies are needed to identify reliable biomarkers and the correlation between the effects in skin, tumor, and clinical outcome. Another promising surrogate source that could potentially be used to assess the effects of targeted agents is the circulating tumor cell or endothelial cell. These cells may better represent the tumor microenvironment and are now being routinely isolated for a variety of applications.[73] Ongoing research efforts are aimed at developing assays to analyze the pharmacodynamic effects of drugs on circulating tumor and endothelial cells. Furthermore, pharmacodynamic studies in tumor tissue may also identify the genomic and proteomic profile of the population with the greatest chance to benefit from treatment. For example, the therapeutic activity of trastuzumab (Herceptin) would likely have been missed if patients had not been preselected based on their HER2 status.

Clearly, there is a need for better strategies to assess the effects of molecular targeted therapies early in clinical development. For example, in a Phase I trial of bevacizumab, no objective responses were observed out of 25 patients.[74] Not until a series of randomized Phase II and III trials over a period of more than 5 years was the clinical activity of bevacizumab established. However, it is generally not practical to perform large randomized trials for drugs without evidence of biological activity early in their development, and therefore, many promising drugs may not be developed. Given the large number of targeted therapies entering clinical testing, it is crucial that Phase I studies incorporate correlative endpoints to determine biological activity and optimal dosing and scheduling for Phase II and III trials. Ultimately, clinical development of targeted therapies would benefit if the recommended dose was identified early and actually known to inhibit the target for which it was designed.

Imaging Techniques in Phase I Studies

A variety of imaging techniques can play an important role in Phase I studies of anticancer drugs when used as an objectively measured indicator of a biological/pathobiological process or pharmacologic response to treatment (i.e., as a biomarker[75]). Imaging biomarkers can be used to determine if the drug is hitting the target and if it has the anticipated biological activity, and they can also provide an early indication of whether or not the new agent has clinical activity.[76] The information provided by imaging biomarkers, taken together with information from molecular biomarkers and clinical pharmacology, provides the input required to determine how aggressively to pursue the development of a particular drug or a backup drug for a given target. In addition, imaging biomarkers can assist in the selection of the dose and/or schedule for Phase II studies.[77]

The ability to detect a labeled drug at one thousandfold lower concentrations than needed to produce pharmacodynamic effects makes nuclear medicine the modality best suited for determining if the drug is hitting the target.[78] A number of imaging modalities can be used to determine if the drug has the anticipated biological or antitumor activity. The more commonly used methods are dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) and [^{18}F]fluoro-2-deoxyglucose (FDG) positron emission tomography (PET). DCE-MRI, which employs a commonly used contrast agent (gadopentetate dimeglumine), has been implemented in several Phase I studies to quantify the effects of antivascular agents on the tumor blood supply within hours to days after the start of treatment.[79] Further research will be needed to determine if it is a suitable marker for predicting clinical activity.

FDG-PET uses an ^{18}F-labeled glucose analog (FDG) that is transported into cells by GLUT-1 and GLUT-3 and phosphorylated by hexokinase. Because FDG-6-P is a poor substrate for glucose-6-phosphatase, there is little dephosphorylation, and the radioactivity is trapped in the cell.[80-82] Glucose metabolism is quantified as the activity in the tumor, normally restricted to the region of highest activity, relative to the amount of activity injected and patient's body weight, the so-called Standardized Uptake Value (SUV). The potential for FDG-PET to assess drug-induced biological effects before a change in tumor size was illustrated clearly in patients with advanced gastrointestinal stromal tumors treated with imatinib mesylate.[83] Tumor FDG activity decreased markedly from baseline as early as 24 hours after a single dose of imatinib in all patients demonstrating a response by computed tomography (CT) or MRI weeks later. Conversely, increased tumor FDG activity, activity at new sites, or both were seen in all patients with disease progression evident at a later date by conventional means. In patients with progressive disease after treatment with imatinib, FDG-PET metabolic response, defined as SUV decrease or increase by 25% from baseline at 4 weeks, provided an early prediction of response to sunitinib.[84] Although a variety of treatment regimens result in reduced FDG activity following the first cycle of therapy, after macrophage activity (which can result in increased FDG uptake) has subsided, yet before response is evaluable by standard methods,[80] such dramatic effects are not generally observed so early after treatment. Nonetheless, FDG-PET shows considerable promise to provide an indication of decreased tumor viability earlier than conventional methods and may provide a valuable downstream biomarker for biologic activity in Phase I trials.

Although it is not reasonable to expect clinical efficacy in the advanced-stage patients entered into Phase I trials and assessment of clinical response is not a primary focus of Phase I trials, any indication that the drug/target affects tumor growth is beneficial. Typically, tumor burden is assessed using either CT or MRI data. The method most commonly used to assess clinical effect is based on Response Evaluation Criteria in Solid Tumors (RECIST), which was put forth in 2000 as a simpler way to measure the response of tumors to experimental treatments.[85] The recently updated criteria (RECIST 1.1) include important changes such as the inclusion of cystic bone lesions with identifiable soft tissue components and progressing previously irradiated lesions as measurable disease, definition of measurable lymph nodes as those with shortest axis at least 1.5 cm, and progressive disease by PET scan defined as the presence of positive PET in a previously negative area.[86] It should be noted that, in practice, RECIST are generally modified to address some of the concerns raised by the International Cancer Imaging Society (ICIS) regarding the strengths and weaknesses of using the RECIST criteria and what other issues should potentially be added to a response criterion.[87] Nonetheless, even with these changes, concerns remain regarding RECIST, especially in the context of early-phase trials.[88] One point of particular concern is whether the single longest tumor dimension, determined in an axial plane, accurately represents changes in tumor burden, because most tumors grow and regress irregularly.[89] Another concern is how relevant the categorical response assessments (complete response, partial response, stable disease, and progressive disease), which were originally based on the error in oncologists' physical measurements of solid spheres arranged in random size order on a soft mattress and covered with a layer of foam rubber, are in the context of early-phase trials.[90,91] It seems an alternative model, where response is considered a continuous variable, the change in tumor size (estimated as the single longest dimension, the cross product of the longest dimension and the perpendicular longest dimension, or volume) after treatment,[92] would be much more useful for evaluating clinical effect in Phase I trials. Some of the limitations from the RECIST criteria, including the evaluation of targeted therapies that frequently cause disease stabilization instead of objective response, may be addressed with the proposed PET

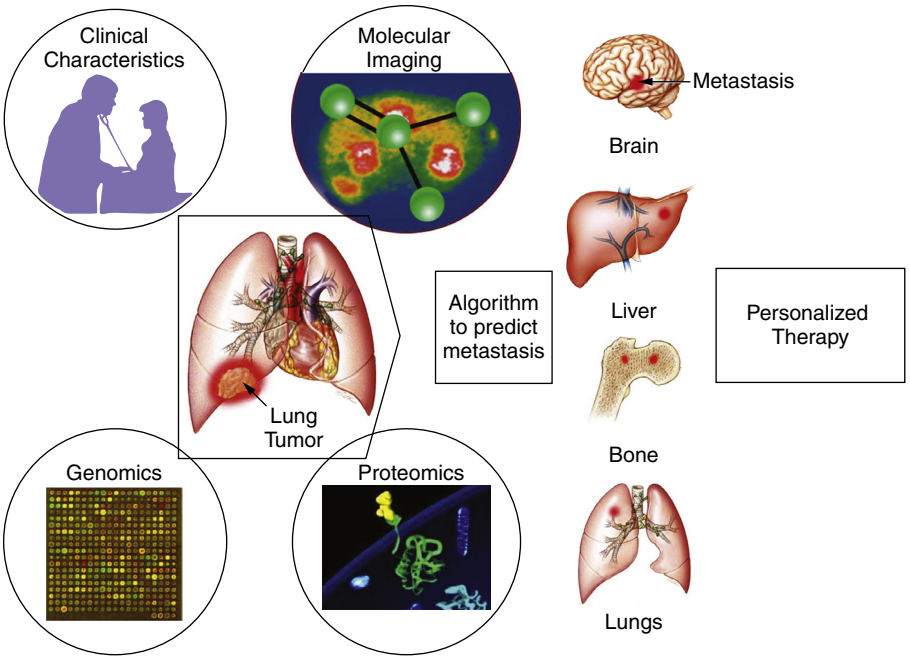

Figure 48-4 An algorithm comprising relevant proteomic, clinical and imaging factors plus genomic factors all indicating a poor prognosis (metastasis) and best choice of molecular-targeted chemotherapy.

response criteria in solid tumors (PERCIST), which classifies the metabolic response into complete (CMR), partial (PMR), stable (SMD), or progressive (PMR) based on complete resolution of FDG uptake in the measurable target lesions, reduction of at least 30% of the FDG uptake, changes from 29% decrease to 30% increase in FDG uptake, or increase of at least 30% in the FDG uptake, respectively.[93]

Conclusion

Cancer is and will be a major cause of death and morbidity in the United States and worldwide. Despite significant improvements in diagnosis, surgical techniques, general patient care, and local and systemic therapies, most deaths from cancer are still due to metastases that are resistant to conventional treatment. Novel therapeutic approaches are critically needed if we are to improve patient outcome. Phase I studies are the critical link in targeting cancer, because they represent the first translation of years of laboratory/preclinical studies to the patient.

As drug development has evolved to a more tumor-targeted or tumor-specific focus, so has the evolution of Phase I trials moved from the more generic, mathematical modeling to a more rational design. In addition, it is increasingly being recognized that incorporation of select endpoints relative to patient eligibility in Phase I trials is needed to more effectively and efficiently develop drugs clinically. Although the classification of most cancers is still based in large part on tissue type, tumor size, nodal status, and metastatic sites, there has been a rapid progress in the molecular characterization of solid tumors. Several Phase I designs are incorporating these tools, not so much as response predictors, but to help determine feasibility and to develop diagnostic/predictive tools for future clinical use. The hope is that a more personalized approach to clinical care will increase the efficacy of treatment, while decreasing its toxicity and cost. The end result is the development of Phase I trials aimed not only at defining dose and safety, but also at assisting in target validation while increasing the probability of benefit through the use of enriched populations (Figure 48-4). Recent studies have shown that effective drugs can be more expeditiously approved if used in a molecularly defined patient population, with a rapid transition from Phase I studies to proof-of-concept Phase II and randomized Phase III trials, with more rapid introduction into clinical practice.

49 Pharmacogenomics

Introduction

The term *pharmacogenetics* is believed to have first been used in 1959 by Vogel who defined it as "the study of genetically determined variations revealed by the effect of drugs."[1] Motulsky described the field similarly, but perhaps from the viewpoint of the clinical observer, calling the interaction "drug responses and their modification by hereditary influences."[2] With the advent of the ability to sequence the entire human genome[3,4]—wherein technology allows one the ability to rapidly and accurately determine billions of pieces of genetic information on a given individual—the term *pharmacogenetics* has slowly been replaced with *pharmacogenomics* to denote the consideration of the entire genome. Notwithstanding the term employed, the field is as relevant as ever. It offers the promise of achieving a paradigm of personalized drug therapy based on an individual's unique genetic makeup.

In reality, personalized care has been practiced for centuries, if one defines personalization as the consideration of all clinical, biologic, and environmental factors that make each patient unique. What changed with the sequencing of the first human genome—and through the simultaneous technological advances of profiling individuals (and, in cancer, tumors) on many levels (DNA, RNA, proteins, epigenetics)—was the expectation that "personalized medicine" would now also mean inclusion of molecular information. Some have termed this type of care *precision medicine*.[5] Pharmacogenomics, using that historical view, is therefore one of the oldest and most foundational pieces of precision medicine and precision therapeutics. Yet from the standpoint of how much there is still to know and implement, even after 50 years, pharmacogenomics is in its relative infancy.

Pharmacogenomics in Oncology

In cancer therapeutics, pharmacogenomic considerations are particularly relevant, for three reasons. First, many oncology drugs can have severe, undesirable toxicities. If genetic determinants or predictors of such toxicity could be identified, it might be possible to dramatically decrease undesirable harm when prescribing chemotherapy. Second, the stakes in cancer therapeutics are high. Lack of efficacy of a given treatment means loss of time, which in cancer care often is of seminal importance. Finally, pharmacogenomic considerations in oncology are complicated by the fact that there are two genomes in play: the genome of the patient (the germline or inherited DNA) and the genome of the tumor (the somatic or cancer DNA). Pharmacogenomic study has come to encompass the consideration of both, and thus it includes single-nucleotide polymorphisms (SNPs), gene copy number alterations (copy number variants, CNVs), and acquired changes (tumor mutations) as they relate to drug response or toxicity.[6,7] Somatic changes are of clear importance, including several that have led to the development of successful therapeutic interventions against a mutational event. However, for the scope of this chapter, we specifically restrict our considerations to germline genetic changes, because somatic changes reflect disease subcategorization at the molecular level, which is distinct from interindividual variability in drug response. In addition, in contrast to disease genetics, pharmacogenomics focuses specifically on predictive genetic markers of outcome from drug interventions, so we do not discuss DNA changes that potentially confer cancer susceptibility.

Even when considering only germline changes, pharmacogenomic questions have broad implications for oncology therapeutics in three very important ways:

1. In oncology, the concept of the therapeutic index is crucial. Many chemotherapy drugs were initially identified through screens for compounds that killed dividing cells.[8] Such drugs are still the mainstay of most anticancer regimens, but these cytotoxic drugs (and also even newer anticancer drugs that may work differently) are limited by possessing a narrow therapeutic index: the ratio between the dose that results in toxicity to the majority of individuals taking the drug, compared to the dose that results

in effect in the majority of individuals taking the drug. It is therefore rational to consider pharmacogenomic factors as potential determinants for drug dosing for chemotherapy drugs, in which relatively small changes in the dose can have dramatic undesirable effects (shifting the therapeutic index toward toxicity). Examples of this are provided later in the chapter.

2. In related fashion, it might be straightforward to understand how germline pharmacogenomic variants can be relevant for predicting the likelihood of toxicity from a drug, because germline variation in genes important for drug metabolism and excretion in the host might directly confer differences in enzyme function within these pathways. Indeed, many of the current, best studied examples of pharmacogenomic findings in oncology relate to toxicity predilection.[9] However, it has been interesting to also find that germline polymorphisms may affect *response* to treatment in malignancies. We explore ways that this occurs in this chapter. The important point is that germline pharmacogenomics has concrete promise for defining both *toxicity* and *response* in cancer therapeutics.
3. Germline pharmacogenomic discoveries have the potential to identify new oncology drug targets. Although this area remains one of ongoing research, germline mutations such as *BRCA1* may allow individuals with cancer to be more susceptible to certain types of DNA-damaging agents, such as poly(ADP-ribose)polymerase (PARP) inhibitors.[10,11] While drugs identified in this way remain under development, the number of examples like this is likely to increase, especially as more is learned about inherited changes in DNA structure and variation.

In this chapter we illustrate explicit examples of the first two points. However, we encourage the reader to simultaneously consider how, from the examples provided, opportunities for new drug discovery/identification of new drug targets (point 3) can also arise through the study of pharmacogenomics.

Genotyping and Phenotyping

Pharmacogenomic discovery and clinical implementation require the technical ability to accurately measure genotypes—the DNA sequence variation at specific genetic loci or regions. Most germline DNA variations fall into the class of SNPs, or single base-pair changes that occur with some relative prevalence in the human population (for example, a change from a guanine (G) to adenine (A) in the DNA strand [i.e., G/A polymorphism] in more than 1% of all individuals). Numerous technologies have been developed to perform genotyping and decipher such information at the DNA level.[12] Combining genetic data and associating it with a phenotype—an outward characteristic or trait—is where genomic information becomes valuable. Genotype-to-phenotype associations lie at the heart of pharmacogenomics, wherein all phenotypes of interest relate to drug effects (toxicities, response, drug levels in the blood, or drug effects on other biomarkers of drug action in the body). Clinical examples might include extreme drug phenotypes such as death, intermediate phenotypes such as development of severe hypertension, or more subtle phenotypes such as drug-induced hyperglycemia. The importance of accurate phenotyping also cannot be understated. Pharmacogenomic associations may not be detectable if phenotypes are not carefully defined and measured (ideally prospectively), or if important covariates such as cumulative drug dose are not considered. Similarly, relevant pharmacogenomic effects could be obscured by inappropriately combining phenotypes that are actually distinct.[13]

Pharmacogenomic Discovery Approaches

Single-Gene Approaches

Initial pharmacogenomic discovery methods typically consisted of "single-gene" approaches. These approaches presuppose that a given single gene (with purported a priori importance) is relevant to that drug's metabolism or action. Typically, these candidate genes code for enzymes involved in the mechanistic pathway of a drug's action or its metabolism. Variants within the candidate gene are then genotyped and analyzed in relation to a given drug phenotype.

The paradigmatic story of irinotecan pharmacogenomics is a classic single-gene example. Irinotecan is an intravenous chemotherapy drug first studied clinically in the late 1980s.[14,15] It is now used widely in the treatment of colorectal cancer. Importantly, irinotecan is a prodrug, requiring activation (through the action of carboxylesterase-2) to SN-38, an inhibitor of topoisomerase I, and then inactivation to SN-38 glucuronide (SN-38G) for elimination.[16,17] The stage for the pharmacogenomic story began with a phase I study conducted at The University of Chicago, which examined irinotecan on a weekly schedule and which suggested that the extent of glucuronidation to SN-38G was inversely correlated with irinotecan's dose-limiting toxicity.[18] Based on the fact that pharmacogenetic variation had been suggested to be related to toxicity for a few other cancer drugs at the time,[19-21] it was hypothesized that genetic factors resulting in reduced glucuronidation may be a cause of predisposition to irinotecan toxicity.[18] Studies in liver tissue from patients with a genetic deficiency of bilirubin

glucuronidation (Crigler-Najjar syndrome) were conducted, and it was found that these liver tissues were unable to form SN-38G.[22] However, transfection with cDNAs encoding the enzyme UDP-glucuronosyltransferase 1A1 (UGT1A1) resulted in SN-38G formation.[22] This result was intriguing, because a genetic polymorphism in *UGT1A1* had recently been identified that was associated with variation in glucuronidation.[23,24] The polymorphism is now known to be an insertion/deletion in the *UGT1A1* promoter (the "TATA" box) that reduces transcription of the gene, such that the resulting enzyme activity is inversely correlated to the number of TA repeats.[25] Six repeats is considered the wild-type (normal function) genotype, and individuals typically have either 6 or 7 repeats, most commonly (5 and 8 are rare).[26] Using a special pharmacogenomic nomenclature, the 6-repeat genotype is termed **1*, whereas having 7 repeats is called **28*.

Given that there was a candidate polymorphism, an in vitro pharmacogenetic study was next conducted. Liver tissues were again used to test the hypothesis that genetic variability in the *UGT1A1* promoter was associated with SN-38G formation (which it was),[27] and then, importantly, with irinotecan toxicity in patients being treated with the drug.[28] The latter was further demonstrated (specifically an association with neutropenia from irinotecan) in a larger study of irinotecan-treated patients (350 mg/m^2 every 3 weeks).[29] Severe neutropenia was significantly more common in patients with two copies of the **28* variant (**28/*28*; 50% of such patients had severe neutropenia) compared to only 12.5% in those with a **1/*28* genotype, and no patients with severe neutropenia among those having **1/*1* genotypes. The relative risk of severe neutropenia was 9.3 (95% confidence interval 2.4-36.4) for the **28/*28* patients.[29] The authors[29] and, later, others[30] also confirmed the metabolic role of UGT1A1 with supportive pharmacokinetic information.

Based on the data, the FDA drug label for irinotecan was revised in 2005 to include the pharmacogenomic information about *UGT1A1*. It recommends that patients with the **28/*28* genotype should be treated with a reduced starting dose of irinotecan.[31]

A large study including 250 metastatic colorectal cancer patients went on to redemonstrate the pharmacogenomic importance of *UGT1A1*, finding an odds ratio of risk of approximately 9 for those with the highest risk genotype (**28/*28*) for developing immediate severe neutropenia after irinotecan, although the pharmacogenomic relationship did not persist for subsequent treatment cycles of irinotecan.[32] A meta-analysis of the data was performed and published in 2007.[33] The meta-analysis included nine studies and a total of 821 patients. It confirmed the importance of **28* homozygosity. However, it interestingly suggested that the pharmacogenomic effect was most important for patients receiving higher doses of irinotecan (150 mg/m^2 or higher). At lower doses (doses that are still in the commonly used range), there was no statistically significant increased risk for patients with the **28/*28* genotype.

Given these nuances and concerns about the predictive power of irinotecan pharmacogenomics during initial dosing, some have argued that *UGT1A1* genotyping cannot be justified as a mandatory test in every patient for the purpose of initial dosage adjustment.[34] Indeed, *UGT1A1 *28* does not meet the typical standards for clinical specificity and sensitivity required of most diagnostic tests (one analysis suggested that its median positive predictive value was 50% [range 15% to 57%] and median negative predictive value was 85% [range 79% to 96%]).[26] Moreover, the **28* genotype alone is not sufficient to describe risk in individuals of some ethnic backgrounds, since the **6* allele also results in decreased UGT1A1 activity.[26,35] Nonetheless, the test clearly has potential clinical value in ethnic groups with a high prevalence of the **28* genotype and when high doses of irinotecan are planned, but these latter considerations emphasize the need for ongoing study of ways to improve the understanding of toxicity risk with irinotecan administration. Including other risk alleles within *UGT1A* in a haplotype-based analysis may increase the predictive value, because several other variants in these genes have now also been shown to alter enzymatic activity and affect irinotecan-related outcomes.[36]

Pathway Approaches

Pathway approaches use the rationale that a single gene may be of limited lone importance from a pharmacogenomic standpoint, because few drugs are metabolized by or have mechanisms involving only one gene product. In other words, most drugs are likely to be under multigenic control.[37] Therefore, pathway approaches hypothesize that a set of genes defining a specific metabolic or mechanistic pathway might sensibly be interrogated as a composite set, for pharmacogenomic relevance. Typically, investigators will select various polymorphisms of interest that have potential biologic relevance in the genes of interest (e.g., exon SNPs that change the coding sequence, or SNPs in promoter regions)—or, less specifically, they will select SNPs that "tag" regions across the genes of interest. Despite the reasonable rationale, to our knowledge this approach to pharmacogenomics has yet to yield any salient, clinically important results. Such studies often suffer from the problem that multiple SNPs are being tested, meaning that there is limited power for demonstrating statistical significance of any one SNP in small sample sizes (see further discussion of this later).

Genome-Wide Approaches

Single-gene approaches like those described earlier have the advantage that the analyses are conducted on very focused areas of the genome, areas having potentially the highest relevance. Typically, some evidence already exists that the gene is important on a functional level, usually through studies showing that the gene product is under differential expression or that the gene product is key to determining the pharmacokinetics of a drug. When only a single gene or even a few genes (as in pathway approaches) are being considered, only a limited amount of genomic information must be tested and assimilated using bioinformatic techniques.

In contrast, genome-wide association studies (GWAS) take an unbiased approach to pharmacogenomic discovery. These are open to the possibility that any gene is important (unbiased) and they can identify new genetic targets (i.e., they are hypothesis generating). The limitations of GWAS include a need for vast computational ability, the possibility of false discovery (explained further later), and, typically, a requirement for genetic information on a large number of individuals to identify compelling associations.

One well-executed example of the power of this approach is illustrated by the work of Yang and colleagues.[38] The authors set out to identify germline genetic factors that might predict therapy response in pediatric acute lymphoblastic leukemia (ALL). They and others had observed that significant interindividual heterogeneity existed for treatment response in ALL, and that most prior work had focused on tumor-related factors which might explain such variation. The authors hypothesized that unidentified germline (host) factors might also be important. Indeed, one pharmacogenomic factor had already been well described for a drug commonly used to treat ALL and other leukemias—6-mercaptopurine—although the pharmacogenomic relationship was that of the role of TPMT (thiopurine methyltransferase) activity in predicting severe toxicity (bone marrow suppression) from that drug,[39,40] not treatment response. The story of TPMT/6-mercaptopurine (and, relatedly, TPMT/thioguanine) toxicity pharmacogenetics is one of the earliest and best-characterized examples of the potential utility of pharmacogenomics. The FDA labels for 6-mercaptopurine and thioguanine have been revised to include TPMT pharmacogenetic information,[41] and some hospitals have implemented routine ordering of TPMT testing before administration of these agents.[42] This pharmacogenomic relationship had been identified through a candidate gene approach.

Yang and associates, however, wanted to determine whether there were germline factors predictive of treatment response in ALL.[28] Rather than restricting their analysis to any one candidate gene, they performed a GWAS of more than 470,000 germline SNPs to identify genotypes that associated with increased risk of minimal residual disease (MRD) in two independent cohorts (318 children and 169 children) with newly diagnosed ALL. They identified 102 SNPs associated with MRD in both cohorts.[38] Twenty-one of these SNPs were also associated with antileukemic drug disposition, strengthening a plausible link between MRD eradication and greater drug exposure. Many SNPs were in regions never previously studied as potential pharmacogenomic loci. Interestingly, five of the top associated SNPs were located in the interleukin 15 gene (*IL-15*) gene.[38] IL-15 was previously shown to protect lymphoid tumors from glucocorticoid-induced apoptosis in vitro,[43] and IL-15 expression in ALL blasts had been linked to central nervous system (CNS) involvement at diagnosis and an increased risk of CNS relapse.[44] Therefore, the link between germline SNPs in *IL-15* and worse outcomes, for several possible reasons, seemed strong. Because the authors did not (for obvious reasons) have an untreated control group in their study, it was impossible to say whether these *IL-15* germline SNPs were truly pharmacogenomic SNPs (predictive of residual disease through their action on antileukemic drug action) or prognostic SNPs that conferred a worse outcome, regardless of treatment. This points to how GWAS approaches can, simultaneously, yield powerful results and be hypothesis-generating, encouraging further follow-up of the role of IL-15 in this disease and its treatment. This point notwithstanding, at least some of the top 102 SNPs in this study were linked to antileukemic drug disposition and can therefore be characterized as pharmacogenomic, showing the power of this approach as a pharmacogenomic discovery tool.

Whole-Genome Sequencing (WGS)

Very recently, WGS methods have begun to become more commonplace.[45] This approach has the advantage of theoretically identifying every piece of genetic information (and also variation) across the entire genome, including every base pair, deletion/insertion, and copy number change. GWAS approaches, in contrast, classically cover only a limited number of such variants across the entire genome. Concrete examples of applications of WGS to pharmacogenomics are still currently awaited.

Bioinformatic Considerations

Last, it is important to describe the potential for false discovery in pharmacogenomic analyses. This is the inherent possibility that a variant will be found to be statistically

associated with a phenotype by chance alone.[46-48] When one is assimilating millions or even billions of pieces of genetic information at once (as in GWAS and WGS methods), the sheer number of association tests being performed is so large that one must adjust the threshold of statistical significance that defines a positive result.[46] As an additional measure of sorting true-positive findings from false positives, it is typically accepted that high-quality pharmacogenomic results are those for which the association can be replicated in an independent population.[49] Here again, assurance that the phenotypes match and were collected in similar fashion is an important methodological step.

Clinical Relevance of Pharmacogenomic Findings During Implementation

A number of oncology drugs have been studied to uncover pharmacogenomic effects,[9,34] and other well-validated oncology drug-gene interactions exist (TPMT/6-mercaptopurine; 5-fluorouracil/DPYD). An even greater number of promising associations have been described for many other drugs that await further characterization and validation.

What remains to be further elucidated for many of these associations is the degree to which individual associations have an effect on a clinical outcome when assimilated within the larger context of all variables that affect a therapeutic decision. By this we mean: when a clinician makes a prescribing choice, he or she already is used to—and is accomplished at—incorporating many factors to make the best drug choice. These include all of the elements of "traditional" personalized care: clinical factors about comorbidities, organ function, allergies, and drug-drug interactions; biologic factors such as disease subtype, age, and gender; and environmental factors such as habits, social environment, and compliance. The question is whether a specific pharmacogenomic association for a drug's toxicity or response likelihood—which is probabilistic by its very nature and is usually identified in a large cohort showing an overall effect—will matter for an individual patient when the clinician has to assimilate the pharmacogenomic information along with all other treatment factors, including potentially other important genetic factors. In many respects, it is a question that resolves around the effect size of the pharmacogenomic effect. The *UGT1A1* example—where the dose of the drug being administered (irinotecan) seems to matter as to whether the pharmacogenomic effect is observable[33]—may be one example of this dynamic and delicate interdependence between genetic effects and other clinical effects (such as dose) interacting (or one predominating) to determine the clinical phenotype.

A nononcology example here is perhaps illustrative. Using a genome-wide approach in a group of 1953 patients with major depressive disorder, researchers were interested in finding pharmacogenomic markers predictive of treatment response for the antidepressant drug citalopram.[50] Their results identified an SNP having an association with response with a P of approximately 1×10^{-6}. This SNP was then positively replicated by the same authors in a smaller, independent cohort of patients. Patients who were homozygous for the allele of interest had an 18% reduction in absolute risk of having no response to treatment.[50] Moreover, when this SNP was considered in a second analysis along with another SNP that had been independently associated with response likelihood, the combined reduction in risk (as one might predict) was even greater: 23%.[51] Despite these exciting findings, the authors examined their own data in another way to estimate the overall independent clinical predictive effect of using the genetic markers themselves. The authors found that it was, at best, modest, with a c-statistic of 0.58 using a receiver operator characteristic analysis, which expresses the probability of correctly identifying a responder from a random pair of patients.[51] This demonstrates that the effect of other clinical and environmental variables—besides pharmacogenomic variables—remains powerful. Others have argued this as well.[52] We believe that multivariate analyses which include genetic variables among other accepted clinical variables are what will be truly needed to demonstrate the clinical effectiveness of pharmacogenomic discoveries. In oncology, where another layer of potential deterministic relevance is involved (i.e., the tumor DNA), the link between a germline pharmacogenomic variant and a clinical outcome of interest is likely to be even more complex. Deciphering the stringency of such genotype-phenotype relationships in clinical use is one of the most pertinent questions currently facing pharmacogenomics.

Conclusions

Studies have led to the identification of genetic factors governing drug response and toxicity for hundreds of drugs,[53] including some chemotherapy drugs and agents used in the long-term therapy of cancer patients. Corresponding pharmacogenomic tests are available for clinical use for certain drugs, including chemotherapies, for which significant evidence has been accumulated, and FDA drug labels are increasingly incorporating consideration of pharmacogenomic factors in the prescribing information. Knowledge about pharmacogenomics can manifest as patient-specific dose modifications, optimization of

treatment choice when several equivalent therapies exist, or avoidance of a therapy when toxicity risks outweigh potential benefits. Even with this progress, important steps remain in navigating the translation of pharmacogenomic knowledge into widespread clinical use. However, precision medicine is unlikely to turn backward, and pharmacogenomics promises to be part of that evolution. On a population scale in oncology, it has the potential to reduce the significant burden of illness that is conferred when chemotherapies cause toxicity, or when chemotherapies do not work. In that regard, there are few more important questions facing oncology today.

Monoclonal Antibodies for the Treatment of Cancer

Introduction

Monoclonal antibodies have emerged as mainstays of cancer therapy and have had a significant impact on the morbidity and mortality of several cancers. This chapter will discuss the attributes that make antibodies powerful cancer therapeutics, how some antibodies are used clinically, and the development of new antibodies with clinical promise.

Antibody Structure and Function

Antibodies are heterodimeric proteins composed of two heavy chains and two light chains connected by disulfide bridges. The two light chains each contain one variable region (V_L) and one constant region (C_L), whereas each heavy chain contains one variable region (V_H) and up to three distinct constant regions (C_H1 to -3) (Figure 50-1). Differential utilization of C_H domains can be used to classify antibodies into five main groups, or *isotypes:* IgD, IgA, IgG, IgM, and IgE. For example, IgM uses heavy-chain constant domains from the $C_H\mu$ gene, whereas IgG uses the $C_H\gamma$ gene. IgG is the isotype most commonly used in cancer immunotherapy and is the focus of this chapter.

Structurally, antibodies can be divided into two functional modalities: the fragment of antigen binding (Fab) and the fragment of crystallization (Fc).

The Fab is responsible for antigen binding and is composed of the full-length light chain (V_L + C_L) and the V_H and C_H1 domains of the heavy chain. The V_L and V_H domains, collectively referred to as the *variable fragment* (Fv), contain six hypervariable regions called *complementary determining regions* (CDRs). The antigen binding pocket, also referred to as the *paratope*, is formed by opposition of three CDRs located on the V_L domain (CDR-L1, -L2, -L3) with three CDRs on the V_H domain (CDR-H1, -H2, -H3). The paratope of the antibody binds to a small region of approximately five to eight amino acids on the antigen called the *epitope*. A complex system of genetic recombinations and rearrangements is responsible for generating diversity among CDR sequences, resulting in a human antibody repertoire with between 10^{10} and 10^{11} distinct paratopes.[1]

The Fc portion of IgG antibodies is composed of C_H2 and C_H3 domains and is required to initiate effector immune responses such as complement-dependent cytotoxicity (CDC) and antibody-dependent cell-mediated cytotoxicity (ADCC). IgGs engage immune effector cells via Fc-γ receptors (FcγRs), which are expressed on a diverse range of hematopoietic cells. In humans, there are three activating FcγRs: FcγRI (CD64), FcγRIIA (CD32A), and FcγRIIIA (CD16). When engaged, these receptors transduce activating signals via immunoreceptor tyrosine-based activation motifs (ITAMs), resulting in initiation of ADCC or phagocytosis. Similarly, FcγRs can transduce inhibitory signals via immunoreceptor tyrosine-based inhibitory motifs (ITIMs). The primary inhibitory receptor in humans is FcγRIIB (CD32) which is expressed on a wide range of effector cells, with the notable exception of natural killer (NK) cells. In addition, neutrophils express FcγRIIIB, which is a GPI-linked isoform that serves as a decoy receptor and a sink for immune complexes. IgGs can also bind to neonatal Fc receptors (FcRn), which mediates transplacental transfer of maternal antibodies to the fetus. FcRns are also expressed in the vascular endothelium, where they bind IgGs and return them to the circulation, thereby prolonging their serum half-life.[2]

Development of Monoclonal Antibodies

The introduction of hybridoma technology in 1975 by Kohler and Milstein allowed for the mass production of murine monoclonal antibodies.[3] This technology used

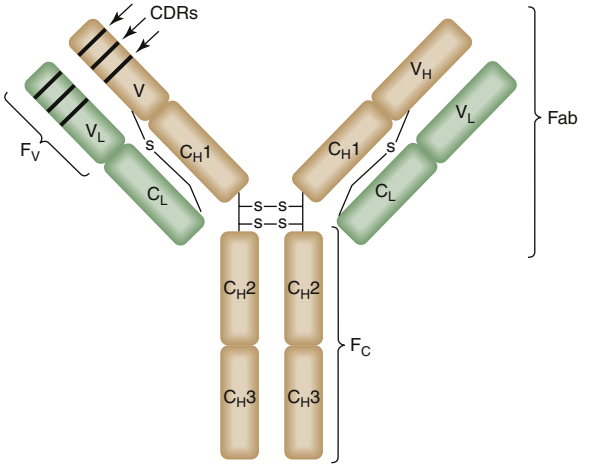

Figure 50-1 Structure of IgG.

murine B cells from immunized mice fused together with an immortalized murine plasma cell line. Through a series of selections and limiting dilutions, a clonal population could be isolated that produced antibodies specific for a single epitope. Eventually, antibodies to tumor antigens were developed and tested in clinical trials. The results of early trials demonstrated limited therapeutic benefit, primarily due to the production of human anti-murine antibodies (HAMAs), which resulted in rapid clearance of the drug and occasionally significant immune-mediated adverse events such as rash and renal failure.[4,5] In addition, the lower affinity of murine Fc to human FcRn may contribute to shorter serum half-life.[6] In the early 1980s, IgG genes were cloned and expressed in mammalian cells, paving the way for the development of chimeric antibodies, which contain murine variable regions and human constant regions.[7,8] Chimeric antibodies have reduced immunogenicity compared to their murine counterpart, but some patients still develop an immune response to the residual murine component (Figure 50-2). Humanized antibodies, which contain human heavy and light chains and murine CDRs, were developed in the late 1980s in an effort to further reduce immunogenicity.[9]

Currently, fully human antibodies are being produced using two common approaches: screening recombinant antibody libraries and engineering transgenic animals to express human immunoglobulin genes. A library of antibody fragments can be generated from human B cells, or by using cloning techniques, and can be used to construct phage or microbial display libraries. These libraries are subjected to multiple rounds of screening against the antigen of interest, and eventually high-affinity antibody fragments can be isolated.[10] These fragments can be used to generate full-length human antibodies.

More recently, transgenic mice expressing various human antibody gene sequences have been used to develop high-affinity, highly specific, fully human antibodies.[11] Panitumumab, an antibody targeting the epidermal growth factor receptor (EGFR), is an example of an antibody generated in transgenic animals and is currently approved for the treatment of refractory metastatic colon cancer.[12]

Mechanisms of Action of Anti-Cancer Antibodies

Signaling Perturbation

Solid tumors often upregulate expression of growth factor receptors or depend on these receptors for their proliferation or survival, with an enhanced capacity to invade and metastasize. Members of the epidermal growth factor (EGF) family of receptors, including EGFR1, HER2/neu (EGFR2), EGFR3, and EGFR4, are often overexpressed on solid tumors and thus serve as attractive targets for antibody therapy.[13] Most antibodies targeting EGFR family members work in part by inhibiting ligand binding and subsequent downstream oncogenic signaling (Figure 50-3). Notable exceptions are antibodies that target HER2/neu. Because this receptor has no known ligand, anti-HER2/neu antibodies such as trastuzumab and pertuzumab perturb signaling by preventing dimerization with other EGFR family members.[14]

ADCC

Several tumor-targeted monoclonal antibodies rely on activation of host immune responses, such as ADCC, in order to exert their full therapeutic benefit. Both IgG1 and IgG3 subclasses can bind with high affinity to FcγRs and initiate ADCC-mediated killing of tumor cell targets. Antibody-coated tumor cells bind to FcγRs on innate effector cells, primarily NK cells, macrophages, and neutrophils, leading to targeted release of cytoplasmic granules containing perforin and granzyme, resulting in tumor cell apoptosis (see Figure 50-3). Preclinical studies demonstrated that FcγRs are critically important for the antitumor activities of trastuzumab and the anti-CD20 antibody rituximab.[15] Furthermore, expression of inhibitory FcγRIIB limits the efficacy of trastuzumab and rituximab in vivo, suggesting that the balance between activating and inhibitory FcγRs is a critical determinant of the antitumor activity of these antibodies. Positive correlations between FcγRIIA-131H and FcγRIIIA-158V polymorphisms and clinical outcomes have been demonstrated in patients with follicular lymphoma treated with rituximab[16,17] and patients with refractory colorectal cancer treated with cetuximab.[18] Similarly, patients with metastatic breast cancer harboring FcγRIIA-131H and/or FcγRIIIA-158V polymorphisms show a greater response to trastuzumab-based treatment regimens compared to patients with

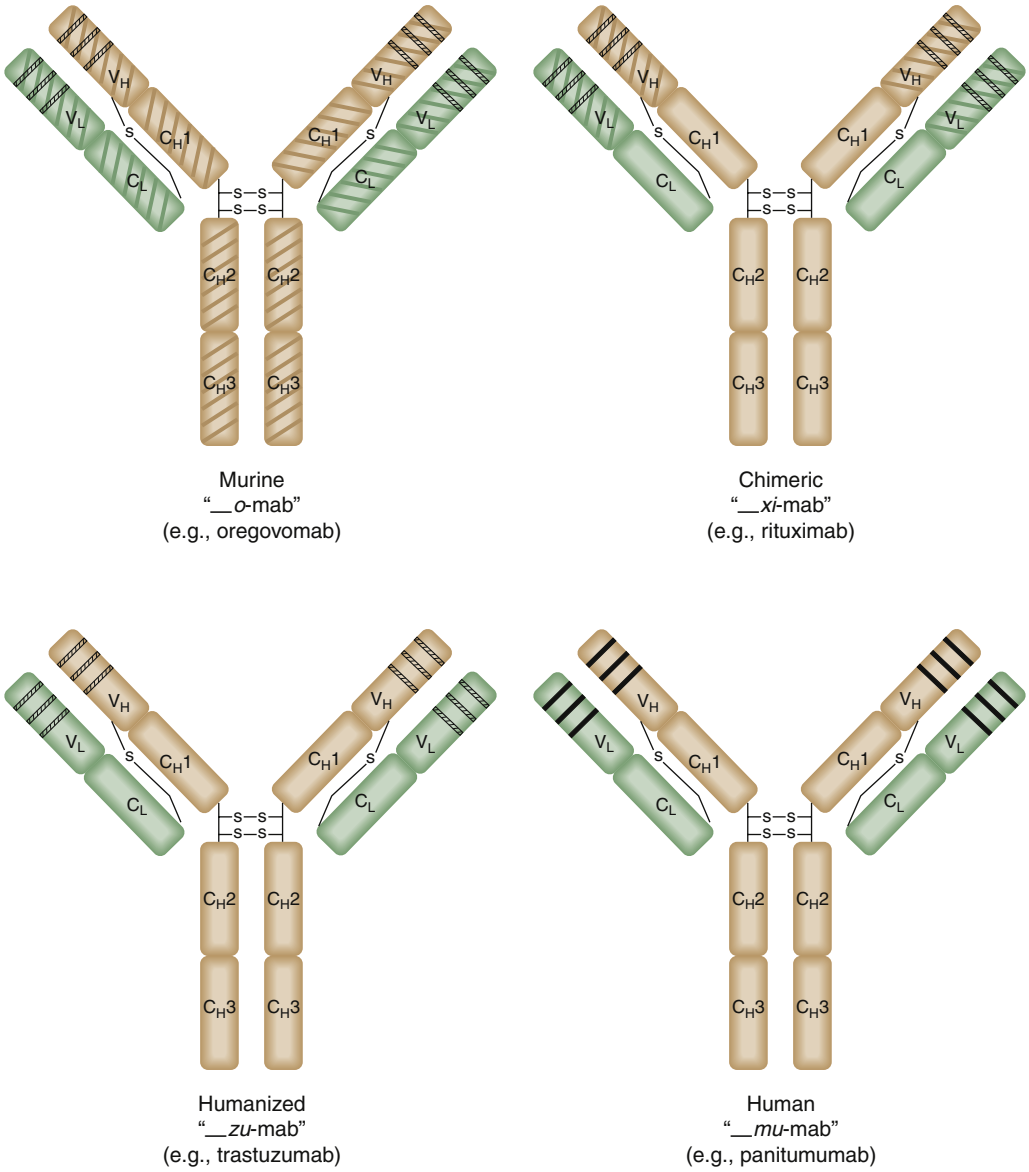

Figure 50-2 Nomenclature of monoclonal antibodies.

the 131R and/or 158F polymorphisms.[19] The FcγRIIIA-158V receptor has a higher affinity for human IgG1 and a greater capacity to mediate ADCC compared to the 158F receptor.[20,21]

CDC

In addition to binding FcγRs, IgG1 and IgG3 subclasses are potent activators of the classical complement cascade. The cascade is initiated with the binding of the C1q complex to the Fc domain of antibodies bound to tumor antigens. The C1q complex is composed of the hexameric C1q protein bound to the zymogens C1r and C1s. Binding of multiple C1q molecules activates its enzymatic activity, resulting in cleavage and activation of the C1s serine protease, which in turn activates downstream complement proteins culminating in the formation of the membrane attack complex (MAC). The MAC forms a pore in the lipid bilayer that compromises membrane integrity and causes target cell death. Certain complement protein fragments, such as C5a, induce a local inflammatory response by functioning as chemoattractants for neutrophils, monocytes, and lymphocytes. Rituximab is capable of mediating CDC against various B-cell malignancies in vitro in part because of its ability to translocate CD20 onto lipid raft microdomains, resulting in more efficient complement fixation.[22] The antitumor activity of rituximab is abolished in C1q knockout animals, supporting CDC as an important mechanism underlying the therapeutic efficacy of rituximab.[23] Clinically, however, the importance of CDC in the context of rituximab therapy is still undetermined. Patients with follicular lymphoma harboring the C1qA276
