THE MOLECULAR BASIS OF CANCER **ISBN: 978-1-4557-4066-6**

Library of Congress Cataloging-in-Publication Data

The molecular basis of cancer / [edited by] John Mendelsohn, Peter M. Howley, Mark A. Israel, Joe W. Gray, Craig B. Thompson. -- 4.
p. ; cm.
Includes bibliographical references and index.
ISBN 978-1-4557-4066-6 (hardcover : alk. paper)
I. Mendelsohn, John, 1936- editor of compilation. II. Howley, Peter M., editor of compilation. III. Israel, Mark A., editor of compilation. IV. Gray, Joe W., editor of compilation. V. Thompson, Craig (Craig B.), editor of compilation.
[DNLM: 1. Neoplasms--genetics. 2. Neoplasms--pathology. 3. Molecular Biology--methods. 4. Molecular Targeted Therapy. QZ 202]
RC268.5
616.99'4071--dc23 2013034109

Senior Content Strategist: Suzanne Toppy
Senior Content Development Specialist: Taylor Ball
Publishing Services Manager: Patricia Tannian
Senior Project Manager: Sharon Corell
Senior Book Designer: Louis Forgione

Preface

Research in molecular genetics and cancer biology and advances in analytical technologies have revolutionized our understanding of cancer. Over the past three decades, there has been a massive acceleration in discoveries and observations that explains the genetic basis of cancer, a disease that until recently was thought about primarily in purely descriptive terms. Conversely, the study of malignancy has transformed our understanding of the molecular and genetic processes that govern the growth and proliferation of normal cells.

By 1995, our knowledge had expanded to the point that we felt it worthwhile to write a textbook describing *the molecular basis of cancer* for students, researchers, and providers of clinical care from a variety of disciplines. The aim in this fourth edition of the textbook continues to explain, rather than to merely recount.

Five editors, selected for their diverse expertise and their reputations as educators, met to design a sequence of sections and chapters that would lead the reader from the basic genetic and molecular mechanisms of carcinogenesis, to the molecular and biological features of cancer cell growth and metastasis, then to advances in sequencing technologies and bioinformatics that enable personalized risk assessment and diagnostics, followed by a description of molecular and genetic abnormalities that drive the common types of cancer, and finally to the molecular basis for new, targeted approaches to cancer therapy.

A purpose of this textbook is to describe the scientific underpinnings that will enable clinicians and other professionals who manage cancer patients to better understand the disease and its therapy. This book will be of equal, or possibly greater, interest to laboratory and clinical investigators in biomedical research and to advanced students and trainees, who need to understand the molecular mechanisms that govern the functioning and malfunctioning of malignant cells. Although the chapters follow a sequence that moves from pathogenesis to therapy, each chapter stands alone in its treatment of the subject matter.

Cancer arises as a result of genetic and epigenetic alterations that either enhance or diminish the activities of critical pathways that mediate normal cellular activities. Impaired capacity to repair genetic alterations can contribute to the likelihood that cells accumulate these genetic abnormalities, leading to malignant transformation. The disease is not merely a disorder of individual transformed cells. These cells grow into tumor masses and attract a blood supply, and they invade through surrounding tissues and metastasize. Molecular influences from the environment around the cancer cells contribute importantly to the capacity of genetically altered cells to produce malignant tumors.

A remarkable lesson gained from cancer research is that the strategies utilized by widely divergent cell lineages to regulate growth and differentiation share common molecular pathways. The accumulation of mutations and altered expression of genes critical for these pathways is a recurrent theme observed in many different types of cancer. Cancers also appear to select for genetic abnormalities that may be most advantageous for escape from normal regulatory mechanisms in their particular microenvironments.

What is most exciting today is the active dialogue between clinical investigators and laboratory scientists who share an interest in applying the new knowledge of genetics and molecular biology to the early diagnosis, targeted treatment, and improved prevention of disease. Today we have the opportunity to select treatments for clinical administration from among hundreds of new biological and chemical anticancer agents targeting pathways altered by specific molecular irregularities that result from aberrant genes. It is only recently that we can detect the genetic aberrations in cancer specimens from individual patients in a reasonable time frame and at a reasonable cost. This means that genomic assays can be used to select therapies that target the products of the aberrant genes in a patient's cancer and are more likely to provide benefit for that patient. The knowledge we present in this textbook should supply a basis upon which these new approaches to cancer therapy can be evaluated and implemented by those interested in understanding and critically assessing the many new products of the biotechnology revolution.

The editors are delighted that we were able to recruit as contributing authors outstanding investigators who are excited about the challenge of presenting their areas of expertise in a textbook format. In many cases this has required more time and effort than they initially anticipated, and we are grateful for their dedication. We hope that we have come at least part of the way toward achieving what we set out to do. We have been assisted and encouraged by the professionals at Elsevier, as well as the patient and ever-essential help of the secretaries in our offices.

1 Cancer: A Genetic Disorder

Our understanding of the origins of cancer has changed dramatically over the past three decades, due in large part to the revolution in molecular biology that has altered the face of all biomedical research. Powerful experimental tools have been thrust into the hands of cancer biologists. These tools, including newly devised and implemented technologies that permit the interrogation of entire genomes, have made it possible to uncover and dissect the complex molecular machinery operating inside the single cell, normal and malignant, to understand its operations, and to pinpoint the defects that cause cancer cells to proliferate abnormally.

Three decades ago, at least three rival models of cancer's origins had substantial following among those interested in the roots of cancer. One model portrayed cancer as a disease of abnormal differentiation. According to this thinking, the changes in cell behavior that occur during the process of development run awry during tumor progression, causing cells to make inappropriate choices in moving up or down differentiation pathways. This concept of cancer's origins had important implications for the molecular origins of cancer: because the process of differentiation involves changes in cell phenotype without underlying changes in the genome, this model suggested that cancer was essentially an epigenetic process—a change in cell behavior without an underlying change in its genetic constitution.

An alternative model was advanced by the virologists. By the early 1970s, a number of distinct cancer-causing viruses had been catalogued in various animal species and in humans. These ranged from the Rous sarcoma virus, whose discovery reached back to the first decade of the century, to Shope papillomavirus, Epstein-Barr virus, papovaviruses such as SV40 and polyomavirus, and a variety of retroviruses that infected various mammals and birds. The existence of these viruses suggested that similar agents operated to trigger human tumors. Such hypothetical human tumor viruses were thought capable of insinuating themselves into human cells and transforming them from a normal to a malignant growth state.[1]

Yet another way of explaining cancer's origins was advanced by those who were impressed by the increasing connections being forged between carcinogens and mutagens. More than half a century of experiments had demonstrated the abilities of radiation as well as a vast array of chemicals to induce tumors in animals and occasionally in humans. Independent of this research, *Drosophila* and bacterial geneticists had documented the abilities of some of these carcinogenic agents to act as mutagens. The most influential of these experiments was to come from the laboratory of Bruce Ames. In the mid-1970s, Ames described a correlation between the mutagenic potencies of various chemical compounds and their respective potencies to induce tumors in laboratory animals.[2]

Ames' correlation (Figure 1-1) yielded the inference that the carcinogenic powers of agents derive directly from their abilities to damage genes and thus the DNA of cells. This strengthened the convictions of those who had long embraced the notion that cancer cells were really mutants and that their abnormal behavior derived from mutant genes that they carried in their genomes. This model implied that such mutant genes arose through somatic mutations, i.e., mutations that occur in somatic tissues during the lifetime of an organism and alter genes that were pristine at the moment of conception.

This last model of cancer's origins would eventually dominate thinking; the other two models largely fell by the scientific wayside. As the 1970s progressed, the search for tumorigenic viruses associated with most types of common human cancers bogged down. Human papillomavirus (HPV) clearly had strong associations with cervical carcinomas, Epstein-Barr virus (EBV) with Burkitt's lymphomas in Africa and nasopharyngeal carcinomas in southeast Asia, and hepatitis B and C viruses (HBV, HCV) with hepatocellular carcinomas in east Asia. Together, these accounted for as much as 20% of tumors worldwide.[3] However, the remaining types of cancers, and thus the vast majority of human cancers arising in the Western world, had no obvious viral associations in spite of extensive attempts to uncover them.

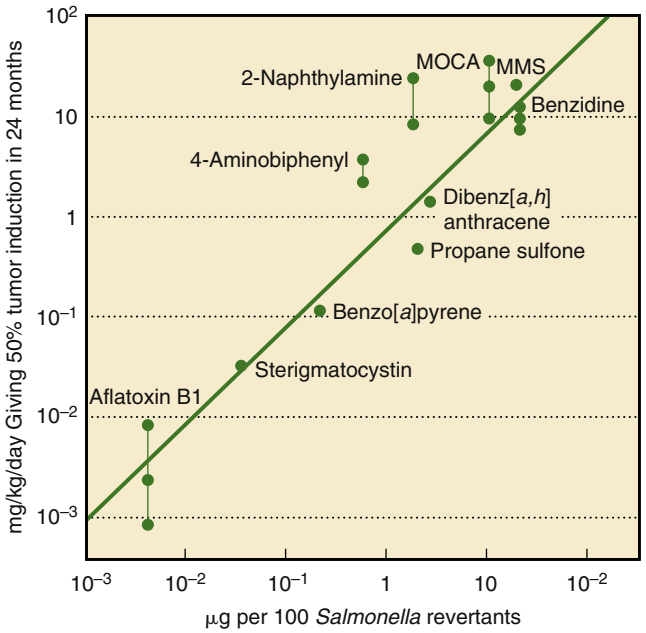

Figure 1-1 Relationship of carcinogenic to mutagenic potencies of chemical compounds The ability to quantify both the mutagenic potencies of a variety of chemical compounds, measured in the Ames mutagenesis test, and to relate this to their carcinogenic potencies, as measured in laboratory rodents, allowed this graph and correlation to be made between the two mechanisms of action. *(Adapted from Meselson M et al. In: Hiatt HH et al., eds.,* Origins of Human Cancer, Book C: Human Risk Assessment. *Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press, 1977.)*

The epigenetic model of cancer lost its attractiveness largely because an extensive array of mutant growth-controlling genes was discovered in the genomes of human tumor cells. So the focus shifted increasingly to genes, more specifically the genomes of cancer cells. Cancer genetics in the 1970s and early 1980s became a branch of somatic cell genetics—the genetics of cells and their somatically mutated genes. Indeed, advances in the technology of DNA sequencing have now enabled the enumeration of mutations present in specific cancer genomes and will eventually lead to a compendium of recurrent genetic alterations in human cancers.

The Discovery of Cellular Oncogenes

The notion that cancer cells were mutants should have motivated a systematic search for genes that suffered mutation during the development of tumors. Moreover, these mutant genes should possess another property: they needed to specify some of the aberrant phenotypes ascribed to tumor cells, including alterations in cell shape, decreased dependence on external mitogenic stimuli, and an ability to grow without tethering to a solid substrate (anchorage independence). The fact that viruses were not important causative agents of most types of human tumors generated another conclusion about these cancer-causing genes: they were likely to be endogenous to the cell rather than being imported into the cell from some external source. Stated differently, it seemed likely that these cancer genes were mutant versions of preexisting normal cellular genes.

In the 1970s, when this line of thinking matured, the experimental opportunities to test its validity were limited. The human genome, which harbored these hypothetical cancer genes, represented daunting complexity. Its vastness precluded any simple, systematic survey strategy designed to locate mutant growth-controlling genes within cancer cells. Indeed, it is only now, three decades later, that the means, deep sequencing of cancer genomes, for conducting effective systematic surveys for cancer genes has been developed. Thus the discovery of cancer-causing genes—oncogenes as they came to be called—depended on a circuitous, indirect experimental strategy.

Ironically, it was tumor viruses, in the midst of being discredited as important etiologic agents of human cancer, that led the way to finding the elusive cancer genes. Varmus and Bishop's study of the Rous sarcoma virus (RSV) broke open the puzzle. Their initial agenda was to understand the replication strategy of this chicken virus. However, in the years after 1974, they focused their attentions to unraveling the mechanism used by RSV to transform an infected normal cell into a tumor cell.

Earlier work of others had indicated that a single gene, named *src*, carried the vital cancer-causing information present in the viral genome. Accordingly, the Varmus and Bishop laboratory launched a research program to trace the origins of this virus-associated *src* oncogene. In fact, the origins of most viral genes were obscure, shrouded in the deep evolutionary past. It seemed that most viruses and thus their genes originated hundreds of millions of years ago, perhaps as derivatives of the cells that they learned to parasitize.

However, as this team reported in 1976, the *src* gene behaved differently: it was a recent acquisition by the Rous virus. Many closely related retroviruses shared with RSV an ability to replicate in chicken cells and a very similar set of genes needed for viral replication. However, these other viruses lacked the *src* gene and the ability to transform infected cells into cancer cells, suggesting that the *src* oncogene carried by RSV was a relatively recent genetic acquisition. The Varmus-Bishop group soon traced the origins of the *src* gene to an unexpected source—a closely related gene that resided in the genome of normal chickens and, by extension, in the genomes of all vertebrates. They named this gene *c-src* (cellular *src*) to distinguish it from the *v-src* (viral *src*) oncogene carried by the virus.[4]

The Varmus-Bishop evidence converged on a simple conceptual model. It explained all their observations and ultimately much more. The progenitor of RSV lacked the

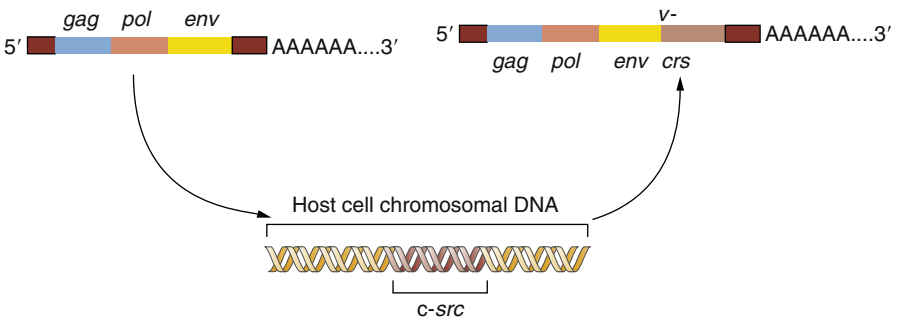

Figure 1-2 The origin of the Rous sarcoma virus *src* oncogene The acquisition of the v-*src* oncogene by a precursor of Rous sarcoma virus apparently occurred when an avian leukosis virus (ALV) lacking this oncogene infected a chicken cell and appropriated the cellular c-*src* proto-oncogene, thereafter carrying this acquired gene and exploiting it to transform subsequently infected cells.

v-*src* gene but grew well in chicken cells. During one of its periodic forays into a chicken cell, this ancestor virus picked up a copy of the c-*src* gene and incorporated it into its own viral genome. Once *src* was present within the viral genome, this slightly remodeled gene—now v-*src*—was exploited by RSV to transform cells it encountered in subsequent rounds of infection.

This provided a testimonial to the cleverness and plasticity of retroviruses, which seemed able to capture and then exploit normal cellular genes to do their bidding. But another implication was even more important: the Varmus-Bishop work pointed to the existence of a normal cellular gene, the c-*src* gene, that seemed to possess a latent ability to induce cancer. This cancer-causing ability was unmasked when the c-*src* gene was abducted by the chicken retrovirus that became the progenitor of RSV (Figure 1-2).

The c-*src* gene was named a *proto-oncogene* to indicate its inherent potential to become activated into a cancer-causing oncogene. Within several years, it became clear that as many as a dozen other tumorigenic retroviruses also carried oncogenes, each of which had been abstracted from the genome of an infected vertebrate cell.[5,6] Hence, there were many proto-oncogenes in the normal cell genome, not just c-*src*. Each seemed to be present in the DNA of a normal mammalian or avian host species, and by extension, present as well in the genomes of all vertebrates.

These discoveries were momentous because they demonstrated that normal cellular genes had the ability to induce cancer if removed from their normal chromosomal context and placed under the control of one or another retrovirus. Still, a key piece was missing from this puzzle. Retroviruses seemed to be absent from most, indeed from almost all, human tumors. Could proto-oncogenes ever become activated without direct intervention by a marauding retrovirus?

An obvious response was that proto-oncogenes might be altered by mutational events that did not remove these genes from their normal chromosomal roosts. Instead, these mutations would alter proto-oncogenes in situ in the chromosome by affecting either the control sequences or the protein-encoding sequences of these genes. This notion led to another question: If some proto-oncogenes could become activated by somatic mutations, such as those inflicted by chemical or physical carcinogens, would these be the same proto-oncogenes that were the targets of mobilization and activation by retroviruses?

In 1979 and 1980, answers came, once again from unexpected quarters. These newer experiments depended on the use of gene transfer, also known as *transfection*. The transfection procedure could be used to convey DNA, and thus genes, from tumor cells into normal recipient cells. The goal here was to see whether the transferred tumor cell DNA could induce some type of malignant transformation in the recipient cells. Success in such an experiment would indicate that the transferred gene(s) previously operated in the donor tumor cell to induce its transformation.

These transfection experiments succeeded (Figure 1-3). DNA extracted from chemically transformed mouse fibroblasts was able to induce normal mouse fibroblasts to undergo transformation.[7] Retroviruses were clearly absent from both the donor tumor cells and the recipients that underwent transformation and so could not be invoked to explain the cancer-causing powers of the transferred DNA. Soon the identity of these transferred genes, which functioned as oncogenes, became apparent. They were members of the *ras* family of oncogenes, which had initially been discovered through their association with rodent sarcoma viruses.[5,8] These rodent retroviruses had acquired *ras* proto-oncogenes from normal rodent cells, much like RSV, which had stolen a copy of the *src* proto-oncogene from a chicken cell.

Unanswered by this was the genetic mechanism that imparted oncogenic powers to the tumor-associated *ras* oncogene, more specifically an H-*ras* oncogene. It soon became clear that the tumor-associated H-*ras* oncogene was closely related to, indeed virtually indistinguishable from, a normal H-*ras* proto-oncogene that was present in the genomes of all vertebrates. Still, the tumor-associated *ras* oncogene carried different information than did the precursor proto-oncogene: the oncogene caused the malignant transformation of cells into which it was introduced, whereas the counterpart proto-oncogene had no obvious effects on cell phenotype. This particular puzzle was solved in 1982 with the finding that an H-*ras* oncogene cloned from a human bladder

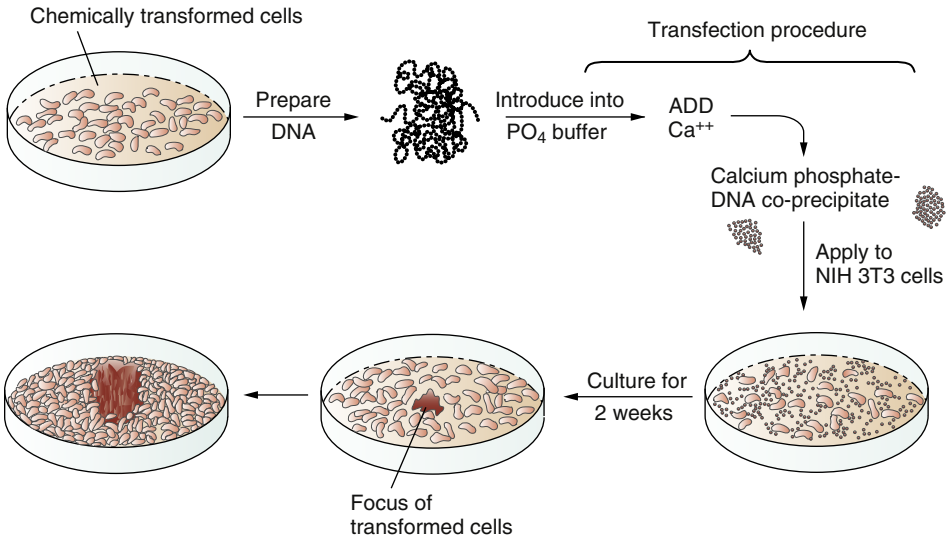

Figure 1-3 Transfection of a cellular oncogene The fact that the carcinogenicity of various chemical compounds was correlated with their mutagenicity suggested that cancer cells often carry mutant, cancer-inducing genes, i.e., oncogenes, in their genomes. This could be proven by an experiment in which DNA was extracted from chemically transformed mouse fibroblasts and introduced, via the procedure of transfection, into untransformed mouse fibroblasts. The appearance of foci of transformed cells in the latter indicated the transmission of a transforming gene from the donor to the recipient cells, indicating that chemical carcinogens could indeed generate a mutant, cancer-causing gene.

carcinoma carried a point mutation—a single nucleotide substitution—that distinguished it from its counterpart proto-oncogene.[9-11] This genetic alteration, clearly a somatic mutation, sufficed to convert a normally benign proto-oncogene into a virulent oncogene.

Within months, yet other activated oncogenes were found in human tumors by using DNA probes prepared from a variety of retrovirus-associated oncogenes. The *myc* oncogene, initially associated with avian myelocytomatosis virus, was found to be present in increased gene copy number (i.e., amplified) in some human hematopoietic tumors[12]; in yet others, *myc* was activated through a chromosomal translocation that juxtaposed its coding sequences with those of immunoglobulin genes, thereby placing the expression of the *myc* gene under the control of these antibody genes rather than its own normal transcriptional control elements.[13] These discoveries extended and solidified a simple point: a common repertoire of proto-oncogenes could be activated either by retroviruses (usually in animal tumors) or by somatic mutations (in human tumors). The activating mutations involved either base substitution, amplification in gene copy number, or chromosomal translocation.

Multistep Tumorigenesis

The discoveries of mutant, tumor-associated oncogenes in human tumors led to a simple model of cancer formation. Mutagenic carcinogens entered into cells of a target tissue and mutated a proto-oncogene. The resulting oncogene then induced the now-mutant cell to initiate a program of malignant growth. Eventually, years later, the progeny of this mutant founder cell formed a large enough mass to become a macroscopically apparent tumor.

While satisfying conceptually, this simple model of cancer formation clearly conflicted with a century's worth of histopathologic analyses, which had indicated that tumor formation is really a multistep process, in which initially normal cell populations pass through a succession of intermediate stages on their way to becoming frankly malignant. Each of these intermediate stages contains cells that were more aberrant than those seen in the preceding steps. This body of observations persuaded many that the formation of a malignancy depended on a succession of phenotypic changes in the cells forming these various growths. Quite possibly, each of these shifts in cell phenotype reflected a change in the underlying genetic makeup of the evolving pre-malignant cell population. Such a multistep genetic model of tumor progression stood in direct conflict with the single-hit model of transformation that was suggested by the discovery of the point-mutated *ras* oncogene.

By 1983, one solution to this dilemma became apparent. In that year, experiments showed that a single introduced oncogene could not transform fully normal rat cells into ones that were tumorigenic. Two and maybe even more oncogenes seemed to be required to effect this conversion.[14,15] For example, whereas an introduced *ras* oncogene could not transform normal embryo cells into tumor cells, the co-introduction of a *ras* plus a *myc* oncogene, or a *ras* plus an adenovirus E1A oncogene, succeeded in doing so. It appeared that such pairs of oncogenes collaborated with one another to induce the full malignant transformation of normal cells (Figure 1-4, *A*). Moreover, this experiment suggested that human tumors carried two or more mutant oncogenes that collaborated with one another to orchestrate the many aberrant phenotypes associated with highly malignant cells.

Observations such as these pointed to a new way of conceptualizing the multistep tumorigenesis long studied by the pathologists. It seemed plausible that each of the

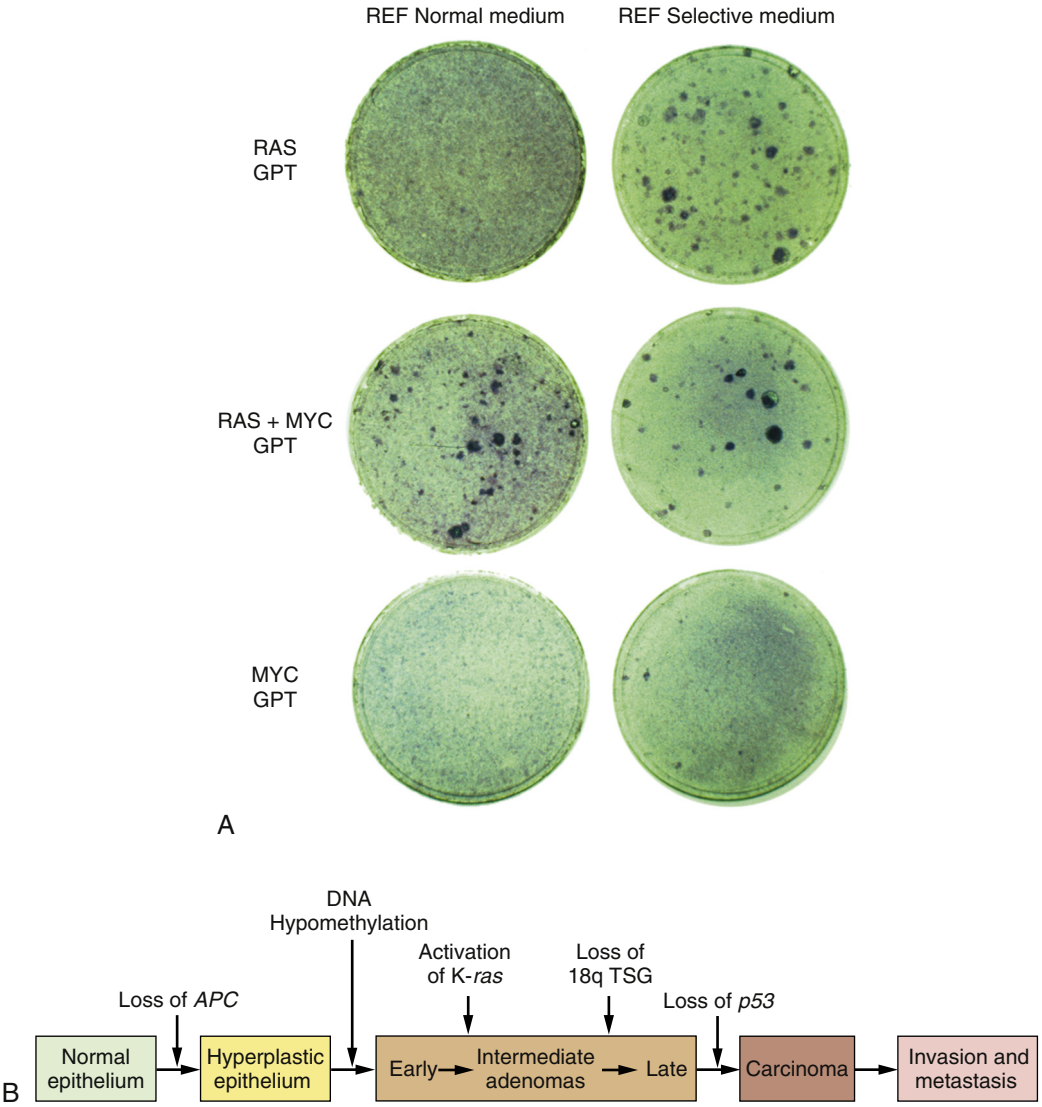

Figure 1-4 Multistep tumorigenesis in vitro and in vivo (A) The ability of oncogenes to collaborate to transform cells in vitro was illustrated in this 1983 experiment in which neither a *ras* nor a *myc* oncogene was found able to induce foci when introduced into early passage rat embryo fibroblasts (REFs). However, when the two were introduced concomitantly, transformation ensued, as indicated by the appearance of foci. This suggested that tumor progression in vivo might involve a succession of mutations that created multiple collaborating cellular oncogenes. **(B)** By 1989, analyses of the genomes of colonic epithelial cells at various stages of tumor progression revealed that the more progressed the cells were, the more mutations they had acquired. In fact, some of the indicated mutations involved inactivation of tumor suppressor genes, to be discussed later. *(A, from Land H, Parada LF, Weinberg RA.* Nature. *1983;304:596-602; B, courtesy B. Vogelstein.)*

histopathological transitions arising during tumor development occurred as a consequence of a new mutation sustained in the genome of an evolving, premalignant cell population (Figure 1-4, *B*). According to this thinking, tumor development was a form of Darwinian evolution, in which each successive mutation in a growth-controlling gene conferred increased proliferative potential and thus selective advantage on the cells bearing the mutant gene.[16,17] Ultimately, a multiply mutated cell bearing half a dozen or more mutant genes might exhibit all of the phenotypes associated with highly malignant cancer cells.

This mechanistic model was validated through the creation of transgenic mice. Cloned copies of mutant oncogenes, such as *ras* and *myc*, were introduced into the germlines of mice. These transgenes were structured so that the oncogene was placed under the control of a transcriptional promoter that ensured expression of the resulting "transgene" in a specific tissue or developmental stage. Now the presence of a mutant oncogene in a particular tissue could be guaranteed through the actions of an appropriately engineered transgene rather than being dependent on the random actions of mutagenic carcinogens.

In one highly instructive group of experiments, a *myc* or a *ras* oncogene was placed under the control of the mouse mammary tumor virus transcriptional promoter, which guaranteed its expression in the mammary epithelium of

the pregnant female mouse.[18] As anticipated, these mice contracted breast cancer at extremely high rates. This demonstrated that mutant oncogenes were far more than markers of cancer progression; indeed, they could actually play a causal role in driving tumor pathogenesis.

Significantly, the transgenic mice did not contract cancer rapidly in their mammary tissue even though a mutant oncogene was implanted and expressed in virtually all of the epithelial cells of their mammary glands. Instead, their mammary carcinomas arose with several months' delay, indicating that a second (and perhaps third) alteration was required in addition to the activated transgene before mammary epithelial cells launched a program of malignant growth. The nature of this additional alteration(s) was not always clear, but it almost certainly involved stochastic somatic mutations striking the mammary epithelial cells, creating mutant growth-controlling genes that collaborated with the transgene to trigger the outgrowth of malignant cell clones. In the years that followed, this work was extended to many types of human tumors, the cells of which were found to possess multiple mutant genes that contributed to tumor formation.

The Discovery of Tumor Suppressor Genes

The model of multistep tumorigenesis implied that a tumor cell carries two or more mutant oncogenes, each activated by somatic mutation during one of the stages of tumor development. However, experimental validation of this model initially proved to be difficult. Most attempts at detecting mutant oncogenes in human tumor genomes yielded a *ras* or perhaps a *myc* oncogene, but rarely were two mutant oncogenes found to coexist in the genomes of human tumor cells. This left two logical alternatives. Either the genome of a typical human tumor cell did not contain multiple mutated genes, as the multistep model of cancer suggested, or there were indeed multiple mutated cancer-causing genes in tumors, but many of these were not oncogenes of the type that had been studied intensively in the 1970s and early 1980s.

In fact, there were candidate genes waiting in the wings. These others operated in a fashion diametrically opposite to that of the oncogenes: they seemed to prevent cancer rather than favoring it and came to be called "tumor suppressor genes." Several independent lines of evidence led to the discovery and characterization of these genes.

Experiments using cell hybridization initiated by Henry Harris in Oxford provided the first indication of the existence of these suppressor genes.[19] These cell hybridizations involved the physical fusion of two distinct types of cells that were propagated in mixed cultures. The conjoined cells would form a common hybrid cytoplasm and ultimately pool their chromosomes, yielding a hybrid genome.

Often these cell hybridizations involved the fusion of cells with two distinct genotypes. In some of these experiments, tumor cells were fused with normal cells. The motive here was to see which genome would dominate in determining the behavior of the resulting hybrids. Counter to the expectations of many, the resulting hybrid cells turned out, more often than not, to be nontumorigenic.[19] This indicated that the genes present in the normal genome dominated over those carried in the cancer cell. In the language of genetics, the normal alleles were dominant, whereas the cancer cell–associated alleles were recessive. (More properly, the alleles present in the cancer cell created a phenotype that was recessive to the normal cell phenotype.)

This unanticipated behavior could most easily be rationalized by assuming that normal cells carried certain growth-normalizing genes, the presence of which was needed to maintain normal proliferation. Cancer cells seemed to have lost these genes, ostensibly through mutations that resulted in inactivated versions of the genes present in normal cells. When reintroduced into the cancer cells via cell fusion, the normal alleles reimposed control on the cancer cells, restoring their behavior to that of a normal cell. In effect, these growth-normalizing genes suppressed the tumorigenic phenotype of the cancer cells and were, for this reason, termed *tumor suppressor genes* (TSGs).

In their normal incarnations, the TSGs seemed to constrain growth, unlike the proto-oncogenes, which seemed to be involved in promoting normal proliferation. Inactivated, null alleles of TSGs were found in tumor cell genomes in contrast to the hyperactivated alleles of proto-oncogenes (i.e., oncogenes) found in these genomes.

The study of retinoblastoma, the childhood eye tumor, converged on these cell hybridization studies in a dramatic way. This work had been pioneered by Alfred Knudson, who, beginning in the early 1970s, studied the genetics of this rare tumor. Knudson learned much by comparing the two forms of this cancer: sporadic retinoblastoma, which seemed to be due exclusively to accidental somatic mutations, and familial retinoblastoma, which appeared, like many familial cancers, to be due to the transmission of a mutated gene in the germline.

Knudson's analysis of the kinetics of retinoblastoma onset persuaded him that a common set of gene(s) operated to generate both kinds of tumors.[20,21] Although the nature of these genes eluded him, their number was clear. Sporadic retinoblastomas seemed to arise following two successive somatic mutations affecting a lineage of cells in the retina. The triggering of familial retinoblastomas seemed to require only a single somatic mutation. Knudson speculated that in these familial tumors, a second mutated gene was required

to trigger tumorigenesis and that this gene was already present in mutant form in all the cells of the retina, having been inherited in mutated form from a parent of the affected child.

For the cancer geneticist, Knudson's most important concept was the notion that a retinal cell needed to lose two mutant genes before it was transformed into a tumor cell. Sometimes one of the two mutant null alleles was contributed by the germline; more often, both genes arose through somatic mutation. However, the nature of these genes and the mutations that recruited them into the tumorigenic process remained elusive. Finally, in 1979, karyotypic analysis of a retinoblastoma revealed an interstitial deletion in the q14 band of chromosome 13.[22] Later work revealed that this resulted in the loss of a gene, termed *RB*. Hence, one of the two mutational events needed to make a retinoblastoma involved the inactivation of an *RB* gene copy, in this particular case through the wholesale deletion of the chromosomal region carrying the *RB* gene.

By 1983, the nature of the second mutational event became clear: it involved the loss of the second, hitherto intact copy of the *RB* gene.[23] Hence, the two mutational events hypothesized by Knudson involved the successive inactivation of the two copies of this gene. Suddenly, the need for two mutations became clear: The first mutation left the cell with a single, still-intact copy of the *RB* gene, which was able, on its own, to continue programming normal proliferation. Only when this surviving gene copy was eliminated from the cell genome did runaway proliferation begin (Figure 1-5). Thus, mutations that inactivate an *RB* gene copy create alleles that function recessively at the cellular level. Only when both wild-type alleles are lost through various mutational mechanisms does a retinal cell begin to behave abnormally.

The *RB* gene became the paradigm for a large cohort of similarly acting TSGs that suffer inactivation during tumor progression. These TSGs are scattered throughout the cell genome and act through a variety of cell-physiologic mechanisms to control cell proliferation.[24] They are united only by the fact that they control proliferation in a negative way, so that their loss permits uncontrolled cell multiplication to proceed.

The discovery of the *RB* gene gave substance and specificity to the genes that Harris had postulated from his cell fusion experiments. Equally important, they opened the door to understanding a variety of familial cancer syndromes. In the case of *RB*, inheritance of a mutant, defective allele predisposes to retinoblastoma early in life with more than 90% probability. Inheritance of a defective allele of the *APC* TSG predisposes with high frequency to adenomatous polyposis coli syndrome and thus to colon cancer. The presence of a mutant *TP53* gene in the germline leads to increased rates of tumors in a number of organ sites, including sarcomas and

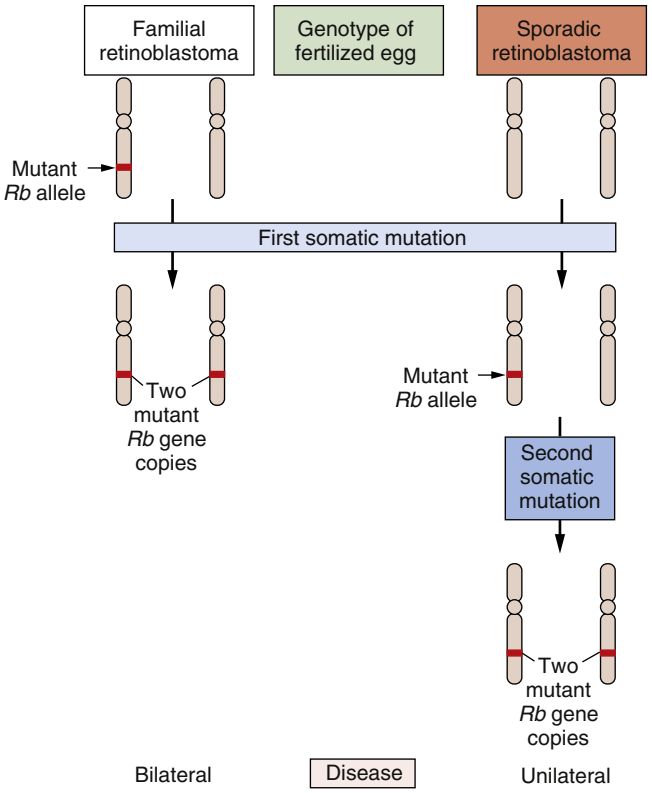

Figure 1-5 Genetics of retinoblastoma development The development of retinoblastomas requires the successive inactivation of two copies of the chromosomal *RB* gene. In the case of familial retinoblastomas, one of the two copies of this gene is already mutated in one or another gamete and is transmitted to the offspring, who is therefore heterozygous at this locus in all cells of the body; subsequent loss, through somatic alterations, of the surviving wild-type gene copy leaves a retinal cell with no functional copies of this gene, enabling tumor formation to begin. In sporadic retinoblastomas, the conceptus is genetically wild type; however, two successive somatic mutations occurring in a lineage of retinal precursor cells leaves some of these cells, once again, without functional *RB* gene copies, and as before permits retinoblastoma tumorigenesis to begin.

carcinomas, yielding the Li-Fraumeni syndrome. More than two dozen heritable cancer syndromes have been associated with germline inheritance of defective TSGs.[25,26]

In each case, the inheritance of a mutant, functionally defective TSG allele obviates one of two usually required somatic mutations. Because an inactivating somatic mutation represents a low-probability event per cell generation, the presence of an already-mutant inherited TSG allele enormously accelerates the overall kinetics of tumor formation. As a consequence, the likelihood of a tumor arising during the course of a normal lifespan is enormously increased.

The search for TSGs has been difficult, as their existence only becomes apparent when they are absent from a cellular genome. However, one peculiarity of TSG genetics has greatly aided the discovery of these genes. This involves the genetic mechanisms by which the second copy of a TSG is lost. In principle, two independent somatic mutations could successively inactivate the two copies of a TSG,

thereby liberating a cell from the growth-constraining influences of this gene. However, each of these mutations normally occurs with a low probability—perhaps 10^{-6} per cell generation. The likelihood of both mutations occurring is therefore roughly 10^{-12} per cell generation, an extremely low probability. (Actually, because cancer cell genomes become progressively destabilized as tumors develop, this probability is usually higher.)

In fact, evolving premalignant cell populations carrying a single, already-inactivated TSG copy often resort to another genetic mechanism to eliminate the second, still-intact copy of this TSG. They discard the chromosomal arm (or chromosomal region) carrying the still-intact TSG copy and replace it with a duplicated copy of the chromosomal region carrying the mutant, already-inactivated TSG copy. All this is achieved via the exchange of genetic material between paired homologous chromosomes.

The end result of these genetic gymnastics is the duplication of the mutant TSG copy. Thus, the TSG goes from a heterozygous state (involving one mutant and one wild-type gene allele) to a homozygous state (involving two mutant gene copies). Almost always, the chromosomal region flanking the TSG suffers the same fate. Consequently, known genes as well as other genetic markers within this flanking region that were initially present in a heterozygous configuration now become reduced to a homozygous configuration. This genetic behavior has motivated cancer geneticists to analyze the genomes of human tumor cells, looking for chromosomal regions that repeatedly suffer loss of heterozygosity (LOH) during tumor progression. Such LOHs represent presumptive evidence for the presence of TSGs in these regions whose second wild-type copies have been eliminated by LOH during the course of tumor development. Once such a region is localized to a chromosomal region, several currently available gene molecular strategies can be exploited to further narrow the chromosomal domain carrying the TSG and ultimately to isolate the TSG through molecular cloning.

The existence of many dozen still-unknown TSGs is suspected because of the documented LOH affecting specific chromosomal regions of various types of human tumor cells. The effort to identify and clone these genes is being greatly facilitated by efforts such as those included in the International Cancer Genome Consortium and the Cancer Genome Anatomy Project (TCGA). Nonetheless, the successful identification and cloning of a significant cohort of TSGs has already provided one solution to a major puzzle posed earlier. As mentioned, although human tumor cells were hypothesized to carry a number of distinct, mutated growth-controlling genes, most tumors appeared to carry only a single activated oncogene. We now realize that many of the other targets of mutation during tumor progression are TSGs. Their inactivation collaborates with the activated oncogenes to create malignant cells and thus tumors. In the widely cited study of human multistep tumor progression—that described in colonic tumors by Vogelstein and his coworkers—the mutation of a K-*ras* oncogene is accompanied by mutations of the *APC* and *TP53* TSGs and a third TSG that maps to chromosome 18.[27] This evidence, together with a wealth of genetic studies reported subsequently, indicates that TSGs are inactivated even more frequently than oncogenes are activated during the course of forming many types of human tumors. Importantly, the inactivation of TSGs often phenocopies the cell-biological effects of oncogenes. This means that the inactivation of TSGs is as important to the biology of tumor progression as oncogene activation.

Unexpectedly, the discovery of TSGs also made it possible to understand how a variety of DNA tumor viruses succeed in transforming the cells that they infect. Unlike retroviruses, these DNA viruses carry oncogenes that have resided in their genomes for millions, and likely hundreds of millions, of years. Any connections with antecedent cellular genes, to the extent they once existed, were obscured long ago by the extensive remodeling that these oncogenes underwent while being carried in the genomes of the various DNA tumor viruses. Independent of their ultimate origins, it was clear in the 1980s that the oncogenes (and encoded oncoproteins) were deployed by DNA viruses to perturb key components of the normal cellular growth-controlling circuitry. However, the precise control points targeted by these viral oncoproteins remained obscure.

In the late 1980s, it was learned that a number of DNA tumor virus oncoproteins bind to the products of two centrally important TSGs, pRB and p53.[28,29] For example, the large T oncoprotein of SV40 binds and sequesters both the p53 and pRB proteins of infected host cells; the E6 and E7 oncoproteins of human papillomaviruses target p53 and pRB, respectively. As a consequence, a virus-infected cell is deprived of the services of these two key negative regulators of its proliferation. Indeed, these virus-mediated inactivations closely mimic the state seen in many nonviral tumors that have been deprived of pRB and p53 function by somatic mutations striking the TSGs specifying these two proteins. So the transforming mechanisms used by these viruses could be rationalized by referring to the same genes and proteins that were known to be inactivated by mutational mechanisms in many types of spontaneous, nonviral human tumors. Importantly, these findings reinforced the notion that a single, central growth-regulating machinery operating in all types of cells suffers disruption by a variety of ostensibly unrelated genetic mechanisms, leading eventually to the formation of cancers.

The activation of oncogenes and the loss of TSGs together explain many of the phenotypes that one associates with cancer cells. These cells are able to grow without attachment to solid substrate, the aforementioned phenotype of anchorage

independence, and they are able to grow on top of one another, which is manifested in culture as the loss of contact inhibition. Moreover, when compared to normal cells, cancer cells exhibit a greatly reduced dependence on mitogens and an ability to resist the antiproliferative effects of growth-inhibitory signals, such as those conveyed by transforming growth factor-β (TGF-β). Alterations of oncogenes and tumor suppressor genes can be invoked to explain these neoplastic cell traits.

Arguably the most interesting trait of cancer cells is their ability to resist a variety of stimuli and stresses that would cause normal cells to activate the cell-suicide program termed *apoptosis*. The fact that virtually all tumor cells have developed various types of resistance to apoptosis indicates that severe pro-apoptotic stresses are experienced repeatedly as normal cells evolve progressively toward a malignant phenotype and that an ability to resist these stresses is strongly selected during this evolution. Thus, changes in the complex array of genes that control entrance in the apoptotic program are frequently demonstrable within tumor cells. Although these genes are specialized in regulating a discrete cancer cell phenotype (apoptosis), they behave operationally like oncogenes and TSGs, i.e., the activation of some of these confers a resistance to apoptosis as does the inactivation of yet others.

Guardians of the Genome

As mentioned previously, the somatic mutations that activate oncogenes or inactivate TSGs are relatively rare events in the life of a cell, occurring perhaps at a rate of 10^{-6} per cell generation. This low mutation frequency represents an important barrier to the development of neoplasia.[30] If cells require multiple mutations in order to progress to a fully malignant growth state, the probability of the entire constellation of mutations occurring within a cell lineage during a normal human lifespan is extremely low. This provides a partial explanation for the fact that we humans develop relatively few cancers during lifespans in which the cells in our bodies undergo more than 10^{16} divisions, each of which represents an opportunity for a genetic disaster.

As described earlier, the inheritance of a mutant growth-controlling gene obviates one of the normally required, rare somatic mutational steps. In doing so, it allows a population of premalignant cells to leapfrog over one of the barriers that usually block its progression toward malignancy. The consequence is the greatly increased risk of certain tumors that characterizes familial cancer syndromes.

However, there is at least one other route by which this multistep tumor pathogenesis can be accelerated: if the rate of gene mutation per cell generation is greatly increased, the time required for a population of cells to surmount all of the mutational hurdles and progress to full-blown malignancy will be correspondingly reduced. As a consequence, the probability of cancer striking during a normal lifespan will be greatly increased.

Xeroderma pigmentosum (XP) is the most thoroughly studied of the inborn cancer susceptibility syndromes that are attributable to greatly increased mutational frequency. Those suffering from XP show abnormally high sensitivity to ultraviolet (UV) radiation, which evokes squamous cell skin carcinomas and melanomas at exposed sites at a high rate. Like the rest of us, XP patients sustain large numbers of mutational events in their skin cells created by ultraviolet photons. In the skin cells of most humans, the pyrimidine dimers created by UV radiation are quickly excised from the damaged DNA and the initial, wild-type nucleotide sequence is restored, thereby erasing all traces of the mutation; this removal of DNA lesions is achieved by a cohort of DNA repair proteins that are specialized to effect this particular alteration of DNA structure. (In the event that skin cells exhibit widespread genomic damage that overwhelms the ability of its DNA repair apparatus to restore normal genome sequence, the cell may opt for another response, apoptosis, as discussed later.) In the XP patient, one or another essential component of this specialized DNA repair apparatus is absent or defective.[31] As a consequence, altered DNA sequences are transmitted to the progeny of the initially irradiated cell, resulting in large numbers of mutations in their genomes. Hence, the effective mutation rate (the number of initially induced mutations minus those that are repaired) increases enormously.

XP represented only the first of the familial cancer syndromes that has been attributable to defective DNA repair. In this particular syndrome, mutational damage is inflicted by an exogenous mutagen—UV radiation. We now know that a variety of other familial cancer syndromes are also attributable to defects in one or another component of the complex apparatus that maintains the integrity of our genome. In many of the more recently characterized cancer syndromes, the initial mutational damage is of endogenous origin, being inflicted by malfunctioning of normal cellular processes, including the mutations that result from mistakes in DNA replication and from the actions of endogenously generated mutagens, such as reactive oxygen species.

The ataxia telangiectasia syndrome, which includes, among its presentations, the development of certain tumors, is also due to defective DNA repair.[31,32] In hereditary nonpolyposis colon cancer (HNPCC), the apparatus that recognizes recently made mistakes in DNA replication, often termed the *mismatch repair apparatus*, is defective.[33,34] At least four different inherited subtypes of HNPCC have been described; each of these is due to defects in one or another component of the complex multicomponent system that recognizes and erases DNA copying mistakes as well as other

lesions that are occasionally inflicted on the cell genome. In the cells of HNPCC patients, one sees widespread genomic instability, the direct results of this defective DNA repair. The resulting genetic damage seems to affect all genes with equal frequency and thus the target proto-oncogenes and TSGs that participate in the formation of non-HNPCC colon cancers. As a consequence, the entire multistep process of colon cancer progression is greatly accelerated. Unexplained at present is why this genetic defect specifically afflicts the colon rather than causing elevated rates of cancer incidence in many sites throughout the body.

Many familial breast cancers have more recently been associated with inheritance of mutant versions of the *BRCA1* and *BRCA2* genes.[35] These were initially thought to be TSGs, but the peculiar behavior of the mutant alleles of these genes suggested otherwise. Mutant alleles of the *BRCA1* and *BRCA2* genes were found to be inherited in the germlines of affected individuals; however, sporadic mammary tumors rarely showed mutant alleles. Recent biochemical and cell biological experiments suggest that both these genes specify proteins that participate in the repair of double-strand DNA breaks. It remains unclear why the inheritance of defective alleles of either of these genes predisposes individuals specifically to breast and ovarian tumors.

There is increasing evidence that a breakdown of DNA repair capability accompanies the formation of the great majority of human tumors. These losses may occur through somatic mutation of DNA repair genes or, perhaps more frequently, through epigenetic mechanisms, such as DNA methylation (see later discussion), that succeed in repressing the expression of these repair genes, thereby depriving cells of the vital functions encoded by these genes.

Epigenetic Mechanisms Leading to Loss of Gene Function

As described earlier, the functions of two major classes of cellular genes are lost during the course of tumor progression—TSGs and DNA repair genes. It is highly likely that the development of the great majority of human tumors depends on these losses. Moreover, the portrayal of cancer as a genetic disorder, as developed previously, would suggest that these genes and their vital functions are lost through various mechanisms of somatic mutation. After all, mutations are by definition heritable, and thus the progeny of a cell that has initially acquired growth advantage through some somatic mutation will be similarly benefited, leading to the progressive expansion of clones of such mutant cells.

Following this logic, the phenotypic changes that occur during the course of tumor progression need to be heritable. In fact, there is a mechanism of heritability that does not depend on genetic alterations, i.e., on alterations of nucleotide sequence in a cell's genome. This mechanism depends on the methylation of the cytidine residues present in CpG dinucleotide sequences that are found in proximity to the promoters of various genes or by modification of histones in chromatin. Methylation or modification of histones often results in major shifts in the configuration of nearby chromatin and in the shutdown of the expression of nearby genes—the process of transcriptional repression.

When a DNA segment containing a methylated CpG is replicated, the complementary CpG in the newly synthesized daughter DNA strand is initially unmethylated. However, soon after this daughter strand is formed, "maintenance" DNA methylases recognize the hemimethylated DNA and attach a methyl group to the recently formed CpG residue, thereby ensuring that both CpGs are now methylated (Figure 1-6). This scheme ensures that DNA methylation events, and thus associated repression of certain genes, can be transmitted from parent to daughter cells with high fidelity. Hence, genes may be inactivated in a heritable fashion without any change in their nucleotide sequence.

In fact, the mechanisms that control DNA methylation result in the inactivation of genes at higher rates per cell generation than those involving somatic mutations. This leads to the obvious conclusion that the functions of TSGs and DNA repair genes are likely to be lost more frequently through DNA methylation than mutation, a notion that

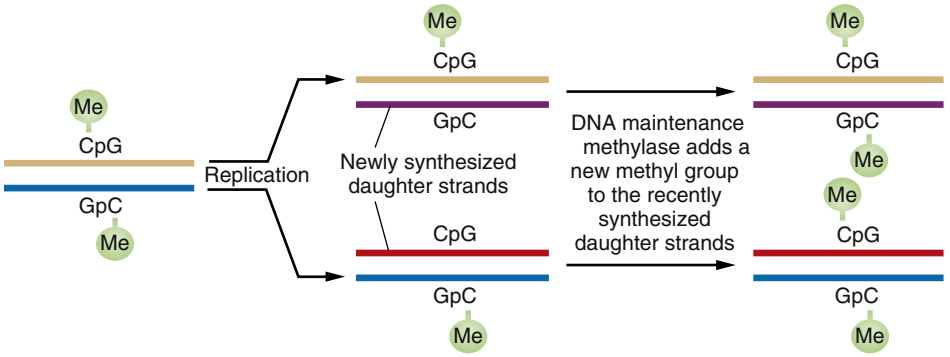

Figure 1-6 Perpetuation of CpG methylation following DNA replication When DNA methylated at CpG residues is replicated, the newly formed daughter strands initially lack methyl groups on the CpG sites complementary to those methylated sequences in the parental DNA strands. However, shortly after replication, maintenance methylases add methyl groups to the newly synthesized CpG sites, ensuring the transmission of the methylated state from one cell generation to the next. Such methylation is often associated with the repression of gene transcription.

is borne out by extensive studies of the genomes of human tumor cells.[36] Indeed, it now seems likely that individual tumor cell genomes bear many dozens if not hundreds of methylated genes. Most of these genes are likely be methylated as a consequence of the relaxed controls on DNA methylation that seem to operate within cancer cells; most such genes are bystanders, i.e., their loss is not functionally important for the cancer cell phenotype and their loss has not conferred selective advantage on the cells that carry them. However, a number of key TSGs and DNA repair genes have indeed been found to be methylated frequently in various types of human cancer cell genomes, and it is clear that the loss of gene function through promoter methylation is as effective in driving tumor progression as the somatic mutations that have been described extensively here.

Moreover, the modification of histones also alters chromatin and gene expression. Recent genome sequencing efforts have uncovered mutations in genes whose products play key roles in maintaining or modifying histone marks. For example, mutations in adenine-thymine (AT)-rich interactive domain-containing protein 1A (ARID1A),[36,37] a protein involved in chromatin remodeling, is mutated in more than 50% of ovarian clear cell cancers, and multiple chromatin-modifying enzymes including PBRM1 are mutated in a large fraction of renal clear cell cancers. These findings provide a link between the genetic and epigenetic origins of cancer. Hence, cancer pathogenesis is a disorder of genes and gene function, but it does not always depend on genetic alterations, because the epigenetic regulation of genes contributes as frequently, if not more frequently, to tumor formation.

Immortalized Proliferation

Yet another phenotype of cancer cells—their ability to grow and divide indefinitely—does indeed depend on changes in DNA structure and is, in this sense, a genetically determined trait. This unlimited proliferative ability, often termed *cell immortality*, stands in stark contrast to the limited proliferative ability of normal cell populations. Thus, when placed into culture, many types of cancer cells are able to proliferate indefinitely, in contrast to the behavior of normal cells, which cease proliferation after a limited, ostensibly predetermined number of doublings. This phenomenon of finite replicative potential suggests the workings of some type of generational clock that tallies the number of cell divisions through which cell lineages have passed since they resided in the early embryo and then informs cells in these lineages when their allotment of doublings has been exhausted. In response to this alarm, cell populations become "senescent," and if they overcome or circumvent senescence, will multiply further until they enter into a state of "crisis," in which almost all of them die.[38,39]

This limitation on replicative potential would seem to represent an important antineoplastic barrier erected by the organism. By limiting the number of successive replicative doublings its component cells may undertake, the organism erects a high barrier to the unlimited expansion of preneoplastic cell clones. Cancer cells must surmount this barrier in order to succeed in their agenda of unlimited growth and the formation of macroscopic tumors.

In fact, very different mechanisms govern the timing of the entrance of cell populations into senescence and into crisis. The senescence observed with cultured cells appears to be determined, in large part, by the conditions of their propagation in vitro. By necessity, the protocols developed for culturing cells create conditions that differ dramatically from those operating within living tissues. These discrepancies derive from the contents of the culture medium as well as the oxygen tensions experienced by cells within tissue culture incubators. As a consequence, cells suffer substantial physiologic stress when placed into culture, and cumulative cell-physiologic stress seems to be a major, if not the major, determinant of the triggering of senescence.

The mechanisms governing entrance into crisis are very different and do indeed involve, quite directly, the cell genome, more specifically the telomeres at the ends of all chromosomes. Evidence accumulated in recent years points to the telomeres as the molecular devices that tally cell generations and govern entrance into crisis. The ends of the telomeric DNA are not copied completely during each cycle of DNA replication because of an intrinsic limitation in the DNA polymerases responsible for the bulk of DNA replication. In addition, the ends of telomeric DNA are susceptible to the actions of exonucleases, which contribute to further erosion of telomeric DNA length. As a consequence, the telomeres shorten progressively as cell lineages pass through repeated cycles of growth and division (Figure 1-7). In normal cell lineages, this shortening eventually results in critically truncated telomeres. Without the protective effects of the telomeres, chromosomes undergo end-to-end fusion with resulting karyotypic instability and cell death. Hence, the progressive shortening of telomeres represents an effective molecular device for counting cumulative generational doublings.[38,39]

Cancer cell populations must overcome this limitation on their proliferation in order to proliferate extensively and generate macroscopic tumors. They do so by activating expression of the telomerase enzyme, which is able to restore and maintain telomeric DNA length, thereby reversing the effects of telomere erosion. Telomerase activity is detectable in almost all human tumors (approximately 90%) but is present at low or undetectable levels in the corresponding

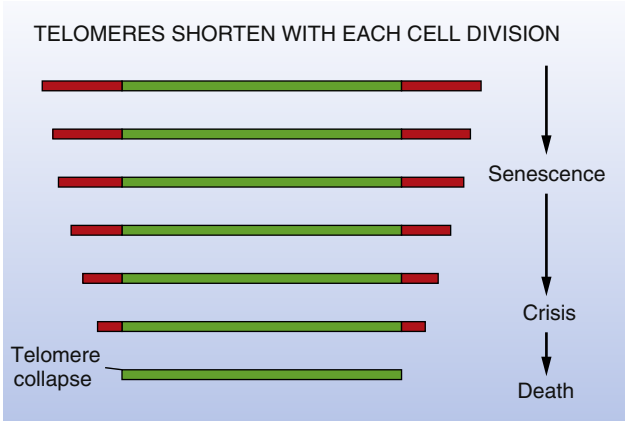

Figure 1-7 Telomere erosion and entrance into crisis In the absence of active intervention by the telomerase enzyme, the telomeres of human chromosomes shorten progressively during each round of cell growth-and-division, eventually losing so much length that they can no longer subserve their normal function of protecting the ends of chromosomal DNA from end-to-end fusions with other chromosomes. This leads to massive cell death, termed crisis, and occasionally, the emergence of a rare variant that has indeed acquired telomerase expression and is accordingly now able to repair and maintain telomeric DNA and thus telomeres. (Although the onset of senescence is indicated here as also being triggered by telomere shortening, it appears that it is largely due to cumulative cell-physiologic stresses sustained by cells both in vitro and in vivo.)

normal tissues. Accordingly, the genes that allow telomerase activation during tumor progression represent yet additional important genetic elements that are affected during the development of almost all human tumors. Importantly, however, the human telomerase gene, termed *hTERT*, is not itself the target of mutation. Instead, its expression is induced by a complex array of *trans*-acting transcriptional regulators, the MYC oncoprotein being one of these.

The critical contribution of telomerase to tumorigenesis is illustrated most dramatically by the protocols that enable the experimental transformation of normal human cells into tumor cells. By adding the *hTERT* gene to a cocktail of other introduced oncogenes, a variety of normal human cells can be converted to a tumorigenic state, as judged by their behavior following implantation into appropriate host mice.[40] The *hTERT* gene clearly affords such cells the ability to proliferate indefinitely; without its actions, cells fail to proliferate extensively in vitro and to form tumors in vivo.

Non-genetic Mechanisms Accelerating Multistep Tumor Progression

The descriptions of tumorigenesis, as developed here, lead to the notions that the functioning of normal cell genomes is progressively degraded by mutagenic mechanisms, promoter methylation, and telomerase erosion and that these mechanisms conspire to drive forward multistep tumor progression. An obvious corollary is that exposure to high levels of mutagenic agents is likely to serve as a major agent that stimulates human tumor formation. Indeed, since the initial experiments of Bruce Ames, such logic has inspired the search for the mutagens that are responsible for instigating human cancers.

In truth, with some notable exceptions, the search for the mutagenic carcinogens that drive human cancer pathogenesis has failed.[41] Tobacco smoke, with its high levels of mutagens, is clearly responsible for almost one-third of human cancers. In addition, the heterocyclic amine mutagens created by the cooking of red meat at high temperatures are attractive candidates for the agents causing many colon and possibly prostate cancers.

In general, however, the carcinogens responsible for most human cancer incidence have eluded identification, apparently because they do not function as mutagens. Instead, it has become increasingly apparent over the past two decades that the major determinants of human cancer incidence are various agents and conditions that operate as "tumor promoters." Thus, as illustrated by the classic experiments involving mouse skin cancers, tumor "initiators" are responsible for triggering the first step of multistep tumorigenesis by mutating certain target genes (e.g., H-*ras*), whereas promoters are responsible for driving the clonal expansion of already-initiated tumor cells, doing so through mechanisms that do not involve genetic damage. It seems increasingly likely that most of the determinants of human cancer incidence operate as promoters.

Possibly the most important promoting mechanisms involve chronic inflammation of tissues and the associated release of growth-stimulating factors by the irritated tissue. Moreover, many of the dietary determinants of tumor incidence would seem to function as promoters rather than as mutagenic initiators. If these notions are sustained by future research, this will mean that a complete understanding of cancer pathogenesis at the molecular level will require detailed elucidation of these non-genetic, tumor-promoting mechanisms.

Invasive and Metastatic Behaviors

In many individuals, the endpoint of multistep tumor progression involves, unfortunately, the acquisition by cancer cells of the ability to invade and to metastasize from the primary tumor to distant sites in the body—the manifestations of high-grade malignancy. Indeed, the metastases that are spawned by malignant tumors are responsible for 90% of cancer-associated mortality.

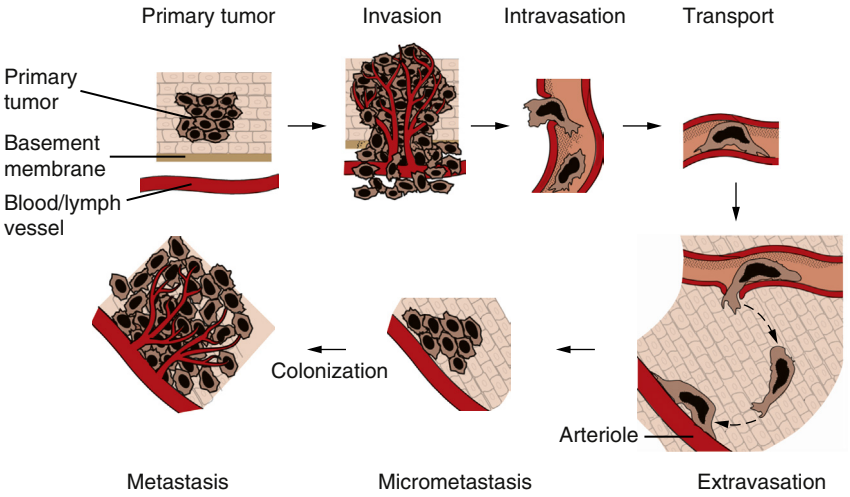

Figure 1-8 The invasion-metastasis cascade The invasion-metastasis cascade is a complex, multistep process through which cancer cells must pass in order to launch macroscopic tumor colonies at distant sites. These steps are executed relatively inefficiently, resulting in vast numbers of cells being disseminated from primary tumors with only a small number of cells being able to eventually form macroscopic metastases.

The formation of metastases is the result of a complex, multistep process that is often termed the *invasion-metastasis cascade* (Figure 1-8). Thus, cancer cells in the primary tumor acquire the ability to invade adjacent tissue, to enter into the vessels of the blood and lymphatic systems (intravasation), to travel in these channels to distant sites in the body, to escape from these vessels (extravasation) into nearby tissues, and to found small tumor colonies (micrometastases) in these tissues. On occasion, the cells forming a micrometastasis will acquire the ability to proliferate vigorously, resulting in the formation of a macroscopic metastasis—the process termed *colonization*.

The complexity of the invasion-metastasis cascade rivals that of the multistep process that leads initially to the formation of a primary tumor. This suggests, in turn, that cancer cells within a primary tumor must suffer a significant number of genetic alterations in order to acquire the ability to complete this cascade. Another alternative has presented itself, however, as the result of recent research on the malignant behavior of carcinoma cells. This alternative mechanism involves the actions of genes that are normally involved in programming certain key steps of early embryonic morphogenesis. In such steps of embryogenesis, epithelial cells, which are normally immobilized in various layers, undergo a profound change in their differentiation program and acquire many of the phenotypes of mesenchymal cells, including motility and invasiveness. This transdifferentiation program is termed the *epithelial-mesenchymal transition* (EMT).

As many as half a dozen transcription factors acting during various stages of early embryogenesis are capable of programming EMTs. These transcription factors have names such as Snail, Slug, Twist, Goosecoid, and SIP-1. Each of these is able to act pleiotropically to program an EMT and thereby is able to cause the repression of epithelial genes and the induction, in their stead, of mesenchymal genes. Increasing experimental evidence indicates that carcinoma cells exploit these early embryonic genes in order to execute most of the steps of the invasion-metastasis cascade.[42,43]

Expression of these embryonic genes seems to be induced by contextual signals that these carcinoma cells experience in the tumor microenvironment and that originate in the tumor-associated stroma. For example, TGF-β impinging on certain cancer cells is able to elicit the expression of several of the transcription factors that are capable, in turn, of programming an EMT. This suggests that the EMT program, and the enabling of the invasion-metastasis cascade, occurs because of a collaboration between the genotype of cancer cells and the contextual signals that these cells receive from the nearby microenvironment, more specifically from the activated stroma that is present in many primary tumors. Moreover, it suggests that certain carcinoma cell genotypes render these cells responsive to such stromal, EMT-inducing signals, whereas other genotypes leave the cancer cells unresponsive, indeed refractory, to these signals; our understanding of these genotypes is still fragmentary.

The discovery of these embryonic transcription programs and their resurrection by carcinoma cells greatly simplifies our conceptualization of the late stages of malignant progression. Rather than needing to acquire a number of distinct mutations in order to execute the various steps of the invasion-metastasis cascade, the genotypes of certain primary cancer cells allow them, in response to stromal signals, to activate long-dormant cell biological programs—EMTs. Once activated, this program seems to enable a carcinoma cell to complete most of the steps of the invasion-metastasis cascade. However, the last step—colonization—appears to involve an adaptation to the novel tissue microenvironment in which disseminated carcinoma cells have landed; such adaptation would not seem to be found among the multiple powers of the EMT program and would seem to acquire yet other changes that remain poorly understood.

Interestingly, the carcinoma cells forming a metastasis often recapitulate the histopathological appearance of the primary tumor, including its distinctive epithelial cell sheets and ducts. This would seem to be at variance with the notion that in order to metastasize, carcinoma cells must shed their epithelial characteristics and acquire, instead, mesenchymal ones. It seems plausible, however, that once carcinoma cells have disseminated and landed in distant tissue sites, they no longer encounter the mix of signals that were released by the activated stroma of the primary tumor and that led initially to their passing through an EMT. This new tissue microenvironment may therefore allow these cells to revert, via a mesenchymal-epithelial transition (MET) to the epithelial phenotype of their progenitors in the primary tumor, thereby generating once again epithelial histomorphology. Importantly, although passage through a partial or complete EMT may explain the malignant behavior of many carcinoma cells, it is less clear how tumors of other tissue origins, namely those arising in neuroectodermal, mesenchymal, and hematopoietic tissues, acquire these aggressive traits. The mechanisms enabling invasive and metastatic behaviors in these other neoplastic cell types remain elusive.

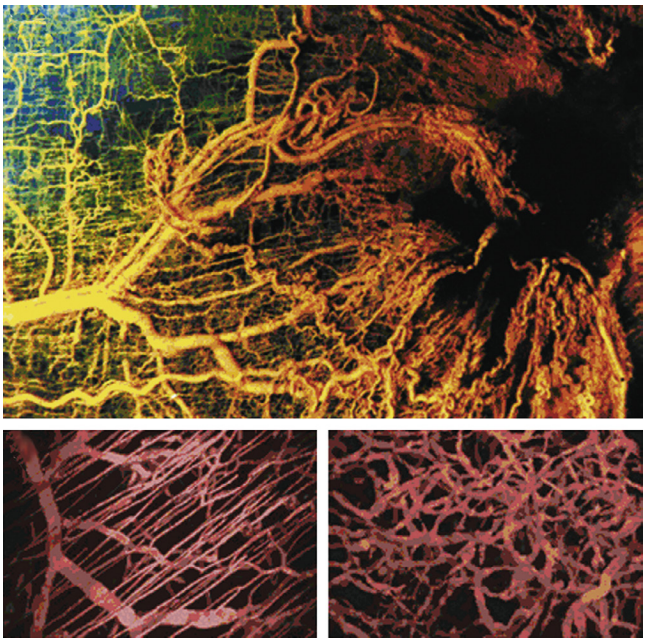

Figure 1-9 Tumor angiogenesis As tumors grow, they develop large networks of blood vessels through the process of angiogenesis. Seen here is a tumor *(black mass, right)* that has attracted blood vessels growing into it from adjacent normal tissue *(left)*. As is the case with most tumor-associated neovasculature, the new vessels developed here are tortuous and often end in dead ends *(right)*, in contrast to the normal vasculature seen here. *(Reproduced from Weinberg RA.* The Biology of Cancer. *New York, NY: Garland Science; 2007:562.)*

Other Phenotypes of Neoplasia

Many of the phenotypes of cancer cells are not readily explained by alterations in their proto-oncogenes and TSGs. Cancer cells acquire other aberrations that favor their growth in the complex environments of living tissues. Included among these is their ability to recruit blood vessels into tumor masses—the process of angiogenesis[44]—and, quite possibly, their ability to evade and overwhelm immune defenses.[45]

The process of tumor angiogenesis, like the EMT, involves a complex array of heterotypic interactions between cancer cells and their mesenchymal microenvironment (Figure 1-9). Indeed, this neoangiogenesis has become a subject of intensive investigation over the past decade, in part because the demonstrated dependence of tumors on vascularization represents an attractive target for therapeutic intervention through the creation and implementation of various antiangiogenic therapies. Thus, without adequate vascularization, cancer cells are limited to forming tumors of less than 1-mm diameter.

The processes of neovascularization depend on the heterotypic interactions of cancer cells with circulating endothelial precursor cells and with existing endothelial cells in the nearby stroma. Moreover, other regulators of this process include macrophages, myofibroblasts, and neutrophils, which may collaborate with the cancer cells to release angiogenic signals and thereby recruit endothelial cells and induce them to construct microvasculature. In addition, pericytes, which form the outer wall of most microvessels, must be recruited in order to ensure the assembly of well-constructed microvessels.

The role of the immune system in defending against the formation of various human tumor types remains a matter of great contention. Actually, in the case of virus-induced cancers, the protective role of the immune system is no longer debated, because of the abundant evidence that immunocompromised individuals suffer dramatically increased rates of virus-induced malignancies, including Kaposi's sarcoma, human papillomavirus–induced squamous cell carcinomas, and certain types of Epstein-Barr virus–induced hematopoietic disorders. In all of these cases, these functions can be readily rationalized by invoking the known antiviral effects of the immune system.

More challenging, however, are the actions of the immune system in reducing the incidence of tumors of nonviral etiology, which constitute more than 80% of the total tumor burden in the population. In these cases, it has been unclear how the immune system can recognize tumor cells as being of foreign origin and proceed to attack and eliminate them. That such attack often occurs is clear, however, as evidenced by the severalfold increased incidence of a variety of common tumors in patients who are immunocompromised

for various reasons, largely involving the preservation of organ transplants. This phenomenon provides hope that the immune system is indeed capable of recognizing and attacking nonviral tumors and that its powers can be exploited to serve as antitumor therapeutic modalities.

The molecular genetic paradigm described here has allowed us to understand the workings of the cancer cell in enormous detail. Thirty years ago, no one could have anticipated this explosion of knowledge. Genes have led to encoded proteins, and the study of these proteins has allowed us to elucidate complex regulatory circuits transmitting signals that flux through the cancer cell and control its proliferation, differentiation, and death.

The discovery of oncogenes has begun to have an impact in the clinic. Small-molecule inhibitors or antibodies directed against activated oncogenes, such as BRAF, BCR-ABL, and HER2, are now approved for the treatment of melanoma, chronic myelogenous leukemia, and breast cancer (Figure 1-10). In addition, large-scale efforts to characterize cancer genomes have confirmed the key role for many of the known oncogenes and tumor suppressor genes and uncovered new classes of potential cancer targets.[46-52] These efforts have also stimulated the development of strategies to perform genome characterization of patient samples. The extension of such efforts is likely to fundamentally alter the diagnosis and classification of cancers. Although it is clear that these initial molecularly targeted therapies will not lead to durable cures in most cases, with the greatly increased understanding of the genetic mechanisms of cancer pathogenesis, many novel ways of detecting and curing tumors are now, finally, within reach.

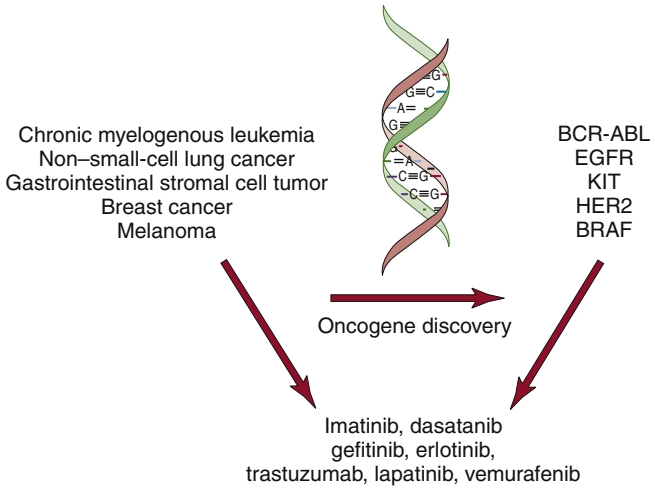

Figure 1-10 Molecularly targeted therapies The discovery of oncogenes in specific types of human cancers has led to the development of molecularly targeted inhibitors. These inhibitors show specificity for cancers that harbor the specific mutations.

Oncogenes and Signal Transduction

Signaling: An Overview

Intercellular communication is critical to embryonic development, tissue differentiation, and systemic responses to wounds and infections. These complex signaling networks are in large part initiated by growth factors. Such factors can influence cell proliferation in positive or negative ways, as well as inducing a series of differentiated responses in appropriate target cells including survival, apoptosis, and differentiation. The interaction of a growth factor with its receptor by specific binding in turn activates a cascade of intracellular biochemical events ultimately responsible for the biological responses observed. Several classes of receptors are involved in transducing these extracellular signals. These include receptor tyrosine kinases, G-protein coupled receptors, and cytokine receptors. Cytoplasmic molecules that mediate these responses have been termed *second messengers*. The transmission of these biochemical signals to the nucleus leads to the altered expression of a wide variety of genes involved in mitogenic, survival, and differentiation responses.

As knowledge has accumulated in the area of signal transduction and the complexities increase, it is becoming apparent that overlap exists in cell signaling. This functional redundancy may be seen at several levels. The simplest example would be the fact that several different extracellular signals can lead to the activation of the same pathway. Physiologically, this may serve to allow a cell to respond to a variety of different situations or stresses while conserving some of the downstream machinery. Although some of the components of certain pathways may be common for two different stimuli, the ultimate physiological response may differ greatly because of the activation of a different repertoire of nuclear response elements. In addition, although redundancy may exist in terms of the ability of a stimulus to perturb a specific pathway, it is conceivable that the kinetics and magnitude of activation may differ, leading to distinct outcomes.

There is often redundancy among different isoforms of certain proteins or with members of particular gene families. This is illustrated by the fact that targeted disruptions of some genes fail to produce detectable phenotypes in mice, indicating that other proteins can compensate for their loss. An attractive explanation for this redundancy is that it serves as a fail-safe mechanism to ensure proper functioning in the face of damaging mutations that lead to a loss of function. Indeed, as discussed in more detail later, proteins within a family often have overlapping functions and may in some situations complement one another.

In order to effectively coordinate signaling cascades, nature has created a variety of molecules known as adaptor and scaffolding proteins.[1] These proteins play an integral role in intracellular signaling by recruiting various proteins to specific locations, as well as by assembling networks of proteins particular to a cascade. Adaptor proteins, through protein-protein interactions via specific motifs, provide a link between molecules of a signaling cascade and proteins such as receptor tyrosine kinases (RTKs; Figure 2-1). Adaptors can be docking proteins, which provide multiple binding sites on which effector molecules can attach, thereby expanding the magnitude of responses from an activated RTK. Scaffolding proteins also exist in signaling cascades and allow the formation of multienzyme complexes that are involved in a particular cascade. These are important for two reasons. The first is that the activation of a signaling cascade by a growth factor is an extremely rapid process and is not likely to occur as a result of proteins randomly floating in the intracellular milieu until they happen to come in contact with each other. Scaffolding proteins ensure the close proximity of the necessary components. The second reason is that several enzymatic components of a particular signaling cascade may be shared, although the substrates of each may differ. Thus, scaffolding proteins ensure the proper routing of signals by preventing unwanted cross talk between pathways.

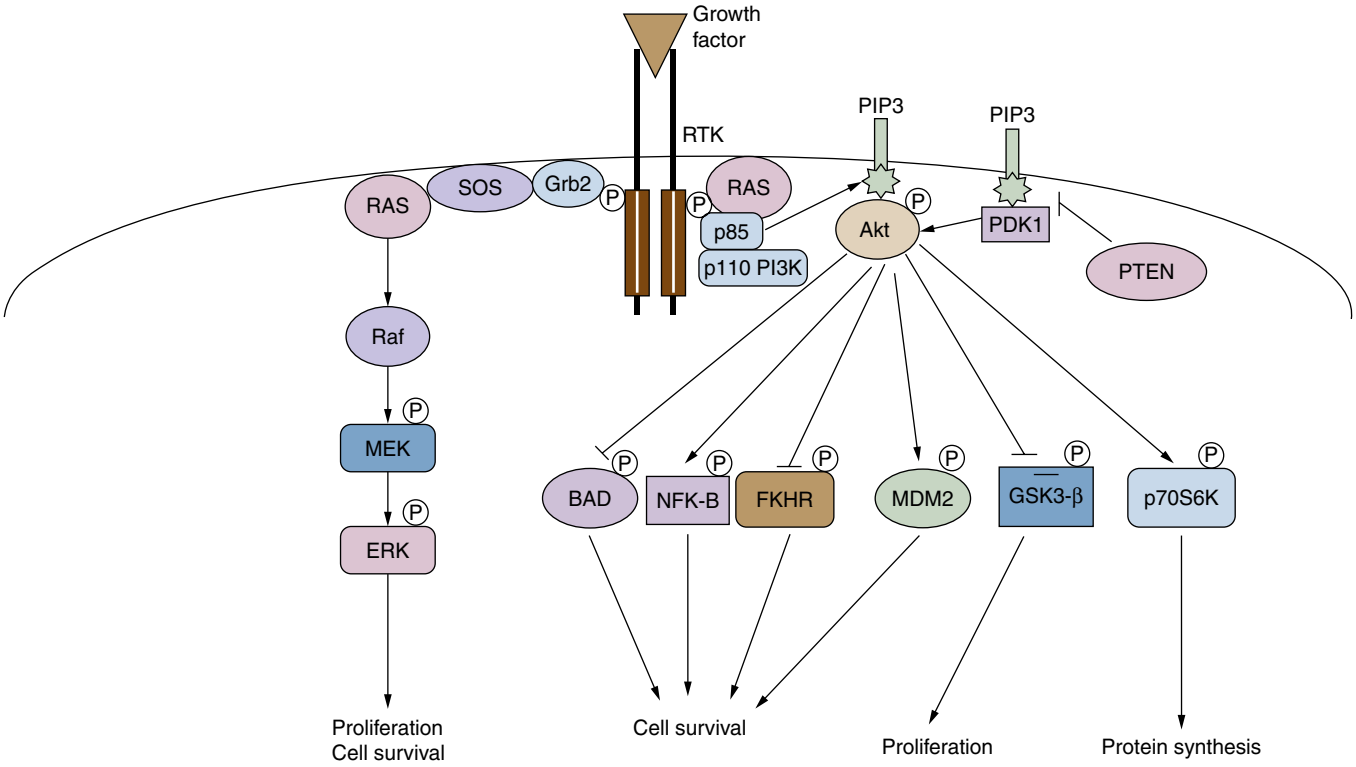

Figure 2-1 Receptor tyrosine kinase signaling in cancer Scheme for growth factor signaling through receptor tyrosine kinases.

Oncogenes

Oncogenes encode proteins that possess the ability to cause cellular transformation. These genes act in a dominant fashion, through either overexpression or activating mutations. There are several criteria that define cellular transformation. These include morphological changes, loss of contact inhibition, anchorage-independent growth, and the ability to form tumors when transplanted into nude mice. For example, under normal physiological situations, a growth factor binding to a receptor produces a very transient activation of a certain signaling cascade allowing tightly regulated responses such as proliferation to occur. When downstream components of these cascades are mutated in a way that causes them to be constitutively active, the signal is no longer transient and regulated but is aberrantly turned on in a continuous fashion. In addition to activating mutations, these genes can be activated by overexpression at levels much higher than in normal cells. Proto-oncogenes are commonly involved in cellular signaling, and specific examples are discussed later in the context of their roles in signal transduction.

Initially, it was believed that cellular transformation was caused solely by unregulated cell proliferation induced by activation of oncogenes. It is now known that although deregulated proliferation is most likely a necessary component for transformation, it is probably not sufficient, and other changes, such as modulation of cell survival functions, are critical as well. In fact, as discussed later, certain oncogenes function to modulate cell survival.

In the early 1980s, approaches aimed at identifying the functions of retroviral oncogenes converged with efforts to investigate normal mitogenic signaling by growth factors. Analysis of the predicted sequences of a number of retroviral oncogene products uncovered several with similarities to the prototype v-src product, whose enzymatic function as a protein kinase had been identified. Unlike many protein kinases, which phosphorylated serine and/or threonine residues, the v-src product was a protein kinase capable of specifically phosphorylating tyrosine residues.[2] Later efforts to identify oncogenes led to the discovery of the small GTPase Ras, which was unmasked as a transforming gene by transfection of tumor cell genomic DNA.[3]

Independent efforts to purify and sequence growth factors led to the discovery that the sequence of the platelet-derived growth factor (PDGF) B chain matched the predicted product of the transforming gene of simian sarcoma virus, designated v-sis.[4,5] The v-erbB gene of avian erythroblastosis virus, which predicted a v-src–related protein tyrosine kinase, was then found to represent a truncated form of the epidermal growth factor receptor (EGFR).[6] Independent evidence demonstrated that EGF triggering of its receptor resulted in tyrosine autophosphorylation.[7] Thus, a direct link between growth factors, receptors with tyrosine

kinase activity, and oncogenes was firmly established. The proliferation, differentiation, functional activity, and survival of cells can be affected by a wide array of other cytokines that signal through transmembrane receptors that lack protein tyrosine kinase activity. Because these signaling systems have also been implicated in malignant transformation, they are described in this chapter as well.

Signal Transduction by Protein Tyrosine Kinase Receptors

Membrane-spanning RTKs contain several discrete domains, including their extracellular ligand binding, transmembrane, juxtamembrane, protein tyrosine kinase, and carboxy-terminal tail domains.[8,9] Interaction of a growth factor with its receptor at the cell surface leads to a tight association, so that growth factors are capable of mediating their activities at very low concentrations. In the general model of RTK activation, ligand binding induces receptor dimer or oligomer formation associated with activation of the tyrosine kinase domain. However, the dimerization mechanism can be very different among the 20 families of RTKs, and the contribution of the ligands varies. For example, nerve growth factor (NGF) dimers directly mediate the coupling of two TrkA receptors, whereas EGF molecules do not contribute to the EGFR dimerization interface, but instead induce a conformational switch, which unmasks a dimerization domain in the EGFR extracellular region.[9] Also, it should be noted that certain RTKs, such as the insulin and insulin-like growth factor receptors, form inactive dimers that are triggered in the presence of their ligands through conformational changes.[9]

Among the different RTKs, the tyrosine kinase is the most conserved domain, and its integrity is absolutely required for receptor signaling. For example, mutation of a single lysine in the ATP binding site, which blocks the ability of the receptor to phosphorylate tyrosine residues, completely inactivates receptor biological function.[10] In the presence of their ligands, the conformational changes in the activated receptors overcome *cis*-autoinhibitory interactions in the kinase, the juxtamembrane, and the carboxy-terminal domains, which allow *trans*-phosphorylation on tyrosine residues that serve as docking sites for different adaptor and second messenger proteins.[9]

The juxtamembrane sequence that separates the transmembrane and cytoplasmic domains is not well conserved among different families of receptors. However, juxtamembrane sequences are highly similar among members of the same family, and studies indicate that this stretch plays a role in the modulation of receptor function. For example, addition of PDGF to many types of cells causes a rapid decrease in high-affinity binding of EGF to its receptor, which is mediated by the phosphorylation of the EGFR juxtamembrane domain induced by PDGF-triggered protein kinase C (PKC), a process termed *receptor transmodulation*.[11] The carboxy-terminal domain of the receptor is thought to play an important role in the regulation of kinase activity. This region typically contains several tyrosine residues, which are autophosphorylated by the activated kinase. In fact, the receptor itself is often the major tyrosine phosphorylated species observed following ligand stimulation. Tyrosine phosphorylation of the carboxy-terminal domain can modulate kinase catalytic activity and/or the ability of the kinase to interact with substrates. Thus, mutations that alter individual tyrosine sites or deletions of this domain have the effect of attenuating kinase function.[9,11]

RTKs and Cancer

The constitutive expression of a growth factor and its specific receptor by the same cell may be sufficient to establish a so-called autocrine loop that contributes to tumor progression. Autocrine transforming interactions have been identified in a number of human malignancies. At least one PDGF chain and one of its receptors have been detected in a high fraction of sarcomas and in glial-derived neoplasms.[12-14] Growth factors also contribute to tumor progression by a paracrine mode. For example, continuous stimulation by growth factors in paracrine as well as autocrine modes during chronic tissue damage and repair associated with cirrhosis and inflammatory bowel disease may predispose to tumors.[15] Some tumor cells produce angiogenic growth factors such as the vascular endothelial growth factors (VEGFs). Such growth factors cause paracrine stimulation of endothelial cells, inducing neoangiogenesis and lymphangiogenesis, which contribute to tumor progression.[16]

RTKs are frequently targets of oncogenic alterations, which create a constitutively activated receptor, independent of the presence of ligand. This was initially demonstrated with retroviral oncogenes, v-erbB and v-fms, encoding activated forms of the EGF and CSF-1 receptor, respectively.[6,17] Alterations affecting a large number of RTKs have been implicated in human malignancies. One mechanism involves the amplification or overexpression of a normal receptor. Examples include EGFR, ERBB-2, and MET (see reviews[18,19]). In some human tumors, deletions within the external domain of the EGFR receptor or mutations in its tyrosine kinase domain are associated with its constitutive activation.[19] The *RET* gene is activated by rearrangement, as a somatic event, in about one third of papillary thyroid

carcinomas. Germline mutations affecting the cysteine residues in the extracellular region, resulting in constitutive dimerization of these receptors caused by the formation of intermolecular cysteine bridges, are responsible for multiple endocrine neoplasia (MEN) 2A and for the familial medullary thyroid carcinoma syndrome. In contrast, point mutations in RET kinase domain, such as those involving codons V804, Y806, A883, and M918, are responsible for MEN 2B.[20] These mutations have been shown to upregulate RET catalytic function, resulting in its genetic transmission as an oncogene. MET is overexpressed and/or mutationally activated in a variety of human tumors, including hepatocellular, gastric, and colorectal carcinomas, and activating mutations of *MET* have been associated with the metastatic progression of head and neck cancers.[18] A direct role of MET in hereditary papillary renal carcinoma has also been established.[21] This hereditary disease is characterized by multiple, bilateral renal papillary tumors, in which mutations activate constitutive kinase activity and transforming properties. Somatic mutations in *MET* have also been detected in some sporadic renal papillary tumors.[21] Several other receptors, including PDGF-β, TrkA, TrkC, and anaplastic lymphoma kinase (ALK) have been shown to be oncogenically activated in human malignancies by gene rearrangements that lead to fusion products containing the activated TK domain.[22-25]

Signaling Pathways of Tyrosine Kinase Receptors

Knowledge of the cascade of biochemical events triggered by ligand stimulation of tyrosine kinase receptors has increased rapidly in recent years and provides further evidence of the importance of these signaling pathways in cancer. The PDGF system has served as the prototype for identification of the components of these systems. Certain molecules become physically associated and/or phosphorylated by the activated PDGF receptor kinase. Those identified to date include phospholipase C (PLC)-γ,[26] phosphatidylinositol-3′-kinase (PI-3K) regulatory subunit (p85),[27] Nck,[28] the phosphatase SHP-2,[29] Grb2,[30] Crk,[31] ras p21 guanosine triphosphatase (GTPase)-activating protein (GAP),[32,33] and src and src-like tyrosine kinases.[34] PLC-γ is one of several PLC isoforms and is involved in the generation of two important second messengers, inositol triphosphate (IP_3) and diacylglycerol (DAG), which cause release of stored intracellular calcium and activation of PKC, respectively.[35,36] PKC participates in cell proliferation, survival, and migration. Although different isoforms can play distinct and sometimes opposite roles in such processes, evidence for the involvement of PKC in tumorigenesis and cancer progression is substantial.[36]

PI-3K phosphorylates the inositol ring in PI in the 3′ position and becomes physically associated with a number of activated tyrosine kinases.[37,38] This protein contains an 85-kDA regulatory subunit, which is tyrosine phosphorylated, and a 110-kDa catalytic subunit. PI3-K appears to play a major role in cell survival signaling, as discussed later (see Figure 2-1).

RAS

Ras small GTP-binding proteins are a major point of convergence in receptor tyrosine kinase signaling and are an important component of the cellular machinery necessary to transduce extracellular signals (see review[39]). These membrane-bound intracellular signaling molecules mediate a wide variety of cellular functions, including proliferation, differentiation, and survival. The Ras family of GTPases contains 39 proteins encoded by 36 genes in the human genome; it includes H-, N-, and K-Ras, R-Ras, Rap1 (A and B), TC21, and Rheb1/2.[39] Ras proteins are synthesized in the cytosol and become associated with the inner leaflet of the plasma membrane via posttranslational modifications, including a form of fatty acid lipidation, isoprenylation, on Cys-186. The carboxy-terminal CAAX box (Cys, two aliphatic amino acids, followed by any residue) is an essential motif required for Ras function, as it targets the unprocessed protein for this essential modification.

Ras proteins act as molecular switches alternating from an inactive guanosine diphosphate (GDP)-bound state to an active GTP-bound state. The paradigm for Ras activation involves the recruitment of a guanine nucleotide exchange factor (GNEF) to the membrane in response to growth factor binding and subsequent activation of a receptor tyrosine kinase.[39] GNEFs promote the release of GDP from the Ras catalytic pocket, and the relative abundance of intracellular GTP as compared to GDP ensures preferential binding of GTP (Figure 2-2). The best example of a Ras GNEF is SOS (son of sevenless), which is brought to the membrane by its stable association with the adaptor protein Grb2 (see Figure 2-1[40]). Grb2 contains an src-homology 2 domain (SH2), which binds to a specific motif containing phosphorylated tyrosine residues on several RTKs, including the PDGFR and the EGFR. Grb2 also has two SH3 domains that mediate its binding to SOS via a carboxy-terminal proline-rich region. Alternatively, another adaptor protein, Shc, can bind to the cytoplasmic tail of the receptor through its SH2 domain, resulting in its phosphorylation on tyrosine and subsequently binding Grb2.[41] The exact sequence of binding of adaptors depends on the receptor and cell type. Once SOS is translocated to the membrane, it can promote the release of GDP from Ras, allowing GTP, which is present in excess in the intracellular environment, to

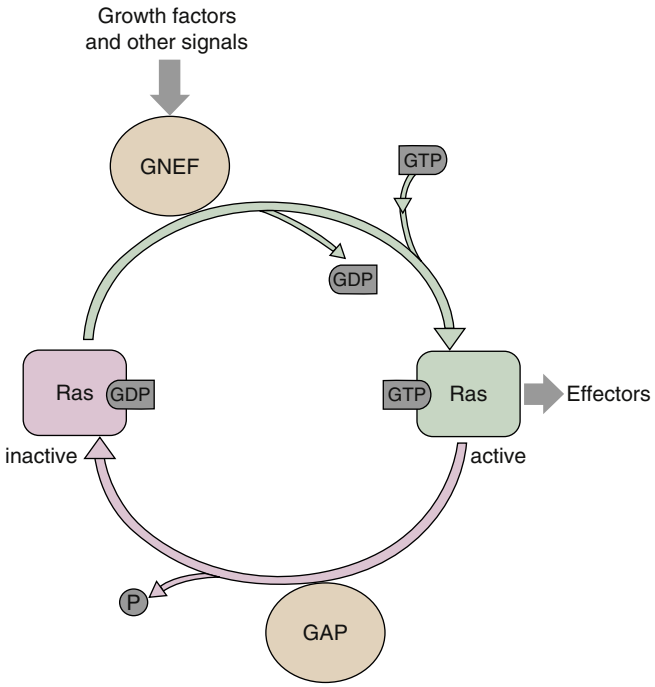

Figure 2-2 Activation of Ras GTPase

bind and ultimately lead to Ras activation. Although Ras is a GTPase, its intrinsic GTPase activity is actually quite inefficient and requires additional proteins known as GTPase activating proteins (GAPs) to promote GTP hydrolysis (see Figure 2-2). GAPs can accelerate GTP hydrolysis by several orders of magnitude and are, thus, negative regulators of Ras functions.[39,42] The mechanism by which GAP accelerates the GTPase reaction is complex and not completely understood. Currently, several GAPs for Ras have been identified, including p120 GAP and NF1-GAP/neurofibromin, as well as GAPs with preferential activity on related proteins such as Rap.[42] Of particular interest is NF1, as it is found to be frequently inactivated by mutation in patients with the familial tumor syndrome neurofibromatosis type 1.

Ras Functions

Ras appears to have a multitude of functions that differ depending on factors such as cell type and extracellular environment. It is paradoxical that a single gene can cause cell cycle entry and DNA synthesis in one type of cell, such as fibroblasts, and terminal differentiation in others, such as PC12.[43,44] In other cell types such as myoblasts, activated Ras seems to oppose cell cycle withdrawal and differentiation into myotubes and downregulates expression of muscle-specific mRNA transcripts.[45] In addition, Ras has been demonstrated to promote cell survival in some cell types such as those of hematopoietic lineages on cytokine withdrawal, and PC12 cells and primary sympathetic neurons on removal of NGF or other trophic factors.[46,47] Although Ras mediates such important cellular processes as proliferation, survival, and differentiation, the exact contribution of H-, N-, and K- isoforms is not clear: targeted knockouts to H- and N-Ras genes resulted in mice that did not exhibit an abnormal phenotype, whereas a K-Ras knockout is an embryonic lethal and exhibits liver and hematopoietic defects.[48,49] Of note, H-Ras knockin into the K-Ras locus does not perturb mouse embryonic development, implying that the phenotype of K-Ras$^{-/-}$ mice is probably due to the different expression pattern of the other Ras isoforms in the embryo, rather than their incapacity to compensate for K-Ras function.[39]

Ras and Cancer

The initial evidence for Ras involvement in cancer came from the discovery of transforming retroviruses, Harvey and Kirsten sarcoma viruses, which contained H- and K-ras cellular derived oncogenes. The first human oncogenes were identified by transfecting genomic DNA from human tumor cell lines into NIH3T3 mouse fibroblasts and isolating the DNA fragments from the transformed foci. These were shown to be the human homologues of the viral ras genes.[43] Subsequent studies have shown that Ras is oncogenically activated by mutations in about 30% of all human tumors, and in some cancers, such as pancreatic carcinoma, the frequency is as high as 60%.[50]

Mutations in human tumors have been found at residues 12, 13, and 61, with positions 12 and 61 being the most common.[50] These mutations decrease the intrinsic rate of GTP hydrolysis by Ras, as well as make the molecule significantly less sensitive to GAP-stimulated GTP hydrolysis. Thus, the outcome is a molecule that is predominantly GTP bound, constitutively active, and able to activate downstream pathways in the absence of growth-factor stimulation. Oncogenic Ras is capable of transforming immortalized rodent fibroblasts or epithelial cells.[43] Ras transformed cells appear refractile and spindle shaped, have disorganized actin filaments, and have a decreased affinity for the substratum. They can proliferate in the absence of adhesion (anchorage independence) or in the presence of low serum concentration. Such cells exhibit a loss of contact inhibition and grow to high saturation density. Of note, however, Ras alone is unable to transform primary mouse or human fibroblasts and instead causes such cells to undergo permanent growth arrest, also termed *replicative senescence*, characteristic of primary cells passed for multiple generations in culture. This senescence response appears to be dependent on the acute upregulation of p16(INK4A) induced by high levels of Ras expression, and it can be overcome by the loss of function of p16(INK4A) and p53 tumor suppressors (see Chapter 3), which may help to explain the selective pressure for inactivation of these genes in tumors containing Ras oncogenic mutations.[39,51]

Not only is Ras itself mutated or overexpressed in cancer, but there are examples of Ras regulatory proteins, which can be affected as well. The best example is NF1, a Ras GAP mentioned earlier. Hereditary transmission of a defective NF1 allele predisposes an individual to a genetic disease called *neurofibromatosis type 1* or *von Recklinghausen's neurofibromatosis*.[52] Somatic mutations result in the inactivation of the second allele, leading to neoplastic development. Neurofibromatosis can manifest itself with the occurrence of multiple benign neurofibromas, as well as a high risk for malignancies of neural crest origin. In cells with defective NF1, cellular Ras accumulates in its GTP-bound state and thus is more active.[52] Other examples of Ras modulators involved in human hereditary diseases are the SH-2–containing tyrosine phosphatase SHP2 and the GNEF SOS1, whose mutations have been detected in patients affected by Noonan syndrome.[39,50]

Signaling Downstream of RAS

Ras>Raf>Map Kinase Cascade

The most wellstudied effector of Ras is the serine/threonine kinase Raf (see Figure 2-1). Raf has been shown to bind to Ras and in many cases has been demonstrated to be indispensable for Ras functions such as cellular transformation.[53] In fact, activated Raf or v-Raf, a truncated form of c-Raf, was initially isolated as a retroviral oncogene. There are three known mammalian Raf isoforms designated A-, B-,and C-Raf (also known as Raf-1) (for review, see Ref. 54). C-Raf is ubiquitous in its tissue expression, whereas A-Raf and B-Raf expression is more restricted. Ras-mediated activation of Raf requires binding to two regions of this cytoplasmic kinase, both of which are located at the amino terminus. In the active state, Raf proteins form homo- or heterodimers, a process that is enhanced by Ras and inhibited by the extracellular signal regulated kinase (ERK) in a negative feedback loop.[55] Several phosphorylation events on both serine/threonine and tyrosine residues play a role in the full activation of Raf,[54,55] and there are major differences in certain phosphorylation sites between A/C-Raf and B-Raf. Also, B-Raf displays the highest basal kinase activity, which may explain why B-Raf, but not A/C-Raf, is frequently mutated in certain types of cancer.[55]

Once activated, Raf can phosphorylate MEK (mitogen/extracellular-signal regulated kinase kinase), a dual-specificity kinase, on Ser_{218} and Ser_{222}, leading to its activation (see review[56] and Figure 2-1). Partial activation can be seen by phosphorylation on only one serine. There are two isoforms of MEK, designated MEK1 and 2, both of which are expressed ubiquitously with an approximate sequence identity of 80%. MEK, once activated, can in turn activate mitogen-activated protein (MAP) kinase (also designated ERK).[56] Activation occurs via tandem phosphorylations on both threonine and tyrosine (Thr_{183}-Glu-Tyr_{185}) with the phosphorylation on tyrosine occurring first. There are two ERK isoforms (1 and 2), ubiquitously expressed and with very similar sequences. These proteins, 44 and 42 kDa, respectively, translocate to the nucleus, where they can activate a variety of proteins through phosphorylation on serine or threonine. For example, ERK can phosphorylate several of the members of the Ets family of transcription factors, and phosphorylation of Ets-1 by ERK dramatically increases c-fos transcription. ERK can also activate a variety of protein kinases via phosphorylation. For example, p90 RSK is a serine/threonine kinase, which has a role in protein translation and has been shown to be a substrate for ERK.[57]

In addition to positive regulation of the MAP kinase pathway by phosphorylation, there are negative regulatory mechanisms that serve to attenuate activation of this cascade. A principal mode of this negative regulation is through a variety of phosphatases, a majority of which are dual specific, meaning they can dephosphorylate both serine/threonine and tyrosine residues. This is consistent with knowledge that ERK must be phosphorylated on both threonine and tyrosine to achieve maximal activation.[58]

Functions of the MAP Kinase Pathway

As mentioned previously, the MAP kinase cascade mediates many Ras downstream functions (see Figure 2-1). ERK activation can lead to increased DNA synthesis and cell proliferation. In fact, activated forms of Ras, Raf, and MEK induce expression of *cyclin D1*, which plays a major role in early cell cycle progression.[59] Dominant negative mutants of members of this cascade can also block this induction in response to growth factor stimulation. In fact, *cyclin D1* is one of the most frequently amplified genes in cancer,[60] and this locus is almost invariably translocated in certain lymphomas, associated with cyclin D1 overexpression.[59]

Raf/Mek/MapK and Cancer

Davies and colleagues[61] identified B-Raf mutations in around 60% of human melanoma cell lines and primary tumors. Of note, these mutations, which in most cases involve the substitution of glutamate for valine 600 (V600E), were not consistent with mutations typically induced by UV. Lower frequencies of analogous mutations were observed in colon carcinoma and small-cell lung cancer (SCLC).[61] These mutations were further shown to oncogenically activate B-Raf, and recently mutant B-Raf has been successfully targeted in melanoma, as discussed later. In contrast to Ras and B-Raf, mutations of other Raf genes, MEK, or ERK are rare in cancer, although rearrangements causing aberrant activation of C-Raf have been recently reported in human prostate cancer.[62]

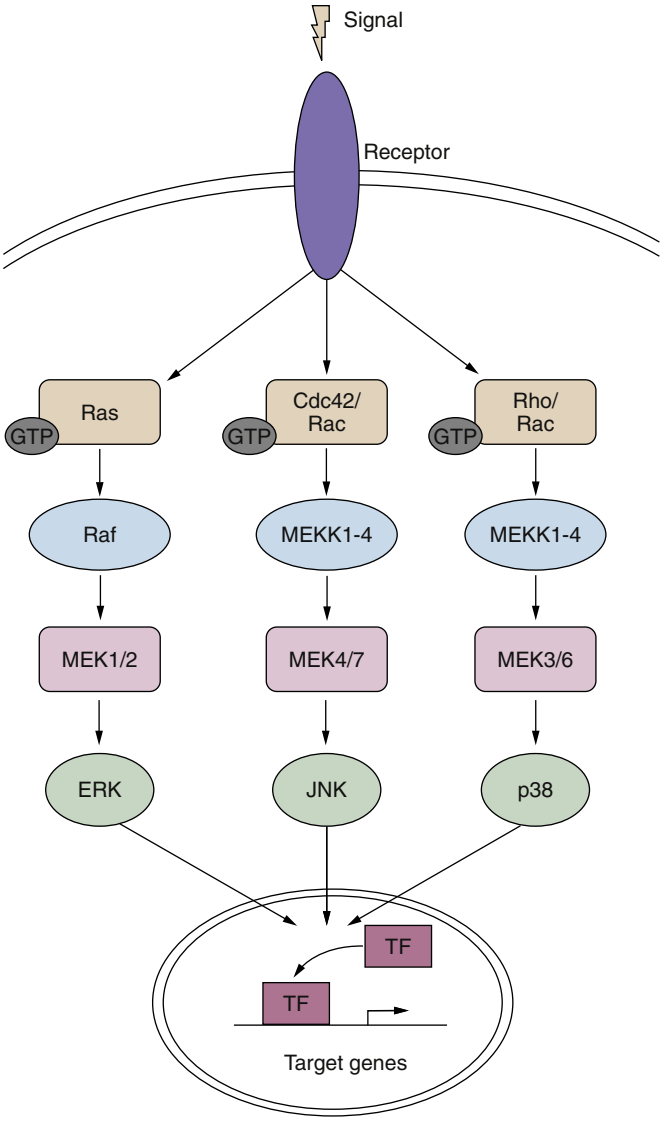

Figure 2-3 MAP kinase pathways in cancer Activation of the three MAP kinase cascades: ERK, JNK, and P38.

Other MAP Kinases

In addition to the ERKs, there are other MAP kinases belonging to distinct MAPK cascades with both different upstream activators and downstream effectors (Figure 2-3). The c-Jun N-terminal kinase (JNK)/stress-activated protein kinase (SAPK) and p38 MAP kinase have been demonstrated to modulate cellular responses to a wide variety of extracellular stimuli including mitogens, inflammatory cytokines, and UV irradiation (see review[63]). There are three JNK genes, each with several alternatively spliced transcripts. In most cell types examined, including fibroblasts, epithelial cells, and neuronal-like PC12 cells, sustained activation of JNK/SAPK has been reported to induce programmed cell death, whereas transient activation can promote cell survival.[63] There is evidence for some redundancy among these three genes, as each of the single knockouts as well as the JNK1/JNK3$^{-/-}$ and JNK2/JNK3$^{-/-}$ double knockouts is viable, but mice lacking both JNK1 and JNK2 are embryonic lethal. However, it has been demonstrated that the three JNK isoforms can also exhibit distinct properties, for example, in their capacity to interact with the oncogene Jun.[63]

In contrast to its ability to activate the MAPK/ERK cascade, H-ras only minimally perturbs JNK/SAPK. However, overexpression of the constitutively activated mutants of the small G-proteins, Rac and Cdc42, leads to the robust stimulation of JNK/SAPK activity. The pathways leading to JNK activation mirror those seen for ERK. Thus, a variety of MAP kinase kinases (MKK) can phosphorylate the various JNK isoforms.[56,63]

As with the ERKs, JNK activation results in phosphorylation of certain transcription factors and increases their transcriptional activity at promoters containing response elements for these factors.[63] Some of the transcription factors activated by ERK or JNK were initially discovered as retroviral oncogenes in mice and chickens, respectively. The FBJ and FBR murine viruses contain the *Fos* sequence under the viral LTR promoter and exhibit changes in regulatory phosphorylation sites that make them more active than the proto-oncogene,[64] and Jun was identified as an avian retrovirus.[65] Overexpression of Fos can cause transformation of cells as well.[66] Jun and Fos belong to the AP-1 family of transcription factors. In response to various stimuli, including UV irradiation, environmental stresses, and PKC activation, Jun homodimers and Jun-Fos heterodimers bind to AP-1 target sequences such as 12-*O*-tetradecanoylphorbol-13-acetate (TPA) responsive elements.[67]

C-Myc

The Myc family includes four transcription factors, c-Myc, N-Myc, L-Myc, and S-Myc, involved in the control of cell growth, differentiation, and apoptosis.[68,69] Myc proteins form heterodimers with another transcription factor, Max, through a basic-region/helix-loop-helix/leucine-zipper domain and bind a specific DNA consensus sequence called E-box to activate the transcription of target genes. In the absence of Myc, Max forms a complex with Mad/Mnt proteins and acts as a repressor of Myc transcriptional targets. A large number of genes are regulated by Myc, including *p21(CIP1)*, *cyclin D1/D2*, *E2F2*, and the microRNA *miR-17-92* cluster. Because the E-box sequence is very frequent in the human genome, more sophisticated approaches, such as genome-wide chromatin immunoprecipitation, have been used to identify authentic and physiologically relevant Myc target genes.[69] Enhanced expression of Myc proteins is estimated to occur in up to 70% of human malignancies. However, the deregulated expression of these proteins is

not sufficient to induce cell transformation, implying that additional genetic events are required. One such event is the activation of the Ras pathway, which affects Myc factors at different levels, including posttranslational stabilization and inhibition of the antagonizing transcription factors FOXO. Also, because high levels of Myc can trigger apoptosis, tumor cells may need for their survival concomitant oncogenic events, such as Ras activation or loss of ARF or p53 tumor suppressors.[68,69] In lymphoid cancers, c-Myc is often found in translocations adjacent to a strong promoter, such as that of the immunoglobulin genes. In other cancers such as breast and lung carcinoma, the genomic locus encoding c-Myc is amplified. c-Myc overexpression can also result from the aberrant activation of upstream pathways, such as in the case of Wnt signaling discussed later.[68,69] Gene amplification is also the mechanism responsible for the increased expression of N-Myc commonly observed in certain cancers, including retinoblastoma, glioblastoma, and medulloblastoma. Of note, N-Myc overexpression in neuroblastoma strongly correlates with an advanced clinical stage, and it is taken into consideration for the assessment of the treatment of these malignancies.[70]

Oncogenes and Survival Signaling

The regulation of cell survival and cell death is of extreme importance both in the development of an organism and in the physiologic functions of the adult. During development of a multicellular organism, certain cells are eliminated by a process known as apoptosis or programmed cell death and others are permitted to survive. The deregulation of these processes can lead to a variety of malformations resulting in deformities or, in extreme cases, incompatibility with life. In adulthood, regulation of cell survival is equally important for proper homeostasis. Damaged cells must be removed, and terminally differentiated cells must be sustained. If this fails to occur, mutations leading to cancer may accumulate. Pro-apoptotic and anti-apoptotic proteins regulate these processes, and many of the oncogenes already discussed modulate cell survival in a positive fashion. Thus, oncogenes can influence proliferation, cell survival, or both, contributing to cellular transformation in a cooperative fashion.

The Bcl-2 Family

The Bcl-2 family of proteins consists of more than 15 members, which can be subdivided into three classes based on functions and the number of Bcl-2 homology (BH) domains present.[71,72] The anti-apoptotic members, including

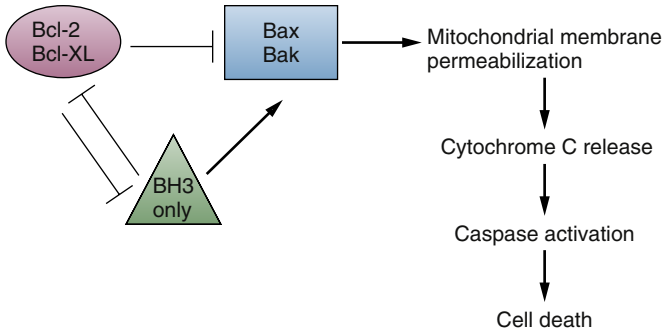

Figure 2-4 Bcl-2 family member interactions regulate cell death

Bcl-2, Mcl-1, and Bcl-XL, contain four BH domains (BH1 to BH4). The pro-apoptotic BCL-2 factors are divided into the effector proteins, such as BAX and BAK, which also contain four BH domains, and the "BH3 only" pro-apoptotic proteins, such as BID and BIM, which include only the BH3 domain. Proteins in all three classes have the ability to form either homo- or heterodimers with one another and play distinct roles in regulating mitochondrial membrane permeabilization[71,72] (Figure 2-4).

The involvement of Bcl-2 and cancer has been firmly established. Not only was the gene cloned as a translocation from a lymphoid tumor, but mice expressing a *Bcl-2*-immunoglobin "mini-gene" that mimicked the translocation seen in human cancers showed follicular hyperplasia that progressed to lymphoma. The *Bcl-2* genomic locus has been found to be translocated in several tumor types, including follicular lymphomas and chronic lymphocytic leukemia, and other oncogenes, such as Ras, can stimulate Bcl-2 expression.[72] The *Mcl-1* and *Bcl-X* genes are frequently amplified in tumors,[60] and overexpression of anti-apoptotic family members as well as downregulation or inactivation of pro-apoptotic proteins has been observed in several human cancers.[72]

PI3K-Dependent Pathways

PI3K is a lipid kinase that catalyzes the transfer of the γ-phosphate from ATP to the D3 position of phosphoinositide (PtdIns), generating PtdIns3P, PtdIns(3,4)P2, and PtdIns(3,4,5)P373 (see Figure 2-1). These lipids can act in a variety of cascades. PI3K activation has been demonstrated to play an important role in cell survival signaling in a number of cell types. There are three classes of PI3Ks, which exhibit variability with respect to their method of activation or their preferred lipid substrate.

The class I of PI3K, and in particular the subclass I_A, is the most relevant for cancer and the best characterized. It consists of two subunits encoded by two distinct loci, a regulatory and a catalytic subunit.[37] The regulatory subunit is a 50- to 85-kDa protein that is tightly associated with the

p110 catalytic subunit. The classical mode of PI3K activation involves its binding to the phosphorylated tyrosine residues of receptor tyrosine kinases via the two SH2 domains of p85. This results in the recruitment of the p85-p110 heterodimer to its substrate at the cell membrane and in a conformational change that relieves the basal inhibition of p110 catalytic activity.[37] In addition, it has been demonstrated that PI3K can be activated independently of receptor binding by the small G-protein Ras[37,74] (see Figure 2-1). Furthermore, the γ isoform of PI3K is activated by heterotrimeric G-proteins.[37] Thus it is clear that PI3K can be activated in response to a wide variety of upstream signals.

There are several known downstream effectors of PI3K. These include Rac, p70(s6k), certain isoforms of PKC, and, most relevant to the discussion of cell survival, Akt/PKB.[37,73] Akt has been shown to be responsible for PI3K-dependent cell survival signaling and is the cellular homologue of the viral oncogene v-Akt. The three human homologues identified encode 57-kDa serine/threonine kinases that contain an amino-terminal pleckstrin homology domain, which binds to the activated PtdIns products of PI3K. These lipids are believed to mediate the localization of this cytoplasmic protein to the plasma membrane. In addition, phosphorylation of Akt on two residues, a serine and a threonine, is required for full activation. These events are catalyzed by two different kinases, one of which, PDK1 (PtdIns(3,4,5)P3 dependent kinase) specifically phosphorylates Thr^{308}; the other, the mTOR (mammalian target of rapamycin) complex 2, phosphorylates Ser^{473}.[37,74] Once activated, Akt directly phosphorylates different proteins, such as BAD, forkhead box O transcription factors, glycogen synthase kinase 3 (GSK3), and tuberous sclerosis 2 (mTOR signaling), thus regulating various processes, including cell survival, proliferation, and protein synthesis[74] (see Figure 2-1).

The striking anti-apoptotic effect of both PI3K and its downstream effector Akt, as well as the fact that these two genes were initially found as transforming viral oncogenes, suggested that these two genes might also be involved in human cancer. Indeed, a myristoylated constitutively active PI3K can cause cellular transformation in chicken embryo fibroblasts.[75] The gene encoding the p110α catalytic subunit is frequently mutated in certain common epithelial cancers, such as breast, colon, and prostate. One class of mutation, which promotes constitutive signaling, involves the kinase domain near the activation loop. The second class of *p110α* mutations is predicted to abrogate the inhibitory intermolecular interaction between p85 and p110. Consistent with this model, mutations affecting the p85 subunit have recently been identified in glioblastomas and in colon and ovarian cancers.[74] Activating mutations of the three Akt isoforms have been also described, although they appear to be far less common than those involving the *p110α* locus. In addition, certain cancers can harbor amplifications of p110α or Akt subunits.[74]

Further evidence of the involvement of the PI3K/Akt pathway in cancer stems from the discovery of PTEN, one of the most frequently inactivated tumor suppressor genes in different types of tumors, including glial and endometrial tumors, as well as melanoma, prostate, renal, and small-cell lung carcinomas (for a review, see Ref. 76). Germline mutations at the *PTEN* locus cause inherited cancer syndromes such as Cowden disease, Lhermitte-Duclos disease, and Bannayan-Zonana syndrome. PTEN dephosphorylates the 3 position of phosphatidylinositol, thus directly opposing PI3K activity[76] (see Figure 2-1).

Cytokine Receptor Signaling

A large number of cytokines, hormones, and growth factors have been shown to activate a class of receptors that lack significant sequence similarity to the RTKs and are grouped under the definition of cytokine receptors.[77] They share a common structural motif in their extracellular domains, including conserved cysteine residues, and lack intrinsic enzymatic activity. The cytokine receptors either homodimerize on ligand binding (receptors for growth hormone, prolactin, erythropoietin, and thrombopoietin) or are composed of two distinct subunits that heterodimerize in response to ligand interaction. This latter group of receptors is composed of a ligand-specific chain and a common chain shared by different cytokines. This includes the receptors for interleukin-6 (IL-6), IL-11, oncostatin M, LIF, cardiotrophin-1, and ciliary neurotrophic factors, all sharing a common chain called gp130; the receptors for IL-3, IL-5, and GM-CSF that share the β common chain; and the receptors for IL-2, IL-4, IL-7, IL-9, and IL-15 that share the γ common chain.[78]

The Janus kinases (JAKs) originally identified as signaling molecules in the interferon pathway are essential transducers of the signal originating from cytokine receptors.[79] Four mammalian JAKS have been identified, JAK-1, JAK-2, JAK-3, and Tyk-2. These kinases are associated with the receptors and contain both a catalytic domain and a pseudokinase domain that is involved in the inhibition of JAK activity in the absence of the ligands. On ligand binding, the activated JAKs cause phosphorylation of the receptor and of molecules containing either a phosphotyrosine-binding or an SH2 domain. These molecules comprise the signal transducers and activators of transcription (STATs).

Seven mammalian STATs have been identified (STAT-1, STAT-2, STAT-3, STAT-4, STAT5a, STAT5b, and STAT-6), and differential splicing increases the number of these molecules. In addition to the SH2 domain, their structure is characterized by a DNA-binding domain and several protein-protein interaction domains. After becoming

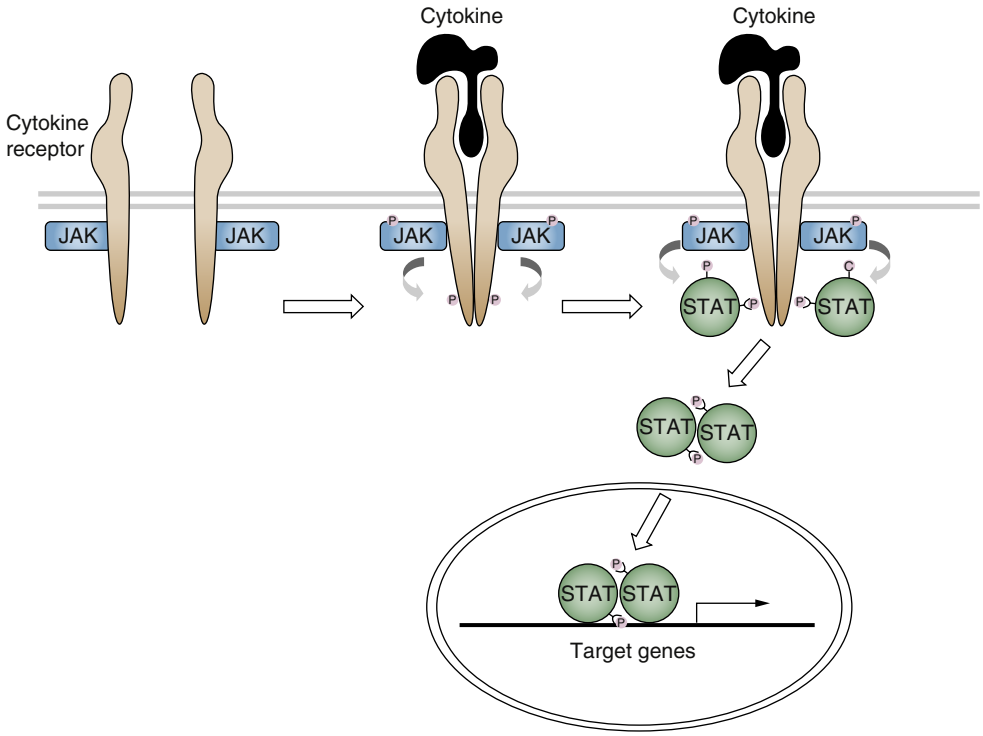

Figure 2-5 Cytokine receptor signaling The binding of cytokines to their receptors activates the JAK/STAT pathway through a series of phosphorylations.

phosphorylated on tyrosine, STATs form homo- or heterodimers through their SH2 domain and translocate to the nucleus, where they activate target genes (Figure 2-5[80,81]). In addition to the cytokine receptors, the JAK/STAT pathway has been shown to transduce signals from a number of tyrosine kinase receptors, including those for EGF, PDGF, and CSF-1.[80]

Several components of the cytokine receptor signaling pathways have been implicated in uncontrolled cell proliferation and cancer. The myeloproliferative virus (MPLV), an acute transforming retrovirus, contains an oncogene called v-mpl, which is a truncated version of a member of the hematopoietin receptor family c-mpl whose ligand has been identified as the thrombopoietin. Ectopic expression of c-mpl induces a lethal myeloproliferative disease in mice,[82] and activating mutations have been identified in myelofibrosis with myeloid metaplasia in humans.[83] The first evidence of involvement of the JAKs/STATs in naturally occurring cancer was the finding of an activating mutation in the *Drosophila* Hop kinase, a member of the JAK family, that caused a leukemia-like phenotype.[84] Stronger evidence implicating the JAKs in a human cancer came from the identification of a chromosomal translocation in a human leukemia resulting in the constitutively activated fusion protein TEL-JAK2.[85] In 2005, various groups identified a mutation in the *JAK2* gene in a large proportion of patients with different types of myeloproliferative neoplasms, including polycythemia vera (PV) and essential thrombocythemia. This mutation involves the substitution of a phenylalanine for valine 617 (V617F) and is believed to disrupt the autoinhibitory activity of the pseudokinase domain, resulting in cytokine hypersensitivity and cytokine-independent growth.[81] It has been shown that in hematopoietic cells containing JAK2(V617F), signaling pathways involved in cell proliferation and survival are activated, including STAT, MAPK, and PI3K-AKT.[81] More recently, activating mutations in JAK2 exon 12, which encodes a region near the pseudokinase domain, were identified in JAK2(V617F) negative PV patients.[81] Although activating mutations of STAT3 have been identified only in a particular type of liver tumor,[86] this transcription factor is very frequently activated through various mechanisms in cancer cells. It is thought not only to participate in tumor cell proliferation, survival, and invasion, but also to suppress antitumor immunity and to maintain a procarcinogenic inflammatory microenvironment.[87]

Neurotransmitters

The transmission of signals generated by the reception of chemical and physical stimuli from the external and internal environments is mediated by a large variety of small molecules known as *neurotransmitters*. These molecules include acetylcholine; amino acid derivatives such as epinephrine, norepinephrine, serotonin, and dopamine; and peptides such as the angiotensins, β-endorphin, enkephalins, and

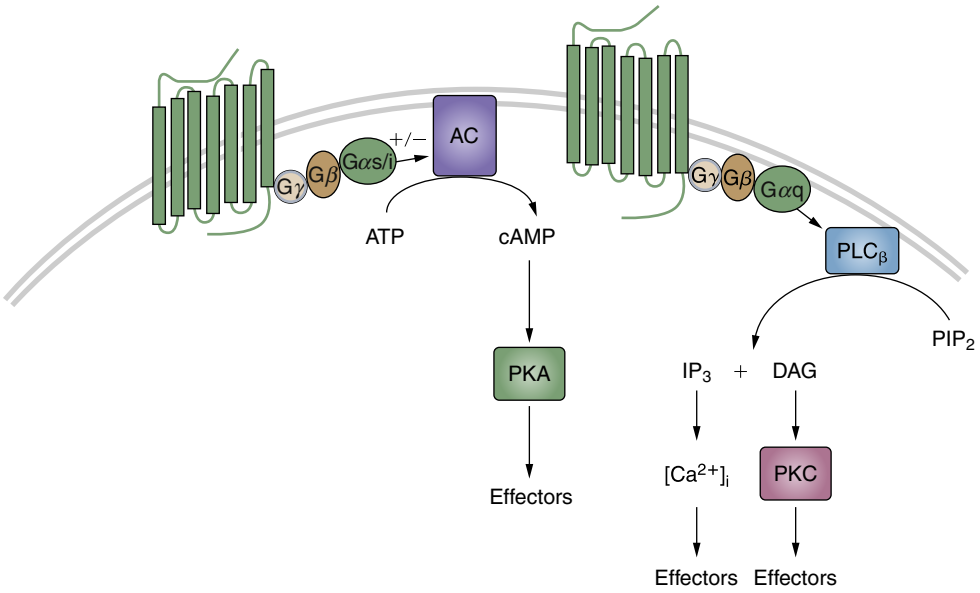

Figure 2-6 G-protein coupled receptors (GPCRs) Diagram showing cyclic adenosine monophosphate (cAMP) and phospholipase C-β (PLC_β) transduction pathways activated by GPCRs.

somatostatin. These ligands can trigger two types of receptors: ion-channel–linked receptors or receptors with seven membrane-spanning domains, which interact with heterotrimeric G proteins composed of α, β, and γ subunits. After binding to their specific ligand, the G-protein coupled receptors (GPCRs) undergo a conformational change, which results in a switch from the inactive GDP-bound G_α to an active GTP-bound state and the dissociation of the $G_{\beta\gamma}$ subunits. Different subfamilies of G_α proteins exist that activate various signaling pathways. For example, $G_{\alpha s}$ and $G_{\alpha i}$, respectively, stimulate or inhibit adenylyl cyclase, provoking an increase (or a decrease) of cyclic AMP levels, which can then activate the protein kinase A (Figure 2-6). The members of another G_α subfamily, $G_{\alpha q}$, activate PLC-β, which catalyzes the cleavage of phosphatidylinositol biphosphate into DAG and IP_3. DAG then stimulates PKC, whereas IP_3 mobilizes the intracellular stocks of calcium (see Figure 2-6). The $G_{\beta\gamma}$ subunits are also implicated in the signaling cascade, by regulating the activity of different effectors, such as phospholipases, ion channels, and various kinases. Of note, GPCR activation can impinge on other transduction pathways, including Rho and Ras GTPases or MAP kinases, while the mechanisms involved are not completely elucidated (for review, see Ref. 88).

The ability of GPCRs to activate various transduction pathways that regulate cell differentiation and proliferation strongly suggests a potential role of these receptors in tumorigenesis. Indeed, activating mutations of the thyroid-stimulating hormone receptor commonly occur in thyroid adenomas and carcinomas, and germline mutations cause familial non-autoimmune hyperthyroidism.[88] Another example is illustrated by studies on two distinct groups within a subset of growth hormone–secreting human pituitary tumors.[89] In one group, $G_{\alpha s}$ was found to be constitutively active, resulting in elevated adenylate cyclase activity and growth hormone levels. This activation was due to point mutations either in a site at which cholera toxin inactivates $G_{\alpha s}$ [Arg 201 → Cys/His] or at a residue equivalent to a GTPase-inhibiting mutation that causes malignant activation of Ras p21 [Gln 227 → Arg]. Because both mutations have the effect of destroying GTPase activity, $G_{\alpha s}$ [designated *gsp*] becomes constitutively activated in a manner analogous to the oncogenic activity of Ras p21. The two mutations are located in regions that are highly conserved among G_α proteins isolated from diverse eukaryotic species, and activating mutations have been identified in some human adrenal, pituitary, and other endocrine tumors.[90] Although mutations in GPCRs and G proteins have been identified in some tumors, the most common mechanisms of GPCR activation in cancer cells are receptor overexpression and autocrine stimulation,[88] as has been shown, for example, for the gastrin-releasing peptide,[91] angiotensin II,[92] and cholecystokinin[93] in pancreas and prostate cancers. Moreover, the receptors for certain neuropeptides and/or neurotransmitters, including acetylcholine, bradykinin, bombesin, and endothelin, can promote the proliferation and invasion of different types of tumor cells through cross talk with the EGFR or the insulin-like growth factor 1 receptor.[94] Of note, the specific expression of neurotransmitters and their cognate receptors in tumors arising from the endocrine system make this signaling a promising target for cancer diagnosis and therapy.[95,96] Finally, it is worth mentioning that other families of ligands triggering GPCRs play important roles in tumor initiation and progression. This is the case, for example, with the prostaglandins, which mediate chronic inflammation, increasing the risk of tumors, and the chemokines, crucially involved in cancer metastasis.[88,94]

Wnt Signaling

Wnts comprise a highly conserved multimember ligand family and play important roles in a variety of developmental processes, including patterning and cell fate determination.[97,98] In different adult tissues, Wnts also play important roles in stem/progenitor cell maintenance and differention.[98-100] Wnts bind to two co-receptors, the seven-transmembrane Frizzled and single-membrane–spanning low-density receptor-related protein 5/6 (LRP5/6), resulting in the phosphorylation of the LRP5/6 intracellular domain.[101] The phosphorylated LRP5/6 provokes the inhibition of a multiprotein complex, referred to as the *destruction complex*, which includes axin, GSK3, casein kinase 1 (CK1), and adenomatous polyposis coli (APC). In the absence of Wnt ligands, this complex induces the sequential phosphorylation of β-catenin by CK1 and GSK3, which provokes its degradation through the ubiquitination pathway. Thus, Wnt-induced inhibition of the destruction complex blocks β-catenin degradation and causes its accumulation in the cytoplasm in an uncomplexed form. The latter is then translocated to the nucleus, where it binds to transcription factors belonging to the T-cell factor/lymphoid enhancer factor family and activates the expression of Wnt target genes, including the proto-oncogene *c-myc* and *cyclin D1* (Figure 2-7[100]).

The prototype *Wnt* gene was originally identified as a cellular gene activated by integration of the mouse mammary tumor virus.[102] Later studies indicated that targeted expression of certain Wnts in transgenic mice caused mammary gland hyperplasia, and several Wnt genes exhibit the ability to transform various epithelial[103] and fibroblast murine cell lines.[104] Recent evidence indicates that Wnt signaling is constitutively activated through an autocrine mechanism in different types of human cancers, including breast cancer,[105] non–small-cell lung cancer,[106] and sarcoma.[107] More commonly, specific downstream components of the Wnt pathway have been implicated in human cancers. Genetic alterations of β-catenin have been identified in human tumors and cancer cell lines, including colon cancer, melanomas, and hepatocellular carcinomas.[97,108] These mutations affect the sites of phosphorylation of β-catenin and result in the inhibition of its degradation, leading to the stabilization of the protein in the cytosolic and/or nuclear compartments.

The *APC* tumor suppressor gene product, which is required for β-catenin phosphorylation and degradation, also regulates the amount of cytosolic β-catenin. Germline mutations in the *APC* gene are responsible for familial adenomatous polyposis (FAP), a dominantly inherited syndrome characterized by the formation of hundreds of colorectal adenomas, some of which inevitably progress to colorectal cancer. Inactivation of the APC gene leading to increased cytosolic β-catenin is also found in

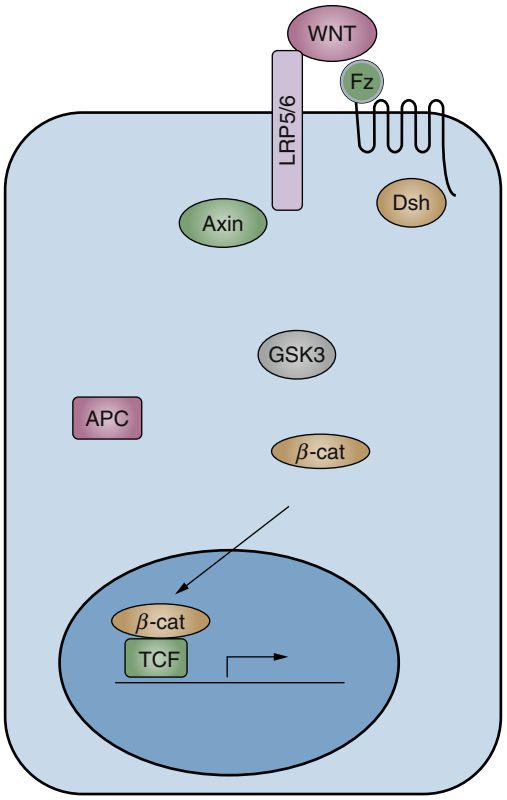

Figure 2-7 Diagram showing the major known components of Wnt signaling in cancer Simplified scheme of canonical Wnt signaling.

80% of sporadic colon cancers, and it represents an early event in tumor progression.[97,108] The major initiating event in the remaining 20% of colon cancer involves mutations in the *β-catenin* gene[97,108] or, as recently uncovered by next-generation sequencing, fusions of the *R-spondin* genes, a family of secreted proteins that enhance Wnt signaling.[109] Of note, these events occur only in those cancer cells with intact APC, implying that activation of this signaling pathway affects almost all colon cancers.

Hedgehog/Patched Signaling

The Hedgehog/Patched signaling pathway was first identified in *Drosophila*, where it plays an important role in a number of developmental processes, including cell fate determination and patterning.[110,111] Although the major core components of the pathway are conserved among species, many differences exist between the fly and vertebrate Hedgehog signaling. In vertebrates, in the absence of the Hedgehog ligands, Sonic, Indian, and Desert Hedgehog, their receptor Patched prevents, through an unknown mechanism, the translocation of the seven-transmembrane domain protein Smoothened to the primary cilium. Under such conditions, the full-length Gli

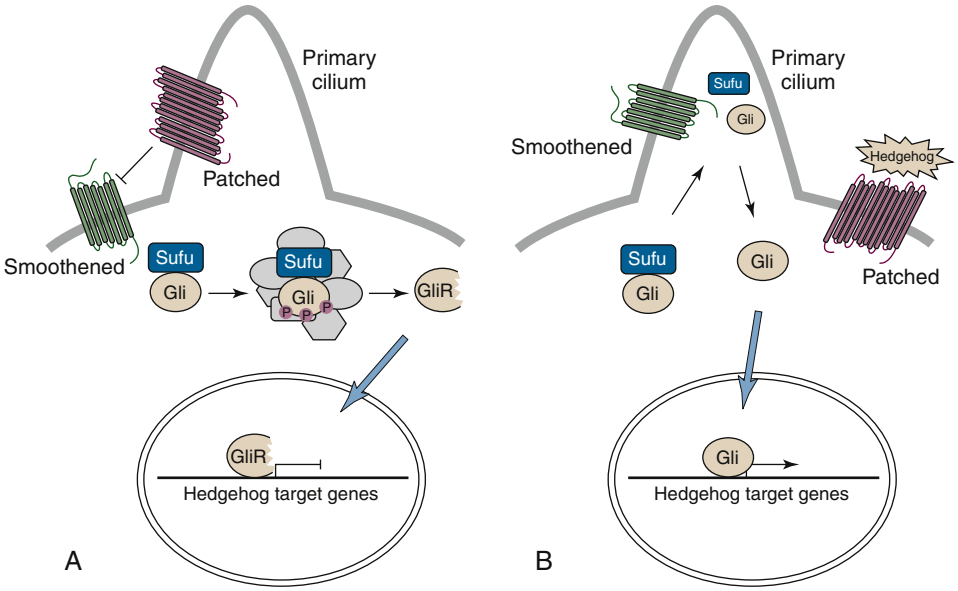

Figure 2-8 Activation of Hedgehog signaling The Hedgehog pathway in vertebrates, in the absence (**A**) or in the presence (**B**) of Hedgehog ligands.

transcription factors bind to suppressor of fused (Sufu) and, following multiple phosphorylation, are cleaved into repressor forms of Gli that inhibit the transcription of Hedgehog target genes. Hedgehog binding to Patched relieves the inhibition of Smoothened, which can then translocate to the primary cilium, where it promotes the disassembly of the Sufu-Gli complex. Gli proteins are shuttled into the nucleus, where they become transcriptionally active, probably after additional posttranslational modifications[112,113] (Figure 2-8).

Several lines of evidence suggest an important role of the Hedgehog pathway in cancer. Mutations in the human homologue of the *Patched* gene have been identified as responsible for the hereditary nevoid basal cell carcinoma (BCC) syndrome,[114] and mutations have also been found in sporadic BCC and medulloblastomas. Loss of Patched would result in the constitutive activation of Smoothened and upregulation of this signaling pathway. Other studies have identified activating missense mutations in *Smoothened* in BCC,[115] further supporting the involvement of this signaling pathway in human cancer. Studies using the Smoothened inhibitor cyclopamine suggested the existence of a Hedgehog autocrine activation loop involved in the growth of different types of cancer. However, it was subsequently demonstrated that Hedgehog ligands do not act cell-autonomously on the tumor cells, but they instead affect the stromal microenvironment through a paracrine mechanism.[116,117]

Implications for Cancer Therapy

The study of signal transduction is crucial to the understanding of the normal cellular processes that govern cellular functioning. Although our knowledge of these intricate events is increasing rapidly, the complexities appear to be growing even more rapidly. What were once believed to be rather simple and linear pathways have now become multidimensional. Signaling pathways converge, diverge, and cross talk so frequently that it is becoming difficult to discuss them as individual pathways. Issues such as cell type specificity, where signaling pathways differ both in how they are activated and in the ultimate outcome, add to the complexities as well. The oncogenes that have been discussed are normally key players in signaling pathways, as illustrated by evidence that constitutive activation of molecules, ranging from receptors to nuclear transcription factors, can cause cellular transformation and/or increased cell survival and are commonly found to be activated in human cancers.

Because many of the signaling pathways involved in cellular transformation by oncogenes have been elucidated, concerted efforts have been made to develop treatment strategies that target these specific signaling molecules or their downstream effectors. Such approaches rely on the idea that tumor cells, despite their complex pattern of mutational events, can become particularly dependent on one or a few signaling pathways for their growth and/or survival, a concept commonly referred to as *oncogenic addiction*.[118] Tremendous strides have been made in developing therapies that target some of the oncogene products discussed in this chapter, and several of these agents have been approved for the treatment of various types of cancer (Table 2-1). Although other approaches are being explored, these new therapeutics consist either of modified monoclonal antibodies, which recognize cell membrane or secreted proteins, such as ERBB2 and VEGF, or of small molecule inhibitors, which target the enzymatic

Table 2-1 Targeted Therapeutics Directed against Oncogene Products

Target	Cancer Drug	Disease
Monoclonal Antibody		
ERBB2	Trastuzumab (Herceptin)	Breast cancer, gastric cancer
ERBB2	Pertuzumab (Perjeta)	Breast cancer
EGFR	Cetuximab (Erbitux)	Colorectal cancer, head and neck cancer
EGFR	Panitumumab (Vectibix)	Colorectal cancer
VEGF	Bevacizumab (Avastin)	Colorectal cancer, NSCLC, RCC, glioblastoma
Fusion Protein		
VEGFA, VEGFB, PGF	Aflibercept (Zaltrap)	Colorectal cancer
Small Molecule		
Abl, PDGFR, c-Kit	Imatinib (Gleevec)	CML, GIST, ALL, dermofibrosarcoma protuberans
Abl, Src	Bosutinib (Bosulif)	CML
Abl, Src	Dasatinib (Sprycel)	CML, ALL
Abl, PDGFR, c-Kit	Nilotinib (Tasigna)	CML
ALK, MET	Crizotinib (Xalkori)	NSCLC
B-Raf (V600E)	Vemurafenib (Zelboraf)	Melanoma
EGFR	Gefitinib (Iressa)	NSCLC
EGFR	Erlotinib (Tarceva)	NSCLC, pancreatic carcinoma
EGFR, ERBB2	Lapatinib (Tykerb)	Breast cancer
mTOR	Everolimus (Afinitor)	RCC, astrocytoma, PNET, breast cancer
mTOR	Temsirolimus (Torisel)	RCC
Smoothened	Vismodegib (Erivedge)	BCC
VEGFR, EGFR, RET	Vandetanib (Caprelsa)	Thyroid cancer
VEGFR, PDGFR, c-Kit	Axitinib (Inlyta)	RCC
VEGFR, PDGFR, c-Kit	Pazopanib (Votrient)	RCC, soft tissue sarcoma
VEGFR, PDGFR, FLT3, c-Kit, Raf, RET	Sorafenib (Nexavar)	RCC, hepatocellular carcinoma
VEGFR, PDGFR, FLT3, c-Kit, RET	Sunitinib (Sutent)	GIST, RCC, PNET

Drugs included in this table have been approved by the Food and Drug Administration (FDA).
ALL, acute lymphoblastic leukemia; *BCC*, basal cell carcinoma; *CML*, chronic myeloid leukemia; *GIST*, gastrointestinal stromal tumor; *NSCLC*, non-small-cell lung carcinoma; *PGF*, placental growth factor; *PNET*, pancreatic neuroendocrine tumor; *RCC*, renal cell carcinoma.

activity of a particular oncogene, generally a kinase, such as Abl, EGFR, or PDGFR. A recent paradigmatic example of such new agents is vemurafenib, an inhibitor of V600E B-Raf approved by the U.S. Food and Drug Administration (FDA) in 2011 for the treatment of unresectable or metastatic melanomas. This small-molecule inhibitor was specifically designed by Plexxikon to selectively block the mutant, but not the wild-type, B-Raf,[119] and it showed a remarkable response rate in melanoma clinical trials.[120] However, as it is often the case with targeted therapy, after an initial response, the tumors relapse and become insensitive to the inhibitor. Several mechanisms have been proposed that allow the tumor cells to bypass the effects of B-Raf(V600E) inhibition, including mutations of Ras and activation of RTKs.[121] Of note, although B-Raf(V600E) occurs in around 10% of colon cancers, this tumor is much less responsive to vemurafenib than is melanoma. It was recently demonstrated that the unresponsiveness of colon cancer is caused by vemurafenib-induced feedback activation of EGFR, a receptor that is highly expressed in colon cancer, but not in melanoma cells.[122] The ability of tumor cells to overcome the inhibition of a particular pathway through activation of alternative mechanisms leading to drug resistance underlines the potential of a therapeutic strategy that simultaneously targets different components of one (e.g., the EGFR and ERBB2 dual inhibitor lapatinib)

or several (e.g., sorafenib, which inhibits VEGFR, PDGFR, FLT3, c-Kit, Raf, and Ret) signaling pathways.

Increased knowledge of oncogene signaling pathways has already led to novel therapeutics, which are in the clinic, and there is great promise that the number of rationally based therapies using such molecules as targets will continue to grow. The astonishing advances in the sequencing of cancer genomes, together with a better understanding of the molecular basis for drug selectivity and acquired resistance, should in the near future allow the design of new therapies based on combinations of targeted agents tailored to the specific genetic alterations of a given tumor.

Tumor Suppressor Genes

Introduction

Over the past 40 years, efforts to understand the underlying rules that govern the transformation of somatic cells into their malignant counterparts have led to the identification of discrete alterations in genes and gene products that, in combination, are responsible for the characteristic hallmarks of cancer.[1] Broadly speaking, cancer-associated genes can be classified into three groups: oncogenes, tumor suppressor genes, and genes responsible for maintaining genome stability. Oncogenes encode the constitutively active or overexpressed versions of otherwise normal cellular proteins involved in cell growth and proliferation (i.e., tyrosine kinase receptors, transduction kinases, and small GTPases). The "gain of function" capabilities of oncogenes are acquired as a result of genetic and epigenetic mechanisms, including chromosomal translocations, gene amplifications, missense activating mutations, and demethylation of gene promoters. Regardless of the activating mechanism, an oncogene always behaves as a dominant allele (a single allele suffices) in its ability to confer malignant properties on cells.[2]

In contrast to oncogenes, tumor suppressor genes encode proteins that are functionally integrated into pathways that prevent unscheduled cell proliferation, stimulate cell death, or trigger the induction of permanent cell cycle arrest.[2] As expected, tumor suppressor genes may act as negative regulators of oncogenes. In many cases, they are responsible for the orchestration of cell cycle checkpoints that ensure faithful cell division under normal or stress-induced conditions.[3] The involvement of tumor suppressor genes in the tumorigenic process is only apparent following complete or partial loss of gene function, which commonly requires the inactivation of both parental alleles in a single cell. This recessive behavior explains the fact that the mutant alleles of these genes can be passed through the germline and cause inherited forms of cancer predisposition in humans.[2,4] Inactivating mechanisms of tumor suppressor genes include deletions, nonsense, and missense mutations and methylation-mediated gene silencing.

The third class of cancer-associated genes comprises those primarily involved in cellular processes that maintain basal levels of genomic or chromosomal stability. The proficiency of a cell in accurately repairing various forms of genomic insult depends on its ability to sense acute genomic damage, usually in the form of single- or double-strand DNA breaks, and to mobilize specific repair enzymatic complexes to sites of DNA damage.[5] As expected, the inactivation of gene products involved in these processes leads to an increase in the rates of spontaneous mutations. This "mutator phenotype" can, in turn, contribute to the accumulation of mutations in oncogenes and tumor suppressor genes.[2] Similar to tumor suppressor genes, defects in genes involved in genomic surveillance underlie a variety of cancer-prone genetic disorders, most of them inherited in a recessive fashion. For example, nucleotide excision repair (a process responsible for the repair of single-strand breaks and crosslinks in DNA produced by UV radiation or chemical mutagens) is defective in *xeroderma pigmentosum*, a group of human disorders associated with the development of tumors on sun-exposed skin.[6]

A major contributor to genomic instability in human cancers is the inactivation of *TP53*, the gene encoding the p53 transcription factor.[7] As mentioned later in this chapter, p53 is normally induced in response to a variety of stresses, including DNA damage. Depending on the cell type and the magnitude of the damage, p53 activation can result in cell cycle arrest, senescence, or cell death (apoptosis), processes that effectively prevent the propagation of damaged DNA within a cell population or give an individual cell time to repair the damage. Hence, cells lacking p53 may continue to replicate damaged DNA, increasing the chances of accumulating potentially oncogenic mutations in other loci.[2,4,7] Notwithstanding its crucial role in sensing and responding to genotoxic insults, for historical reasons p53 is often described as a prototypical tumor suppressor gene.

Tumor Suppressor Genes: A Historical Perspective

From a historical point of view, the articulation of the modern concept of tumor suppressor gene (TSG) was possible through the convergence of three major lines of research: somatic cell hybridization experiments, the detection of loss of heterozygosity (LOH) in tumors, and the study of highly penetrant familial cancers.[8,9] It is worth mentioning, however, that the existence of TSGs had already been anticipated early in the 20th century by Theodor Boveri (1862-1915), one of the founders of the chromosomal theory of inheritance (the modern concept of the gene had not been developed at the time). Boveri suggested that the uncontrolled growth characteristic of tumors arises as a result of an incorrect chromosomal dosage, which could be explained by an abnormal segregation of chromosomes during cell division. Thus, "growth inhibitory chromosomes" are removed from cells during the process of tumorigenesis. As a corollary, Boveri suggested that these inhibitory chromosomes were part of a mechanism that kept normal cells in a proliferation-arrested state unless they were stimulated to divide.[10] It was not until the mid-20th century, however, that more sensitive cytogenetic techniques allowed the identification of LOH (loss of heterozygosity), indicative of chromosomal loss, in human tumors.

The next piece of evidence linking loss of function mutations and tumorigenesis came from somatic cell hybridization experiments performed in the early 1970s.[11-13] The crucial observation here was that cell hybrids generated through fusion of normal somatic cells with tumor-derived cells were usually nontumorigenic. The dominant effect of normal traits over the malignant phenotype seemed to indicate that loss of growth-regulatory genetic information had contributed to the transformation of the parental tumor cell line in the first place. Conversely, the neoplastic phenotype could be reversed following the reacquisition of the normal complement of genetic information.

Ultimately, however, it was the study of familial cases of cancer predisposition that led to the identification, and subsequent cloning and characterization, of the first TSGs. Highly penetrant cancer susceptibility syndromes constitute a small group of inherited disorders in which the affected individuals develop a unique type of tumor (or a narrow set of tumors) with an unusual high incidence and at a younger age compared with sporadic (noninherited) cases.[14] Although cancer-associated syndromes display a dominant mode of inheritance, the experimental evidence gathered from in vitro cell fusion experiments and LOH analyses seemed to indicate that TSGs acted in a recessive manner at the cellular level. A theoretical explanation for this paradox was first provided by Alfred Knudson and became later known as the "two-hit" hypothesis.[8,15]

In 1971, Knudson was studying the epidemiology of retinoblastoma, a relatively rare pediatric tumor that originates in the fetal retina. Retinoblastoma is associated with an inherited predisposition in approximately 40% of the cases. Most children with an affected parent develop multiple retinoblastomas in both eyes, which are diagnosed at a younger age compared with the sporadic forms of the disease. In contrast, children diagnosed with sporadic retinoblastoma (children with no family history of the disease, about 60% of the cases) show unilateral involvement and typically a single tumor in the affected eye. Based on these differences, Knudson postulated that the cell of origin of retinoblastoma (the retinoblast) must undergo two critical genetic events at a single locus in order to initiate a tumor. Because the first mutation or "hit" is already present in every somatic cell (including retinoblasts) of an individual with hereditary retinoblastoma, an inactivating mutation of the remaining allele (the second "hit") would be sufficient to drive tumor formation. The increased probability of tumor initiation in the context of a large population of already mutated retinoblasts helps explain the multiplicity of tumors per retina and the characteristic early onset of hereditary retinoblastoma. In cases of sporadic retinoblastoma, on the other hand, the hypothesis postulated that both hits must take place in a single somatic cell, itself a much less probable event, thus explaining the unilateral involvement and the lower number of tumors per retina.[15]

Evidence for the "two-hit" model was later provided by cytogenetic analyses of blood samples from patients with inherited retinoblastoma. These studies identified germline deletions of chromosomal band 13q14 in these patients, and similar changes were subsequently found in sporadic tumors, providing strong support for the notion that the same genetic locus was affected in both variants of the disease. Although several mechanisms were initially proposed to explain the second hit, their final documentation was only possible through DNA restriction fragment length polymorphism (RFLP) analysis. RFLP-based studies demonstrated that LOH achieved through deletion, mutation, or recombination can all occur as second events in retinoblastomas.[16,17] Finally, these studies provided the necessary molecular clues that led to the cloning of the retinoblastoma susceptibility gene (*RB-1*) in 1986.[18]

The protein encoded by *RB-1* (pRB) is now recognized as a key suppressor of cell cycle progression.[19] Evidence for pRB's function dates back to studies on cellular immortalization mediated by viral oncoproteins, including the simian virus 40 (SV40) large T antigen. These studies demonstrated that cellular immortalization was in part a result of the direct inactivation of pRB by the SV40 large T antigen. Because immortalized cells were especially sensitive to transformation by several oncogenes, the natural conclusion was that

inactivation of pRB might represent a common requirement for the initiation of most cancers. However, it soon became evident that inactivating mutations in *RB-1* are found in a rather narrow group of human malignancies, most typically in small-cell lung carcinomas and osteosarcomas. As mentioned later in this chapter, we know now that deregulation of numerous cancer-associated genes can lead to the inactivation of pRB in more indirect ways, a hallmark shared by virtually all cancers.[19,20]

At around the same time, the status of *TP53* (also known as *p53*) as a TSG was also established. Its gene product, the transcription factor p53, was originally identified as an interacting partner of the SV40 large T antigen. Although the mechanisms of tumorigenesis involving p53-large T antigen interaction initially suggested that *TP53* acted as an oncogene, further experimental evidence challenged this notion. For example, wild-type p53 was shown to act as a suppressor of transformation in cultured cells, and genetic rearrangements at the *TP53* locus, which resulted in loss of function instead of activation, were discovered in some leukemia cell lines.[21] In addition, it was suggested that the interaction between p53 and the SV40 large T antigen resulted in loss of p53 function, in a manner reminiscent of pRB inactivation. Nevertheless, it was not until *TP53* was mapped within a region consistently deleted in human tumors that the gene gained its final recognition as a bona fide TSG. Seminal among these studies was the discovery that *TP53* was biallelically deleted in human colorectal cancers, which was soon followed by the identification of mutations in other malignancies.[2] Loss-of-function mutations in *TP53* were then linked to Li-Fraumeni syndrome, a known dominantly inherited condition that predisposes individuals to several cancers, most typically breast cancer.[22] Over the following 40 years, an explosion of research has confirmed *TP53* as one of the most frequently mutated genes in human tumors. As mentioned later, p53 is involved in the orchestration of a variety of tumor-suppressive processes, including cell cycle arrest, apoptosis, and senescence. Deregulation of each one of these processes following p53 inactivation can thus increase the probability that a cell will become malignant.[4]

In summary, the *RB-1* and *p53* paradigms defined three important properties of "classic" TSGs: (1) TSGs are recessive at the cellular level, with biallelic inactivation typically found in tumors; (2) inheritance of a single mutant allele increases tumor susceptibility because only one additional inactivating event is required for complete loss of gene function; and (3) the same gene is frequently inactivated in sporadic cancers. Theoretically, reversion of the tumorigenic phenotype following the reintroduction of the relevant TSG into a cancer cell may also serve as a functional criterion to classify a gene as tumor suppressor. However, this requirement is not always met experimentally, presumably because loss of a TSG can allow further genetic changes that may confer resistance to its restoration at a later time.[4]

These principles served as guidance for the identification and cloning of other cancer susceptibility loci. Table 3-1 lists selected TSGs along with the function of their encoded proteins, the cancer syndrome they are associated with, and examples of sporadic cancers associated with their loss of function.

Complications of Tumor Suppression

Moderate and Low Penetrance Cancer Susceptibility Loci

Despite their importance in the discovery of TSGs, highly penetrant cancer syndromes account for a relatively small proportion of human malignancies (typically less than 0.1%). In fact, the excess in familial risk for some types of cancer has remained, to a large extent, unexplained. For example, breast cancer shows a pattern in which relative risk increases by two- to threefold in first-degree relatives of early-onset cancer cases. However, mutations in *BRCA1* and *BRCA2* account for only ~20% of this overall risk increase. It has been proposed that much of the inherited risk may result from a polygenic mode of cancer predisposition. In this scenario, multiple loci, each one having a modest individual effect, may ultimately dictate the relative risk of an individual to develop cancer.[9] In support for this idea, recent reports have identified susceptibility alleles associated with a wide range of risk in human populations. For example, the screening of genes associated with *BRCA1*- and *BRCA2*-dependent pathways demonstrated "moderate" breast cancer risk in individuals who are heterozygous for allelic variants of *CHEK2*. These rare alleles function dominantly, each conferring a moderate but detectable increase in the relative risk of developing breast cancer.[23,24] More recently, genome-wide association (GWA) studies based on differences in single-nucleotide polymorphism (SNP) across human populations have begun to identify "low-penetrance" cancer susceptibility loci for the most common types of cancer.[25,26]

Haploinsufficiency

The two-hit hypothesis has been challenged by recent studies indicating that many chromosomal deletions in cancer cells consistently affect a single allele. Although these monoallelic deletions were initially considered to be mere "passenger events" with no actual causal role, numerous genes that behave as TSGs in vitro have been identified in these regions. This observation implies that a single-copy mutation or loss of these loci might be sufficient to explain their

Table 3-1 Representative Tumor Suppressor Genes

Gene	Familial Cancer Syndrome	Protein Function	Sporadic Tumors with Mutations
RB1	Hereditary retinoblastoma	Transcriptional co-repression	Sporadic retinoblastoma, osteosarcoma, small-cell lung carcinoma (SCLC), breast carcinoma, bladder carcinoma
TP53 (p53)	Li-Fraumeni syndrome	Transcription factor	>50% of all cancers
APC	Familial adenomatous polyposis (FAP)	Wnt signaling, degrades beta-catenin	Colorectal cancer, gastric cancer
WT1	Wilms tumor (nephroblastoma)	Transcription factor	Pediatric kidney cancer
NF1	Neurofibromatosis type 1	GTPase activating protein for Ras	Sarcoma, gliomas
NF2	Neurofibromatosis type 2	Membrane-cytoskeleton binding protein	Schwannoma, meningioma, ependymoma
INK4a (p16)	Familial melanoma	CDK4/6 inhibitor (pRB activation)	Many
ARF	Melanoma	MDM2 antagonist (p53 stability)	Many
VHL	Von Hippel-Lindau syndrome (renal tumor)	E3 ligase recognition factor for HIF1 (hypoxia response)	Renal carcinoma (clear cell), cerebellar hemangio-sarcoma, pheochromocytoma
PTEN	Cowden disease	Lipid phosphatase (phosphoinositide metabolism)	Glioblastoma, endometrial carcinoma, prostate carcinoma, breast carcinoma, thyroid cancer
LKB1 (STK11)	Peutz-Jeghers syndrome	Energy (glucose) sensor kinase (phos-phorylates AMPK)	Non–small-cell lung carcinoma (NSCLC) cervical carcinoma
TSC1, TSC2	Tuberous sclerosis (hamartomas)	GTPase activating complex for Rheb (mTORC1 inhibition)	Renal cell carcinoma (rare), angiofibroma
BRCA1	Familial breast and ovarian cancer	DNA repair, cell cycle control (genomic stability)	Unknown
BRCA2	Familial breast and ovarian cancer	DNA repair (homologous recombination, genomic stability)	Unknown
PTCH	Nevoid basal cell carcinoma (Gorlin) syndrome	Hedgehog signaling (transmembrane receptor)	Basal cell (skin) carcinoma, medulloblastoma, rhabdomyosarcoma
SMAD4 (DPC4)	Familial juvenile polyposis (hamartomas)	TGF-beta signaling (transcription factor)	Pancreatic and colon carcinomas
MSH2, MLH1, PMS1, PMS2	Hereditary nonpolyposis colorectal cancer (HNPCC, Lynch syndrome)	DNA mismatch repair	Endometrial, ovarian, gastric, hepatobiliary, and urinary tract cancer
CDH1 (E-cadherin)	Familial gastric carcinoma (diffuse type)	Cell-cell adhesion	Gastric cancer, lobular breast cancer

tumorigenic effect, a genetic property known as *haploinsufficiency*. For some alleles, haploinsufficiency may even confer a relative advantage to cells, most typically in situations where complete loss of function leads to apoptosis or senescence. For example, whereas a monoallelic deletion of the tumor suppressor *PTEN* is sufficient to produce prostate cancer in mice, loss of both parental alleles triggers a p53-dependent senescence program.[8,27] Alternatively, a monoallelic mutation may confer *dominant-negative* capabilities on TSG products. In this modality, the mutant protein may negatively interfere with the function of the wild-type protein produced by the unaffected allele. Because dominant-negative mutations can result in considerable loss of function, there is no selective pressure in tumors to inactivate or delete the wild-type allele. A classic example of a dominant-negative effect is provided by mutant p53. As part of its function as a transcription factor, wild-type p53 binds DNA as a tetramer, a capacity impaired in mutated p53 because of missense mutations affecting the DNA binding domain. Although the wild-type and the mutant p53 proteins are still able to form hetero-oligomers in cells harboring monoallelic mutations, these complexes show impaired DNA association and transcriptional activity, resulting in loss of p53 function.[22]

A third interpretation of the role of haploinsufficiency in tumorigenesis is based on the exquisite sensitivity of cells to even small changes in the levels of some cancer-associated proteins. Thus, a 50% functional reduction in a TSG product may be sufficient to endow a cell with a relative advantage for proliferation. Experimental evidence for this dosage-sensitivity effect has been shown for several TSGs, including *TP53*, *BRCA1*, *BRCA2*, and *PTEN*. For example, a subset of tumors arising in $p53^{+/-}$ mice, or in patients with

Li-Fraumeni syndrome, retain the wild-type allele, suggesting that haploinsufficiency of *TP53* may be sufficient for tumor initiation.[28-30] Finally, the pro-tumorigenic effect imparted by haploinsufficiency might also be dependent on the loss or gain of function of other alleles. An example of this interaction is illustrated in mouse models of *Pten* and *Tp53* deficiency. Haploinsufficiency of *Pten* in the context of wild-type p53 enhances proliferation and subsequent transformation of prostate epithelial cells. In contrast, complete loss of *Pten* in this tissue triggers a p53-dependent senescence program, with tumors arising only after *Tp53* inactivation.[8]

Interconnecting the pRB, p53, and mTORC1 Pathways

Similar to an evolutionary process driven by natural selection, the acquisition of the malignant phenotype can be best described as an iterative process of somatic mutation followed by clonal expansion. The current consensus is that normal cells must acquire at least four distinct mutational or epigenetic events (including gain- and loss-of-function alterations) in order to bypass proliferative control. These events alter critical signaling networks that ultimately control the decision of a cell to proliferate, senesce, or die. The discovery of these pathways represented a major success in the history of cancer biology, for it made possible the assignment of a growing number of cancer-associated gene products to a much more limited number of interacting networks.[2] Because of their high association with human malignancies, a more detailed description of pathways centered on pRB, p53, and mTORC1 is used in the next sections to illustrate the emergent complexities of tumor suppression. Whenever necessary, the relevant nodes interconnecting these pathways are stressed.

The pRB Tumor Suppressor Pathway

Despite the low incidence of *RB-1* mutations, it has become clear that deregulation of the pRB pathway is present in most (if not all) human cancers. Deregulation can occur through gain or loss of function of various components of the pathway. In most cases, these alterations ultimately result in pRB phosphorylation, a modification necessary for G1-S cell cycle transition.[31,32] In G1, *hypo*phosphorylated (active) pRB forms repressive complexes with E2F transcription factors at gene promoters of S-phase genes, a function in part mediated by the recruitment of histone-modifying complexes to these sites. These modifications result in a silent chromatin configuration that effectively turns off S-phase genes. Signals that promote proliferation must reverse this inhibition, and they do so through pRB phosphorylation.[19] In mammalian cells, pRB is phosphorylated by cyclin-dependent kinases (CDKs), a group of enzymes that require the binding of short-lived proteins called *cyclins* in order to become active. As shown in Figure 3-1, CDK4 and CDK6 form active complexes with D-type cyclins in *early* G1, whereas CDK2 is activated by E-type cyclins in *late* G1 and S phase. Following phosphorylation, *hyper*phosphorylated (inactive) pRB releases E2F transcription factors, which leads to derepression of S-phase genes (see Figure 3-1). Predictably, cyclins and CDKs act as oncoproteins in human cancers. For example, *CCD1* (encoding cyclin D1) is amplified or overexpressed in more than 50% of human breast cancers.[31,33]

CDKs are also subject to negative regulation by two families of CDK inhibitors. Members of the INK4 family, such as $p16^{INK4a}$, bind to CDK4 or CDK6 and prevent their association with D-type cyclins. On the other hand, members of the CIP1/KIP1 family, which include $p21^{CIP1}$ and $p27^{KIP1}$, form inhibitory complexes with CDK2 and cyclin E.[31] In both cases, CDK inhibition results in pRB activation and cell cycle arrest (see Figure 3-1). As expected, many CDK inhibitors behave as tumor suppressors in human malignancies. For example, *CDKN2A*, the gene encoding $p16^{INK4a}$, is frequently deleted or epigenetically silenced in cases of familial melanoma and in several sporadic tumors.[34]

The *CDKN2A*-containing locus is also remarkable in that it encodes a second, structurally and functionally unrelated protein from an alternative reading frame and a different gene promoter.[35] This alternative reading frame protein (ARF, also called $p14^{ARF}$ in humans and $p19^{Arf}$ in mice) stabilizes p53 by directly inactivating MDM2, the E3-ubiquitin ligase that targets p53 for degradation. Therefore, loss-of-function mutations affecting *ARF*, as well as gain-of-function mutations in *MDM2*, can both have a similar destabilizing effect on p53. *ARF*-specific inactivating mutations have been described in a subset of human melanomas; *MDM2* amplifications, on the other hand, are common in human sarcomas.[2] Notice that the unique genomic arrangement of the *CDKN2A* locus, encoding both $p16^{INK4a}$ and $p14^{ARF}$, means that deletions of this locus would simultaneously compromise the functions of the pRB and p53 pathways. Hence, in a manner reminiscent of the inactivation of pRB and p53 by the SV40 large T antigen, cells harboring certain *CDKN2A* mutations display an enhanced proliferative capacity in vitro, which in many cases is sufficient for the establishment of continuously proliferating (immortal) cell lines. This immortalization step, in turn, sensitizes cells to oncogene-mediated transformation.[36]

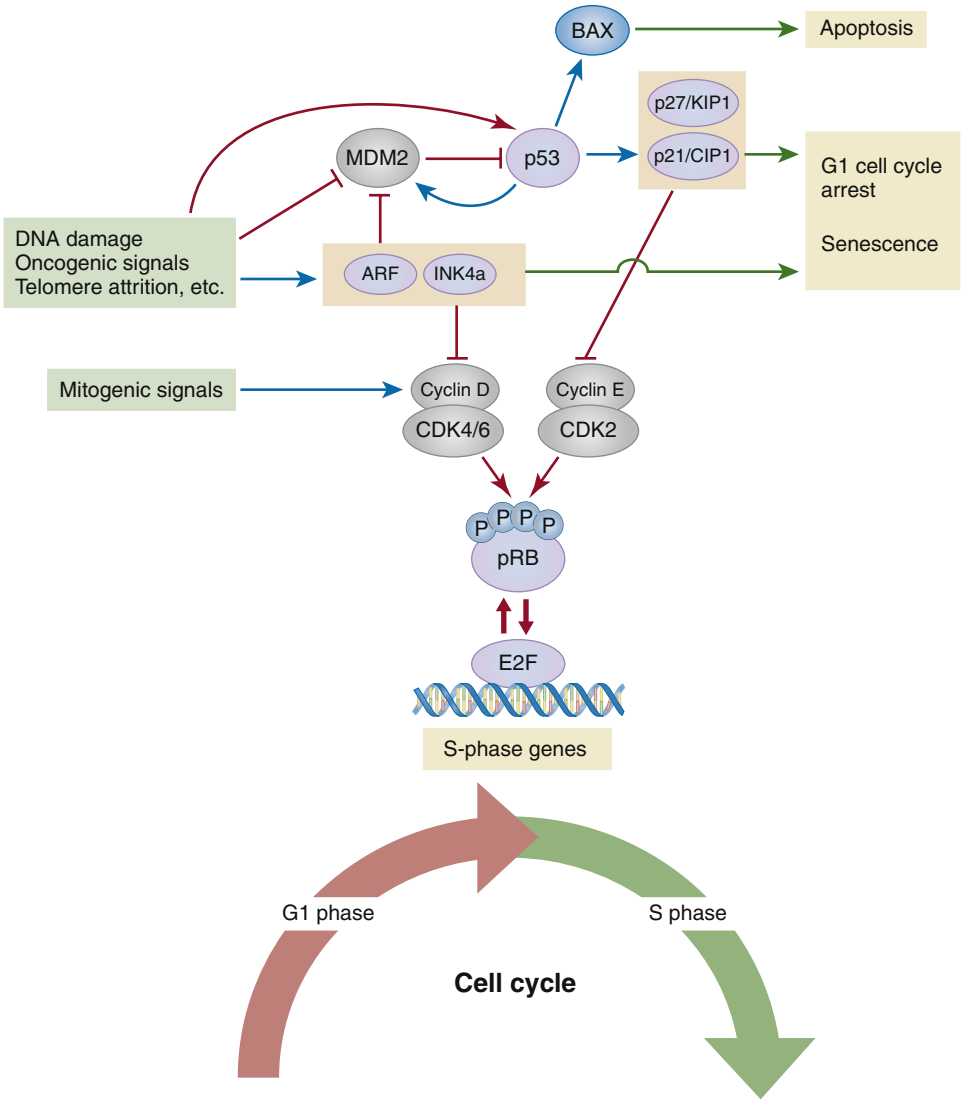

Figure 3-1 The pRB and p53 tumor suppressor pathways Under physiological conditions, signals that promote proliferation (i.e., growth factors) induce the expression of D-type cyclins, short-lived proteins required for the activation of CDK4 and CDK6 (CDK4/6) in early G1. In cooperation with cyclin E–CDK2 complexes, cyclin D1–CDK4/6 complexes contribute to the phosphorylation-mediated inactivation of pRB and the derepression of E2F-responsive (S-phase) genes. A variety of stresses, including DNA damage, telomere erosion, and oncogenic stress, turn on signaling cascades that activate the *CDKN2A* locus. ARF, one of the tumor suppressors produced from this locus, inhibits MDM2 (the E3-ubiquitin ligase that targets p53 for degradation), resulting in the stabilization of p53 and the induction of p53-dependent transcriptional programs (the transcriptional activity of p53 can also be affected by numerous posttranslational modifications that, for simplicity, are not depicted here). Depending on the cell type and/or the nature and magnitude of the stress, p53 can induce the expression of genes that promote apoptosis or, alternatively, genes involved in cell cycle arrest, such as the gene encoding the CDK inhibitor $p21^{CIP1}$. $p21^{CIP1}$, in turn, inhibits cyclin E–CDK2 complexes and leads to pRB-dependent cell cycle arrest. The second tumor suppressor encoded by the *CDKN2A* locus, $p16^{INK4a}$ (INK4a), is also induced in response to stress (with or without concomitant induction of ARF), most typically oncogenic-dependent stress. By antagonizing CDK4/6, $p16^{INK4a}$ also activates pRB and prevents entry into S phase. *Red* arrows and *red* T-shaped connectors indicate activating and inhibitory processes, respectively; *blue* arrows indicate transcriptional induction; *green* arrows point to final cellular outcomes.

The p53 Tumor Suppressor Pathway

As already mentioned, p53 is a multifunctional transcription factor that is activated in response to a variety of stress conditions, including DNA damage, activated oncogenes, telomere shortening, spindle damage, hypoxia, and metabolic stress.[7] Depending on the cell type and the magnitude or nature of the stress, the transcriptional program activated by p53 can lead to one of three outcomes: cellular senescence, G1/G2 arrest, or apoptosis (see Figure 3-1). Mirroring the diversity of stress signals is the equally diverse number of intracellular networks involved in the transmission of these signals to p53. What all these networks have in common, however, is the ability to activate p53 via posttranslational modifications (including phosphorylation, acetylation, methylation, and sumoylation) that enhance p53's capacity to transcribe target genes and also increase the half-life of the protein. We have seen already that one way to stabilize p53 involves the ARF-dependent inhibition of MDM2.

Among numerous p53 targets, the gene encoding $p21^{CIP1}$ (*CDKN1A*) is probably the best-known example that connects p53 to the pRB pathway (p53-mediated upregulation of $p21^{CIP1}$ leads to CDK inhibition and pRB-mediated cell cycle arrest). In addition to targets involved in cell cycle arrest, p53 also induces genes that control or promote apoptosis (such as *BAX*, *PUMA*, and *PIG3*), a cellular outcome favored by some cell types undergoing extensive DNA damage.[37]

Given the pleiotropic roles of p53 in tumor suppression, it is not surprising that mutations in *TP53* are almost a universal feature of human cancers. Most of these mutations (~74%) are missense mutations that fall within the DNA-binding domain and therefore disrupt p53's ability to bind cognate promoter sequences on target genes.[22]

pRB and p53 Pathways in Action: Cellular Senescence

The connection between the two major tumor suppressors, pRB and p53, and cellular senescence is a recurrent theme throughout this chapter. Because of the growing awareness that cellular senescence constitutes a physiological barrier against tumor initiation and progression, a brief description of two related variants of senescence, and their connection with the pRB and p53 pathways, is necessary (see Figure 3-1).

Cellular senescence is a form of *irreversible* cell cycle arrest associated with a unique gene expression profile and distinctive cell morphology.[38] The first description of this phenomenon can be traced back to efforts to propagate human cells in vitro. Explanted human cells typically proliferate for a variable period of time but eventually undergo "replicative" senescence in response to the attrition of telomeres (the protective chromosomal termini) that accompanies each cell division. Telomere disruption triggers a stress response that in many respects is identical to a p53-dependent DNA damage response (DDR).[39] Before the signs of DDR are evident, however, an early induction of $p16^{INK4a}$ also contributes to limit the proliferative capacity of human cells, which is illustrated by the significant delay in the onset of replicative senescence observed in $p16^{INK4a}$-deficient cells. Nonetheless, in order to completely bypass senescence, human cells must also overcome the p53 pathway and reactivate telomerase (the enzyme responsible for telomere maintenance).[38,40]

A form of replicative senescence associated with the induction of $p16^{INK4a}$ and p53 is also observed in primary mouse cells, but, in contrast to human cells, the inactivation of just one of these tumor suppressors suffices to bypass senescence. Because murine cells constitutively express telomerase, senescence in this case might be a response to nonphysiological culture conditions (i.e., high oxygen levels).[38]

In addition to replicative senescence, primary cells also undergo "premature" senescence in response to oncogenic stress (i.e., overexpression of activated *HRAS*), a phenomenon known as "oncogene-induced senescence" (OIS). Similar to replicative senescence, OIS is also dependent on the induction of $p16^{INK4a}$ and p53, although the relative contribution of these tumor suppressors varies between species and cell types.[38,41] Recently, OIS has been confirmed as a barrier to tumorigenesis in vivo. For example, benign melanocytic tumors called "nevi" are associated with activating mutations in the oncoprotein BRAF. These lesions are typically positive for markers of senescence, including elevated levels of $p16^{INK4a}$. As expected, loss of $p16^{INK4a}$ in these lesions accelerates the formation of malignant melanomas.[42,43]

The mTORC1-Dependent Pathways

Alterations in a cell's ability to respond to metabolic and growth-promoting signals constitute common features of cancers. At the center of these regulatory networks is mTORC1 (mammalian target of rapamycin complex 1), a kinase complex that integrates nutrient and growth factor availability with downstream effectors involved in cell growth and proliferation. mTORC1's main function is to promote biosynthetic processes (i.e., protein synthesis and ribosome biogenesis) that increase cell mass. Two pathways that converge on mTORC1 (the PI3K- and AMPK-dependent pathways) are particularly relevant to cancer[44,45] (Figure 3-2).

Activation of tyrosine kinase receptors, most classically insulin-like growth factor receptor (IGFR), activates the lipid kinase PI3K (class I phosphatidylinositol-3-kinase), an enzymatic complex that catalyzes the production of phosphatidylinositol-3-phosphate (PIP3). The local increase in PIP3 is in turn required for the activation of AKT kinases. AKTs inhibit the GTPase activating complex TSC (tuberous sclerosis complex, composed of TSC1 and TSC2 subunits), a process required to keep Rheb (a small GTPase) in its GTP-bound (active) conformation. As a result, AKT-mediated inactivation of TSC increases the pool of active Rheb, which in turn enables mTORC1 activation (see Figure 3-2). AKT-mediated phosphorylation of substrates other than TSC can also affect proliferation by controlling pRB activity. These substrates include the FoxO (Forkhead box O) family of transcription factors and GSK3-β (glycogen synthase kinase 3-beta). Under basal conditions, FoxOs induce the expression of the CDK inhibitors $p21^{CIP1}$ and $p27^{KIP1}$, whereas GSK3-β participates in the degradation of cyclin D1 (see Figure 3-2). Therefore, AKT-mediated inactivation of FoxO and GSK3-β reduces the levels of CDK inhibitors

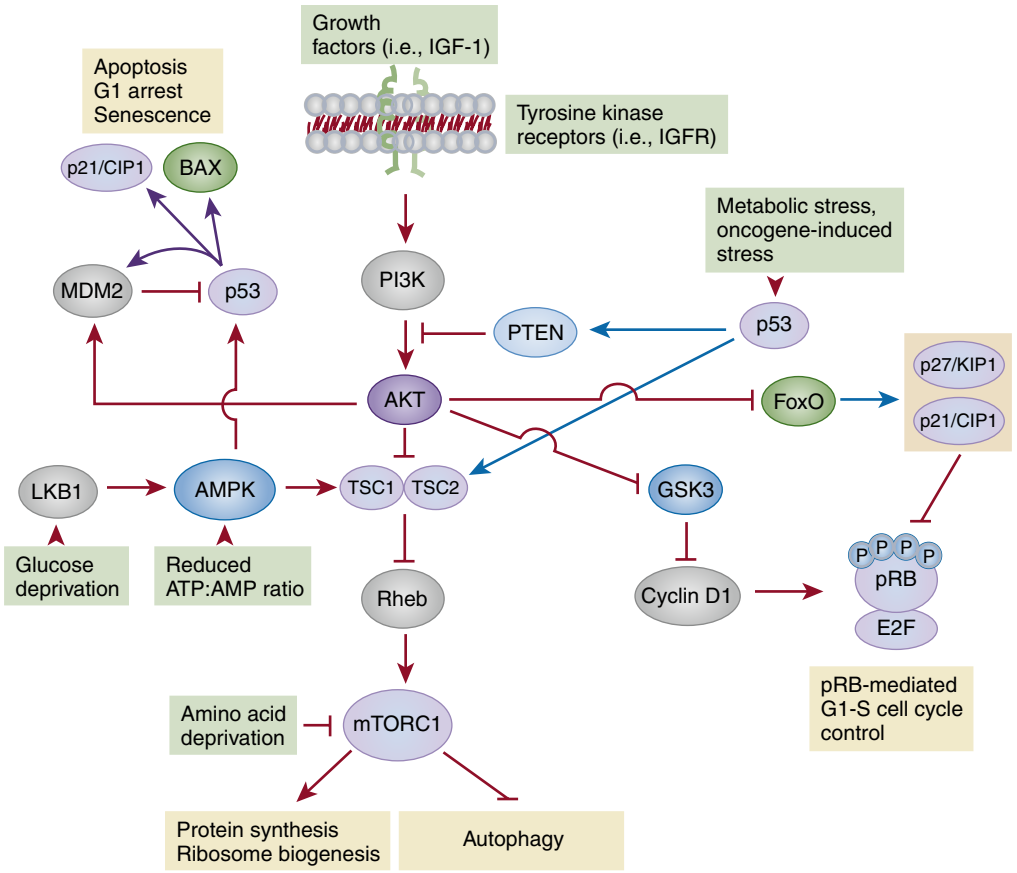

Figure 3-2 The PI3K-AKT-mTORC1 and LKB1-AMPK-mTORC1 pathways The main function of mTORC1 is to regulate biosynthetic pathways involved in cell growth, cell survival and proliferation. The proper function of mTORC1 depends on its ability to integrate inputs from two pathways: the PI3K-AKT axis, involved in the transduction of growth-promoting signals and the LKB1-AMPK axis, which monitors the energy status of the cell. Ligand-mediated activation of tyrosine kinase receptors (i.e., insulin-like growth factor receptor, IGFR) activates PI3K, which increases the local concentration of the lipid second messenger phosphatidylinositol-3-phosphate, PIP3. This activity is counteracted by PTEN, a lipid phosphatase that removes phosphate groups from PIP3. PI3K-mediated increase of PIP3 levels activates the AKT family of kinases, which inhibit the GTPase activating complex TSC (TSC1-TSC2). Inhibition of TSC allows Rheb to remain in its active (GTP-bound) conformation, resulting in mTORC1 activation. In addition, AKT-mediated phosphorylation of FoxO transcription factors and GSK3-β can also lead to pRB inactivation and cell cycle entry by reducing the expression of CDK inhibitors ($p21^{CIP1}$ and $p27^{KIP1}$) and increasing the stability of cyclin D1. The AMPK complex and its upstream activator LKB1 monitor the intracellular levels of glucose and ATP and modify the functional status of mTORC1 accordingly. In situations of metabolic stress, the resulting increase in the AMP:ATP ratio leads to the activation of LKB1, which phosphorylates and activates AMPK. Active AMPK can then inhibit mTORC1 through TSC-dependent and TSC-independent mechanisms. As shown here, in response to metabolic stress, p53 can directly induce the expression of TSC2 and PTEN, contributing to mTORC1 inhibition. Conversely, AMPK can also phosphorylate and activate p53. *Red* arrows and T-shaped connectors indicate activating and inhibitory processes, respectively; *blue* arrows indicate transcriptional induction.

and increases the levels of cyclin D1, outcomes that cooperate to promote cell cycle progression (see Figure 3-2).[46]

Normal cells must also implement mechanisms to reduce the PI3K-AKT activity in order to adjust the rates of protein synthesis to the available growth factors. One important mechanism of inhibition involves the activation of PTEN (phosphatase and tensin homologue), a lipid phosphatase that catalyzes the dephosphorylation of PIP3 and thus counteracts PI3K activation (see Figure 3-2).[44]

In cancer cells, activation of the PI3K-AKT-mTORC1 pathway can occur through several mechanisms. These include aberrant activation of tyrosine kinase receptors (TKRs), activating mutations in *PI3KCA* (the gene encoding the p110α subunit of PI3K), amplification of *AKT1*, downregulation of *TSC2*, or loss-of-function mutations in *PTEN*.[46] Loss of *PTEN* in particular constitutes a remarkably frequent alteration in human malignancies. Similar to other tumor suppressors, germline mutations in *PTEN* are also associated with inherited cancer syndromes (including Cowden disease), and hemiallelic loss of *Pten* in mice results in tumors arising in multiple epithelial tissues, including the intestine, prostate, and mammary gland. However, unlike other tumor suppressors, biallelic deletion of *Pten* can activate a p53-dependent senescence program that opposes transformation, suggesting that PTEN is an obligate haploinsufficient tumor suppressor. By comparison, mutations affecting other negative regulators of the PI3K-AKT-mTORC1 pathway are rare events in sporadic tumors, although germline deletions of *TSC1* or *TSC2* are known to be associated with cancer-prone syndromes.[44]

The second signaling pathway that modulates mTORC1 is the AMP-activated protein kinase (AMPK) pathway. During periods of *nutrient deprivation*, AMPK is activated by at least two mechanisms: (1) increased levels of AMP (due to a drop in ATP production) and (2) phosphorylation by LKB-1, a kinase that is itself activated in response to metabolic stress (i.e., glucose reduction) (see Figure 3-2). Active AMPK phosphorylates TSC2, leading to the activation of the TSC complex, inactivation of Rheb and mTORC1, and the consequent inhibition of protein synthesis and cell growth.[44] An important consequence of mTORC1 inhibition is a shift toward a predominantly catabolic metabolism. This is in part achieved through the induction of autophagy, the process in which organelles and protein complexes are targeted to the lysosome for degradation.[47]

It follows from this account that cancer cells must overcome the AMPK-dependent checkpoint in order to sustain proliferation under suboptimal metabolic conditions. Among the mechanisms of AMPK inactivation, loss of function of LKB-1 is probably the best known. Inactivating mutations of the gene encoding LKB1 (*STK11*) have been identified in patients with Peutz-Jeghers syndrome, a condition that predisposes individuals to the development of several types of cancer. Recently, *STK11* was also found mutated in sporadic cases of non–small-cell lung and cervical carcinomas.[44]

In recent years, it has become evident that most alterations in cancer-associated genes can result in metabolic changes that involve mTORC1-dependent pathways to variable degrees. In particular, the role of p53 in mediating adaptation to metabolic stress is becoming increasingly evident. Thus, inhibition of the AKT-mTORC1 axis, as well as activation of AMPK, can both lead to the induction of p53. The first mechanism is a consequence of the ability of AKT to activate MDM2. Therefore, a reduction in AKT function (i.e., secondary to PTEN activation) activates p53 by removing the negative regulation imposed by MDM2. On the other hand, in situations of nutrient deprivation, AMPK-mediated phosphorylation of p53 increases its half-life and transcriptional activity.[48]

Epigenetic Modifications and Tumor Suppression

Evidence accumulated in the past decade has led to the realization that *epigenetic* changes affecting oncogenes and TSGs constitute important events contributing to the hallmarks of cancer. The cancer "epigenome" is characterized by global and gene-specific heritable modifications that affect gene expression but do not involve changes in DNA sequence. Three types of cancer-associated epigenetic modifications are currently recognized: DNA methylation, histone modifications, and micro-RNA (miRNA)-mediated gene silencing.[49] Although they are discussed separately in this chapter, we should emphasize that these are functionally interdependent mechanisms. For example, some miRNAs can modify the epigenetic landscape by regulating the expression of proteins involved in histone modifications or DNA methylation. Conversely, miRNA expression itself can be altered by DNA methylation or histone modifications (Figure 3-3 is a summary of the most relevant epigenetic changes observed in cancer cells).

DNA Methylation

DNA methylation is the covalent addition of a methyl group to the cytosine ring of a CpG dinucleotide. Although CpG dinucleotides are widely distributed throughout the genomes of eukaryotic organisms, CpG-rich regions (also called CpG islands) are particularly enriched in the promoter regions of genes. The silencing effect of DNA methylation can result from the direct inhibition of transcription factor binding to promoter regions or from the recruitment of repressive protein complexes to methylated regions. As explained later in this chapter, this latter mechanism often results in a more condensed, transcriptionally silent chromatin configuration.[49]

Genome-wide hypomethylation and promoter-specific hypermethylation are common features of cancer. These alterations can be detected in benign lesions and early-stage tumors, suggesting that they may precede classical genetic events. Global loss of DNA methylation at CpG islands was the first epigenetic alteration identified in cancers. In particular, hypomethylation at repetitive sequences in the genome is associated with genomic instability.[50,51] However, the most recognized epigenetic alteration in cancer cells is the promoter hypermethylation affecting TSGs. One of the first examples of this silencing mechanism was discovered in some *RB1* alleles associated with retinoblastoma.[50] Since then, hypermethylation as a mechanism of gene inactivation has been demonstrated for other TSGs, including *INK4a/p16* (*CDKN2A*), *MLH1*, *BRCA1*, *VHL* and *CDH1* (encoding E-cadherin). In many cases, collaboration between hypermethylation and genetic inactivation can also be documented. For example, promoter hypermethylation contributes to the inactivation of the wild-type allele of *CDKN2A* in colorectal cancer cells that have already lost one allele through deletion. That hypermethylation is causally involved in the repression of TSGs has been confirmed through the use of demethylating procedures. For example, acute elimination or inhibition of DNMT1 (a DNA methyltransferase) in colon cancer cells is sufficient to reactivate INK4a/p16 and induce cell cycle arrest.[51]

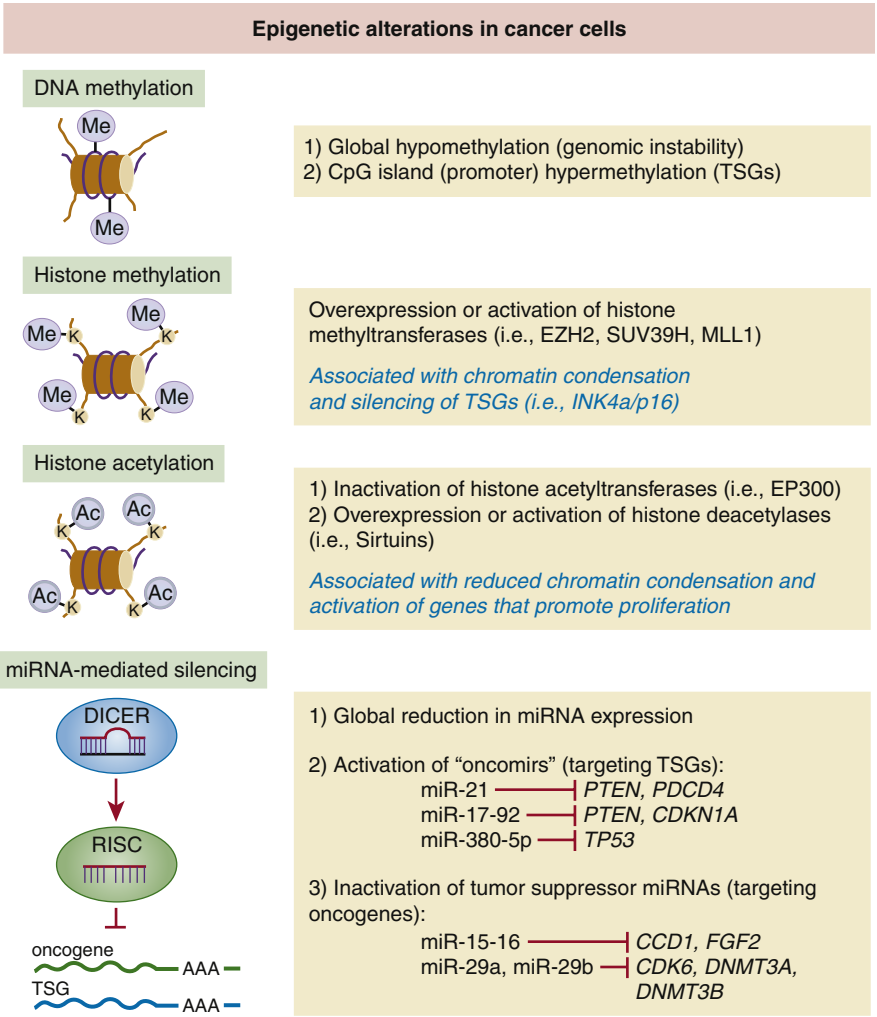

Figure 3-3 Epigenetic mechanisms involved in tumor suppression A brief summary of the main epigenetic changes affecting cancer cells.

Histone Modifications

The second group of cancer-associated epigenetic changes involves the covalent modification of histones, the proteins that form the core of nucleosomes. Among numerous modifications, acetylation and methylation of lysine (K) residues at the N termini of histones H3 and H4 are probably the best known. It has been proposed that the combinatorial addition or removal of acetyl and methyl groups to several K residues of H3 and H4 may serve as a "histone code" that dictates the degree of chromatin condensation and, therefore, the extent to which a genomic locus becomes transcriptionally active. For example, *trimethylation* of lysines 4, 36, or 79 and *acetylation* of lysines 9 or 14 of histone H3 are both associated with a relaxed chromatin configuration that facilitates transcription. Conversely, di- or trimethylation of lysine 9 or 27 of histone H3 is associated with a more condensed, transcriptionally silent chromatin configuration. It is important to keep in mind that the enzymatic complexes involved in these modifications (see later discussion) cooperate extensively with DNA methyltransferases (the enzymes that catalyze DNA methylation) to produce stable chromatin states.[51]

Although systematic analyses of histone modifications at the global level are still limited, some studies indicate that the disruption of normal patterns of *histone acetylation* can enhance tumorigenesis. For example, inactivation of two histone acetyltransferases (HATs), EP300 and CREBBP, by viral oncoproteins leads to a global reduction in acetylation of H3K18 (lysine 18 of histone H3), a modification that results in the transcriptional activation of a subset of genes that promote proliferation. Moreover, inactivating mutations of *EP300* have been reported in colorectal, gastric, breast, and pancreatic tumors. Similarly, the overexpression of histone deacetylases (HDACs) and *Sirtuins* (a class of HDAC) is also associated with cellular transformation, as observed in a variety of malignancies[51] (see Figure 3-3).

Finally, aberrant expression or activation of histone methyltransferases (HMTs) and histone demethylases (HDMs) is also associated with cancer. For example, overexpression of *EZH2* (an H3K27-specific HMT) is found in prostate, breast, and lung cancers. In prostate cancer, *EZH2* overexpression

correlates with H3K27 trimethylation and the silencing of TSGs. Similarly, the H3K9-specific methyltransferase SUV39H has been linked to tumor initiation and progression through silencing of the *CDKN2A* tumor suppressor locus in several cancers.[51] Perhaps the most paradigmatic and clinically relevant example of HMT activation is observed in leukemias affecting children. Translocation-mediated activation of *MLL1*, a gene encoding a H3K4 methyltransferase, has been reported in up to 80% of leukemias. Almost universally, translocations involving *MLL1* result in fusion proteins that function as constitutively active transcription factors, leading to the deregulation of several leukemia-promoting pathways.[49]

In contrast to HMTs, much less is known about the role of HDMs in tumorigenesis. So far, both overexpression and inactivation of HDMs seem to contribute to tumorigenesis.[51]

Micro-RNAs

The discovery of noncoding RNAs has unveiled unexpected complexities in the regulation of gene expression. As described here, these new regulatory factors can play significant roles during cancer initiation and progression by way of modulating classic oncogenic pathways.

Micro-RNAs (miRNAs) are small (18 to 25 nucleotides long), evolutionarily conserved, noncoding RNAs that control the translation and stability of protein-encoding messenger RNAs (mRNAs). miRNAs are produced through the sequential processing of primary transcripts (pri-miRNAs) by the ribonucleases Drosha and Dicer1. After processing, the guide RNA strand of a mature miRNA (which is complementary to a mRNA target) combines with *Argonaut* proteins to form an RNA-induced silencing complex (RISC), the final effector that targets mRNAs for cleavage or translational repression.[52]

High-throughput genetic screens have identified more than 1000 miRNA-encoding sequences in the human genome, which are typically arranged in large clusters expressed polycistronically. Together, they are predicted to control the expression of thousands of protein-encoding genes. Given their wide spectrum of functions, it is hardly surprising that aberrant miRNA expression contributes to tumorigenesis. Remarkably, although many miRNA-encoding sequences have been mapped to genomic regions that are amplified in human cancers, miRNA expression profiles reveal a global downregulation of miRNA expression in cancer cells. Although the mechanisms responsible for this phenomenon are not completely understood, it has been proposed that some oncoproteins (i.e., MYC) can directly contribute to the global silencing of miRNAs. Alternatively, cancer initiation may require the partial repression of miRNA biogenesis. In support of this idea, human tumors often show monoallelic deletions of *DICER1* and, accordingly, tumor formation is accelerated by monoallelic deletion of *DROSHA* or *DICER1* in mouse models.[52,53]

Deregulation of individual miRNAs can contribute to tumorigenesis by altering the expression of conventional oncogenes and TSGs. For example, "oncogenic miRNAs" (also known as *oncomirs*) negatively regulate the expression of TSGs, whereas "tumor suppressor miRNAs" downregulate the expression of oncogenes. Among oncomirs, *miR-21* was one of the first miRNAs found to be elevated in human cancers. In animal models, overexpression of *miR-21* enhances the tumorigenic effect of *K-Ras* in the lung in part by targeting *PTEN*. Similarly, amplification of the *miR-17~92* cluster has been documented in both solid and hematopoietic cancers. Genes targeted by individual miRNAs in this cluster include the tumor suppressors *PTEN*, *BIM*, and *CDKN1A*.[53,54]

The first tumor suppressor miRNA identified was *miR-15~16*, a cluster localized in a genomic region that is deleted in more than 50% of patients with B-cell chronic lymphocytic leukemia (B-CLL). Targets of this cluster include the oncogenes *CCD1*, *FGF2*, and *FGFR1*. Similarly, *miR-29a* and *miR-29b*, which are inactivated in mantle cell lymphoma, can target multiple cell cycle regulators and oncogenes.[52]

Given the relevance of the *TP53* tumor suppressor in human cancers, efforts to link p53 function to miRNA regulation have already led to important discoveries. For example, p53 induces several miRNAs, including *miR-34*, *miR-200*, and *miR-192*. Among these, the *miR-34* family represses genes that promote proliferation and survival, such as *CDK6* and *BCL2*. Conversely, *TP53* can be itself targeted by oncomirs in some cancers.[53]

It is worth mentioning that the extent to which an individual miRNA or miRNA cluster behaves as an oncomir or tumor suppressor is highly dependent on cellular context. Because a single miRNA can target multiple mRNAs, the differential expression of potential target mRNAs in different cell types means that the deregulation of a miRNA may lead to different outcomes depending on the cell type. For example, despite the fact that the *miR-29* family acts as a tumor suppressor in many tumors, it can behave as an oncomir in breast cancer, presumably because of the particular constellation of target mRNAs in breast cancer cells.

Conclusions

During the past 40 years, the exhaustive characterization of TSG products has provided us with a relatively robust conceptual framework to understand the genetic and epigenetic

bases of cancer. From the preceding sections, it should be clear that tumor suppressor proteins and cancer-associated micro-RNAs are involved in the control of almost any cellular function, and yet the disruption of their activities must somehow confer a proliferative advantage by influencing the decision of a cell to continue cycling. This feature helps explain the almost universal involvement of the pRB and p53 signaling networks in the pathogenesis of most human cancers. It is believed that a better understanding of this Achilles' heel of cancer will lead some day to more effective therapies. As data accumulate, however, it is becoming increasingly evident that the emergent picture calls for a much-needed contextualization of TSG functions. A full understanding of the different contexts in which (or against which) a TSG functions remains a daunting task for the future. So far, significant progress has been made in the identification of signaling or metabolic pathways disrupted by the loss of function of some TSGs. By comparison, we know much less about the relationships between various genetic alterations, or the relevance of their temporal appearance, for the tumorigenic outcome. On a different level, given the rather universal functions that most TSGs have in normal cells, it is remarkable that the inactivation of many TSGs leads to specific tumor types. Although we still do not understand the basis of tissue specificity, answers to this question will be most certainly provided by a better understanding of the connection among tumor suppression, tissue development, and processes that govern the differentiation and self-renewal of normal stem cells. Finally, advances in whole-genome sequencing are already revealing the existence of low-penetrance cancer susceptibility genes, which might play an important role as modifiers of cancer risk in human populations.

DNA Repair Pathways and Human Cancer

Introduction

DNA repair is central to the field of cancer biology, and it has important implications for cancer diagnosis and treatment. Cancer cells are often deficient in a normal DNA repair function, and this deficiency allows the tumor to develop genomic instability.[1,2] With defective DNA repair, the tumor cell can break and reform chromosomes, generate new oncogenic fusion genes, disrupt tumor suppressor genes, amplify drug resistance genes, and progress to a more malignant state. A DNA repair deficiency also accounts for the enhanced sensitivity of tumor cells to genotoxic agents, such as ionizing radiation (IR) and genotoxic chemotherapy. A specific defect in homologous recombination DNA repair also renders a tumor cell hypersensitive to polyADP ribose polymerase (PARP) inhibitors. A thorough knowledge of DNA repair mechanisms in normal and cancer cells may therefore lead to better clinical management of cancer.

The Spectrum of DNA Damage

Spontaneous DNA Damage

In order to understand the process of DNA repair, one must first consider the wide range of DNA-damaging events in a cell. DNA may undergo spontaneous damage, such as deamination of cytosine or spontaneous hydrolysis of the phosphodiester backbone. DNA may develop mismatched bases, perhaps resulting from the deployment of an error-prone DNA polymerase during S phase progression. DNA may be attacked by reactive oxygen species (ROS). Indeed, some of the most sophisticated DNA repair mechanisms in a cell are mechanisms that cope with the removal of oxidative DNA lesions.

Of particular relevance to cancer is the DNA damage from alkylating agents or from ultraviolet (UV) light or IR. DNA damage resulting from these environmental agents can lead to heightened mutagenesis and oncogenesis. Also, many of these agents themselves have anticancer activity. Thus, DNA-damaging agents can cause human cancer but, ironically, are among the primary means available to clinicians for treating cancer. Accordingly, some chemotherapeutic agents have effective anticancer activity in the short run but are responsible for causing secondary cancers in the long run.

DNA Damage from Antineoplastic Therapeutic Agents

Most anticancer agents function by directly damaging DNA. Effective anticancer drugs include monofunctional alkylating agents (cyclophosphamide, BCNU), bifunctional alkylating agents, (cisplatin, carboplatin, oxaliplatin), and DNA intercalating agents (adriamycin). In addition, IR and the radiomimetic agent bleomycin can cause double-strand breaks in DNA directly. Bleomycin is a small glycopeptide that chelates ferrous ion and binds to specific sequences of double-stranded DNA containing pyrimidine repeats. In the presence of oxygen, bleomycin generates a local high concentration of hydroxyl radicals capable of causing local double-strand breaks. Other drugs, such as the topoisomerase inhibitors etoposide and camptothecin, can lead to the accumulation of DNA damage. Thus, known anticancer agents can generate a wide range of DNA damage, including damaged bases, single-strand breaks, and double-strand breaks.

It is important for oncologists to bear in mind that anticancer drugs generate their cytotoxic effects through DNA damage. First, effective anticancer protocols often include a combination of chemotherapeutic agents and IR. Together, these agents cause a broader spectrum of DNA damage in the tumor than single agent therapy (monotherapy). This broad spectrum may contribute to the synergy observed with these agents. Second, chemotherapy combinations are often chosen to limit toxicity to normal tissue. Agents that generate the same class of DNA damage (such as IR and bleomycin, which both generate double-strand breaks) may have enhanced toxicity compared to other combinations.

Some newer classes of drugs inhibit normal DNA repair processes. These so-called chemosensitizers may be particularly effective when used in combination with a more traditional cytotoxic, DNA-damaging drug. A combination of a DNA repair inhibitor and a direct DNA damaging agent can also result in significant toxicity to normal tissue. One way to limit this toxicity would be to deliver one agent such as the chemosensitizer systemically but to deliver the other agent, such as IR, locally to the tumor.

DNA Repair

DNA repair is strictly defined as the cellular responses that are associated with the restoration of the normal base pair sequence and structure of damaged DNA. As described in the following section, there are six primary DNA repair pathways, and each pathway is composed of a series of biochemical events leading to the sensing, excision, and restoration of the normal DNA sequence.

The Systematic Study of DNA Repair

It is instructive to consider the history of DNA repair research as it relates to cancer biology. Early studies of DNA repair evolved from the study of normal DNA replication and metabolism. These early studies relied heavily on the use of damaged DNA templates as substrates for the purification of DNA repair enzymes. Such templates were incubated with cell-free extracts, and the recovered DNA was analyzed for specific incision and excision events. Not surprisingly, these assays uncovered many of the pertinent endonuclease and exonuclease activities required for DNA repair. It has become increasingly apparent that DNA repair proteins are assembled in protein/protein complexes, such as the excision repair complex or the mismatch repair complex. Still, the regulatory networks and relevant posttranslational modifications of DNA repair proteins (i.e., phosphorylations and ubiquitinations) were largely missed by these early biochemical studies.

The study of inherited human DNA repair disorders also contributed greatly to the recognition of the six major DNA repair pathways (see later discussion). These studies depended on the establishment of mutant human cell lines derived from patients with genetic diseases. For instance, in 1968, James Cleaver isolated fibroblast lines from humans with the disease xeroderma pigmentosum (XP).[3,4] Importantly, these lines retained their UV light–hypersensitivity phenotype and have been invaluable tools for somatic cell fusion, complementation analysis, and expression cloning of XP genes. Subsequently, other investigators were able to establish mutant cell lines from humans with other DNA repair disorders such as ataxia-telangiectasis (A-T), Fanconi anemia (FA), and Nijmegen breakage syndrome (NBS).[5] These cell lines continue to be used extensively as models of human cancers that also lack the relevant DNA repair pathways.

The study of model organisms has contributed greatly to our understanding of DNA repair processes. For instance, investigators isolated mutants in the yeast *Saccharomyces cerevisiae*, which were hypersensitive to UV light, IR, or DNA crosslinking agents. In many cases, the genes that were mutated in these yeast strains cooperated in common DNA repair and DNA damage response pathways. IR-induced double-strand breaks in DNA are normally repaired by the DNA repair process of homologous recombination (HR). Accordingly, many of the relevant genes corresponding to these mutant strains and required for normal HR repair were first isolated in yeast. Thereafter, the human homologues of these genes were identified. Other model organisms and cell lines have been especially important in the identification of genes involved in DNA repair pathways, such as mismatch repair[6] and translesion DNA synthesis.[7] Among the most useful model systems for studying DNA repair are the *Caenorhabditis elegans*[8] and chicken (DT40) genetic systems.[9]

In the postgenomic era, and following the identification of a large number (perhaps 130) of distinct DNA repair proteins,[10] investigators have turned to x-ray crystallography for a detailed understanding of DNA repair protein interaction with damaged DNA. The structures of many endonucleases, helicases, and ligases are now available, providing the opportunity for computer-assisted drug development (CADD) of DNA repair enzyme inhibitors. Also, mass spectrometry has been used to identify critical posttranslational modifications of DNA repair proteins. These modifications appear to be essential to the proper localization and assembly of DNA repair complexes around sites of DNA damage. The modifications may also regulate the intrinsic catalytic activity of the repair complexes. These protein modifications can be used as surrogate markers, or biomarkers, of DNA repair activity in a given tumor type as well (see later discussion).

The Six Major DNA Repair Pathways in Human Cells

As described previously, the combination of (1) biochemistry with damaged DNA templates, (2) human mutant cell lines with genetic deficiencies of DNA repair, (3) genetics of yeast mutants with IR or UV sensitivity, and (4) structural studies of DNA repair proteins has led to the establishment of six major DNA repair pathways. These pathways

Table 4-1 The Six Major DNA Repair Pathways

DNA Damage Repair Pathway	Function	Examples of Gene Mutation	Examples of Altered Expression of a Normal Gene	Effect of Loss of Pathway on Clinical Response
Base-excision repair (BER)	Repair of damaged bases or single-strand DNA breaks	None reported	None reported	None reported
Mismatch repair (MMR)	Repair of mispaired nucleotides	Mutation of *MSH2*, *MSH6*, and *MLH1* in Turcot syndrome (brain and colon tumors) and *HNPCC* (colon and gynecologic cancers)	Loss of expression of *MSH2* or *MLH1* in sporadic colon cancer	Resistance to DNA monoadducts Sensitivity to DNA crosslinks
Nucleotide-excision repair (NER)	Excision of a variety of helix-distorting DNA lesions	Mutation of *XPA*, *XPB*, *XPC*, *XPE*, *XPF*, or *XPG* in xeroderma pigmentosum (skin cancer) Variant expression of *ERCC1* or *XPD* in lung cancer	Loss of *XPA* expression in testicular germ-cell tumors	Sensitivity to DNA adducts
Homologous recombination (HR)	Repair of double-strand DNA breaks	*BRCA1/2* mutated in early-onset breast/ovarian, prostate, pancreas, and gastric cancers *FANC* genes mutated in Fanconi anemia	Loss of expression of *BRCA1/2* in ovarian and lung cancers Loss of *NBS1* expression in prostate cancer	Sensitivity to DNA double-strand breaks
Nonhomologous end joining (NHEJ)	Repair of double-strand DNA breaks	DNA ligase IV mutated in Lig4 syndrome (leukemia) Artemis mutated in Omenn syndrome (lymphoma)	Loss of *Ku70* expression in cervical, rectal, and colon cancers Loss of *Ku86* expression in rectal cancer	Sensitivity to DNA double-strand breaks
Translesional synthesis (TLS)	Bypass of DNA adducts during DNA replication	DNA pol E mutated in xeroderma pigmentosum variant (XPV; skin cancers)	Pol β overexpressed in uterus, ovary, prostate, and stomach cancers Pol iota overexpressed in breast cancer	Resistance to DNA adducts

are base-excision repair (BER), nucleotide-excision repair (NER), mismatch repair (MMR), homologous recombination (HR), nonhomologous end joining (NHEJ), and translesion DNA synthesis (TLS) (Table 4-1).

There is also considerable redundancy in the function of the DNA repair pathways. When one pathway is disrupted, another pathway can partially compensate, especially if the second pathway is upregulated. For instance, a cell that is deficient in HR repair may depend more on the error-prone NHEJ repair pathway for the repair of double-strand breaks. Also, thymine dimers, which are generated by UV light exposure, can be repaired by NER repair or bypassed and effectively ignored by TLS polymerases. In some cases, the absence of one DNA repair pathway results in a hyperdependence on one or more other DNA repair pathways.[11,12] This so-called synthetic lethality among DNA repair pathways has important implications for the design of new anticancer drugs (see later discussion).

The six DNA repair pathways are not constitutively activated, but instead are highly regulated. The pathways are often activated at discrete times in the cell cycle. For instance, HR repair and TLS repair are active during the S phase of the cell cycle. Also, the DNA repair pathways are differentially active in various tissues and cell types. For instance, HR and TLS are more active in rapidly growing cells, such as hematopoietic cells, whereas NHEJ is more active in postreplicative cells. Accordingly, absence of a particular DNA repair pathway may be particularly disruptive to the growth and survival of some normal tissues and some cancers. Here is a brief description of the six DNA repair pathways, with an emphasis on the enzymes in the pathways and the preference for DNA lesions repaired.

Base-Excision Repair

BER has been reviewed by Wilson.[13] The cell uses BER to correct damaged DNA bases or single-strand DNA breaks. These lesions often result from spontaneous DNA damage (DNA deamination or hydroxylation of bases) or from exposure to environmental alkylating agents. In this pathway, damaged bases are removed by one of at least 10 DNA glycosylases. The resulting apurinic/apyrimidinic (AP) sites are processed first by the Ape1 AP endonuclease, leaving a 5′ deoxyribose phosphate; then by an AP lyase activity, leaving a 3′-elimination product. Single-strand breaks are then filled in by a DNA polymerase, either with a single nucleotide or with a longer repair patch, followed by ligation. The latter events in the BER pathway are regulated by the enzyme PARP1 (polyADP ribose polymerase 1). During the DNA

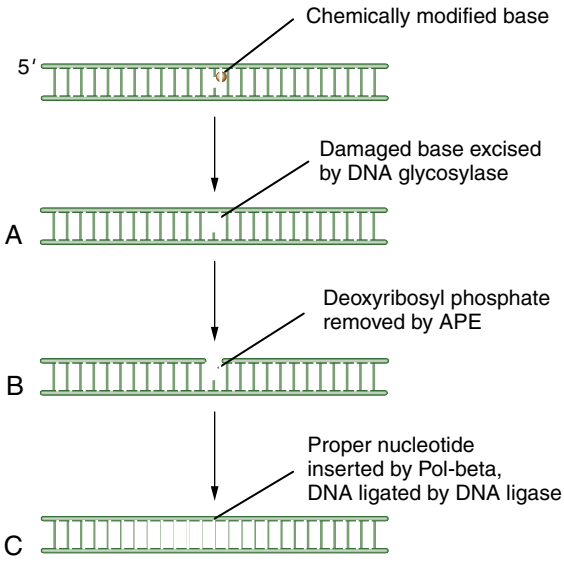

Figure 4-1 Schematic description of base-excision repair (BER) BER is focused on small DNA lesions, often from endogenous sources, resulting in minor helix distortions. Initially, the lesion is recognized by one of the cellular DNA glycosylases, which cleaves the covalent bond between the abnormal base and the deoxyribose sugar **(A)**. This cleavage leaves a so-called apurinic (A-P) site. Next, the apurinic endonuclease *(APE)* is recruited to cleave the phosphodiester backbone of the DNA **(B)**. Finally, an error-free polymerase, Pol-beta, is engaged to replace the normal nucleotide, followed by DNA ligation **(C)** and restoration of the normal double-stranded DNA sequence.

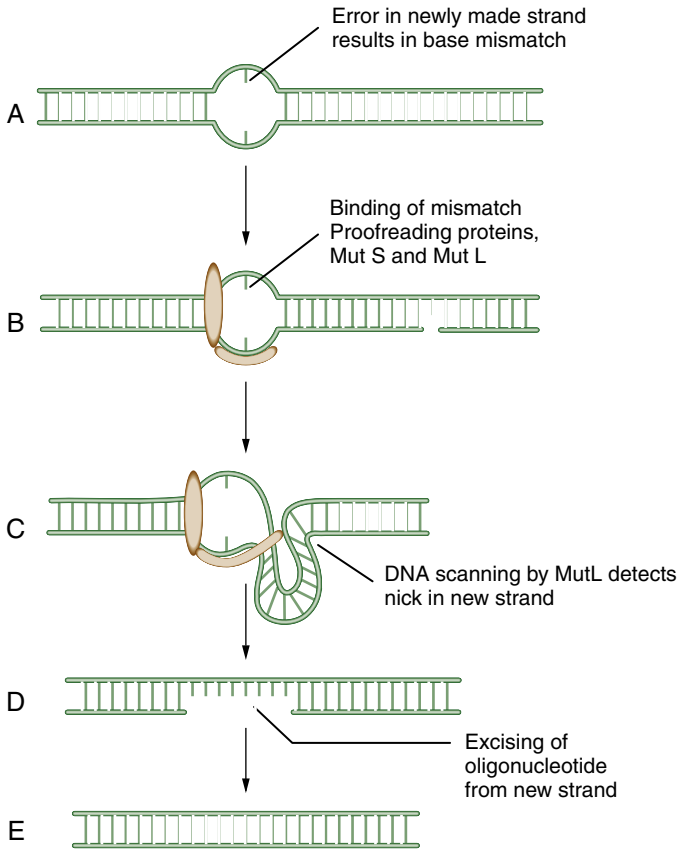

Figure 4-2 Schematic model of mismatch repair (MMR) Mismatch repair proteins function by sensing, binding, and repairing mistakes made during DNA replication. These mistakes include misincorporated bases and errors made during replication of microsatellite sequences **(A)**. MutS can bind to the mismatch **(B)** and generate a kink in the DNA **(C)**. This allows MutL to scan the DNA for a nearby single-strand nick in the newly replicated DNA. MutL then identifies, cleaves, and removes an oligonucleotide patch from the newly replicated strand **(D,E)**. This allows replication and the insertion of the proper DNA base at the site of the former mismatch. Mutations in the human genes encoding homologues of these bacterial proteins play a critical role in the inherited disease hereditary nonpolyposis colon cancer (HNPCC).

damage response, the PARP1 enzyme polyADP ribosylates BER enzymes and enhances BER activity. Accordingly, tumors that have high levels of BER activity may be hypersensitive to PARP inhibitors.[14] A schematic representation of BER is shown in Figure 4-1.

Mismatch Repair (MMR)

MMR has been reviewed by Modrich.[6] MMR rapidly removes mispaired nucleotides that result from replication errors and is also involved in the detection and repair of DNA adducts such as those resulting from platinum-based chemotherapeutic agents. Initially, the heterodimeric MSH complex recognizes the nucleotide mismatch, followed by its interaction with MLH1/PMS2 and MLH1/MLH3 complexes. Several proteins participate in the process of nucleotide excision and resynthesis. Tumor cells deficient in MMR have much higher mutation frequencies than normal cells and exhibit microsatellite instability, a genomic biomarker of the underlying defect. Patients with the genetic disease HNPCC (hereditary nonpolyposis colon cancer) have germline mutations of MMR genes and are predisposed to MMR-deficient colon cancers. Recent studies suggest that MMR-deficient cells may be hypersensitive to inhibitors of various DNA polymerases, such as POLB and POLG.[15] At least six genes—MSH2, MLH1, PMS2, MSH3, MSH6, and MLH3—are involved in mismatch repair. A schematic representation of MMR is shown in Figure 4-2.

Nucleotide-Excision Repair (NER)

NER acts on a variety of helix-distorting DNA lesions, caused mostly by exogenous sources that interfere with normal base pairing. This pathway may be particularly important in the response to adduct-forming chemotherapeutic agents such as platinum-based chemotherapy.[16] The primary function of NER appears to be the removal of damage such as pyrimidine dimers, which are induced by UV light. Members of the NER pathway include the XPA, XPB, XPC, XPD, XPE, and XPG proteins. Two other NER proteins, XPF and ERCC1, are especially important for the

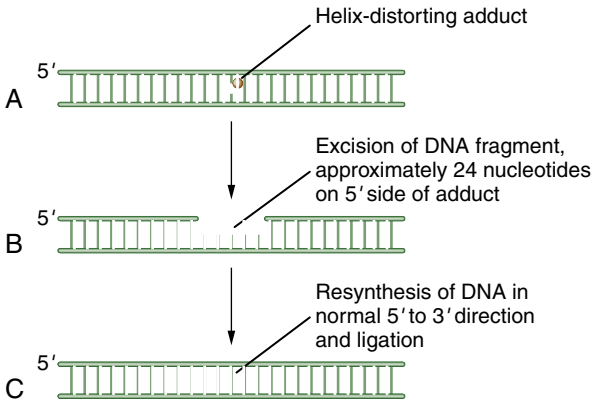

Figure 4-3 Schematic model of nucleotide excision repair (NER) NER is invoked when a base is modified by a larger helix-distorting lesion **(A)**, such as a UV-generated thymine dimer. Initially, the bulky lesion is recognized by a sensor complex, including the XPE protein (also known as DDB2). This protein is part of a ubiquitin conjugating complex, containing Cul4A and DDB1. The complex polyubiquitinates XPC, allowing for the recruitment of the excision repair complex. Next, a patch of nucleotides is excised from the damaged DNA. In general, the excision occurs approximately 24 nucleotides 5′ to the damaged base and 3 nucleotides to the 3′ side **(B)**. Finally, new DNA polymerization can occur, and the repaired DNA is ligated **(C)**. The nucleotide excision repair complex is a large multisubunit complex. Mutations in genes encoding subunits of this complex underlie the human disease xeroderma pigmentosum (XP). The complex also contains proteins that can recognize and remove bases with large bulky adducts, such as those generated by polycyclic hydrocarbons and aflatoxin B1.

processing of DNA crosslink repair. Recent studies indicate that monitoring the levels of these proteins in tumors may provide important biomarkers for predicting crosslinker drug sensitivity. For instance, some non–small-cell lung cancers are deficient in ERCC1, and this deficiency correlates with the cisplatin sensitivity of the specific tumor.[17]

As for the other DNA repair pathways, these proteins cooperate to recognize and excise the damaged nucleotides and resynthesize and ligate the damaged DNA strand. In the process of NER, initially a DNA-binding component, the DDB, binds to sites of damaged DNA, such as cyclopyrimidine dimers or 6-4 photoproducts. The DDB consists of DDB1 and DDB2. Mutations in the DDB2 gene cause the genetic complementation group XPE. DDB is part of a ubiquitin E3 ligase that polyubiquitinates XPC. Polyubiquitination of XPC enhances its DNA binding. This binding sets the stage for the downstream binding of the entire excision repair complex, TFIIH, thus leading to excision of the damaged bases.

Eukaryotic NER includes two major branches, transcription-coupled repair (TCR) and global genome repair (GGR). GGR is a slow, random process of inspecting the entire genome for injuries, whereas TCR is highly specific and efficient and concentrates on damage-blocking RNA polymerase II. The two mechanisms differ in substrate specificity and recognition, and hence the enzymes involved are important nodal points for posttranslational modifications. A schematic representation of NER is shown in Figure 4-3.

Homologous Recombination Repair

DNA double-strand breaks (DSBs) can be caused by many different environmental factors, including reactive oxygen species, IR, and certain antineoplastic drugs, such as bleomycin, anthracyclines, and topoisomerase inhibitors. Alternatively, DSBs can result from endogenous factors, especially during normal S-phase progression. Failure to repair DSBs can lead to a number of consequences, including mutations, gross chromosomal rearrangements, and other aberrations and eventually cell death. HR is a process by which DSBs are repaired through the alignment of homologous sequences of DNA and occurs primarily during the late S to M phase of the cell cycle. Initially the RAD50, MRE11, and NBS1 complex, which possesses a 3′-5′ exonuclease activity, exposes the 3′ ends on either side of the DSB, a process that may also require BRCA1. The 3′ advancing strand from the damaged chromosome then invades the complementary sequence of the homologous chromosome. The breast cancer susceptibility protein BRCA2 and the single-strand DNA binding protein RAD51 are required for the process. The 3′ end of this strand is then extended by an HR polymerase, by reading off of this complementary sequence. After replication has extended past the region of the DSB, the 3′ end of the advancing strand returns to the original chromosome, and replication continues. A schematic representation of HR is shown in Figure 4-4. HR repair is especially important in the repair of DSBs and DNA interstrand crosslinks. Because some tumors, particularly breast and ovarian tumors, are defective in HR repair, drugs that cause these lesions may be particularly effective in this setting.

Nonhomologous End Joining (NHEJ)

NHEJ, which has been reviewed by Lieber et al.,[18] is another major pathway for repairing DSBs. In common with HR, this pathway is important in the repair of agents that result in DSBs such as IR, bleomycin, topoisomerase II poisons, and anthracyclines. The DNA-dependent protein kinase (DNA-PK) consists of the catalytic subunit (DNA-PKcs) and the regulatory subunit (the Ku70/Ku80 heterodimer). The DNA-PKcs subunit is a serine/threonine kinase that belongs to the phosphatidylinositol-3 kinase family. The Ku80/Ku70 heterodimer (Ku) exhibits sequence-independent affinity for double-stranded termini and, on binding to DNA, recruits and activates the DNA-PKcs catalytic subunit.

Additional proteins are required for the completion of NHEJ, including the Artemis protein and DNA ligase IV. Importantly, NHEJ is an error-prone repair pathway. Because the process does not use a complementary template, the fusion of the blunt-ended DNA duplexes may result in

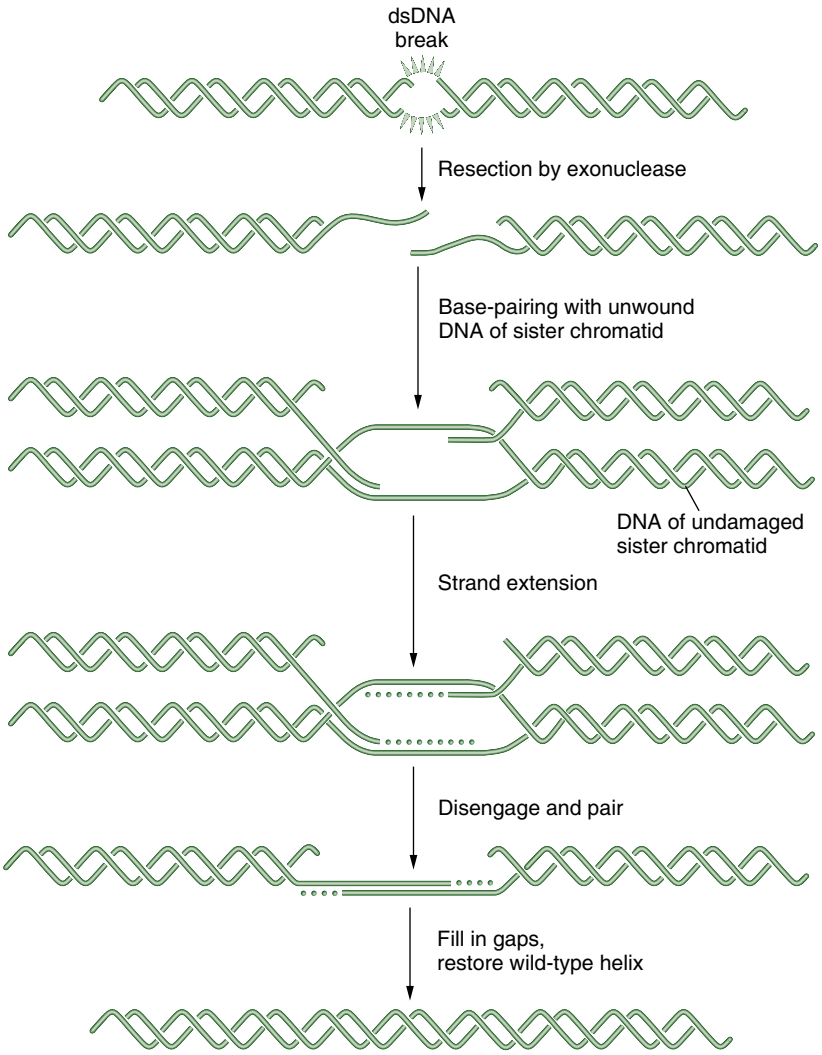

Figure 4-4 Schematic representation of homologous recombination (HR) HR repair is required for the normal repair of double-strand breaks (DSBs) as well as covalent interstrand DNA crosslinks. Initially, the DSB is recognized by a sensor. Some tumors have defects in HR repair, such as BRCA1 or BRCA2-deficient breast cancers. These tumor cells have prolonged time periods with unrepaired DSBs, thus leading to chromosome translocation events and a more malignant phenotype. Alternatively, the defective HR repair results in hyperdependence on the more error-prone NHEJ mechanism.

deletion or insertion of base pairs. A schematic representation of NHEJ is shown in Figure 4-5. NHEJ has a normal function in immune cells to generate diversity at the immunoglobulin and T-cell receptor gene loci.

Translesion DNA Synthesis (TLS)

The process of TLS is another mechanism for dealing with thymine dimers and bases with bulky chemical adducts. At a DNA replication fork, DNA adducts may cause a replicative polymerase such as DNA polymerase delta to stall. Cells have, therefore, developed sophisticated mechanisms for switching off the replicative polymerase and switching on alternative polymerases (i.e., a polymerase such as pol eta, which will replicate past certain DNA lesions with high fidelity).[19] Interestingly, human cells have at least 15 DNA polymerases, although the situations and mechanisms of their deployment are largely unknown.[20] Cancer may have a heightened dependence on one of the error-prone TLS polymerases, such as polymerases β or kappa, accounting for high rates of mutagenesis. A schematic representation of TLS is shown in Figure 4-6.

Examples of Redundancy among the DNA Repair Pathways

Specific DNA repair pathways can antagonize the activity of anticancer agents. The status of a particular DNA repair pathway in a tumor may therefore predict the best antitumor therapy. As described earlier, at least two DNA repair pathways, BER and NER, are dedicated to the removal of DNA bases modified by monofunctional alkylating agents. BER can cleave the bond linking the modified base to the deoxyribose. NER, in contrast, will remove the entire modified nucleotide, along with a small stretch of surrounding nucleotides. In either case, the undamaged DNA can be used to synthesize the normal DNA sequence, followed by ligation of the segments.

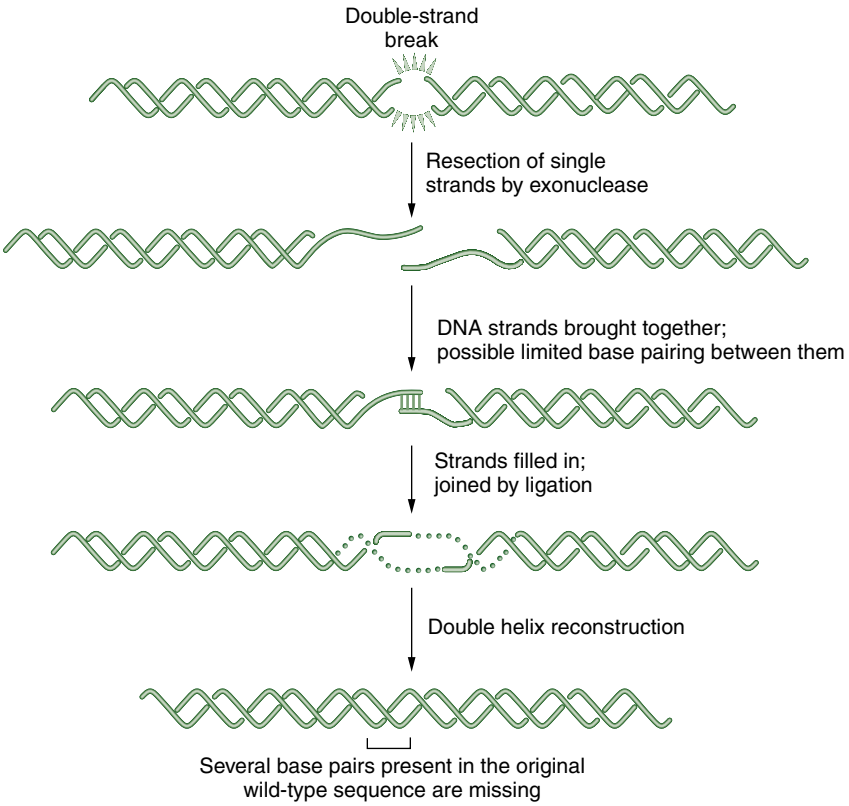

Figure 4-5 Schematic representation of nonhomologous end joining (NHEJ) NHEJ is an error-prone alternative to HR repair that can also be employed to repair double strand breaks. Since NHEJ does not use a homologous DNA template, such as a sister chromatid or a homologous chromosome, it often results in the insertion or deletion of new nucleotides at the fused DSB junction. In NHEJ, the DSBs are coated by the blunt end binding protein Ku. In some cases, the blunt ends may be brought together by limited microsequence homology. The enzymes DNA-PK, XRCC4, Artemis, and DNA ligase IV are required for the successful religation of the free ends. Interestingly, NHEJ appears to be the repair mechanism used for the cleavage and religation of immunoglobulin gene variable regions; thus the error-prone religation adds to the diversity of the somatically generated Ig gene repertoire. Germline mutations in some NHEJ genes, such as DNA-PK and Artemis, result in an inherited defect in NHEJ and a severe combined immunodeficiency syndrome.

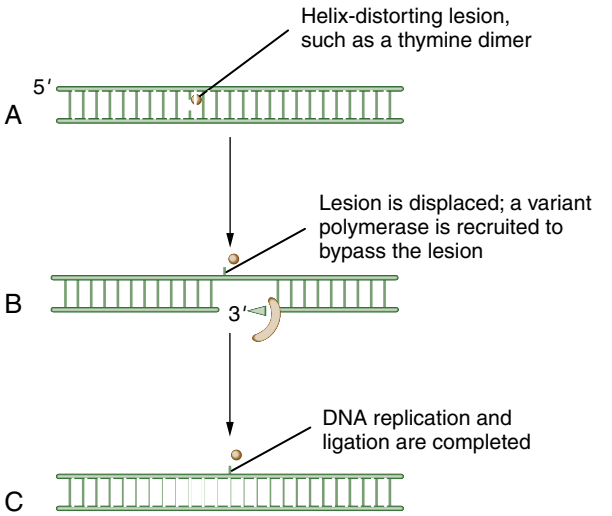

Figure 4-6 Schematic model of translesion DNA synthesis (TLS) repair TLS is not a DNA repair pathway per se; it is instead a mechanism of DNA damage bypass. In this process, an advancing replication fork encounters a damaged DNA base **(A)**. Although the replicative polymerase (the Pol delta complex) cannot read through the damaged base, a variant polymerase such as Pol eta can bypass the lesion. Cells have developed sophisticated mechanisms for switching polymerases **(B)**. For instance, in response to UV damage and the generation of a CPD (cyclopyrimidine dimer), the processivity factor, PCNA, becomes monoubiquitinated by RAD18. Modified PCNA now excludes Pol delta binding and has preferred binding for Pol eta. Pol eta is recruited, and it has the ability to "read through" the damaged base and insert the proper nucleotide (i.e., AA residues are replaced opposite the TT residues of a thymine dimer). Less is known about the regulation of TLS than about other DNA repair pathways. Depending on the kind of DNA damage, it is becoming increasingly clear that there are biochemical "switching" mechanisms for recruiting one of the other 12 TLS polymerases, as needed.

Cancer cells have other mechanisms for coping with modified bases. One enzyme, MGMT (0-6 methylguanine DNA methyltransferase), is capable of catalyzing the reversal of the chemical modification. Interestingly, this enzyme is switched off by MGMT gene promoter methylation in some solid tumors (gliomas and colorectal tumors), accounting, at least in part, for the hypersensitivity of these tumors to some monofunctional alkylating agents such as temozolamide.[21]

In addition, damaged bases in the DNA can be bypassed through the use of TLS. Through this mechanism, the modified lesions are sensed, the normal replicative polymerase is removed from the replication fork, and a new polymerase is invoked to bypass the lesions. Rapid TLS (damage avoidance) is essential in order for a cell to transverse S phase rapidly, without succumbing to replication arrest and apoptosis. Interestingly, however, TLS is an error-prone process, and the promiscuous use of TLS by cancer cells may result in their increased mutation frequency (see later discussion).

Some of the 15 variant polymerases can extend a nascent DNA strand past a thymine dimer or past a bulky DNA lesion. Other variant polymerases can replace a single nucleotide at the site of an unpaired base. One of these variant polymerases, referred to as POLeta, is mutated in the autosomal recessive human disease XP-variant (xeroderma pigmentosum variant). Absence of the POLeta enzyme results in UV light hypersensitivity, an inability to replicate

past thymine dimers, and a predisposition to squamous cell cancers.

The variant polymerases exhibit a variable level of fidelity. Important unanswered questions in the TLS research field include the following: (1) What are the circumstances and mechanisms for recruiting the variant polymerase to a specific damaged DNA site? and (2) Are any of these variant polymerases overexpressed or dysregulated in cancer, accounting for the elevated mutation frequency of solid tumors?

As described previously, IR causes double-strand breaks as well as a wide range of oxidative DNA damage. Two redundant DNA repair pathways, HR repair and NHEJ repair, are particularly adept at dealing with double-strand break damage in a cancer cell. In clinical oncology, some tumors that have defects in these DNA repair processes are particularly sensitive to the cytolytic activity of IR. Also, radiation resistance can emerge through the induction of these DNA repair activities in treated tumor cells. Tumor cells that grow in a more hypoxic environment may also be more resistant to the killing effect of IR, perhaps because of the decrease in oxidative damage generated in these cells.

Regulation of the Six DNA Repair Pathways

As described earlier, the major proteins involved with DNA repair include sensory (DNA binding) proteins, enzymes that remove damaged bases, and enzymes that restore the normal DNA sequence. A large number of regulatory enzymes also control each DNA repair pathway. These enzymes are required for switching DNA repair on and off, as needed by the cells. Regulatory enzymes, such as helicases, serve to load DNA repair complexes at the sites of DNA damage. Other regulatory enzymes, such as topoisomerases, serve to unwind damaged DNA, in order to facilitate DNA repair complex assembly, loading into chromatin, and disassembly.

A major subclass of regulatory enzymes add critical posttranslational modifications to DNA repair enzymes. For instance, in BER, a sumoylating enzyme modifies one of the glycosylases, TDG, thereby enhancing the activity of the glycosylase in removing damages bases.[22,23] In NER, an E3 ligase complex (Cul4A, DDB1, DDB2) activates the polyubiquitination of the XPC protein. This XPC modification is a necessary event for the downstream activity of the nucleotide excision repair complex.[24] In TLS, an E3 ligase, RAD18, monoubiquitinates the DNA processivity factor, PCNA, and allows this clamp to interact with the downstream DNA polymerase Pol eta. Many of these regulatory processes have recently been reviewed.[25]

Regulatory enzymes are also required to disassemble DNA repair enzymes after a repair pathway has been completed. For instance, the negative regulatory phosphatase, PP2A, removes phosphate from ATM substrates and thereby switches off the DNA damage response.[26] The deubiquitinating enzyme, USP1, can remove ubiquitin from activated FANCD2 and thereby switch off HR repair.[27] USP1 can also deubiquitinate PCNA and switch off TLS repair.[28,29] These negative regulatory events have also recently been reviewed.[25] The function of these regulatory enzymes underscores the dynamic nature of DNA repair. Loss of these regulatory mechanisms may result in the failure to (1) activate an error-free DNA repair pathway or (2) inactivate an error-prone DNA repair pathway. In either case, the consequence may be a heightened mutation frequency of the dysregulated cell and a predisposition to cancer.

Recent studies, generated through human cancer genome sequencing projects,[30] have demonstrated that some tumors, primarily melanomas and squamous cell lung cancers, have elevated levels of random point mutagenesis. This elevated point mutation signature indicates that these tumors (1) may have an underlying dysregulation of DNA repair and (2) may be more sensitive to specific therapies (see later discussion of synthetic lethality relationships). Finally, the regulation of DNA repair is a major focus of the DNA repair research field. For instance, it is unknown how DNA repair pathways are activated in specific cell types or at specific stages of the cell cycle. Because some DNA repair processes, such as HR repair, are specifically activated in S phase, it is likely that these pathways are activated by the cdk family of cyclin-dependent kinases. Several recent studies have performed shRNA screens to identify other regulatory genes that control DNA repair.[31-33] Many of these genes encode proteins that control the posttranslational modification of known DNA repair proteins or that regulate chromatin disassembly. Disruption of these gene products with shRNAs or small molecules can block DNA repair and further sensitize tumors to conventional cytotoxic cancer therapies.

Sequential Use of Three DNA Repair Pathways to Repair DNA Crosslinks

Interstrand DNA crosslinks (ICLs) make up a particular subtype of DNA lesions, and these lesions have an especially potent biological effect. Because ICLs involve the covalent modification of both strands of DNA, the lesions can prevent DNA strand separation during DNA replication. The lesions can also prevent the access of some DNA repair enzymes and transcription factors that normally require DNA strand separation for DNA binding to occur. DNA crosslinking agents, such as cisplatin derivatives (carboplatin

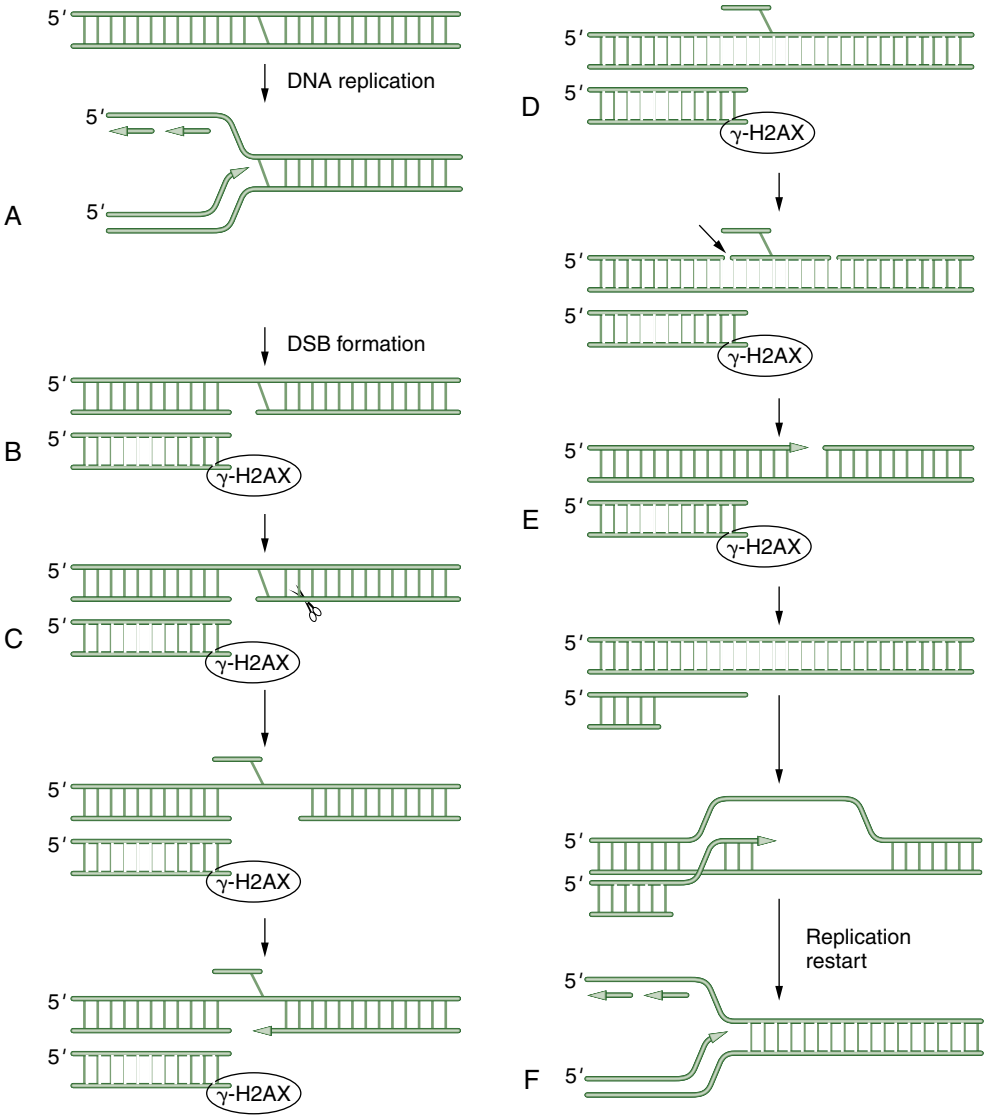

Figure 4-7 A schematic model of DNA crosslink repair DNA crosslink repair is believed to occur primarily during the S phase of the cell cycle. When a replication fork encounters an interstrand crosslink **(A)**, DNA replication arrests. Initially, a double-strand break is generated by an unknown endonuclease **(B)**. This DSB is next surrounded by phosphorylated histone 2AX. Next, another endonuclease (perhaps ERCC1/XPF) cleaves on the opposite side of the crosslink, allowing extrusion of the crosslinked bases from the double helix **(C)**. Next, a series of three DNA repair pathways act sequentially. Translesion synthesis (TLS) repair allows bypass of the damaged bases **(D)**. Then nucleotide excision repair (NER) excises the damaged oligonucleotide and allows gap filling **(E)**. Finally, end resection occurs, and the double-strand break can be repaired by homologous recombination (HR). The replication fork is regenerated in an error-free mechanism **(F)**.

and oxaliplatin) and mitomycin C, are especially cytotoxic to tumor cells, and their therapeutic index derives, at least in part, from the high proliferative rate of tumor cells versus normal cells.

The mechanism of DNA crosslink repair in human cells is poorly understood, and our understanding to date is derived more from the study of crosslink repair in prokaryotes and in the yeast *Saccharomyces cerevisiae*. As shown in Figure 4-7, crosslink repair in human cells probably requires multiple DNA repair pathways. According to this model, the ICL is only repaired during S phase progression. Initially, an advancing replication fork encounters an ICL. An unknown endonuclease cleaves the DNA, thus generating a double-strand break (DSB). Next, a second endonuclease is invoked to cleave the DNA after the DNA crosslink. Recent data suggest that this endonuclease may be made up of the ERCC1/XPF proteins.

Now that an endonucleolytic event has occurred on each side of the crosslink, the crosslinked single-strand fragment can be flipped out of the helix. This allows three of the normal DNA repair pathways to work sequentially. First, TLS allows bypass of the crosslink and replication and ligation of the upper double helix. Recent studies indicate that some variant polymerases, such as POL eta, are particularly important to the translesion synthesis across MMC adducts. Next, the NER pathway can excise a stretch of damaged DNA and allow gap filling of the excised oligonucleotide. Finally, HR repair can be used for the error-free, template-driven repair of the damage. The end result of this sequential use of three independent DNA repair pathways is to resume DNA replication and restart the replication fork.

Consistent with this model of crosslink repair, some repair-deficient cells are especially prone to the cytotoxic effects of DNA crosslinking drugs. For instance, cells that are

deficient in ERCC1/XPF generate the first double-strand break upstream of the DNA crosslink. However, these double-strand breaks, as measured indirectly by the presence of histone 2AX foci, persist in the repair-deficient cells, suggesting that ERCC1/XPF may work farther downstream in the pathway. Similarly, cells deficient in the FA pathway have persistent double-strand breaks after MMC exposure.[34] Thus, the presence or absence of the double-strand break intermediates is helpful in determining the level at which a repair process is disrupted and the sequence of repair events in the pathway.

DNA Repair and the DNA Damage Response

DNA repair is, in fact, only one class of a broader set of cellular responses referred to as the DNA damage response. DNA damage responses include the activation of cell cycle checkpoints, the activation of apoptosis, and the activation of DNA damage tolerance. This last mechanism allows a cell to "accept" DNA damage and continue DNA replication even in the setting of a heightened mutation frequency. The DNA damage response is therefore a highly coordinated set of signaling events. These responses require a DNA damage sensor (such as a sensor kinase, ATM, or ATR) and an effector kinase, as well as downstream protein machines dedicated to DNA repair, apoptosis, or checkpoint activities.[35]

The DNA Damage Response Is Mediated by Sensor and Effector Kinases

The DNA damage response can be activated by a wide range of environmental exposures or drug interactions. An important early player in the damage response is the molecular "sensor" of DNA damage. A local distortion in the DNA double helix, perhaps resulting from a DNA adduct or a thymine dimer, can activate a sensor kinase, such as ATM, ATR, or DNA-PK. These kinases are believed to autophosphorylate[36,37] and go on to phosphorylate a large number of substrates thereafter. The ATM kinase is the product of the ATM gene, the gene mutated in the cancer susceptibility disorder ataxia-telangiectasia.

Activated ATM and ATR proteins phosphorylate additional downstream "effector" kinases, such as the checkpoint kinases, Chk1 and Chk2. Activated Chk1 and Chk2 then go on to phosphorylate a wide array of protein targets involved in the machinery of DNA repair or DNA damage checkpoints.

One of the best-characterized DNA damage checkpoints is regulated by the ATM/Chk2/Cdc25A axis.[38,39] In response to IR, a double-strand break is generated, and this break activates ATM. ATM subsequently phosphorylates Chk2, which in turn phosphorylates the cell cycle activator cdc25A. Cdc25A phosphorylation leads to its rapid degradation and to cell-cycle arrest. This appears to be an important mechanism by which a cell can respond to DNA damage by arresting its cell cycle progression in S phase. By stopping S-phase entry, a cell allows itself the opportunity to slow down and to repair its DNA or, in the setting of severe damage, to undergo apoptosis. Importantly, a failure to activate this checkpoint response, as in ATM-deficient cells, results in S-phase progression even in the setting of DNA damage. Continuing to replicate DNA in the setting of DNA damage has dire consequences for the cells. The cell may have an elevated mutation rate or may complete DNA replication, only to experience a mitotic catastrophe at the end of the cell cycle.

Failure of ATM to activate the intra–S-phase checkpoint results in a characteristic cellular phenotype. When ATM-deficient cells are exposed to IR, they fail to arrest in S phase but instead continue to replicate their DNA and to incorporate tritiated thymidine in the postradiation period. This phenotype is known as radioresistant DNA synthesis (RDS), and it is the hallmark of a cell with a defect in the ATM/Chk2/cdc25A axis. An active area of DNA repair research is the identification of other CHK1 and CHK2 phosphorylated substrates.

Phosphorylated Effector Proteins Assemble in DNA Damage Foci

An important downstream event in the DNA damage response is the assembly of proteins in subnuclear foci.[40,41] These foci are often referred to as IRIFs (ionizing radiation inducible foci). Multiple ATM and ATR phosphorylated substrates, such as Chk1, BRCA1, and BARD1, assemble in foci following DNA damage. The assembly of these large protein complexes is mediated, at least in part, by the phosphorylated SQ or TQ sequences of the ATM/ATR substrates. Recent studies have indicated that these phosphorylated amino acid residues bind directly to phosphoamino acid receptors found on other adaptor proteins. For instance, phosphorylated BACH1 can bind directly to the BRCT domain (a phosphoserine receptor) of the BRCA1 protein.[42,43] The precise structure and function of these protein foci in eukaryote nuclei is not known. Clearly, the number of foci correlates with the number of unprocessed double-strand DNA breaks, and the foci are widely believed to be sites of double-strand break repair.

From immunofluorescence analysis, it is clear that multiple phosphorylated DNA-damage activated proteins colocalize in these foci. The foci have been helpful to researchers in the establishment of signaling pathways. For instance, pATM, pBRCA1, and pFANCD2 colocalize in IRIFs. Disruption of one upstream protein, say, by a germline or acquired mutation in the upstream signaling protein, ATM, results in loss of downstream proteins in the foci. The assembly of the foci therefore has become a useful tool in understanding the interrelationships of DNA response proteins.

A few DNA damage-response proteins deserve special attention here. Bonner and colleagues[40] have identified a variant histone protein, histone 2AX, that is rapidly phosphorylated by ATM after radiation damage. H2AX is an important early signaling protein in the DNA damage response. The phospho H2AX protein is incorporated in chromatin in vast stretches emanating from the site of the DNA DSB. An absence of histone 2AX, as in an H2AX knockout mouse model, results in chromosome instability and cancer predisposition,[44,45] apparently due to failure to mount the proper DNA damage response.

Another important DNA damage response protein is RAD51, which is phosphorylated by the Chk1 kinase during normal S-phase progression.[46] RAD51 is a single-strand DNA binding protein that plays a critical role in DNA repair by HR. Phosphorylated RAD51 also assembles in foci during normal S-phase progression. These "replication foci" are believed to be sites of DNA repair by HR between sister chromatids, which occurs during normal DNA replication.

A comprehensive analysis of proteins that are rapidly phosphorylated after DNA damage (and that form nuclear foci) has provided an important database for laboratories studying the DNA damage response. These phosphorylated proteins, and foci, provide a useful set of biomarkers for DNA repair activities. For instance, cells that are defective in the formation of DNA repair foci are themselves defective in DNA repair. The specific kind of focus that is absent correlates with the particular kind of DNA repair deficiency. For instance, cells deficient in RAD51 foci are defective in HR repair and are hypersensitive to IR. Cells defective in the assembly of polyADP ribose (PAR) foci are defective in the repair of single-strand breaks and may therefore have an underlying defect in BER. As such, tumor cells missing particular types of DNA repair foci may be more sensitive to certain kinds of chemotherapy or radiation.

Importantly, human cancers are often deficient in the DNA damage response. Germline mutations in DNA damage response genes, such as ATM, NBS1, FANCD2, BRCA1, and BRCA2, can result in an increased susceptibility to cancer. Individuals who inherit a single mutant allele of, say, BRCA1, have a high risk of developing a breast, ovarian, or prostate cancer during their lifetime. The tumor results from the inactivation of the second *BRCA1* allele, through deletion and loss of heterozygosity, thus resulting in a tumor with a specific DNA repair defect. BRCA(−/−) tumors therefore have genomic instability, but also have increased sensitivity to some DNA-damaging agents such as IR and DNA crosslinkers.

Study of the DNA damage response reveals that cells have highly regulated responses to different levels and types of DNA damage. Whereas some DNA repair pathways may be viewed as constitutive, housekeeping pathways, other pathways are highly controlled. Some DNA repair pathways, such as ATR and CHK1, are activated primarily at the site of the advancing replication fork, leading to the activation of HR repair.[47] Other DNA repair processes are activated in nondividing cells, such as in postmitotic neurons. For instance, NHEJ is hyperactive in nondividing cells and functions as the major mechanism of double-strand break repair in these cells.

The cellular context of the DNA repair pathway is also important. Germline or somatic disruption of a pathway may result in a strikingly different phenotype, depending on the cell and tissue of origin. For instance, gene line disruption of a DNA damage response, as in the inherited disease ataxia-telangiectasia, may lead to a characteristic constellation of clinical findings, including cerebellar degeneration and lymphoma predisposition. A somatic disruption of the same pathway (say, ATM CHk2-p53) may lead to a very different set of cancers, such as solid tumors of the bladder and ovary.[48,49]

Recent studies indicate that the DNA damage response provides an important "barrier" to the transformation of a normal cell to a malignant cell.[48,50] Specifically, early premalignant cells have heightened constitutive activation of the DNA damage response pathways, as exemplified by increased immunohistochemical staining with antibodies to activated ATM and to the activated checkpoint kinase CHK2. Interestingly, as cells progress from the premalignant state to the malignant state, they lose these DNA damage responses, perhaps through acquired disruptions of ATM or CHK2 activity. Because individuals with genetic diseases such as ataxia-telangiectasia already have a defect in the checkpoint response, they may be prone to earlier onset of cancers for this reason.

Inherited Chromosome Instability Syndromes as Models for DNA Repair Defects

Rare pediatric chromosome instability disorders, such as FA and XP, provide important insights into the function

of DNA repair pathways and their role in cancers in the general population. Children born with these syndromes generally have congenital abnormalities, cellular hypersensitivity to DNA-damaging agents, genomic instability, and an increased risk of specific cancers. Although these syndromes are rare, the DNA repair pathways disrupted by germline mutations in these individuals are often the same pathways disrupted by somatic mutation or epigenetic inactivation in cancers from the general population. For these sporadic cancers, a knowledge of which DNA repair mechanism is disrupted provides important clues to the behavior of the cancer or its drug sensitivity spectrum.

At least five of the major DNA repair pathways have corresponding inherited human diseases (Table 4-1). HR and TLS repair is defective in FA cells.[51] NER repair is defective in XP cells, Cockayne syndrome (CS) cells, and trichothiodystrophy cells.[52] MMR repair is defective in children with Turcot syndrome and in tumor cells derived from adult patients with HNPCC. TLS repair is defective in patients with the XP-V (xeroderma pigmentosum variant) disease. Most of these pediatric diseases exhibit autosomal recessive inheritance, such as XP, FA, and CS. Turcot syndrome has been reported to exhibit autosomal dominant or autosomal recessive inheritance depending on the particular mutation affecting mismatch repair. Inherited mutations in BER genes have not been observed in humans, suggesting that this pathway is essential for human development.

It is interesting that patients with inherited DNA repair syndromes, such as CS and FA, have congenital abnormalities. For instance, CS patients have developmental abnormalities of the skin and skeletal system. FA patients have skeletal, kidney, cardiac, and bone marrow defects. Consistent with these findings, the NER and FA pathways appear to play dual roles. For instance, the NER excision repair complex, TFIIH, plays an important transcriptional role during embryonic development. Germline dysfunction therefore leads to defects during embryonic organogenesis. The NER complex also plays a critical role in DNA repair in somatic cells after organism development. Similarly, the FA pathway appears to have a dual role in both development and DNA repair in somatic cells.

The systematic study of these rare diseases has led to (1) a better understanding of the genes and proteins involved in the six major DNA repair pathways, (2) how an inherited (or germline) defect in a DNA repair pathway can lead to genomic instability, cancer progression, and drug hypersensitivity, and (3) how an acquired (or somatic) defect in a DNA repair pathway can influence tumor progression and drug sensitivity of tumors in the general population. Although the specific details of these individual inherited diseases is beyond the scope of this review, an example of how a study of these rare diseases can lead to general insights to tumor biology can be appreciated from recent insights into the FA pathway.

Fanconi Anemia: A Specific Inherited DNA Repair Defect

FA is an autosomal recessive or X-linked recessive cancer susceptibility syndrome characterized by multiple congenital abnormalities, progressive bone marrow failure, and cellular hypersensitivity to DNA crosslinking agents, such as cisplatin and mitomycin C (MMC). FA patients are prone to developing acute myeloid leukemia as well as squamous cell carcinomas of the head and neck or gynecologic system.[53]

The study of FA cells has led to the elucidation of a DNA repair pathway for interstrand crosslinks. Clinically, this pathway is particularly important because many DNA crosslinking agents such as cisplatin or mitomycin C are used for cancer treatment. The FA defect results from biallelic mutation of any one of 15 known FA genes (A, B, C, D1, D2, E, F, G, I, J, L, M, N, O, P). The proteins encoded by these FA genes cooperate in a common DNA repair pathway, referred to as the FA/BRCA pathway.[53,54] A central event in this pathway is the monoubiquitination of the FANCD2 protein, and this event is a useful biomarker for DNA repair activity (see later discussion). Disruption of this pathway results in the characteristic clinical and cellular phenotype of FA patients.

Patients with an Inherited Germline DNA Repair Deficiency Exhibit a Characteristic Tumor Spectrum

Patients with inherited DNA repair deficiency syndromes are prone to the development of specific tumors. FA patients, for example, are predisposed to acute myeloid leukemia and squamous cell carcinomas, primarily of the head and neck or gynecologic system. Patients with XP are prone to skin squamous cell carcinomas, primarily on body surfaces with more sunlight exposure. Patients with HNPCC and an inherited MMR deficiency are prone to colon cancer and ovarian cancer.

Tumors arising from somatic disruptions of DNA repair pathways may arise in other organ systems. A specific oncogenic lesion, such as the activation of an oncogene or the disruption of a tumor suppressor gene, may have a vastly different effect depending on the cellular context of the lesion. For instance, a germline mutation in the Rb gene may result in an embryonal tumor, such as a retinoblastoma or a pineoblastoma, but a somatic disruption of the Rb gene may lead to the development of a sarcoma.

Similarly, disruptions of a DNA repair pathway by a germline mechanism, rather than a somatic mechanism, may yield a very different spectrum and behavior. Examples are shown in Table 4-1. Somatic disruption of the FA pathway results in a wide range of tumor types, including tumors of the ovary, lung, and cervix.[51,55] Moreover, somatic disruptions result from methylation and silencing of an upstream FA gene (FANCF). Germline disruption of the same genes results from inherited mutations, such as missense mutations or nonsense mutations. Somatic disruption of the NER pathway plays a role in the development of testicular cancer and appears to account for the hypersensitivity of this tumor to the drug cisplatin. Paradoxically, somatic disruption of a DNA repair pathway can also result in chemotherapy resistance. Studies indicate that methylation and silencing of the MLH1 gene may account, at least in part, for the cisplatin resistance of some ovarian tumors.

Disruption of the other DNA repair pathways has been observed in sporadic human tumors, accounting, at least in part, for the specific drug and radiation sensitivity spectrum of these tumors and their clinical outcome. HR is disrupted in breast and ovarian cancer, NER is disrupted in testicular cancer, and MMR is disrupted in sporadic colon cancer. A few studies suggest that TLS may be disrupted in human cancers. Human cancer cells exhibit an elevation in spontaneous and damage-inducible point mutagenesis, compared to nonmalignant cells, suggesting an underlying TLS defect. Recent studies indicate that an elevation in the expression and activity of the error-prone polymerase Pol beta accounts for the increase in cisplatin resistance and mutagenesis of these cancers. Consistent with this hypothesis, inhibition of Pol beta in these cells results in resensitization to cisplatin.[56]

Somatic Disruption of DNA Repair Pathways by Methylation and Gene Silencing

One of the most common mechanisms of inactivation of DNA repair pathways in sporadic cancer is the epigenetic silencing of a critical gene through methylation of the promoter region. Increasing evidence shows that the FA/BRCA pathway is one of the DNA repair mechanisms that is targeted in sporadic cancers. *FANCF* methylation occurs in 24% of ovarian granulosa cell tumors, 30% of cervical cancer, 14% of squamous cell head and neck cancers, 6.7% of germ cell tumors of the testis, and 15% of non–small-cell lung cancers, where it correlates with a worse prognosis. An example of how methylation of a DNA repair gene can promote tumor progression is shown in Figure 4-8.

By regulating the activity of DNA repair pathways, cancer cells have a propensity to progress to a more malignant state. According to this model, early in the course of tumorigenesis, a premalignant cell may undergo a methylation and silencing of a DNA repair gene. In the case of the FA/BRCA pathway, the gene most commonly silenced by methylation is the *FANCF* gene on chromosome 11p15. Inactivation of *FANCF* results in a disruption of DNA repair and in genomic instability. The premalignant cell is therefore prone to multiple oncogenic events, such as the upregulation of a tyrosine kinase oncogene or the disruption of p53. A tumor with multiple somatic mutations eventually develops (see Figure 4-8), but this tumor still has a defective DNA repair pathway and is hypersensitive to genotoxic chemotherapy. After antitumor therapy, however, there is a selective pressure for tumor cells with an intact FA/BRCA

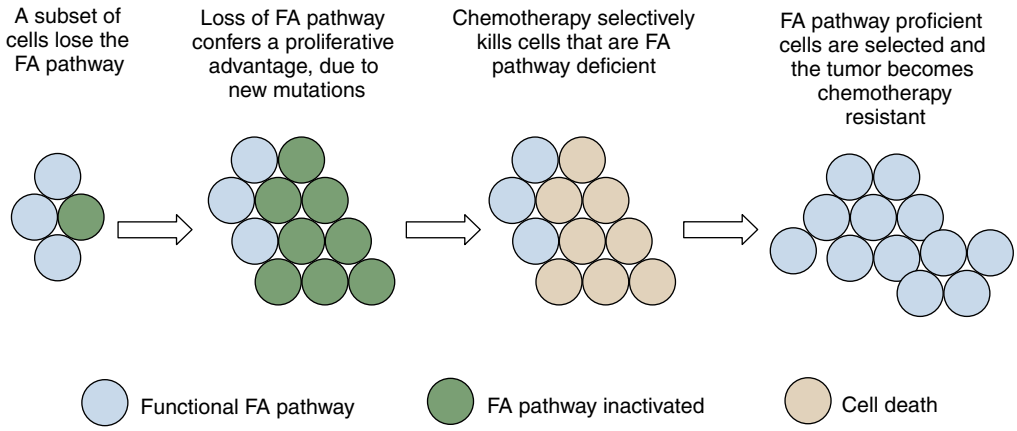

Figure 4-8 Tumor progression by serial inactivation and reactivation of DNA repair pathways According to this model, early in the course of carcinogenesis, a DNA repair pathway becomes inactivated. For instance, the *FANCF* gene may undergo biallelic methylation and silencing. This loss of the FA/BRCA pathway results in a state of chromosome instability, leading to secondary mutations (activation of K-Ras, inactivation of p53, for example). A tumor evolves, and the tumor is initially hypersensitive to cisplatin, as is often the case for ovarian epithelial cancer. Cisplatin causes rapid cytolysis of the tumor; however, rare tumor cells undergo a restoration of FANCF expression. Restoration may result either from an active demethylation of the *FANCF* gene or from positive selection of rare cells that experienced a stochastic demethylation event. Tumor cells regrow, and these cells are now cisplatin-resistant. In principle, an inhibitor of the FA/BRCA pathway can resensitize the tumor cells to cisplatin, as described in the text.

pathway. Tumor cells with a demethylated *FANCF* gene are selected, and a drug-resistant tumor emerges. By following this pattern, tumors can silence and reactivate DNA repair pathways, leading to drug resistance and tumor progression.

The converse scenario may occur for the MMR pathway. MMR-proficient cells are hypersensitive to the DNA crosslinking drug cisplatin. In this case, it is believed that the active MMR pathway generates a cisplatin-inducible lesion that is tumoricidal. Inactivation of MMR by methylation of the MSH2 gene therefore provides the tumor with a mechanism for achieving cisplatin resistance. Based on these examples, it appears that understanding the methylation state of various DNA repair genes may allow the prediction of drug responsiveness of some tumors.

Epigenetic silencing of *BRCA1* through methylation occurs in 13% of breast cancers, 23% of advanced ovarian cancers, 6% of cervical cancers, and 4% of non–small-cell lung cancers. Epigenetic disruption of the FA pathway may also be important in the development of sporadic acute myeloid leukemia (AML), where absent or reduced expression of the FA proteins FANCA, FANCC, FANCF, and FANCG has been reported. Loss of BRCA2 mRNA and protein expression has been reported in 13% of ovarian adenocarcinomas; in contrast to the other FA genes described earlier, this loss does not result from promoter methylation.

Prognostic and Predictive DNA Repair Biomarkers in Cancer Treatment

Both hereditary cancer syndromes and sporadic cancers can arise from abnormalities in DNA repair pathways. This may be clinically important because these tumors are expected to be hypersensitive to DNA-damaging therapeutic agents or strategies that inhibit alternative DNA repair pathways. In the case of sporadic cancers, the patient's normal cells, such as those in the bone marrow, possess a functional DNA repair pathway and are predicted to be resistant to these targeted treatments. Assessment of the status of the FA pathway or other DNA repair pathways requires the use of diagnostic biomarkers.

Selection of Biomarkers of DNA Repair Pathways

Biomarkers of DNA repair pathways can be divided into two major groups: functional biomarkers that characterize the activity of a pathway following damage and expression biomarkers that measure the availability of pathway components before damage.

Functional DNA Repair Biomarkers

These are biomarkers that indicate an intact DNA repair pathway. These biomarkers have the advantage of giving a functional measure of a particular pathway and will detect repair defects due to epigenetic events or gene mutations. Moreover, they give a global measurement of a particular pathway's function without the need to know the identities of all the components. They could also be used to differentiate between insignificant single-nucleotide polymorphisms (SNPs) and functionally important point mutations in DNA repair pathway genes. Functional biomarkers can be applied to serial tumor samples from the same patient, at diagnosis and at the time of relapse. In this way, one can determine whether the tumor remains drug sensitive or has restored its DNA repair mechanisms. However, these markers rely on tumor tissue having been exposed to some form of DNA damage in vivo or in vitro before the assay. Functional biomarkers of DNA repair pathways include the monoubiquitination of the FANCD2 protein (a biomarker for HR repair) and the phosphorylation of DNA-PK (a biomarker of a functional NHEJ pathway). Abnormal DNA-damage–induced nuclear foci may identify disruption of the downstream events in the pathway, such as that observed in BRCA1- or BRCA2-deficient cells.

DNA Repair Biomarkers of Gene/Protein Expression

These biomarkers indicate the preexisting function of a DNA damage pathway before damage. Examples are real-time polymerase chain reaction (rt-PCR) or immunohistochemistry to test for epigenetic silencing of critical DNA repair genes. Some studies have used a microarray approach to look for genetic expression profiles indicative of abnormal DNA repair gene function. Because some DNA repair genes, such as MLH1 and MSH2, are inactivated by methylation, measurement of gene methylation via the methylation-PCR assay can also be applied as a biomarker assay. These approaches have the advantage of not requiring prior DNA damage and can be performed on fixed specimens. However, they provide only an indirect measurement of the functional capabilities of a DNA repair pathway. In addition, mutant genes can express normal levels of mRNA, and mutant protein and would not be detected by this method.

Clinical Application of DNA Repair Biomarkers

DNA Repair Biomarkers as Predictors of Response to Conventional Therapy

Loss or increased activity of particular DNA repair pathways may influence the response to DNA-damaging therapeutic strategies. For instance, a failure of a pathway

involved in the repair of DNA crosslinks such as HR would be predicted to sensitize a tumor to DNA crosslinking agents such as alkylating chemotherapeutic drugs. Indeed, BRCA1 expression levels as measured by rt-PCR have been used as a biomarker of survival following cisplatin-based chemotherapy for non–small-cell lung cancer. Methylation-specific PCR, which indicates loss of gene expression through promoter methylation, has been used to correlate loss of BRCA1 function with cisplatin sensitivity in ovarian cancer. Loss of *BRCA2/FANCD1* function through mutation in breast or ovarian cancer has also been reported to correlate with a high response to DNA-damaging chemotherapeutic agents. Absence of FANCD2 monoubiquitination may be a biomarker for loss of function of upstream FA pathway components and could be expected to predict sensitivity to DNA crosslinkers such as cisplatin or cyclophosphamide.

A recent example of the use of DNA repair biomarker in clinical medicine is the evaluation of ERCC1 protein expression levels in lung cancer. The NER pathway is important for the correction of UV-light–induced thymine dimers and for the excision of small single-base adducts. In addition, two of the proteins involved in NER, ERCC1 and XP-F, appear to have special relevance to the repair of DNA interstrand crosslinks. Primary cells derived from XP patients with germline mutations in ERCC1 or XPF are hypersensitive to UV and to DNA crosslinking agents.[57] Recent studies also suggest that the protein level of ERCC1 in cell lines correlates with the level of functional DNA crosslink repair in the cell.

Several groups have performed retrospective analyses of non–small-cell lung cancer patients who had been treated with adjuvant chemotherapy, including cisplatin. The banked primary tumor samples, which were stored in paraffin blocks, were evaluated for the level of ERCC1 protein by immunohistochemistry (IHC). Interestingly, the patients with tumors exhibiting low ERCC1 levels were more sensitive to cisplatin, based on their longer average time to relapse after cisplatin, compared to patients whose tumors had high levels of ERCC1. Together these studies indicate that ERCC1 protein expression may be a useful predictive biomarker for assessing tumor response to cisplatin.

DNA Repair Biomarkers to Guide Chemo- and Radiosensitization

Resistance to DNA-damaging chemotherapy or radiotherapy may be due to enhanced repair of DNA lesions. Therefore, a possible therapeutic strategy is to use drugs that specifically inhibit DNA repair pathways. Theoretically, this strategy may be limited because the drug may also increase the toxicity of therapeutic DNA damage in normal tissue. A therapeutic index can be achieved, in principle, by (1) selective uptake of the DNA damage sensitizers by the tumor cell, versus the normal cell, or (2) delivering one of the modalities (such as the radiation) directly to the tumor.

An understanding of the precise molecular mechanisms of new classes of sensitizing agents has important implications. First, if an agent functions by inhibiting a specific DNA repair pathway, then active derivatives of this agent should function similarly. DNA repair pathway inhibition provides an important biomarker for determining the proper dosing of the drug. Second, the chemosensitizer would be predicted to be more efficacious when used in combination with specific classes of DNA damage drugs.

DNA Repair Biomarkers as Predictors of Response to Targeted Monotherapy

Another important application for biomarkers of DNA repair pathway integrity is the potential to develop nontoxic monotherapy for tumors with specific DNA repair defects. The upregulated DNA repair pathway is the "Achilles heel" of the cancer. In principle, a nontoxic inhibitor of this second pathway, delivered as a monotherapy, may selectively kill the cancer cell. A normal cell, in comparison, may be able to tolerate the loss of this second pathway because other pathways are functioning and there is more redundancy in its DNA repair capacity.

This principle has recently been demonstrated by the use of PARP inhibitors in BRCA1- and BRCA2-deficient cells.[11,12] As discussed earlier, under normal physiological conditions DNA is being damaged continuously. The result of these stresses is the development of damaged bases or regions of single-strand DNA breaks that are repaired through the BER pathway. Part of the BER pathway requires PARP, a DNA-binding zinc finger protein that catalyzes the transfer of ADP-ribose residues from NAD^+ to itself and different chromatin constituents, forming branched ADP-ribose polymers. Initially it was observed that PARP-deficient (and therefore BER-deficient) mice develop normally but have high levels of sister chromatid exchange, a feature of HR. This observation suggested that HR could compensate for a loss of PARP-dependent BER. Consequently it was demonstrated in preclinical models that BRCA1- and BRCA2-deficient human and murine cells were sensitive to PARP-inhibiting drugs, whereas cells expressing normal levels of BRCA1 or BRCA2 were unaffected. PARP1 inhibitors are well tolerated in preclinical murine models and, in addition to being a potential treatment for BRCA1 and BRCA2 mutant tumors, may also represent an attractive strategy for chemoprevention of malignancies in mutation carriers. Clearly a biomarker that indicates a failure of BRCA1 or BRCA2 function in tumor cells may allow the application of PARP inhibitors to a wider spectrum of sporadic human malignancies.

The Development of New DNA Repair Biomarkers

Few biomarkers exist at present for evaluating the integrity of the other DNA repair pathways. Several studies have attempted to assay these pathways, using expression biomarkers (i.e., testing the expression levels of known DNA repair proteins in the pathways.) Better functional biomarkers are needed. Recent studies have indicated that posttranslational modifications of DNA repair proteins in these pathways are also required for pathway activity. For instance, polyubiquitination of XP-C is required for functional NER,[24] and sumoylation of thymine-DNA glycosylase[22] is required for function of BER. The development of antibodies specific for these activated states and the testing of these biomarkers may allow the rapid assessment of drug sensitivity and acquired resistance in clinical samples.

DNA Repair Inhibitors as a New Area for Anticancer Drug Development

As shown in Figure 4-9, normal human cells may have six functional DNA repair pathways, whereas a tumor cell may have disruptions of one pathway. In the tumor, disruption of one pathway, such as HR repair, results in genomic instability and hyperdependence on a second pathway, such as BER. Because of this hyperdependent state, the tumor cell may be hypersensitive to an inhibitor of BER, such as a PARP1 inhibitor.

In this case, the tumor may respond to the PARP1 inhibitor as a single agent (monotherapy).[58-60] DNA damage, activated by the hyperproliferative state of the tumor cell, may be sufficient to kill the tumor cell. Alternatively, the PARP1 inhibitor may have a greater tumoricidal effect when it is used in combination with another cytotoxic agent, such as IR or an alkylating agent (TMZ).

Based on the early success with PARP1 inhibitor therapy, there is increasing interest in the identification of inhibitors of other DNA repair pathways.[61] For instance, an inhibitor of the sensor kinase ATM has been shown to have potent tumoricidal effects.[62] Also, inhibitors of the Chk1 kinase UCNO1 have been used in clinical trials.[35,63,64] Investigators have also begun to screen for inhibitors of HR repair that may potentially sensitize tumor cells to IR or to crosslinker damage.[65,66] Although DNA repair inhibitors may sensitize a tumor to the cytotoxic activity of conventional IR or chemotherapy, they may also enhance the toxicity of these therapies to normal human cells.

Importance of DNA Repair to Clinical Oncology: Other Specific Examples

BRCA1 and BRCA2

The importance of DNA repair to the pathogenesis and treatment of cancer is exemplified by studies of the breast cancer susceptibility gene BRCA1. Approximately 10% of women who develop breast cancer in their lifetime have a strong family history of (inherited) breast cancer. Of these women, approximately half are heterozygous carriers for mutations in either the *BRCA1* or *BRCA2* gene.

The *BRCA1* gene was originally mapped to human chromosome 17,[67] and it was subsequently cloned by position.[68] Strong evidence emerged that *BRCA1* is a tumor suppressor gene, since breast carriers have loss of heterozygosity at the *BRCA1* locus.[69] *BRCA1*-deficient breast tumor cells are hypersensitive to IR and to DNA crosslinking agents,

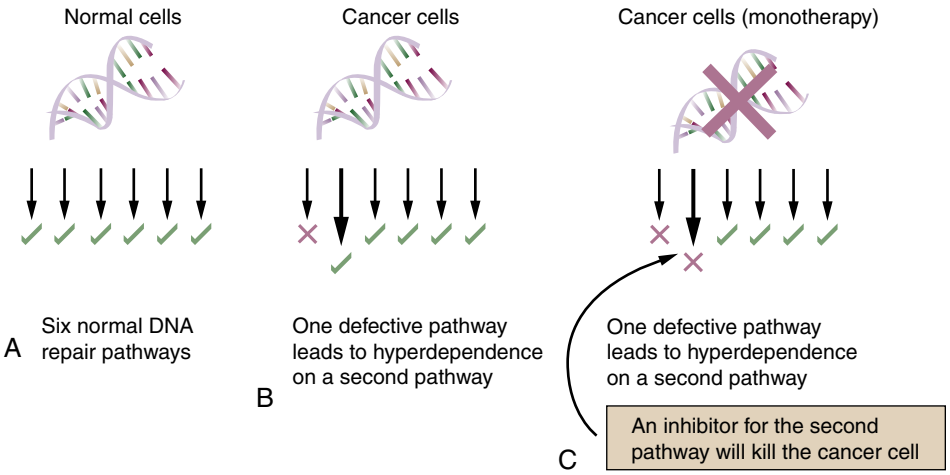

Figure 4-9 Principle of DNA inhibitor monotherapy (A). Normal human cells have six DNA repair pathways. **(B)** Tumor cells, in contrast, have disrupted one DNA repair pathway through somatic mutation, loss of heterozygosity (LOH), or epigenetic silencing of a DNA repair gene in that pathway. The tumor cell has genomic instability and has partially compensated for its DNA repair defect by upregulating a second pathway. **(C)** The tumor is hyperdependent on this second pathway, and a specific inhibitor kills the tumor cells but has little effect on the normal cells. An example of this monotherapy approach has been described for PARP inhibitors.[11,12]

suggesting that *BRCA1* may function in the regulation of HR repair.

Studies with the BRCA1 protein indicate that, during the DNA damage response following cellular exposure to a genotoxic stress, BRCA1 is phosphorylated and accumulates in subnuclear foci that colocalize with BRCA2 and RAD51 proteins.[70,71] These foci are required for competent DNA repair. The precise role of BRCA1 in DNA repair is unknown. Because BRCA1 is itself an E3 ubiquitin ligase,[72] it may function by ubiquitinating other DNA repair proteins and regulating DNA repair indirectly. Recent studies have identified key ubiquitinated substrates of BRCA1, including the protein CTIP.[73]

Because BRCA1 (and BRCA2) tumors are deficient in HR repair, this genotype may be useful in the selection of chemotherapy, as described earlier for these tumors. Recent studies indicate that BRCA1-deficient tumors are hyperdependent on BER and have elevated PARP1 activity.[11,12] Accordingly, BRCA1- and BRCA2-deficient tumors appear to be hypersensitive to PARP1 inhibitors.

Defects in DNA Repair Pathways Can Account for the Elevated Mutation Rate of Cancer

Cancer cells have an increased mutation rate compared to normal cells, and this phenotype has important clinical consequences. The increased mutation frequency can lead to point mutation and inactivation of tumor suppressor genes or to increased tumor cell resistance to chemotherapy. The increased mutation rate may also account for the increased spontaneous cell death observed in solid tumor samples (i.e., some of the mutations may be lethal to individual tumor cells), but may also enhance the outgrowth of a more malignant clone.

This increased mutation rate results in large part through the disruption of DNA repair pathways. The MMR pathway normally functions to improve the fidelity of DNA replication by quickly identifying and excising mismatched bases generated by faulty DNA replication. Loss of the MMR pathway by germline or somatic mutation can lead to a "mutator" phenotype. This phenotype can be readily detected by microsatellite instability in the genome of the cancer cell.

This increase in mutation rate can also be accounted for by an increase in error-prone DNA repair mechanisms.[74] In the setting of elevated translesion synthesis, some error-prone polymerases, such as Rev3, may increase the frequency of point mutations in the genome of the human cancer. Also, an elevation in the error-prone NHEJ pathway may account for the elevated complex mutations (insertions and deletions) observed in some cancers. Many human tumors have recently been found to express abnormal levels of polymerase β,[75,76] which may also contribute to their increased mutation frequency.

Multiple Mechanisms of Cisplatin Resistance

Recent studies indicate that the status of DNA repair pathways in human tumors may be highly predictive of cisplatin sensitivity. As mentioned previously, defects in the NER pathway may account for cisplatin sensitivity of some testicular and non–small-cell lung cancers.

Defects in HR repair may account for the cisplatin sensitivity of ovarian and head and neck carcinomas. Other cellular mechanisms may also account for the intrinsic cisplatin resistance of many human tumors. Cisplatin-mediated tumoricidal activity can be affected by (1) the expression of cell surface P-glycoprotein, an efflux mechanism for removing cisplatin, and (2) the relative antiapoptotic state of the tumor cell, based at least in part of the level of BCL-2 and BCL-X expression. Primary cisplatin resistance may therefore rely on the systematic assay of many of these mechanisms in a given tumor cell.[77]

DNA Repair Gene Polymorphisms as Predictors of Chemotherapy Responsiveness

As described earlier, disruption of the NER pathway appears to account, at least in part, for the cisplatin hypersensitivity of testicular cancers and of some ERCC1-deficient non–small-cell lung cancers.[17] The disruption of the NER pathway may result from definitive mutations (i.e., frame-shift or nonsense mutations) in NER genes or from epigenetic changes, such as methylation and silencing of NER genes. In some cases, the disruption of the NER pathway may be partial, and it may result from DNA repair gene polymorphisms carried in the germline of the cancer patient.

In principle, DNA repair polymorphisms may result in a subtler DNA repair defect. Such a defect may increase the risk that an individual develops a cancer or may increase the likelihood that the resulting tumor is sensitive to a specific genotoxic agent. Based on this idea, investigators have screened large tumor sets for the enrichment of particular SNPs in DNA repair genes. Common SNPs are known for the NER genes XPD, ERCC1, and XRCC1. SNPs in multiple NER genes appear to account, at least in part, for the cisplatin hypersensitivity of some squamous cell carcinomas and lung cancers. Whether these SNPs will serve as

predictive biomarkers for chemotherapy or radiation sensitivity remains unproven.

Conclusion

Genomic instability is characteristic of most human malignancies, and this phenotype can arise from acquired defects in any one of six DNA repair pathways. These pathways are MMR, BER, NHEJ, NER, HR, and TLS. The germline disruption of these pathways accounts for the pathogenesis of several inherited DNA repair disorders including FA, XP, and HNPCC. The somatic disruption of these pathways can account for the genomic instability and drug sensitivity of many tumor types. The six pathways differ significantly in their ability to repair modified DNA bases and DNA crosslinks. Different cell types and tumor cell types have differential dependence on these pathways for growth and survival.

In the future, the development of biomarkers for the function of other DNA repair pathways may allow the better targeting of conventional agents or the use of monotherapies designed to inhibit specific repair pathways. The biomarkers can also be used as screening tools to find inhibitors of DNA repair that function as chemosensitizers. We predict that these approaches should reduce the toxicity of existing cancer treatments by eliminating the use of noneffective agents and by directing the development of novel treatment strategies.

Understanding the status of DNA repair pathways in tumor cells will have considerable use in clinical oncology. If a tumor is defective in one pathway (say, NHEJ), it may be directly sensitive to IR, a modality that generates double-strand breaks in DNA. If a tumor is defective in another pathway (say, HR) it may be hyperdependent on a second pathway (say, BER) for its survival. Accordingly, a drug, such as a PARP1 inhibitor, that targets the BER pathway may be selectively toxic to these tumors. Recent studies indicate new synthetic lethal relationships among DNA repair pathways. MMR-deficient tumors are hypersensitive to ATM inhibition.[78] A complete understanding of the synthetic lethal relationships of all six of the major DNA repair pathways is an important future goal of DNA repair research in cancer.[66]

5 Epigenetics and Cancer

It has been known for decades that genetic alterations are a fundamental driving force in the initiation and progression of human cancers. It is also now apparent, through a more recent and growing body of work, that epigenetic changes may be equally important in tumor development. *Epigenetics* refers to heritable changes in gene expression in somatic cells that are determined by other than alterations in the primary base sequence of DNA.[1] In essence, the primary sequence of DNA provides the "hard drive," storing all information to determine cell phenotypes. However, to selectively function, DNA requires the "software packaging" of epigenetics to guide patterns of heritable gene expression. In this way, different cell phenotypes emerge against a common DNA sequence background to facilitate processes such as embryonic development and cell differentiation. Just as DNA mutations can mediate individual stages of tumor development by fostering over-, or under-, function of key genes, epigenetic abnormalities can heritably allow similar gene expression aberrations. In this chapter, features are outlined of this latter form of altered gene function and how it is coming to affect the understanding and management of human cancer.

The Molecular Basis for Epigenetic Control of Gene Expression

To specify regions of DNA that contribute to gene expression patterns in a cell, the exposure of sequences to, and the function of, the transcriptional machinery is controlled by packaging of the DNA in the nucleus.[1] This is accomplished, as described later, through a complex and dynamic interaction of DNA with proteins to constitute cellular chromatin, which undergoes posttranslational modifications to establish the transcriptional and regulatory activity of DNA regions and individual genes.[1] This DNA regulation is also modulated by patterns of the only postreplicative modification made directly to DNA, methylation at cytosines located ahead of guanosines (the CpG dinucleotide) in the genome.[1] Alterations to all of these processes are being increasingly identified as important to the evolution of cancer.

The basic molecular unit of DNA packaging, the nucleosome is a structure characterized by the wrapping of approximately 146 bp of DNA around what is termed the *histone octamer* consisting of a tetramer of two histone H3, H4 dimers and a dimer of histone H2.[2] Groups of nucleosomes may in turn be organized into higher order structures through the actions of chromatin remodeling complexes.[3-5] Tightly compacted nucleosome aggregates, or "closed chromatin," are characteristic of DNA regions that are transcriptionally silent, versus more irregularly and linearly spaced nucleosomes, or "open" chromatin, characteristic of DNA regions where transcription is active.[6,7]

One of the most exciting and dynamic areas of chromatin biology concerns another key facet of nucleosome function, posttranslational modification of key amino acid residues of the histones, that helps determine the transcriptional status of genomic regions (Figure 5-1). These modifications constitute what has been termed the *histone code* for gene expression regulation.[8-10] Thus, acetylation of key residues, such as lysine 9 of histone H3 (H3K9acetyl), by enzymes known as histone acetylases (HATs) usually specifies for transcriptionally active regions while deacetylation at these sites, mediated by histone deacetylases (HDACs), is usually associated with transcriptional repression. Methylation of key amino acids also occurs and may be an activating or inactivating mark, depending on the site. For example, the mark of H3K4 methylation is enriched at active areas, whereas H3K9 methylation or H3K27 methylation is characteristic of transcriptionally repressed regions.[8-10] These methylation marks are controlled by a dynamic process involving individual histone methyltransferases, which place the marks, and demethylases, which can remove them.[11-15]

Interacting with all of the dynamics for nucleosome assembly, placement, and histone modifications, to mediate nuclear packaging of DNA, is the modification of DNA methylation (see Figures 5-1 and 5-2). This process, which as noted earlier occurs predominantly in all but embryonic stem cells (ESCs) at CpG dinucleotides, is mediated by three DNA

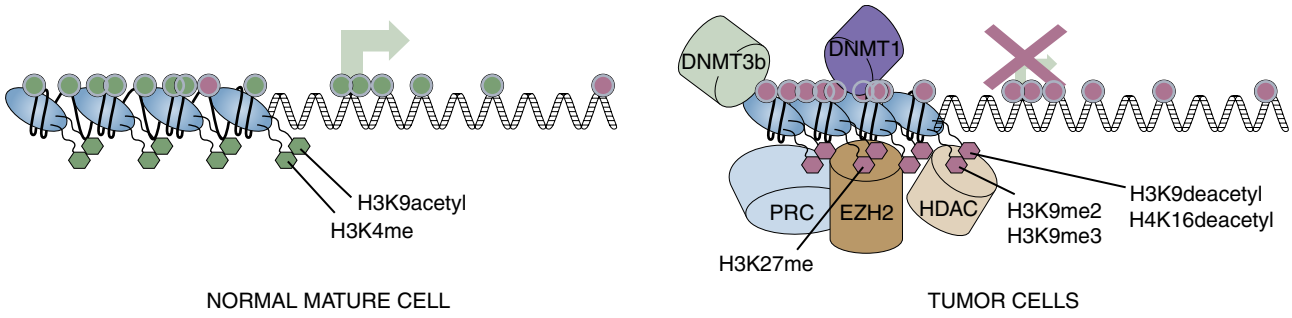

Figure 5-1 Chromatin surrounding an actively expressed gene in a normal mature cell versus surrounding that same gene when it is DNA hypermethylated and aberrantly, heritably, silenced in a tumor cell. On the left, the chromatin is composed of histone modifications associated with active transcription (H_3K_4me) and (H_3K_9acetyl), and the DNA is largely unmethylated at CpG sites *(green circles)* with only occasional methylation (*red circles*). The nucleosomes *(large blue ovals)* are linearly arranged as associated with the areas of active transcription defined in Figure 5-2. The gene on the right is fully transcriptionally repressed *(large red X);* the DNA is methylated and DNA methylating enzymes are present (DNMT1 and -3b); HDACs are present to catalyze histone deacetylation; the machinery of transcriptional repression is present, including the PcG proteins (PRC) with EZH_2, which catalyzes the H_3K_{27}me3 mark *(red hexagons);* and the key silencing marks of H_3K_9me2 and me3 are also present *(red hexagons)*. The nucleosomes are more tightly compacted, as is representative of the repressive chromatin shown in Figure 5-2. *(From Ting AH, McGarvey KM, Baylin SB. The cancer epigenome: components and functional correlates.* Genes Dev *2006;20:3215-3231, with permission.)*

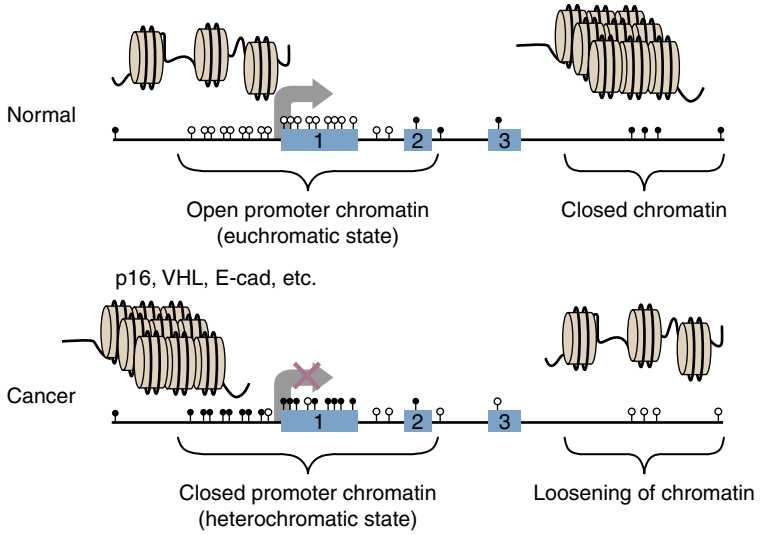

Figure 5-2 The normal versus cancer epigenome *Top:* In normal mammalian cells, CpG islands in proximal gene promoter regions (a three-exon gene is shown, with each exon marked in blue and numbered) are largely protected from DNA methylation (cytosines, *open lollipops*) and reside in restricted regions of open chromatin (*inset*, upstream of transcription start shows three nucleosomes with wide spacing), or euchromatic states, favorable for gene transcription *(large gray arrow)*. In contrast, for most regions of the genome, such as in the bodies of many genes and areas outside genes, particularly including repeat elements and pericentromeric regions, the cytosines in CpG dinucleotides are methylated *(black lollipops)*. This DNA methylation is characteristic of the bulk of the human genome, which is packaged as closed chromatin (the inset above methylated CpGs shows multiple nucleosomes with higher-order, tight compaction) unfavorable for transcription. *Bottom:* In cancer cells, there tends to be a reversal of this pattern. Proximal promoter CpG islands for many abnormally silenced genes (as represented by the same gene as shown in the top panel, which is depicted as representing the tumor suppressor genes listed) become DNA hypermethylated and reside in a closed chromatin, or more heterochromatic-type state, which is not favorable for transcription *(red X)*. In contrast, cytosines in CpG dinucleotides in other regions of the genome display hypomethylation and are associated with states of aberrantly loosened chromatin. The overall result is abnormal chromatin packaging with the potential for underpinning an abnormal cellular memory for gene expression and for conveying abnormal structural function for chromosomes. *(From Ting AH, McGarvey KM, Baylin SB. The cancer epigenome: components and functional correlates.* Genes Dev *2006;20:3215-3231, with permission.)*

methyltransferase (DNMT) enzymes that utilize *S*-adenosylmethionine as a methyl donor group to transfer this moiety for covalent linkage to the cytosines.[6,7] DNA methylation adds a dimension to packaging of DNA and nucleosomes into repressive domains by stabilizing the heritable nature of transcriptional silencing.[6,7] A key aspect of this dimension concerns the distribution of DNA methylation in the genome (see Figure 5-2). In most genomic regions, the CpG dinucleotide is underrepresented because, over evolution, these cytosines have been depleted through deamination of methylcytosines to form thymines.[6,7] However, as many as 80% of these remaining CpG sites are DNA methylated in the human genome, and this has an important functional correlate. This methylation corresponds to the fact that most of our genome, in adult cells, is packaged away into nucleosome-compacted DNA characteristic of regions of transcriptional repression (see Figure 5-2). This may constitute one of the most important functions of genomic DNA methylation, which is to ensure tight

heritability of overall genomic transcriptional repression to prevent unwanted expression of elements such as viral insertions, repeat elements, and other potentially deleterious sequences.[16]

In contradistinction to the depletion of CpGs throughout most of the genome, approximately half of the genes in the genome have regions in their promoters, termed *CpG islands* where the expected frequency of the nucleotide has been preserved (see Figure 5-2). For most such genes, these islands are protected from DNA methylation, and this methylation-free state is associated with active transcription of these genes, or preservation of their being in a transcription-ready state.[6,7,17] These CpG islands are the target of key epigenetic abnormalities in cancer cells, as discussed in detail in subsequent sections of this chapter.

In addition to the previously described role of DNA methylation in global DNA packaging, it is also linked to regulation of expression for specific genes in normal cells. In this regard, when localized to gene promoter regions, it may act to provide a tightening of heritable states for gene silencing. Examples include the imposition of DNA methylation in the promoters of genes shortly after other processes initiate their silencing in regions on the inactive X-chromosome of females.[18] A similar role is apparent in genes that are imprinted in mammals wherein DNA methylation of promoter regions is seen on the silenced allele of such genes.[19,20] DNA methylation also may participate in regulating expression of certain genes in normal cells that are expressed in a tissue-specific manner, such as the silencing of globin genes in all but cells actively engaged in erythropoiesis.[21,22]

In the gene-silencing roles, there is a tight interplay between the modification of key histone amino acid residues and DNA methylation. Thus, at least in lower organisms such as *Neurospora* and *Arabidopsis*, methylation of lysine 9 of histone H3 (H3K9me) may help determine positions where cytosine methylation is placed in the genome.[23,24] Increased levels of the active histone modification H3K4 methylation can be inhibitory to the recruitment of the DNA methylating enzymes.[25] In turn, DNA methylation recruits a series of proteins, methylcytosine binding proteins (MBPs), which are complexed, in turn, with HDACs, which help maintain the deacetylation of H3K9 and other key histone lysines in regions of silenced genes.[6,7]

Abnormalities of DNA Methylation and Chromatin Organization in Cancer: The Cancer "Epigenome"

Overall Characterization

The organization of the genome, as mediated by chromatin and DNA methylation, appears to be quite abnormal in cancer cells of all types when compared with the corresponding cells in normal renewing adult tissues.[26-28] In many cancers, total levels of DNA methylation are decreased with losses apparent within repeat sequences, the bodies and promoters of selected genes, and in the pericentromeric regions of chromosomes.[26-28] The full ramifications of these losses are still being explored, but the changes have the potential for associating with unwanted gene expression and especially, in terms of the pericentromeric abnormalities, with chromosomal instability.[26-30]

Table 5-1 Examples of Pathways Affected by Aberrant Gene Silencing in Cancer

Pathway	Genes
Cell cycle control	*p16, p15*
Apoptosis	*DAP-kinase, ASC/TMS1, HIC1*
Increased stem/developmental pathway activity (Wnt, etc.)	*SFRPs*
DNA damage repair	*MLH_1, O^6-MGM, GST Pi*
Cell adhesion	*E-cadherin*
Cell migration	*TIMPs*
Differentiation	*GATA-4, GATA-5, TGF-β receptor*
Chromosomal stability	*CHFR*

Recently, extensive analyses of DNA methylation patterns in cancer have revealed that, in addition to the regions mentioned previously, there are large megabase regions for loss of DNA methylation scattered over many chromosomes.[31] Within these regions, more localized gains of DNA methylation simultaneously reside in the normally unmethylated CpG islands of promoters of many genes. These methylation gains are, to date, the most studied of the epigenetic abnormalities in cancer[31-33] and are associated with repressive chromatin changes and potentials for aberrant loss of gene expression and function.[26-28,32-34] In fact, it is increasingly apparent that potential disruption of gene function as a consequence of promoter DNA hypermethylation is as frequent, or more frequent, in cancers than mutations as a potential mechanism for loss of tumor suppressor gene function.[26] Individual tumors may actually contain hundreds of such affected genes, which include many of the best characterized tumor suppressor genes[26-28,35] and genes involved with virtually every cellular pathway for which alterations are thought to drive the initiation and progression of cancer[36] (Table 5-1),[26-28,35,37] including those for cell cycle events, apoptosis, developmental biology signal transduction for stem cell function, differentiation, cell-cell adhesion, cell-cell recognition, cell migration and invasion, and others.[33-35,37] The list of involved genes, as identified by study of candidate genes and techniques for randomly screening the cancer epigenome,[33-35,38,39] is steadily growing for virtually all major cancer types.

Chromatin Abnormalities in Cancer and Interplay with DNA Methylation Changes

In addition to abnormalities in DNA methylation in cancer, chromatin alterations are also frequent, and there can be interplay between the two. Indeed, one of the most active areas of cancer epigenetics research at present, and one of utmost importance to the translational impact for cancer prevention, diagnosis, and treatment, concerns delineation of the molecular underpinnings of how the cancer epigenome evolves.[32] This investigation has benefited from, and contributed to, the explosion of knowledge over the past 5 to 10 years in understanding how chromatin functions for packaging of the genome and for modulation of gene expression.[40] Although many remain to be elucidated, important findings are emerging that provide clues to the origins of epigenetic abnormalities in cancer.

The initiation of DNA methylation, its maintenance, and its role in transcriptional repression are all dependent on its interaction with chromatin organization (see Figure 5-1). As previously alluded to, the sites of DNA methylation themselves may be dependent, initially, on histone modifications. Thus, H3K9 methylation, and the histone methyltransferases that catalyze this mark, appears required for DNA methylation in lower organisms such as *Arabidopsis* and *Neurospora*.[23,24] In addition, the polycomb group of proteins,[41-43] discussed in more detail later, which target another key gene repression mark to nucleosomes, H3K27me, have been implicated in the targeting and maintenance of DNA methylation. Also, a series of proteins called methylcytosine binding proteins (MBPs), and the protein complexes in which they reside, can bind to methylated CpG sites to help relay, and/or maintain, a silencing signal.[6,7] These complexes contain the previously mentioned enzymes, histone deacetylases (HDACs), which catalyze the deacetylation of key amino acid residues, such as H3K9, that are highly characteristic of transcriptionally silent regions of DNA.[6,7,44] The DNMTs themselves also interact with HDACs to help target these enzymes to sites of DNA methylation.[45-47]

The alterations in the levels or ratios of factors that mediate epigenetic abnormalities in cancer cells are first manifest by certain global abnormalities. Thus, increases in the levels and activities of the DNA methylation catalyzing enzymes[48]; of the proteins in complexes that modulate the enzymes that catalyze transcriptional repression histone modifications[49-51]; and altered levels of the repressive histone marks themselves, including loss of acetylation at H4K16 and increased levels of H4K20 acetylation,[52] are all reported as common hallmarks of human cancer. Locally, at gene promoters affected by promoter DNA methylation and aberrant gene silencing (see Figure 5-1), there are decreases in histone modifications associated with active gene transcription, such as acetylation of H3K9 and H4K16; increases in modifications associated with transcriptionally repressive chromatin, including H3K9me2 and me3 and H3K27me3; and increases in the enzymes that catalyze these latter repressive marks.[48,53]

The precise manner in which all of these chromatin components interact to initiate and/or maintain abnormal gene promoter DNA methylation and the attendant silencing of involved genes is not yet known. As noted earlier, in cancer, these gains of DNA methylation can occur as focal changes within large regions of loss of normal DNA methylation.[31] These data suggest that molecular maintenance of chromatin and DNA methylation boundaries "break down" during tumor progression. Factors such as "insulator" proteins, which maintain separation between transcriptionally repressive and active chromatin states, are altered and/or chromatin states that associate with such transcription states and are also shifted.[32]

How might such chromatin alterations come about? One potential mechanism concerns recent exciting findings stemming from deep sequencing analyses of most solid and liquid tumor types that are revealing many frequent mutations in genes encoding for proteins that normally ensure formation of chromatin in normal cell epigenomes[32,54] (see Figure 5-2 and Table 5-1). The high frequency of these changes suggests that they are fundamentally important to the initiation and progression of cancer[32,54] and may justify considering their roles as "driver" mutations. As such, they would contribute important steps in the initiation and/or progression of cancer. A major challenge, however, is to understand the exact consequences of these mutations for key steps in tumorigenesis and for their precise contribution to cancer-specific alterations of chromatin and DNA methylation. One mutation particularly, in the IDH1 and 2 genes in glioblastomas and leukemias,[55-57] appears to cause a metabolic balance that inhibits enzymes that remove key gene expression silencing histone marks and/or that can remove DNA methylation.[58,59] These mutations, when studied experimentally, appear to disrupt normal stem/progenitor cell function and commitment of cells to proper lineages. Moreover, the tumors that harbor them have an increased frequency of abnormal promoter region CpG island DNA methylation.[60,61]

The studies just referred to concerning regional changes in epigenetic patterns in cancer suggest that many genes with CpG island–containing promoters are particularly vulnerable to adopting abnormal DNA methylation during the abnormal cellular expansion that underlies the earliest phases of tumor progression[48,62-64] (Figure 5-3). A growing number of studies reveal that these genes are enriched for those that are important for developmental functions.[65] Importantly, in normal embryonic and adult stem cells, these genes are

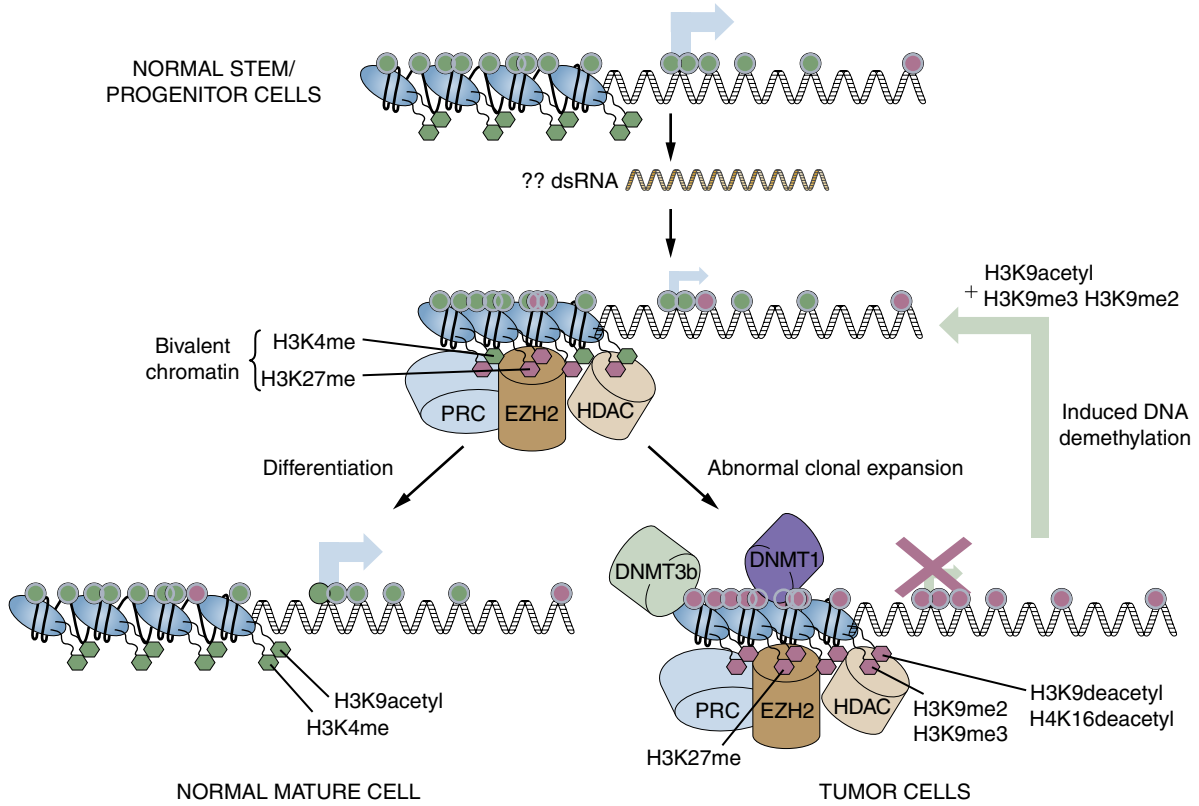

Figure 5-3 A model for the potential contribution of stem cell chromatin to the initiation and maintenance of aberrant epigenetic gene silencing in cancers During normal ES cell formation, a bivalent chromatin is recruited to the promoters of a subset of genes that need to be held in a low-expression state to prevent lineage commitment. The involvement of small interfering RNA (siRNA) species could be a trigger to this process, and the chromatin is composed of histone modifications associated with active transcription (H3K4me) and inactive transcription (H3K27me). The PcG proteins (PRC) are responsible for the H3K27me3 mark through the HMT, EZH2, and deacetylation of key histone lysine residues is catalyzed by HDACs that are recruited by multiple transcriptional repressive complexes. At such genes, DNA is largely unmethylated *(green circles),* and histones may be maintained in a mixture of acetylated *(green hexagons)* and deacetylated *(red hexagons)* states. *Bottom left:* With normal cell differentiation and lineage commitment, the genes become transcriptionally active, and the silencing marks are reduced while active histone marks are retained. DNA remains unmethylated. However, as shown at *bottom right,* during cancer-predisposing events, abnormal pressure for stem/progenitor cell proliferation with retained bivalent chromatin may allow polycomb proteins and/or marks to recruit other silencing marks such as H3K9me2 and H3K9me3 and DNA methyltransferases. The promoter evolves abnormal DNA methylation *(red circles)* and a tight heritable gene silencing *(large red X),* which results in loss of function for genes. Tumors may arise in such clones with subsequent progression steps. Experimentally, the potential underlying bivalent chromatin for such tumor genes, plus retained H3K9me3, can be revealed by induced DNA demethylation *(large green arrow)* and resultant gene re-expression. *(From Ting AH, McGarvey KM, Baylin SB. The cancer epigenome: components and functional correlates.* Genes Dev *2006;20:3215-3231, with permission.)*

maintained in a low, poised transcription state in which their promoter regions are marked, not by DNA methylation, but by a "bivalent" chromatin pattern characterized by a broad distribution of the PcG-mediated H3K27me3, repressive histone modification accompanied by a more narrow zone of the active mark, H3K4 methylation surrounding the transcription start site.[48,62-64] This bivalency may allow regulatory flexibility by keeping these genes in a low, poised quiescent transcription state to maintain stem cell pluripotency and/or prevent their undergoing premature lineage or differentiation commitment.[65] Interestingly, these genes in ESC typically reside in the large regions mentioned earlier that broadly lose DNA methylation in cancer but gain CpG island methylation focally around promoter regions.[31] Thus, it appears that for these vulnerable genes, during tumorigenesis, there is imposition of abnormal, promoter CpG island DNA methylation as opposed to the control of expression of these genes in normal cell renewal by a balance involving polycomb proteins and active gene histone marks. The more stabilizing silencing process in association with DNA methylation may, then, provide a mechanism by which inability to induce at least some of the foregoing genes could help foster maintenance of stemlike cells and/or a block in their ability to differentiate.[65,66]

Relationships of Epigenetic Changes in General, and Aberrant Gene Silencing in Particular, to the Progression of Cancer

Although losses and gains of DNA methylation in cancer may arise at any point during tumor progression, it has become apparent that many of the changes arise early, before

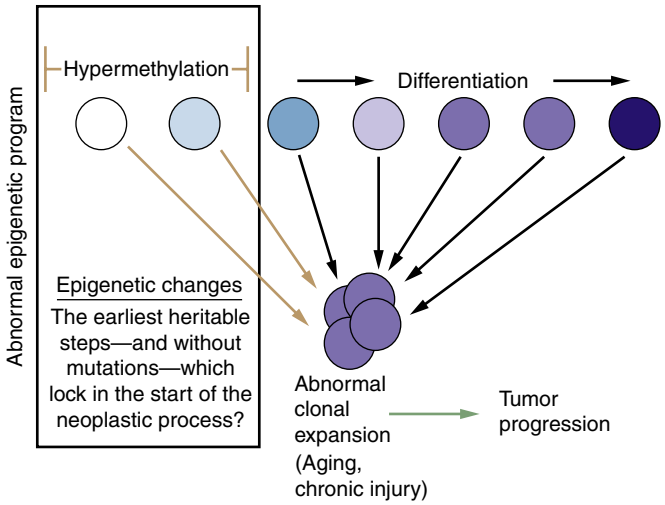

Figure 5-4 The potential that epigenetic gene-silencing events have for participation in the earliest stages of tumor progression As discussed in the text and Figure 5-3, suppression of gene transcription can be a normal event for a group of key genes in stem cells and progenitor cells as adult epithelial-cell renewal takes place *(left large box)*. This low-level gene expression is accomplished by a balance of chromatin modifications that associate with active and repressed transcription (bivalent chromatin; see Figure 5-3), but transcription can increase in maturing cells during normal cell renewal. This balance of control for gene expression allows stem and progenitor cells to progress along a normal differentiation pathway (moving with *arrow* from left to right across the top of the figure). During chronic and abnormal pressures on stem-cell and progenitor-cell pools for tissue repair, there is a tendency for the gene chromatin constituents in these cells (see Figure 5-3) to recruit promoter DNA hypermethylation *(top of large box)*, and this becomes associated with heritable silencing of the genes (abnormal epigenetic program, *large box*). This inability of the genes to increase with maturation cues facilitates abnormal clonal expansion of stem/progenitor cells *(heavier arrows)*, at the expense of differentiation. Such expansion may occur in stroma, leading to an abnormal environment that helps support epithelial tumor growth. This process renders the abnormal clones at risk for further tumor progression *(bottom arrow)* driven by subsequent genetic or epigenetic events.

frank carcinomas.[34,37,48,67] In fact, it is possible that some of the events, such as silencing of key genes, could even initiate the abnormal clonal expansion that creates early preinvasive lesions, which are then at risk for subsequent genetic and epigenetic events that further tumor progression and lead to invasive and metastatic cancer (Figure 5-4).[34,37,48,67] The genes silenced, or groups of such genes, may provide loss of tumor suppressor function that allows cells to abnormally survive the hostile environments that are risk factors for cancer development, such as chronic inflammation, and expose cells to DNA-damaging agents such as reactive oxygen species (ROS). In fact, experimental data now indicate that increases in ROS can rapidly trigger localization of protein complexes, including DNA methyltransferases, to CpG islands in gene promoters.[68] During this period, for the types of low-transcription genes that, as discussed in a previous section, seem vulnerable to adopting abnormal promoter DNA methylation, abnormal DNA methylation begins to appear.[68] This change in key groups of genes during injury repair may enable cells that would normally undergo apoptosis from DNA damage to survive and expand. They may, then, more easily select for mutations and/or chromatin damage that may favor subsequent tumor progression (see Figure 5-4).

There are now several key examples of this proposed early role for DNA hypermethylation and gene silencing in tumor progression. One of the major tumor suppressor genes in cancer, where loss of function leads to cell cycle abnormalities and uncontrolled growth, is *p16*.[69] A role for this loss of function in early tumorigenesis, via early expansion of stem cells, would be predicted from data in *p16* knockout mice revealing that germline loss of this gene can increase stem-cell lifespan.[70-72] The rate of point mutations in *p16* in most cancer types is low, but the gene is a frequent target for early methylation in these same tumors, such as breast cancer and non–small-cell lung cancer (NSCLC).[73,74] This methylation occurs early in tumor progression, before invasive cancer.[73,75] In fact, histologically normal mammary epithelium from some healthy women without malignancy can harbor focal *p16* promoter hypermethylation.[76] Experimentally, early loss of *p16* in mammary epithelial cells precedes genomic and epigenetic instability.[77-79] A recent study in the Cancer Genome Atlas project (TCGA) further emphasizes how, in the squamous form of NSCLC, abnormal methylation of p16 is mutually exclusive to mutations of the gene.[80]

Another excellent example of the potential role for early epigenetic abnormalities and stem/precursor cell expansion to contribute to early steps in tumor progression involves colon cancer. In this disease, cancer risk can begin with the appearance of aberrant crypt foci in the colonic epithelium, and these harbor premalignant, hyperplastic, preadenomatous cells.[81,82] The evolution of colon cancer is highly dependent on abnormal activation of the stem/precursor cell Wnt pathway, which by the time frank polyps and/or invasive lesions appear, is driven by classic inactivating mutations in the *APC* gene or activating mutations of β-catenin, key downstream players in the pathway.[83,84] In aberrant crypt foci, however, such mutations may not be present, yet there is DNA hypermethylation[37,85] of a family of genes, the SFRPs, which encode for membrane region proteins that antagonize Wnt interaction with its receptors.[85,86] This hypermethylation persists throughout colon tumor progression and can later collaborate with the downstream mutations in driving the Wnt pathway.[37,85]

Translational Implications of Epigenetic Changes in Cancer

The delineation of epigenetic abnormalities in tumorigenesis is now actively contributing not only to our understanding

of the biology of cancer but also to potentially new ways for managing these diseases. First, the overall abnormalities in chromatin organization and DNA methylation provide potential biomarkers for use in cancer risk assessment, early diagnosis, and prognosis assessment. Second, the molecular features that contribute to the epigenetic abnormalities in cancer are increasingly offering new targets for devising novel therapy strategies for all types of cancers. Some of the progress in these arenas is reviewed in this section.

Epigenetic Changes and Development of Biomarker Strategies

Overall and local chromatin changes in cancer provide potential markers for cancer management. For example, during the early stages of tumor progression, some of the histone modifications altered in cancer cells (see Figures 5-1 and 5-3) are manifest, as previously discussed. These can be global in tumor cells such that levels of these parameters, including losses of monoacetylated and trimethylated forms of histone H4 and losses of acetylated Lys16 and trimethylated Lys20 residues of histone H4, reflect either the presence of cancer or its stages.[52,87] Changes in modification marks on histones H3 and H4 have been correlated with aggressiveness of prostate cancer.[87] These global changes are hypothesized to be common hallmarks of human tumor cells and hold promise for the development of important biomarkers. Similarly, increases in levels of enzymes that catalyze key facets of cancer epigenetic abnormalities, such as the DNA methyltransferases for DNA methylation[48] and, more recently, histone methyltransferases such as EZH2[50,51] or H3K27 methylation, and other PcG gene silencing constituents,[88] have been correlated with several cancer types and correlated with aggressive behavior.

The most developed biomarker strategies have been centered on the gene promoter DNA hypermethylation and gene silencing. The use of promoter-hypermethylation sequences as a molecular signature is providing one of the most promising biomarker strategies for cancer.[89-91] One advantage of the approaches being adopted relies on the relative stability of DNA as compared with many proteins and RNA, which allows for use of paraffin-embedded clinical samples for detection strategies. Given the fact that, as discussed, the numbers of genes DNA hypermethylated is so high in individual tumors, and that this phenomenon is common in all cancer types, it is not difficult to build profiles of relatively small hypermethylated gene panels in which one or more markers are positive in virtually any cancer.[92] Combined with a repertoire of sensitive polymerase chain reaction (PCR)-based assay procedures to specifically detect the hypermethylated sequences,[90,91,93] and the fact that these assays can be targeted to constant positions of the abnormal CpG methylation in gene promoter regions, relatively simple detection strategies are being constructed and now include adaptation of the assays to nanoparticle-based platforms.[94,95] With such assays, abnormally methylated gene sequences have been detected in sources as diverse as DNA extracted from tumor, lymph nodes, serum, sputum, bronchial-lavage fluid, and urine for patients with all varieties of cancer types.[89-91] The strategies range from determining whether the methylation patterns in tumors reflect prognosis for behavior, to use of marker detection in distal sites for purposes of cancer risk assessment, early diagnosis, and staging. For example, studies of sputum DNA from patients at high risk for lung cancer have found that invasive tumors may be predicted, with odds ratios of 6 or more, more than a year before clinical detection of cancer,[96] and findings of abnormal methylation markers in sputum may be useful for predicting which patients with surgically resected early-stage lung cancers may experience a recurrence.[97] The occurrence of hypermethylation of specific genes in tumor DNA may predict future behavior of a cancer; reportedly, this change for the *p16* gene in DNA from lung cancers predicts high likelihood of poor outcome.[98] Assays to detect DNA hypermethylation of the GST-pi gene in needle biopsies of the prostate are reaching clinical use as an aid to refine the diagnosis of prostate cancer. Recently, simultaneous detection of abnormal promoter DNA methylation of a panel of four genes, in DNA from tumor and chest lymph nodes assessed to be microscopically free of tumor by pathology exam, provides a potential strategy for predicting recurrence in early-stage non–small-cell lung cancer (NSCLC).[99] Similarly, sensitive detection of these types of gene promoter DNA methylation abnormalities in stool and/or serum DNA appears promising for the early detection of colon polyps and/or cancer.[100,101]

The promise of these biomarker approaches will be realized only through continued studies of ever-increasing size. The precise assays best suited for routine clinical use must be determined, and approaches that build the most quantitative determinations into these assays, increasingly being applied,[102] must be evaluated. Confounding issues must be continuously considered. A most critical one is to always consider whether the presence of hypermethylated gene markers in normal-appearing tissue settings means cancer risk as opposed to actual cancer presence. This accentuates the importance of the information discussed earlier in this chapter concerning the biology of cancer as it involves epigenetic abnormalities. The position for appearance of individual gene markers in tumor progression is critical and must be paired with consideration of risk factors. For example, gene promoter methylation in normal tissues can increase with age, as best studied in the colon,[103] and

parallels the risk of cancer at a given site. All of this information defines the potential power of marker strategies using gene promoter hypermethylated sequences and the caveats that must be considered in using these strategies.

Perhaps one of the most promising uses for gene hypermethylation markers, and another that is now close to general clinical realization, concerns their use for prediction of drug sensitivity. This strategy exploits the fact that aberrantly silenced genes involved with this epigenetic abnormality can belong to pathways that dictate cellular pathways integral to drug responsiveness. The most developed example of this is the silencing of the DNA repair gene *O⁶-MGMT*, which encodes for a protein that mediates removal of bulky alkylation adducts from guanosines.[89] Several tumor types lose the function of *O⁶-MGMT* via aberrant silencing of the gene, and constituent cells have a diminished capacity to repair alkylation damage, rendering them sensitive to alkylating agents such as temozolomide.[104,105] Thus, multiple studies reveal that patients with brain tumors harboring *O⁶-MGMT* respond remarkably better to this agent than those whose tumors lack this change, providing an exceptionally promising marker to stratify patients with this lethal tumor type for best therapy approaches.[105,106] If ongoing trials continue to validate this, a relatively easy and rapid marker will be available for routine clinical use.

Targeting Epigenetic Abnormalities for Cancer Prevention and Therapy

There is now growing appreciation that our expanding knowledge of epigenetic abnormalities in cancer, in general, and most especially, at present, the definition of aberrant gene silencing as an alternative mechanism to mutations for loss of tumor suppressor gene function, offers extraordinary potential for exploitation in managing cancer.[89,107] First, there is the critical difference that, as compared with mutations, epigenetic gene silencing, as we have discussed in this chapter, is potentially reversible. Second, the growing list of molecular steps being defined as components of the silencing offers more individual and combinatorial targets for considering interventions. Third, the early position of aberrant genes in tumor progression makes reversal of the silencing an attractive target for prevention approaches. Also, the potential of the silenced genes to participate in tumor recurrence suggests that the adjuvant treatment arena may be an attractive area for epigenetic therapy. Fourth, and perhaps most important, the biology discussed in this chapter, including the high frequency of the gene silencing abnormality in all cancer types, the numbers of genes involved in individual tumors, and the critical pathways for cancer development in which the involved genes participate, makes reversal of gene silencing not only a rational target for therapy, but an essential one to consider (Figure 5-5). If successful, reversal of the entire gene silencing in a given patient's tumor could, with one targeted therapy approach, reverse virtually every key signal pathway involved in the initiation, progression, and maintenance of the cancer (see Table 5-1 and Figure 5-5).

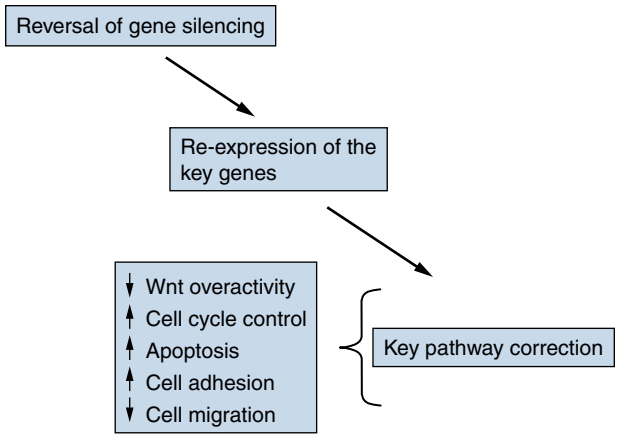

Figure 5-5 The theory behind emphasizing targeting reversal of aberrant gene silencing as a strategy for cancer prevention and therapy The concept is depicted that, based on the numbers of epigenetically silenced genes in a given tumor, the numbers of pathways affected by the epigenetically mediated loss of gene function, and the network effects of the silencing within and between the pathways, the strategy of reactivating silenced genes presents a unique opportunity to counter, via a single therapy, virtually all the steps that drive tumorigenesis.

Where do we stand in this important cancer prevention/therapy endeavor? Indeed, drugs that reverse DNA demethylation, such as 5-azacytidine and 5-aza-2′-deoxycytidine, and histone deacetylase inhibitors that target the histone deacetylation component of gene silencing are already in the clinic[89,106-108] and approved by the U.S. Food and Drug Administration (FDA) for the preleukemic disorder myelodysplasia (MDS) and cutaneous T-cell lymphoma and peripheral T-cell lymphomas,[109,110] respectively. The concept that initial use of azacytidines followed by administration of histone deacetylase inhibitors (HDACis) may be synergistic for inducing reexpression of aberrantly silenced cancer genes is receiving attention and encouraging early clinical results. It must be stressed, however, that it remains to be established to what degree the individual or combined effects of these drugs on their targets, DNMTs and HDACis, plays a role in their therapeutic efficacy in patients with MDS, related leukemias, and cutaneous lymphomas for the HDACis.[89,107,111-115] Encouraging results indicate that at least some of the clinical effects are due to true reversal of epigenetic targets. First, clinical efficacy is being accomplished, especially for the azacytidines, at far lower doses than the ones initially used. This greatly reduces the toxic effects that may be due to nonepigenetic effects of the drugs, such as DNA damage.[116,117] Indeed, recent preclinical studies indicate

that transient exposure of leukemia and solid tumor cells to low-nanomolar doses of the foregoing DNA-demethylating drugs, without initial cell killing, provide a cell-reprogramming–like effect that can give long-term blunting of cell tumorigenicity and self-renewal capacities.[118]

Second, emerging data suggest that the efficacy of the azacytidines correlates with the acute reversal of gene silencing. In the preclinical studies just mentioned, the low doses of the DNA-demethylating agents can reduce overall, and abnormal gene promoter, DNA methylation with simultaneous reexpression of tumor suppressor genes such as the cyclin-dependent kinase inhibitor encoding gene, *p15*, in leukemia cells.[118] Early reactivation in MDS and leukemias appears to correlate with subsequent patient responses in one study,[111] although others have not found such correlation even though the gene is clearly reexpressed in patients' tumor cells during acute drug treatment.[119] In another study, combination decitabine and trichostatin A, an HDACi, resulted in decreased expression of the multidrug resistance transporter ABCG2 as well as markers of enhanced self-renewal populations in ovarian cancer cells, and increased sensitivity to cisplatin in vivo.[120]

Despite these encouraging developments, much remains to be done if epigenetic therapies are to make a powerful impact on the prevention and treatment of cancer. First, little efficacy for the common solid tumors has been shown. However, most attempts to treat these tumors occurred before it was appreciated that lower, and less toxic, doses of drugs such as the azacytidines and HDACis can be used. The time is ripe for the regimens showing such promise in the liquid tumors to be applied to the treatment of solid tumors. In this regard, a low-dose regimen of 5-azacytidine (Vidaza) plus a histone deacetylase inhibitor, entinostat, has achieved very promising results in a clinical trial for the world's most deadly malignancy, multiply treated, advanced NSCLC.[121] Some 3% of the patients achieved high-grade tumor regression that was durable from nearly 3 to 4 years. Moreover, some 20% of the patients exhibited unusually good, durable tumor responses to subsequent therapies even after short courses of the epigenetic therapy.[121] These are all unusually good response trends in advanced NSCLC and, if verified in subsequent clinical trials, would provide an important role for epigenetic therapy in the management of solid tumors. In this regard, several groups have now reported the use of demethylating agents to restore platinum sensitivity in platinum-resistant ovarian cancer. Bast and colleagues reported a phase I/II study of azacitidine and carboplatin showing durable responses and stable disease (median duration of therapy 7.5 months) in 46% of platinum-resistant or refractory ovarian cancer patients.[122] A similar study using a demethylating agent and carboplatin in the same patient population reported a 40% 6-month progression-free survival, with one patient having a complete response.[123] Larger trials testing the use of demethylating agents to overcome platinum resistance are presently ongoing.

Along with the foregoing progress and potential for use of DNA demethylating agents, much work is still needed to optimize the approaches. New classes of inhibitors of the DNMTs may be needed that do not incorporate into DNA and, for ease of patient use, can be administered orally. Also, as discussed previously in this chapter, our increasing knowledge of the chromatin components of gene DNA hypermethylation-associated gene silencing must be exploited. As shown in Figure 5-3, the retention of key silencing chromatin marks for reexpressed genes following promoter DNA demethylation predicts that, as experimentally seen,[53,124] once administration of drugs such as the azacytidines is stopped, the silencing will return. Thus, feasibility for prolonged drug regimens may need to be shown and, indeed, such chronic administration appears possible for the azacytidines.[114,115] Finally, the other chromatin components of the aberrant gene silencing represent additional drug targets that may enrich therapy possibilities.

As previously mentioned, HDACis are the other major class of epigenetic modulating agents that have been tested and approved for treatment of malignancy. As single agents, their activity has been limited to the lymphoma disorders for which they are now FDA approved.[125] Nevertheless, an emerging series of preclinical studies and clinical trials suggest that HDACis could be important drugs for improving cancer management. One recent example is the suggestion that HDACis may be able to inhibit subpopulations of cancer cells that drive tumorigenesis and are usually resistant to most therapies. The precise definition of these "stem-cell–like" cells is still controversial, but the evidence is strong that most cancers harbor subpopulations, to a variable percentage, of such cells.[126-128] In this regard, although resistance to chemotherapy and other therapies may often result from new mutations that emerge during the course of treatment, epigenetic control may also come into play. Settleman and colleagues recently reported that resistance to treatment of multiple types of cancer cells, with both targeted therapy drugs and chemotherapy agents, can be involved with drug-tolerant, stemlike cells on an epigenetic basis.[129] Low doses of several HDACis could reverse this drug resistance.[129] These findings suggest that a potential use for HDACis is reversing or delaying drug resistance. Indeed, this potential may be emerging in clinical trials. In a randomized phase II trial, combination therapy with the HDACi entinostat plus the epidermal growth factor inhibitor erlotinib provided survival benefit in a subset of the patients with baseline high tumor levels of E-cadherin. This same drug, in a phase II trial for advanced breast cancer, also increased survival when combined with an aromatase blocker.[130] It is important to note

that the exact mechanisms involved in the potential efficacy of HDACis in these trials remain to be determined, and, of course, the results must be validated in trials to follow.

In addition to the work with epigenetic therapy agents that are already in clinical trials, the future is very bright for the use of new agents that target other molecular steps that control the epigenome. In fact, the emerging clinical potential of existing epigenetic drugs, and the explosion in knowledge about chromatin and DNA methylation biology, has led most large pharmaceutical companies to establish programs in developing compounds that target epigenetic abnormalities in cancers. For example, whereas the HDACis just discussed target one class of these enzymes, another class that includes the deacetylase SIRT1 may lie downstream of the abnormal DNA methylation.[131] Thus, inhibition of the activity of this protein appears to cause reactivation of aberrantly silenced cancer genes without the necessity for removal of the promoter DNA hypermethylation.[131] A very exciting development is targeting of the DOT1L protein, which mediates the effects of MLL translocations in leukemia. A small molecule inhibitor has selective antitumor effects on mixed-lineage leukemia (MLL) cells.[132,133] Clinical trials with this type of drug should be forthcoming soon. Also, inhibitors of BRD4, a protein containing domains that recognize acetylated histone lysines, are generating much excitement.[134-136] This protein appears to be a key regulator for the activation of the pervasive oncogene c-MYC and its targets.[134-136] In preclinical studies, BRD4 inhibitors have selective antitumor effects on MLL-fusion leukemias with blocking of c-MYC overactivity.[137,138] These drugs will shortly be appearing in clinical trials.

It is thus apparent that our knowledge of chromatin biology is already being robustly exploited to develop novel approaches to cancer therapy. The era is an exciting one for realizing the major impact on cancer control from targeting epigenetic abnormalities involved in the initiation and progression of cancer.

Infectious Agents and Cancer

Overview of Cancer and Infectious Agents

Infectious agents are second only to tobacco use as a potentially preventable cause of cancer in humans. Estimates vary between 15% and 30% as to the percentage of cancers worldwide that are associated with an infectious etiology.[1,2] The burden is greater in the developing world, but the impact even in the United States and other developed countries is significant. Specific viruses, parasites, and bacteria are now associated with specific human cancers. These are discussed in some detail in this chapter.

There are three major mechanisms by which an infectious agent can cause a cancer, and these may involve the initiation as well as the promotion of carcinogenesis.[3] The first is perhaps the most common, resulting from the infectious agent causing a persistent infection with chronic inflammation. This can result in the formation of reactive oxygen and nitrogen species by macrophages at the site of the infection. These reactive molecules can damage DNA and proteins as well as membranes and thus contribute to carcinogenesis.[4] Chronic inflammation due to the persistent infection can then lead to repeated cycles of cell damage and cellular proliferation. Cells that are cycling in the presence of reactive molecules are more likely to acquire genetic mutations that could contribute to the initiation as well as the promotion of cancer. A second mechanism involves the direct participation of the infectious agent in the transformation of the cell through the activation of a cellular oncogene pathway or the inactivation of a tumor suppressor gene. A third mechanism, relevant to the human immunodeficiency virus (HIV), is that the infection may result in immunosuppression and the decreased recognition of infected or transformed cells by the host immune system. Indeed, many of the cancers observed in immunosuppressed patients, such as those infected with HIV, are those that have been associated with other viruses.

The recognition of an infectious etiology for specific cancers provides the opportunities to prevent those cancers by preventing or controlling the infections. Depending on the infectious agent, this could involve public health measures or changes in cultural practices. It could also involve the development of vaccines to prevent the initial infections, as has now been achieved for hepatitis B virus (HBV) and the genital-tract human papillomaviruses (HPVs). It could also involve the treatment of the infections with specific therapeutics or the development of novel therapies for those agents for which there are not yet specific or effective drugs.

Viruses and Cancer

History of Viral Oncology

Viral oncology has its beginnings as a discipline from observations made during the early part of the 20th century: in 1908, when the transmissibility of avian leukemia was first described by Ellermann in Denmark, and in 1911, when the transmissibility of an avian sarcoma in chickens was described by Rous.[5,6] The importance of these findings was not appreciated at the time, and the full impact on virology and medicine was not recognized until the 1950s. Indeed, the work of Peyton Rous[6] showing that cell-free extracts containing a filterable agent from a sarcoma in chickens could induce tumors in injected chickens within a few weeks was finally recognized with a Nobel Prize in 1966. Rous's original work pointed out that a filterable agent (the working definition of a virus at that time) not only was capable of inducing tumors, but also was responsible for determining the phenotypic characteristics of the tumor. Because these studies were carried out in birds and not in mammals, however, this early work was consigned to the rank of avian curiosities.

In the 1930s, Richard Shope published a series of papers demonstrating the cell-free transmission of tumors in rabbits. The first studies involved fibromatous tumors found in the footpads of wild cottontail rabbits that could be transmitted by injecting cell-free extracts in either wild or domestic rabbits; a virus referred to as the Shope fibroma

virus is now known to be a pox virus. Other studies carried out by Shope demonstrated that cutaneous papillomatosis in wild cottontail rabbits could also be transmitted by cell-free extracts. In a number of cases, these benign papillomas would progress spontaneously into squamous cell carcinomas in infected domestic rabbits or in the infected cottontail rabbits.[7,8] In general, however, the field of viral oncology lay dormant until the early 1950s, with the discovery of the murine leukemia viruses by Ludwig Gross[9] and of the mouse polyomavirus by Gross, Stewart, and Eddy.[10,11] The identification of tumor viruses in mice opened the field of experimental viral oncology. Researchers had the hope that these initial observations in mammals could be extended to humans and that a fair proportion of human tumors might also be found to have a viral etiology. The Special Viral Cancer Program in the 1960s at the National Cancer Institute grew from this intense interest in viral oncology and the belief that human tumor viruses would be identified.

Many of the most important developments in modern molecular biology derive from studies in viral oncology from the 1960s and 1970s. The discovery of reverse transcriptase, the development of recombinant DNA technology, the discovery of messenger RNA splicing, and the discovery of oncogenes and, more recently, tumor suppressor genes all have been developments that emerged directly from studies in viral oncology. Oncogenes were first recognized as cellular genes that had been acquired by retroviruses through recombination processes to convert them into acute transforming RNA tumor viruses. It is now recognized that oncogenes participate in many different types of tumors and can be involved at different stages of tumorigenesis and viral oncology. This has contributed significantly to our concepts in nonviral carcinogenesis. It is likely that the direct-transforming, oncogene-transducing retroviruses do not play a major causative role in naturally occurring cancers in animals or in humans, but rather represent laboratory-generated recombinants. A list of human viruses that are now associated with human cancer is presented in Table 6-1. Also included on this list are viruses such as the transforming adenoviruses that, although capable of transforming normal cells into malignant cells in the laboratory, have not been associated with any known human tumors.

Also listed in Table 6-1 are cofactors that are believed to be important in the carcinogenic processes associated with each of these viruses. It is clear that none of these viruses by themselves is sufficient for the induction of the specific neoplasias with which they have been associated. Each of the viruses associated with these human cancers is thought to be involved at an early step in carcinogenesis. Subsequent cellular genetic events such as somatic mutations are thought to

Table 6-1 Human Viruses with Oncogenic Properties

Virus Family	Type	Human Tumor	Cofactors	Comments
Adenovirus	Types 2, 5, 12	None	N/A	Important experimental model
Hepadnavirus	Hepatitis B virus (HBV)	Hepatocellular carcinoma (HCC)	Aflatoxin, alcohol, smoking	Causative
Herpesvirus	Epstein-Barr virus (EBV)	Burkitt's lymphoma	Malaria	EBV
		EBV-associated malignancies in immunosuppressed individuals	Immunodeficiency	Causative
		Nasopharyngeal carcinoma	Nitrosamines, genetic	Causative

Retroviruses	HTLV-1	ATL	?Genetic	Causative
	HTLV-2	None	N/A	Not associated with human malignancy

ATL, Adult T-cell lymphoma; *N/A*, not applicable; *SV40*, simian virus 40. AIDS, Acquired Immunodeficiency Syndrome; HPV, human papillomavirus; MCV, Merkel cell virus; BK, BK human polyomavirus; JC, JC human polyomavirus; HTLV, human T-cell leukemia virus; UV, ultraviolet irradiation.
*SV40 is simian virus 40, a nonhuman primate virus closely related to the human polyomaviruses BK and JC.

be important at the subsequent steps involved in the multistep process of malignant progression.

Human Papillomaviruses

The human papillomaviruses cause warts and papillomas and are associated with some specific human cancers. The papillomaviruses have been found exclusively in higher vertebrates, in species ranging from birds to man. More than 140 different types of HPVs are now recognized, and new types are still being recognized. Because serologic reagents are not available for all types, some HPVs have been typed by their DNA sequence. Many of the HPVs have now been fully or partially sequenced, and these DNA sequence data now lead their phylogenetic organization (Figure 6-1).[12] Some of these viruses as well as the clinical syndromes with which they are associated are presented in Table 6-2.

Virus-Host Interactions

The papillomaviruses have a specific tropism for squamous epithelial cells (keratinocytes). The functions of the

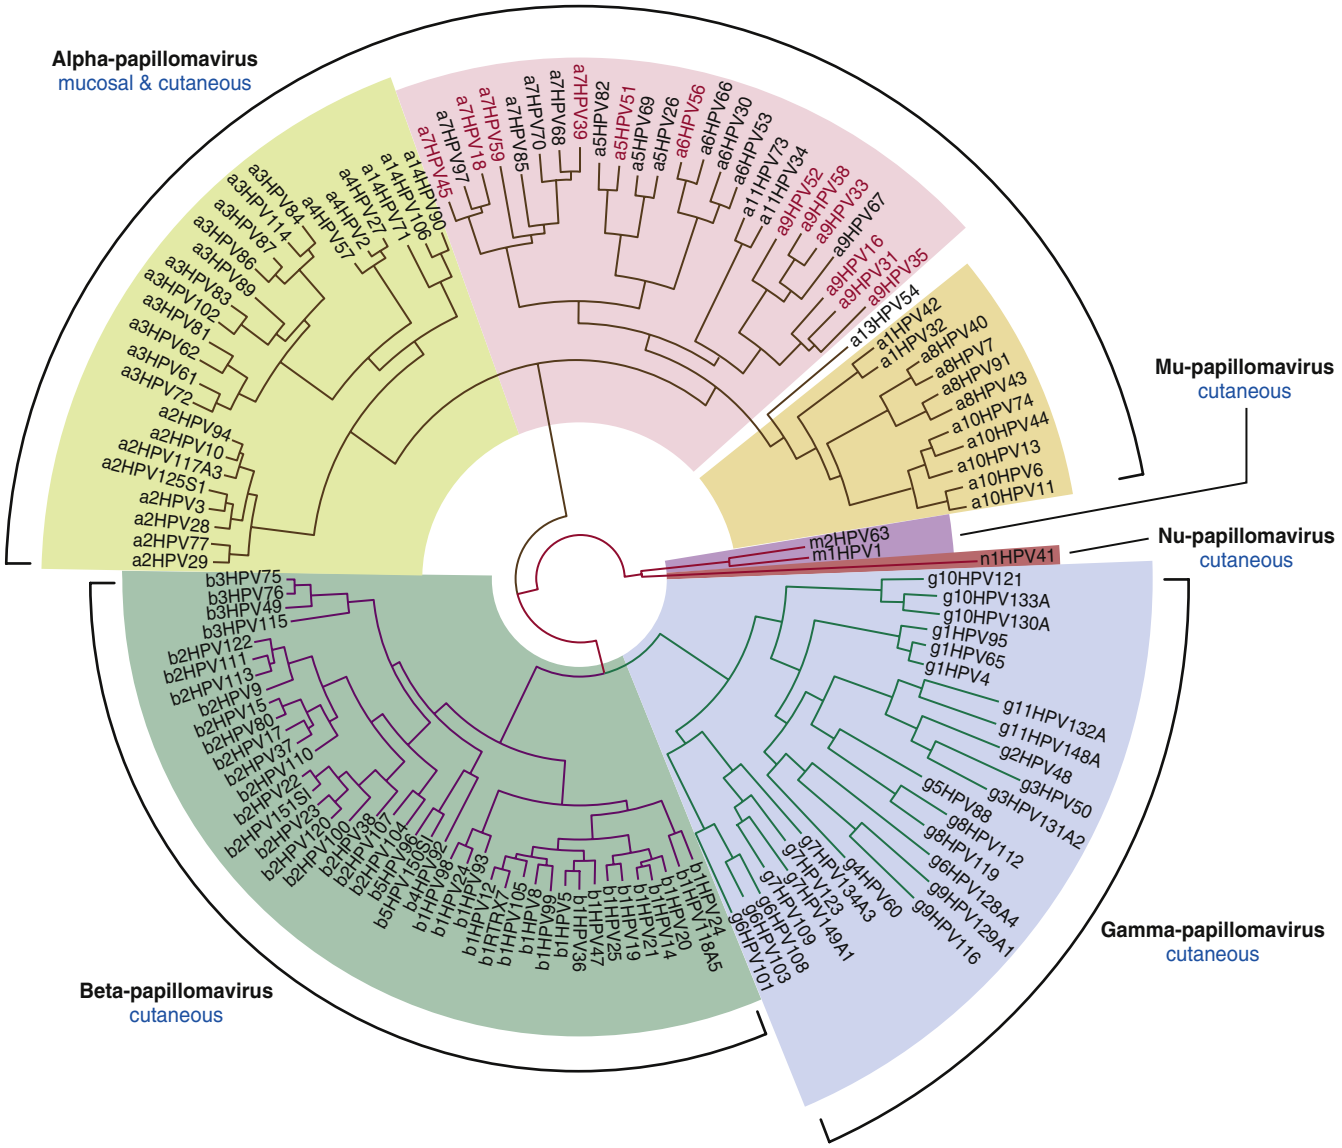

Figure 6-1 Phylogenetic tree demonstrating the evolutionary relationship among HPVs HPVs comprise five groups with different epithelial tropisms and disease associations. The alpha-papillomaviruses include the low-risk mucosal types (many of which are within the tan-shaded branch) that cause genital warts, and the high-risk mucosal types (contained within the branch highlighted with pink shading) associated with anogenital preneoplasias and cancers. Although the cutaneous HPV types (most of which are contained within the light green-[alpha], green-[beta], and blue-[gamma] shaded branches) are not generally associated with cancers, certain beta types have been implicated in the development of nonmelanoma skin cancers (NMSCs) in immunosuppressed individuals and in epidermodysplasia verruciformis (EV) patients. The lowercase letter and number preceding the HPV type refer to its genus and species. (*Reprinted with permission from Doorbar J, Quint W, Banks L, et al. The biology and life-cycle of human papillomaviruses.* Vaccine. *2012;30 Suppl 5:55-70).*

Table 6-2 Association of HPVs and Clinical Lesions

A. Cutaneous Lesions and HPVs		
Clinical association viral types		
Plantar wart	HPV1	
Common wart	HPV2, 4	
Mosaic wart	HPV2	
Multiple flat warts	HPV3, 10, 28, 41	
Macular plaques in EV	HPV5, 8, and other beta HPV types	
Butcher's warts	HPV7	
B. Genital Tract HPVs		
Condyloma acuminata (exophytic)	HPV6, 11	
Giant condyloma (Bushke-Lowenstein tumor)	HPV6, 11	
Subclinical infection	All genital tract HPV types	
Squamous intraepithelial lesions	HPV16, 18, 31, 33, etc.	
Bowenoid papulosis	HPV16, 18, etc.	
Cervical cancer	Strong association, "high risk"	HPV16, 18, 31, 45
	Moderate association	HPV33, 35, 39, 51, 52, 56, 58, 59, 68
	Weak or no association, "low risk"	HPV6, 11, 26, 42, 43, 44, 51, 53, 54, 55, 66
Other anogenital cancers (vulvar, penile, etc.)	HPV16 and other "high-risk" HPV types	
Respiratory papillomas	HPV6, 11	
Conjunctival papillomas	HPV6, 11	
Focal epithelial hyperplasia (oral cavity)	HPV13, 32	
Oropharyngeal cancer	HPV16	

EV, Epidermodysplasia verruciformis; *HPV*, human papillomavirus.

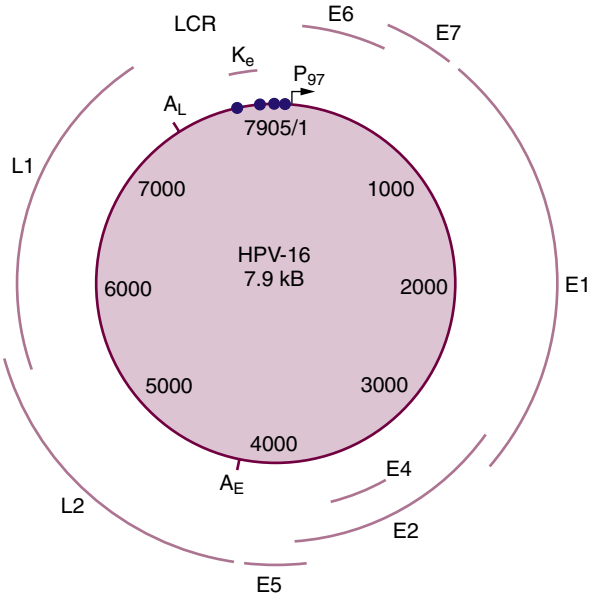

Figure 6-2 Map of the HPV16 genome The nucleotide numbers are noted within the circular maps, transcription proceeds clockwise, and the major open reading frames (E1 to E7, L1, and L2) are indicated. The transcriptional promoter that directs the expression of E6 and E7 is designated P_{97}. A_E and A_L represent the polyadenylation signals for the early and late transcripts, respectively. The viral long control region *(LCR)* contains the viral transcriptional and replication regulatory elements. The closed circles on the genome represent the four E2 binding sites that have been noted in the LCR.

papillomaviruses necessary for the production of infectious virions, which include vegetative viral DNA replication and the synthesis of the capsid proteins, occur only in the fully differentiated squamous epithelial cells of a papilloma. Viral capsid protein synthesis and virion assembly occur only in the terminally differentiated cells of the upper layers of the epithelium. The viral genome is present in the epithelial cells of all layers of the epithelium, including the basal layer. It is generally believed that the expression of specific viral genes in the basal layer and in the lower layers of the epidermis stimulates cellular proliferation and alters the keratinocyte differentiation profile, characteristic of a wart. As squamous epithelial cells migrate upward through the layers and differentiate, the pattern of viral gene expression changes, resulting in the expression of the late genes (L1 and L2) that encode the capsid proteins.

The genomic organization of all the papillomaviruses is quite similar. All of the open reading frames (ORFs) that could serve to encode proteins for these viruses are located on only one of the two viral DNA strands, and only one strand is transcribed. The HPV genome can be divided into three distinct regions: (1) an "early" region that encodes the viral proteins (E1, E2, etc.) involved in viral DNA replication, transcriptional regulation, and cellular transformation, (2) a "late" region that encodes the viral major (L1) and minor (L2) capsid proteins, and (3) a region called the "long control region" (LCR) or alternatively, the upstream regulatory region (URR) that does not contain any ORFs, but does contain cis-regulatory elements, including the origin of DNA replication and important transcription factor binding sites. A diagram of the organization of the HPV16 genome, which is typical of all the HPVs, is shown in Figure 6-2.

The late genes (L1 and L2) are expressed only in the more differentiated cells of the epithelium, whereas the early (E) region genes are expressed throughout the epithelium. A more detailed description of the biology and molecular biology of the papillomaviruses can be found in *Fields Virology*.[13]

Papillomaviruses and Cancer

Only some papillomaviruses are associated with cancer. These include several animal PVs as well as a subset of the HPVs. From an experimental standpoint, the cottontail

Table 6-3 Papillomaviruses Associated with Cancers in Their Natural Host

Species	Cancers	Viruses	Other Factors

rabbit papillomavirus (CRPV) that was first identified by Richard Shope has been extensively studied as a model for papillomavirus-induced carcinogenesis.[7] One of the principal features of carcinogenic progression associated with PVs is the synergy often observed between a specific virus and other carcinogenic factors (Table 6-3). In the case of CRPV, carcinomas develop at an increased frequency in papillomas that are painted with coal tar or with methylcholanthrene.[14,15] These CRPV-associated carcinomas contain viral DNA that is transcriptionally active, and the carcinogenic properties are believed to map to specific viral genes. There are additional instances where animal papillomaviruses have been associated with naturally occurring cancers, including the bovine papillomavirus type 4 (BPV-4) that causes esophageal papillomatosis and is associated with squamous cell carcinomas of upper alimentary tract.[16] Major interest today, however, is in the role of specific HPVs with the human cancers with which they have been associated.

HPV and Cervical Cancer

Cervical cancer is the third most common malignancy among women worldwide, with approximately 530,000 newly diagnosed cases each year and about 275,000 deaths annually.[2,17] About 80% of cervical cancer occurs in developing countries, where it is frequently the most common cancer of women, accounting for as many as one quarter of female cancers. It occurs less frequently in developed countries. In the United States, there are about 12,000 newly diagnosed cases annually, and about one third of these women will die of their malignant disease. The incidence of cervical cancer in the United States varies considerably among ethnic and socioeconomic groups, with the rate among African American women being about twice that of White women.[18]

Most cervical cancers develop in the transformation zone, the region of the cervix where the columnar cells of the endocervix adjoin with the stratified squamous epithelium of the exocervix. About 85% of cervical cancers are squamous cell cancers, the remainder being adenocarcinomas and small-cell neuroendocrine tumors. The progression of normal cervical epithelial cells to malignant squamous cell carcinomas typically occurs through a series of dysplastic changes over a time span of many years, a process that is the basis of the Pap smear screening program. The histologic classifications of cervical intraepithelial neoplasia (CIN) grades 1, 2, and 3 correspond, respectively, to mild dysplasia, moderate dysplasia, and severe dysplasia or carcinoma in situ. Because of the long interval for the progression of cervical dysplasia to invasive cancer, Pap smear screening programs can identify the vast majority of premalignant lesions for appropriate treatment, thereby preventing the development of most cases of cervical cancer in countries with screening programs. Most CIN lesions do not progress to cancer but resolve; the lesser the degree of dysplasia, the more likely the lesion is to resolve.

Cervical cancer had been recognized for decades as linked to a sexually transmitted agent, long before sexually transmitted HPV infection was implicated in its pathogenesis. Venereal transmission of a carcinogenic factor with a long latency had been suggested by the early epidemiologic studies. Sexual promiscuity, an early age of onset of sexual activity, and poor sexual hygiene conditions were identified by these studies as risk factors in women for cervical carcinoma. The counterpart to cervical cancer in the male is penile cancer, because there is a correlation between the incidence rates of these two cancers in different geographic areas. Compelling evidence linking an HPV infection with cervical carcinoma followed the observation that some of the morphologic changes characteristic of cervical dysplasia seen on Pap smears were due to a papillomavirus infection.[19] The cell with its characteristic perinuclear clearing and abnormally shaped nucleus that is diagnostic for a cervical papillomavirus infection is the koilocyte. The presence of papillomavirus particles, papillomavirus-specific capsid antigens, and HPV DNA within the cervical preneoplastic lesions provides confirmation of the HPV etiology of cervical dysplasia.

Harald zur Hausen and his colleagues identified the first papillomavirus DNAs, HPV16 and HPV18, in cervical cancer tissues in the 1980s.[20,21] Using HPV DNAs as probes under conditions of reduced hybridization stringency, most cervical carcinomas were shown to harbor these or related HPV DNAs. Subsequent studies led to the identification of approximately 40 different HPVs, mostly from the alpha genus, associated with genital tract lesions, a subset of which are associated with human cervical cancer.

In addition to HPV16 and HPV18, which account for approximately 70% of human cervical cancers, HPV types 31, 33, 35, 45, 52 and 58 account for a total of 95% of HPV-positive cancers.[22] DNAs from these same HPV types are found in other human genital carcinomas, including penile carcinomas, some vulvar carcinomas, and some perianal carcinomas, as well as in the precancerous intraepithelial lesions of each of theses sites (PIN, VIN, and PAIN).

The genital-tract–associated HPVs have been classified as either high risk or low risk based on whether the lesions with which they are associated are at significant risk for malignant progression. The low-risk viruses such as HPV6 and HPV11 are associated with venereal warts, lesions that only rarely progress to cancer. The high-risk viruses such as HPV16 and HPV18 are associated with CIN and cervical cancer. The other high-risk viruses include HPV31, HPV33, HPV35, HPV39, HPV45, HPV51, HPV52, HPV56, HPV58, HPV59, HPV68, and HPV82. Virtually all cases of CIN3 and cervical cancer contain a high-risk HPV DNA.[13] HPV-positive cervical cancers and cell lines derived from HPV-positive cervical cancer tissues often, but not always, contain integrated viral DNA. In those cancers in which the viral DNA is integrated, the pattern of integration is clonal, indicating that the integration event preceded the clonal outgrowth of the tumor. Integration of the viral DNA does not occur at specific sites in the host chromosome, although in some cancers the HPV DNA has integrated in the vicinity of known oncogenes. For instance, in the HeLa cell line (which is an HPV18-positive cervical carcinoma cell line), integration of the HPV18 genome is within approximately 50 kilobases of the c-myc locus on human chromosome 8. It is possible that such an integration event might provide a selective growth advantage to the cell and thus might contribute to neoplastic progression.

The Role of HPV in Cervical Cancer

In cervical cancers, only a subset of the viral genes is expressed, and there is no production of virus by the cancer cells. The integration of the viral genome appears to play an important role leading to the deregulated expression of the viral E6 and E7 genes.[13] The E6 and E7 genes are invariably expressed in HPV-positive cervical cancers. Integration of the HPV genome into the host chromosome in the cancers often results in the disruption of the viral E1 or E2 genes. Because HPV E2 is a viral regulatory factor that negatively regulates expression of the E6 and E7 genes, the disruption of E2 results in the derepression of the E6/E7 promoter, leading to deregulated expression of E6 and E7. Indeed, the introduction of E2 into cervical cancer cell lines results in the induction of cellular senescence by repressing E6 and E7 expression.

The E6 and E7 genes of the high-risk genital-tract–associated HPVs function as oncogenes. Expression of E6 and E7 together is sufficient for the efficient immortalization of primary human cells, most notably primary human keratinocytes, the normal host cell for the human papillomaviruses.[23] In contrast to the immortalization properties of the HPV16 and HPV18 E6 and E7 proteins, the E6 and E7 proteins encoded by the low-risk viruses are either inactive or only weakly active in the same assays.

The major cellular targets for E6 and E7 are the tumor suppressor proteins p53 and pRB, respectively. E6 and E7 are, however, polyfunctional proteins and have many other biochemical activities and biologic properties that may be relevant to their activities in cervical carcinogenesis.[13] A common theme among the small DNA tumor viruses (i.e., the polyomaviruses, the adenoviruses, and the cancer-associated HPVs) is that the immortalization and transformation properties of their encoded oncoproteins are in part due to their interactions with critical cellular regulatory proteins (Figure 6-3). The HPV E7 proteins share some amino acid sequence similarity to adenovirus E1A and with portions of the SV40 large T antigen, in regions that are critical for the transformation activities of these oncoproteins. These regions of amino acid sequence similarity shared by these viral oncoproteins specify the binding to the product of the retinoblastoma tumor suppressor gene, pRB, and the related pocket proteins p107 and p130. Studies have established that a major component of the transformation activities of these viral oncoproteins is due to their respective abilities to complex and functionally inactivate pRB and the related pocket proteins. The binding of these viral oncoproteins to pRB, p107, and p130 leads to cellular proliferation rough the activation of genes under the control of the E2F family of transcription factors. The transcriptional activities of the E2F family of transcription factors are modulated by

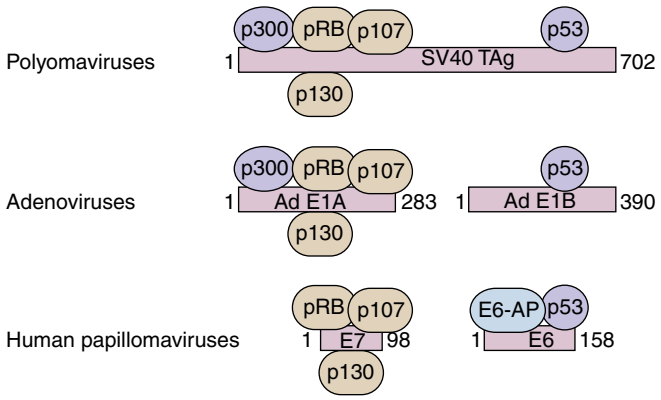

Figure 6-3 The transforming proteins encoded by three distinct groups of DNA tumor viruses target similar cellular proteins The binding of HPV E6 oncoproteins to p53 is mediated by the cellular ubiquitin ligase E6AP (also known as UBE3A) that is hijacked by E6 to target the ubiquitylation of p53.

pRB and the other pocket proteins. When complexed with E2F proteins, they act as transcriptional repressors, and when dissociated from the pocket proteins by E7, E1A, or SV40 T-antigen, the E2F proteins function to activate transcription of their target genes. In the normal life cycle of the papillomaviruses, the binding of E7 to pRB is essential for the activation of the cell-cycle DNA replication machinery in differentiated keratinocytes that had otherwise exited the cell cycle. The small DNA tumor viruses, including HPV, depend on the host cell DNA replication machinery for the replication of their viral genomes. Because this machinery is only expressed in the S phase of the cell cycle, these viruses must stimulate cellular proliferation and drive the cell into the S phase in order to replicate the viral genomes. In the case of HPV, this occurs through E7 binding pRB, freeing up the E2F family of transcription factors.

A number of genetic studies indicate that E7 binding to pRB and its related pocket proteins is not sufficient to account for its immortalization and transforming functions, indicating that there are additional cellular targets and activities of E7 that are relevant to cellular transformation. Indeed, a large number of putative cellular targets for E7 have been identified using a variety of biochemical approaches and proteomic approaches. The physiologic relevance of many of these interactions is not yet clear,[24] but some of these targets appear to be relevant to cancer. For instance, E7 can interact with cyclin-dependent kinase inhibitors. Like Ad E1A, HPV16 E7 interacts with and abrogates the inhibitory activity of p21(cip1) and p27(kip1) and thus has effects on cell cycle progression and keratinocyte differentiation. In addition, high-risk HPV E7 can cause genomic instability in normal human cells.[25] HPV16 E7 induces G1/S and mitotic cell cycle checkpoint defects and uncouples synthesis of centrosomes from the cell division cycle.[26] This causes formation of abnormal multipolar mitoses, leading to chromosome missegregation and aneuploidy.[27] Moreover, there is an increased incidence of double-strand DNA breaks and anaphase bridges, suggesting that in addition to numerical abnormalities, high-risk E7 proteins also induce structural chromosome aberrations.[28] Abnormal centrosome duplication rapidly results in genomic instability and aneuploidy, one of the hallmarks of a cancer cell. This activity is therefore likely to be functionally relevant to the contribution of high-risk HPVs to malignant progression.

The immortalization/transformation properties of the E6 protein were first revealed by studies using primary human genital squamous epithelial cells.[29,30] Efficient immortalization of primary human cells by HPV16 or HPV18 requires both the E6 and E7 genes. Like SV40 large T antigen and the 55-kDa protein encoded by adenovirus E1B, the E6 proteins of the high-risk HPVs can complex with p53.[31] The interaction of E6 with p53 is not direct but is mediated by a cellular protein, called the *E6-a*ssociated *p*rotein (E6AP).[32] E6AP is a ubiquitin protein ligase and, in the presence of E6, directly participates in the ubiquitylation of p53.[33] Multi-ubiquitylated p53 is then recognized and degraded by the 26S proteasome. Consequently, the half-life and level of p53 are low in E6-immortalized cell lines and in HPV-positive cancers. Through its ubiquitylation of p53, HPV 16 E6 can abrogate the transcriptional activation and repression properties of p53 and disrupt the ability of wt p53 to mediate cell-cycle arrest in response to DNA damage. The p53 protein can sense DNA damage and prevent the replication of mutated DNA through its transcriptional activation of the p21 cyclin-dependent kinase inhibitor. Thus, the functional abrogation of p53 by high-risk HPV E6 results in decreased genomic stability and accumulation of DNA abnormalities in high-risk HPV E6–expressing cells. Hence, E6 can be directly implicated in the establishment and propagation of genomic instability, a hallmark in the pathology of malignant progression of cervical lesions.

The development of centrosome abnormalities and aneuploidy, two important related pathologic processes, appears to be initiated before viral DNA integration and may contribute to this process.[34] High-risk HPV can induce abnormal centrosome duplication, which can result in genomic instability and aneuploidy.[27] The deregulation of this mitotic event appears to depend on both E6 and E7, with the latter protein being most responsible for the effect. Indeed, the deregulated viral oncogene expression may result in chromosomal instability and aneuploidy, enhancing the likelihood of viral DNA integration.

A number of additional cellular targets have now been identified for the high-risk E6 proteins in an attempt to define additional p53-independent cellular targets. The reader is referred to the current edition of *Fields Virology*[13] for a more comprehensive discussion of these additional activities, some of which may be relevant to the role of E6 in cervical carcinogenesis. Two activities are of particular importance, however, and are discussed here. The first is the binding to cellular PDZ domain–containing proteins. Interestingly, the high-risk E6 oncoproteins contain an X-(S/T)-X-(V/I/L)-COOH motif at the extreme C terminus that can mediate the binding to cellular PDZ domain–containing proteins. This motif is unique in the high-risk HPV E6 proteins and is not present in the E6 proteins of the low-risk HPV types. E6 serves as a molecular bridge between these PDZ domain proteins and E6AP, facilitating their ubiquitylation and mediating their proteolysis. Among the PDZ domain proteins implicated as E6 targets are hDlg, the human homologue of the *Drosophila melanogaster* Discs large tumor suppressor, and hScrib, the human homologue of the *Drosophila* Scribble tumor suppressor.[35,36] Additional PDZ domain proteins have also been shown to be capable of

binding to E6. Several PDZ-containing proteins have been shown to be involved in negatively regulating cellular proliferation. Therefore, some of the p53-independent transforming activities of the high-risk E6 oncoproteins may be linked to their ability to bind and degrade some of these PDZ motif–containing proteins.

A second important p53-independent activity of HPV16 E6 is its ability to activate telomerase in keratinocytes through the transcriptional upregulation of the rate-limiting catalytic subunit of human telomerase (hTERT).[37,38] Maintenance of telomere length is an important step in cancer and can occur through the transcriptional activation of hTERT expression or through the activation of the ALT recombination pathway. Activation of hTERT is observed in most human cancers, including HPV-positive cervical cancers. The mechanism by which E6 activates the hTERT promoter has not been yet fully elucidated but could involve the direct activation of a cellular transcription factor by E6 or perhaps the E6AP-dependent degradation of a negative regulator of the hTERT promoter.

Infection by a high-risk HPV does not always cause cancer. Indeed, cancer is a rare outcome of an HPV infection, even for HPV16 and HPV18. Expression of the E6 and E7 oncogenes is not sufficient for malignant progression. The time period between infection by a high-risk HPV and the development of invasive cancer can be several decades. Thus, infection with a high-risk HPV constitutes only the initial step in cervical carcinogenesis; the genetic information carried by the virus per se is not sufficient to cause cancer. Epidemiologic studies have suggested that smoking is a risk factor for developing cervical carcinoma.[39] The recognition that other factors are involved in the progression to cervical carcinomas suggests that papillomavirus infections may work synergistically with these other factors.

Tumor progression is, however, a complex process that involves multiple additional genetic loci. Specific chromosomal abnormalities have been detected in cervical cancer, including the loss of heterozygosity on the short arm of chromosome 3 (3p).[40] This locus contains the FHIT (fragile histidine triad) gene,[41] and its expression is inversely correlated with the severity of the lesion and prognosis.[42] In addition, loss of 11q23 may involve the tumor suppressor of lung cancer gene (TSLC1), which is implicated in cell adhesion.[43] An additional possibility is that cellular mutations or epigenetic changes could be involved in downregulating HLA antigen class I alleles and the ability of an HPV-positive cancer cell to be recognized by the host cellular immune response.

HPV and Other Cancers

The high-risk genital tract HPV types can infect other genital areas that contain stratified squamous epithelium and cause intraepithelial neoplasias and cancer. HPV DNA, usually HPV16, can be found in a subset of cancers of the vulva, vagina, and penis.[44,45] Giant condyloma acuminata, also called the Buschke-Lowenstein tumor, is a low-grade, locally invasive squamous cell carcinoma that involves the external genitalia and is associated with low-risk HPV types, usually 6 or 11.[46,47]

Anal cancer is also associated with high-risk HPV infection, and the rate of anal HPV infection appears to be similar to that of cervical infection, although anal HPV infection has been studied less systematically than cervical infection.[48] As with cervical cancer, high-risk HPV can be found in most anal cancers, usually HPV16; most anal cancers arise in the transition zone between columnar and squamous epithelium. The risk of anal cancer in the general population appears to be much lower than for cervical cancer, and the incidence of anal cancer in women is less than one tenth that of cervical cancer. The risk of anal cancer among individuals who are human immunodeficiency virus (HIV)-positive is much greater than in the general population, with especially high rates for HIV-positive male homosexuals.[49]

HPV is linked to some head and neck cancers, although not to the majority of the cancers in this region. HPV16 accounts for about 90% of the HPV-positive tumors. Most of these HPV-associated cancers are located in the oropharynx, which includes the tonsils, tonsillar fossa, base of the tongue, and soft palate. It is not understood why the HPV-positive tumors preferentially develop in the oropharynx. In the United Sates, the incidence of these oropharyngeal cancers, which usually develop at a younger age than the HPV-negative cancers, increased more than threefold between 1988 and 2004.[50] Genital-oral sex may be a risk factor for these tumors, and the risk of HPV infection and cigarette smoking may be more than additive. The HPV-positive tumors tend to have a characteristic basaloid pathology and share many molecular features with those of HPV-positive anogenital tumors. The tumors usually have integrated HPV DNA expressing E6 and E7. Their p53 and pRB genes are wild type, and the vast majority of them expresses p16,[51] in contrast to the HPV-negative tumors, which tend to have mutant p53 and to be p16-negative. There is thus far, however, no clearly identifiable premalignant oropharyngeal lesion for HPV-positive tumors. HPV-positive oropharyngeal cancers carry a better prognosis than the HPV-negative ones.[52,53]

Esophageal carcinomas in humans have also been reported to have some association with HPVs; however, the data as yet are not as convincing as they are with the anogenital cancers and with oropharyngeal cancers. The esophagus is lined by a squamous epithelium, and squamous cell papillomas of the esophagus have been described in humans.

Additional studies seem warranted to investigate a possible role of HPV in human esophageal cancers. There have also been sporadic reports associating occasional human tumors, including colon cancer, ovarian cancer, prostate cancer, and even melanomas, with the presence of HPV DNA in the literature. In general it seems prudent to be skeptical of such reports until systematic and well-carried-out studies are confirmed in multiple laboratories.

HPV and Epidermodysplasia Verruciformis

EV is a very rare disorder in which affected individuals have a unique susceptibility to cutaneous HPV infection.[54] The warts usually develop in childhood, become widespread, do not tend to regress, and in approximately 30% of patients may progress to squamous cell cancers. Several types of lesions may occur in the same patient. Some lesions are typical flat warts (usually caused by HPV3 or HPV10), whereas others are flat, scaly, red-brown macules. The scaly lesions are associated with a range of beta-HPV types, most frequently HPV5 and HPV8. Patients with EV are often infected by multiple HPV types.

In approximately one half of affected patients, EV occurs as an inherited disorder. Inheritance appears to have an autosomal recessive pattern in most affected families, although one family with apparent X-linked recessive inheritance has been reported. Cases with autosomal recessive inheritance appear to be genetically heterogeneous, because the condition in different families has been mapped to two distinct chromosomal loci,[55] and two adjacent novel genes (EVER1 and EVER2) have now been molecularly identified at one of these loci (17q25).[56]

EV patients do not have an increased susceptibility to clinical infection with other microbial agents, including other HPVs. In addition, the EV-specific HPV types have now been found in normal skin of many individuals, so the EV patients are unusual in that these HPV types produce clinically apparent lesions. However, clinical lesions associated with EV-specific HPV types have been described in other immunosuppressed individuals, such as renal transplant patients.[57] Patients with EV often have impaired cell-mediated immunity, which is believed to be important with regard to the manner in which they respond to infections by this subset of cutaneous HPVs.

About one third of EV patients develop skin cancers in association with their lesions. Most of the malignant tumors remain local, but regional and distant metastases may occur. The risk of malignant progression is limited to the pityriasis-like lesions, which are the lesions that contain the beta-HPV types. HPV5 and HPV8 appear to be the most oncogenic, because most of the skin cancers contain one of these two types. The EV carcinomas usually arise in sun-exposed areas, suggesting that ultraviolet radiation may play a co-carcinogenic role with the specific HPVs in the etiology of these cancers. Mutations in the p53 gene are common in EV-associated cancer,[58] in contrast to the mucosal cancers associated with HPV. Studies have also established that the viral genomes are transcriptionally active within these carcinomas.[59]

HPV and Nonmelanoma Skin Cancer

Nonmelanomas skin cancers (NMSCs) are subdivided into basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs). They generally arise on exposed areas, and UV exposure is a predominant risk factor. Immunosuppressed individuals are at high risk for developing warts as well as premalignant lesions and NMSC, especially SCC, in sun-exposed areas.[60,61] The consistent finding of certain beta genus HPV types in SCC associated with EV and other immunosuppressed individuals makes HPV infection an attractive etiologic agent for at least some NMSCs in individuals who do not have EV.[62] Beta HPVs encode potential viral oncoproteins that could interfere with UV-induced apoptosis,[63] which might allow keratinocytes with UV-induced mutations to survive and progress to carcinomas. Although beta HPV DNA can be frequently detected in SCC using sensitive PCR-based detection methods, it is also frequently detected in normal skin.[64-66] The genome copy number is usually much less than one copy per tumor cell.[67] A recent study employing an unbiased analysis involving high-throughput sequencing of randomly primed mRNAs detected virtually no HPV transcripts in SCC specimens.[68] Overall, the association between HPV infection and NMSC is therefore considered weak at present, because expression of predominant HPV types has not been as clearly identified in NMSC as it is in EV-associated skin cancers or in mucosal cancers associated with the high-risk alpha genus HPV types. It is formally possible that the beta HPV types have a role in the initiation of NMSC but that they are not required for cancer maintenance.[67]

HPV Preventive Vaccine

A major advance in the prevention of human cancer has been the development of an effective preventive vaccine for the major genital tract HPVs. The vaccine is a subunit vaccine consisting of the major capsid protein (L1) that can self-assemble into virus-like particles (VLPs), which are empty capsids that closely resemble authentic virions morphologically and immunologically.[69] The L1 VLPs are highly immunogenic, inducing high titers of neutralizing antibodies that are conformationally dependent and type specific. Two commercial prophylactic HPV vaccines have been developed and approved by the FDA. GlaxoSmithKline's Cervarix is a bivalent vaccine composed of L1 VLPs of HPV16 and 18, whereas Merck's Gardasil is a quadrivalent

vaccine composed of L1 VLPs of HPV6, 11, 16, and 18. Both vaccines are generally safe, able to induce high titers of capsid-reactive antibodies, and highly effective at preventing acquisition of cervical infection and low- and high-grade CIN caused by the types targeted by the vaccine.[70] Both vaccines also induce a modest degree of protection against cervical infection caused by specific nonvaccine types closely related to HPV16 or 18. For instance, both vaccines induced partial protection against persistent infection by HPV31. Cervarix, but not Gardasil, induced significant protection against HPV45, and neither vaccine protected significantly against HPV35 or 58.[71-73] One can anticipate that second-generation VLP vaccines may be able to protect against an even higher proportion of HPV infection by incorporating VLPs from a larger number of HPV types. Although 70% of cervical cancers are caused by HPV16 or HPV18, 30% are caused by the other high-risk HPV types.

Although Cervarix and Gardasil have now been licensed in more than 100 countries, they have been introduced into the national vaccination programs of only about 30 countries, mostly the most developed ones. National programs have been centered on vaccination of preadolescent or adolescent girls, ages 9 to 15 years, because more than 90% of HPV-associated cancer worldwide occurs in women.[74] However, recent evidence indicates that Gardasil protects young men from genital warts and anal cancer precursors, providing a rationale for considering male vaccination programs. Furthermore, the increase in HPV-positive head and neck oropharyngeal cancer also suggests a rationale for male vaccination programs.

There are several important unresolved issues for the current VLP vaccines.[69] For instance, the VLP vaccine is expensive and is not heat stable, two characteristics that might impede its use in developing countries where the cervical cancer disease burden is greatest. Because of the type specificity, the current vaccines are unlikely to protect against a substantial proportion of other high-risk HPV-type infections, so it will be important for vaccinated women to continue to undergo cervical cancer screening. Additional approaches to improve the vaccine seem warranted. Merck has indicated that a nonavalent (nine HPV targets) VLP vaccine is currently in clinical trials.[75] In addition, the use of L2 represents a potential alternative approach to developing a prophylactic vaccine against a broader spectrum of HPV types. Although they are not as immunogenic as the L1 neutralization epitopes, at least some of the L2 neutralization epitopes induce cross-neutralizing antibodies against papillomaviruses from different types.[76,77] In addition, modifications of the L1 capsid protein allow the self-assembly of capsomeres that are highly immunoprotective, can be produced in bacteria, and are more stable.[78]

Epstein-Barr Virus

Epstein-Barr virus (EBV) is a common virus with a worldwide distribution. More than 90% of individuals worldwide have been infected by the time they reach adulthood. EBV was discovered through studies of a lymphoma described in young children in certain parts of East Africa. Although this childhood lymphoma had been previously recognized, it was first clearly defined as a unique entity with characteristic clinical, pathologic, and epidemiologic features by Dennis Burkitt in 1958.[79,80] His early descriptive studies speculated that the lymphoma could be due to a virus because its geographic distribution in a belt across equatorial Africa was similar to that of yellow fever. In 1964, Epstein and Barr described virus particles of the herpesvirus family in lymphoblastoid cells from patients with Burkitt's lymphoma (BL).[81,82] The finding of such virus particles in lymphoid lines, however, was not restricted to tissues from BL patients; these particles could also be observed in cell lines established from patients with other malignancies, from patients with infectious mononucleosis, and even occasionally from normal individuals. Nonetheless, EBV was the first virus to be recognized as a human tumor virus.

Virus-Host Cell Interactions

EBV is a double-stranded DNA virus and is a member of the herpesvirus family. Other members of the human herpesvirus family include herpes simplex viruses types 1 and 2, varicella zoster virus, cytomegalovirus, human herpesvirus types 6 and 7, and Kaposi's sarcoma herpesvirus (KSHV, also known as HSV8). The mature EBV particle is essentially indistinguishable from those of the other herpesviruses. Herpesviruses are large viruses, measuring 150 to 180 nm in diameter, and contain a large double-stranded DNA genome of about 170,000 base pairs. In addition to this central core of genetic material, the virus particle consists of a capsid layer made up of capsomeres in an icosahedral shape and an outer lipoprotein envelope. EBV is considered a member of the gamma herpesviruses because of its tropism for lymphoid cells, both in vivo and in vitro. EBV infects epithelial cells of the oropharynx and B-lymphocytes. The infection of B cells is a latent infection in which there is no replication of the virus and the cells are not killed. EBV proteins are serologically distinct from proteins of other human herpesviruses.

Antibodies to EBV are prevalent in all human populations, and high titers of antibody correlate with infectious mononucleosis.[83] Primary infection in adolescents in developed countries causes infectious mononucleosis. EBV also causes X-linked lymphoproliferative disease type 1 (XLP-1), an often fatal disease, in patients with a mutation in the *SAP* (SLAM-associated protein) gene.[84] High titers of EBV are

also often seen in patients with specific malignancies: BL, nasopharyngeal carcinoma (NPC), and Hodgkin's lymphoma, as discussed later.[84] EBV is associated with B-cell lymphomas in immunosuppressed individuals, particularly those with HIV or organ transplant recipients.

EBV has several distinct programs of gene expression in infected cells, a lytic cycle and a latent cycle. The lytic cycle results from the phased expression of viral proteins that ultimately results in the replication of the virus and the production of infectious virions. The replicative cycle of EBV does not inevitably result in the lysis of the infected host cell, because EBV virions are produced by budding from the infected cell. Latent infections do not result in the production of progeny virions. In latently infected B lymphocytes, the genome circularizes an episome in the cell nucleus. In B-lymphoid cells that harbor and express the EBV genome in a latent state, there is expression of a distinct subset of viral proteins, including the EBV-induced nuclear antigens (EBNAs): EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, and EBNA-leader protein (EBNA-LP). In addition, EBV encodes two latent-infection–associated membrane proteins (LMPs), and two small nonpolyadenylated RNAs (EBERs) that are also expressed in EBV latently infected cells. Molecular genetic analyses using specifically mutated EBV recombinants have revealed that EBNA-3B, LMP2, the EBERs, and most of the viral genome that is expressed in lytic infection can be mutated without a significant effect on the ability of the virus to transform primary B lymphocytes.[84] The other EBNAs and LMP1 are important for lymphocyte transformation. LMP2 is important in maintaining latency by preventing lytic infection in response to lymphocyte activation signals. A detailed description of the molecular biology of EBV and its normal biology is provided in the recent edition of *Fields Virology*.[84]

Two of these genes, EBNA-2 and LMP1, are particularly important with regard to viral latency and EBV immortalization of human B cells. EBNA-1 is a DNA binding protein that binds to an EBV origin of DNA replication called oriP and mediates genome replication and partitioning during division of the latently infected cells. EBNA-1 also possesses a glycine-alanine repeat that functions to impair antigen processing and MHC class I–restricted antigen presentation of EBNA-1, thereby inhibiting the CD8-restricted cytotoxic T-cell recognition of virus-infected cells.

LMP1 has been shown to alter the effect of the growth properties of rodent cells, epithelial cells, and B lymphocytes. LMP-1 is a transmembrane protein that is essential for EBV-mediated growth transformation. LMP-1 mediates signaling through the tumor necrosis factor-alpha/CD40 pathway. When expressed in normal resting B lymphocytes or in EBV-negative lymphoblastoid cell lines, LMP1 induces most B lymphocyte activation and adhesion markers, activates NFκB, and induces Bcl2 and A20, proteins important in preventing apoptosis. The C-terminal LMP1 cytoplasmic domain interacts with cellular proteins that transduce signals from the tumor necrosis factor receptor (TNFR) family. TNF signaling is critical in normal lymphoid development, and the B-lymphocyte TNFR family member, CD40, is remarkably similar in its growth-promoting and NFκB-activating effects to LMP1. The evidence supports a model that LMP1 mimics a constitutively activated TNFR.[84]

EBNA-2 is the main viral transcriptional transactivator that has effects both on viral and cellular genes. Viral proteins whose expression can be increased by EBNA-2 include the latent membrane protein (LMP1) and another membrane protein that is expressed in latently infected cells called terminal protein. EBNA-2 lacks DNA sequence-specific binding activity and is dependent on interactions with sequence-specific cell proteins for the recognition of enhancer elements. EBNA-2 binds the cellular RBPJκ protein and is recruited to promoters regulated by RBPJκ, including the Notch pathway. EBNA-3A and -3C also regulate transcription in lymphocyte transformation and, like EBNA-2, EBNA-3A and -3C also achieve specificity in their interaction with viral and cellular promoters by interacting with the cell protein RBPJκ. Through the interactions of EBNA-2, EBNA-3A, and EBNA-3C with the cell protein JK, EBV therefore affects the cellular Notch signaling pathway.[84]

Burkitt's Lymphoma

Endemic BL that occurs in Africa and New Guinea in the malaria belt is an EBV-positive malignancy that occurs several years after the primary infection with EBV. BL is a monoclonal lymphoma, as opposed to infectious mononucleosis, which is a polyclonal disease caused by EBV. African BL is clinically characterized by rapid growth of the tumor at nonlymphoid sites such as the jaw or the retroperitoneum. The tumor is of B-cell origin and is morphologically similar to the small noncleaved cells of normal lymphoid follicles.[85] The proliferation of the B lymphocytes and the reduction in virus-specific cytotoxic T cells associated with malaria is believed to result in an increased EBV viral load, enhancing the risk of the c-myc translocations characteristic of BL.[86] The failure of the T-cell immune response to control this proliferation might be an early step providing the enhanced opportunity for further mutation, oncogenic transformation, and lymphomagenesis in the actively dividing B-cell population. In contrast, only 15% to 20% of the non-African, sporadic BL tumors are EBV positive. BLs regularly contain chromosomal abnormalities, often in regions that contain the immunoglobulin genes, most notably chromosomes 2, 14, and 22. In more than 90% of BL, a translocation of the long arm of chromosome 14 (containing the heavy chain immunoglobulin genes) to chromosome

8 (containing the *c-myc* oncogene) is observed.[87] Less frequent translocations involve chromosome 2 (kappa light chain) and chromosome 22 (lambda light chain).[88] The translocations with chromosomes 2 and 22 generally involve reciprocal translocations to the distal arm of chromosome 8, containing *c-myc*. The expression of the *c-myc* oncogene following this translocation is deregulated because of the proximity of the *c-myc* oncogene to the transcriptional control elements of the immunoglobulin genes that are active in B cells. Overexpression of the *c-myc* oncogene itself is not sufficient for malignant transformation of a B cell. Additional mutations can then occur in these B cells, leading eventually to the emergence of a monoclonal B-cell neoplasm. Thus EBV does not act directly as an oncogene, but rather indirectly as a polyclonal B-cell mitogen, setting the stage for the translocation to activate the *c-myc* oncogene and other mutations.

What is the role of specific EBV genes in the maintenance of BL? As noted earlier, EBNA-2 and LMP1 appear to be the mediators of EBV-induced growth effects in B lymphocytes. These, however, are not expressed in BL and are therefore not required for BL growth. It is possible that altered *myc* expression may replace the need for EBV oncogenic functions. Furthermore, the down-modulation of the EBV EBNA and LMP functions may actually be advantageous to tumor development, allowing the cell to escape from T-cell–mediated immune surveillance. It has been shown that the EBNAs and LMP can serve as targets of immune cytotoxic T cells, and that LMP-1 induction of cell adhesion molecules can enhance the HLA-restricted killing of EBV-infected T cells.[89]

Nasopharyngeal Carcinoma

NPC is also linked to EBV. NPC occurs in adults and, in general, males outnumber females 2 to 1. Although worldwide the annual incidence rates are low, there are areas in China (especially the southern provinces) where the rate of disease can be 50 cases per 100,000 per year in men over 50. Because the incidence among individuals of Chinese descent remains high, irrespective of where they live, a genetic susceptibility has been proposed. Environmental factors have been implicated as risk factors for NPC, including fumes, chemicals, smoke, and ingestion of salt-cured fish that contain nitrosamines. The rate of NPC in the United States and Europe is between 0.5 and 2 per 100,000.

EBV genomes are found in nearly all biopsies of anaplastic NPC specimens from all over the world.[90,91] The genome is present in the epithelial cells of the tumors (but not in the infiltrating lymphocytes), and it is noteworthy that all forms of NPC contain clonal EBV episomes, indicating that the tumors arise from a single infected cell.[92] The EBV genome is transcriptionally active within these tumors, and the regions that are transcribed in the NPC biopsies are the same as those expressed in latently infected lymphocytes.[93] These molecular observations are consistent with an active role for EBV in the neoplastic processes involved in NPC. Patients with NPC have elevated levels of IgG antibodies to EBV capsid and early antigens. NPC patients have serum IgA antibodies to capsid and early antigen, likely reflecting the local production of such antibodies in the nasopharynx. Cytogenetic studies on NPC xenografts have identified abnormal markers on a number of different chromosomes. Loss of heterozygosity has been noted by studies using restriction fragment length polymorphisms (RFLPs) on two different regions of chromosome 3 mapping to 3p25 and 3q14 in a very high percentage of NPC specimens.

The presence of immunoglobulin markers for EBV (IgA/VCA and IgA/EA) has provided the opportunity for early serologic identification of patients with NPC. The frequency of IgA antibody to the EBV capsid antigen of 150,000 Chinese studied was found to be 1%. About 20% of the patients with elevated IgA antibodies to VCA had NPC, however, when biopsied. Thus, early detection using serologic tests can be applied in areas where NPC is prevalent, possibly leading to early therapeutic intervention.

EBV-Associated Malignancies in Immunocompromised Individuals

Strong evidence for the oncogenic potential for EBV comes from its association with a variety of malignancies in immunocompromised individuals. These include EBV-positive lymphoproliferative disease in children with primary immunodeficiencies affecting T-cell competence (such as those with the Wiskott-Aldrich syndrome), posttransplant lymphoproliferative disease (PTLD), B-cell lymphomas in patients with acquired immunodeficiency syndrome (AIDS), and smooth muscle cell tumors of the immunocompromised patient.[84]

EBV is associated with B-cell lymphomas in patients with acquired or congenital immunodeficiencies and in organ transplant recipients. These lymphomas can be distinguished from the classical BLs in that the tumors are often polyclonal. Also, the tumors do not demonstrate the characteristic chromosomal abnormalities of BL described earlier. The pathogenesis of these lymphomas involves a deficiency in the affector mechanisms needed to control EBV-transformed cells.

The association between EBV and leiomyomas and leiomyosarcomas in immunocompromised patients was unexpected and has now been seen in the context of acquired immunodeficiency and in organ transplant patients. From

the EBV standpoint, the pathogenesis and role of EBV are not yet well understood.[84]

Hodgkin's Lymphoma

Serologic and epidemiologic studies suggesting a possible link between Hodgkin's lymphoma (HL) and EBV were supported by molecular studies that demonstrated EBV DNA, RNA, and proteins in HL pathologic specimens.[94-97] The four histologic types of HD vary in the rate of their EBV positivity: 80% to 90% for lymphocyte depleted, 60% to 75% for mixed cellularity, 20% to 40% for nodular sclerosis, and 10% for lymphocyte rich.[84] EBV proteins and DNA can be demonstrated in approximately 40% of Reed-Sternberg cells. Furthermore, expression of LMP1 in the Reed-Sternberg and Hodgkin's cells can be demonstrated in a large percentage of the EBV-positive cases of MC and NS subtypes, although EBNA-2 expression is not detected.[96,98] Activation of the NFκB pathway is a common feature of HD, and the activation of this pathway by LMP1 to promote lymphocyte proliferation and survival may suggest a role for EBV in promoting HD. The evidence that EBV, when present, plays a causative role in the pathogenesis of some cases of HD is considered strong.[84]

Gastric Carcinoma

EBV is present in about 10% of gastric cancers worldwide, with a similar prevalence in the United States and Asia. As in NPC, it is the epithelial cells, not infiltrating lymphocytes, that contain the EBV DNA, and the DNA is clonal or oligoclonal, consistent with a role for EBV in tumor development. The EBV genes expressed in the cancers include EBNA-1 and the nonpolyadenylated viral RNAs known as the EBERs, as well as several other genes including the latent membrane protein 2A (LMP2A).[84]

Non-Hodgkin's Lymphomas and Other Malignancies in Nonimmunocompromised Individuals

EBV is present in approximately 6% of non-Hodgkin's lymphoma (NHL) cases, including some B-cell lymphoma, peripheral T-cell lymphoma, angioblastic T-cell lymphoma, lymphomatoid granulomatosis, pyothorax-associated lymphoma, extranodal NK/T-cell lymphoma (nasal type), aggressive NK-cell leukemia/lymphoma, and inflammatory pseudotumor-like follicular dendritic cell sarcoma.[84,99] Although there have also been reports of EBV associated with breast cancer, there is not yet compelling evidence associating the virus with the disease.[84]

Kaposi's Sarcoma Herpesvirus

The Kaposi's sarcoma–associated herpesvirus (KSHV), also known as human herpesvirus 8 (HSV8), is a gamma-2 herpesvirus. Chang, Moore, and colleagues discovered this virus in 1994 by representational difference analysis of an AIDS Kaposi's sarcoma (KS) skin lesion.[100] Since its discovery, KSHV has been linked with several other different tumors in addition to KS, namely, body-cavity–based or primary effusion lymphomas (PEL) and some plasma cell forms of multicentric Castleman's disease (MCD).

KS was initially described as an aggressive tumor by Moritz Kaposi in the 19th century. Before the onset of the AIDS epidemic, KS had been described as a rare and indolent tumor of elderly Mediterranean men and was later recognized to occur more frequently in parts of Africa. KS had also been observed among immunosuppressed organ transplant patients. KS is the most common neoplasm associated with AIDS.[101,102] The histology of KS in all of these clinical settings is similar. KS lesions contain multiple cell types, including spindle cells, which are believed to arise from an endothelial cell precursor, and infiltrating mononuclear cells. KS lesions are histologically characterized by slitlike vascular channels that give the lesions their distinctive reddish clinical appearance.

Research with PEL cell lines and on the KSHV itself quickly moved the field along and established an etiologic role for the virus in KS.[103] The identification of KSHV-positive PEL cell lines[104,105] led to the development of some initial serologic assays for epidemiologic and virologic studies of the agent. KSHV is a member of the rhadinovirus (or gamma-2) subfamily of the herpesviruses. It is the only known human rhadinovirus and is closely related to the herpesvirus saimiri of squirrel monkeys. Humans are the only known host for KSHV. Unlike other human herpesviruses, infection by KSHV is not ubiquitous, and only a small percentage of humans in developed countries are serologically positive for the virus. Infection by KSHV is characterized by a prolonged viral and clinical latency that, as with other herpesviruses, may be lifelong. In a setting of immunosuppression or immunodeficiency, individuals infected with KSHV may then develop KS or other KSHV-associated tumors, years after the primary infection. At this point, a role for KSHV has been established for KS and for PEL and MCD.

Despite the progress in the epidemiology and the molecular biology associated with KSHV, our understanding of the virology and the mechanisms of pathogenesis and carcinogenesis associated with this virus is still at an early stage. The virus has been difficult to culture in the laboratory, and much of our knowledge has been discerned from the analysis of the primary sequence by studying individually encoded genes. One characteristic of the rhadinovirus subfamily of the herpesviruses is the presence of recognizable variants of cellular genes that appear to have been captured into the viral genomes, a process that has been termed "molecular piracy." These genes are believed to play important regulatory roles

in the virus life cycle, in evading the cell's host defenses and in causing its associated pathology in the host.[106] Among the KSHV regulatory genes are viral genes that resemble cellular cytokines, cellular chemokines, the cellular interferon regulatory factor (IRF-1), the cellular apoptosis factor (FLIP), a viral homologue of Bcl-2, a viral cyclin that is resistant to inhibition by cdk inhibitors, and a chemokine receptor, among others. In addition, many of the KSHV regulatory genes resemble EBV genes or target cellular pathways that are also targeted by other DNA tumor viruses, particularly EBV. Included among this group of genes is LAMP, which is similar to the EBV LMP1 and LMP2A genes. Much of the effort in the field has been focused on these individual genes and their properties. It is beyond the scope of this chapter to go into detail about the molecular biology of KSHV and these particular studies. Instead, I refer the reader to the comprehensive chapter on the molecular biology of KSHV in the recent edition of *Fields Virology*.[107]

Viruses and Liver Cancer

Hepatocellular carcinoma (HCC) is one of the world's commonest malignancies. In China alone, there are between 500,000 and 1 million cases of HCC per year. HCC is etiologically linked to infections by two different types of viruses, hepatitis B virus (HBV) and hepatitis C virus (HCV). Though relatively rare in the West, HCC is quite prevalent in Southeast Asia and in sub-Saharan Africa. In the 1970s, this distribution was recognized to mirror the distribution of chronic HBV infection. Indeed, the long-recognized association between HCC and chronic hepatitis led to the strong presumption that chronic HBV infection predisposes to hepatic cancer. This presumption was validated in large prospective epidemiologic studies in Taiwan, in which chronic infection with HBV leading to cirrhosis was shown to be of major importance in the etiology of this tumor.[108] Chronic HBV infection was found to be associated with about a 19-fold increase of HCC mortality risk in men and a 33.5-fold increase in women.[109] The World Health Organization has estimated that 80% of HCC worldwide occurs in individuals who are chronically infected by HBV. For the remaining 20% of HCC not associated with HBV, there are a number of additional risk factors, including chronic hepatitis associated with HCV. Between 30% and 70% of HBV-negative cases of HCC are seropositive for HCV. In the United States, it has been estimated that as many as 40% of cases of HCC are due to HCV.

Hepatitis B Virus (Virus-Host Interactions)

HBV is a member of a group of the hepadnaviruses (for hepatotropic DNA viruses). HBV is the only human member of this group of viruses. Other members of this group include the woodchuck hepatitis virus (WHV), the Beechey ground squirrel hepatitis virus (GSHV), the Pekin duck hepatitis B virus (DHBV), and the grey heron hepatitis virus. These viruses share a similar structure, and each is hepatotropic, leading to persistent viral infections of the liver. The animal hepatitis viruses have been very important contributors to our understanding of the molecular biology of these viruses. Of the hepadnaviruses, only HBV and WHV have been associated with chronic active hepatitis and HCC.

The reader is referred to the *Fields Virology* chapter on the molecular biology of the hepadnaviruses for details on the virus and aspects of virus/host cell interactions.[110] Hepatitis B viral particles contain small, circular DNA molecules that are only partially double stranded. The DNA consists of a long strand with a constant length of 3220 bases and a shorter strand that varies in length from 1700 to 2800 bases in different molecules. A map of the HBV DNA genome is shown in Figure 6-4. The virion particles contain a DNA polymerase activity that is capable of repairing the single-stranded DNA region to make two fully double-stranded molecules, each approximately 3220 bases in length. For this reaction, DNA synthesis initiates at the 3′ end of the short strand that, as noted earlier, is heterogeneous among different DNA molecules. DNA synthesis terminates at the uniquely located 5′ end of the short strand when it is reached. The long strand is not a closed molecule

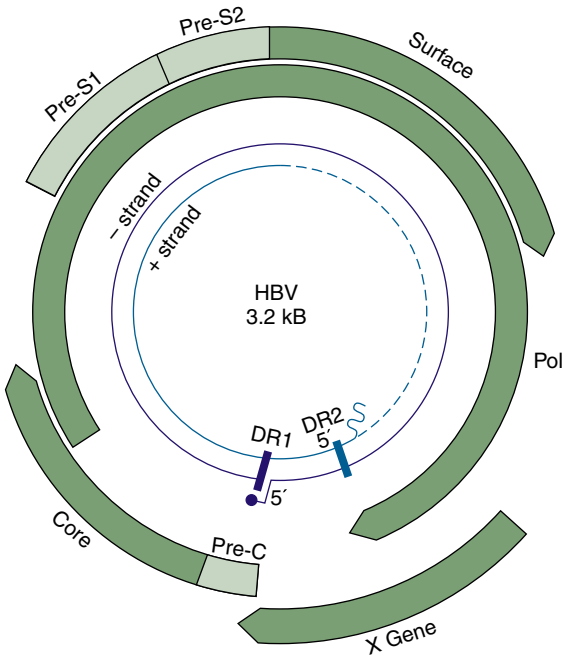

Figure 6-4 Map of the HBV genome The arrows surrounding the genome represent the four large open reading frames of the L⁻ strand with the genes they encode indicated. The broken line is the S⁺ DNA strand. The positions of the 5′ ends of the DNA strands are indicated. The locations of the direct repeats (DR1 and DR2) involved in the initiation of DNA replication are also indicated.

but contains a nick at a unique site approximately 300 base pairs from the 5′ end of the short strand.

The HBV genome has four ORFs and encodes four genes. These ORFs are designated as S and pre-S, C, P, and X. S and pre-S represent two contiguous reading frames and code for the viral surface glycoproteins. C contains the coding sequences for the core structural protein of the nucleocapsid. The P gene encodes the viral polymerase that contains reverse transcriptase activity. The X ORF encodes a basic polypeptide that has transcriptional transactivation properties that can upregulate the activity of hepadnavirus promoters. The overall structure of the genomes of all of the animal hepadnaviruses is quite similar. The WHV and GSHV genomes are approximately 3300 base pairs in size, and that of DHBV is approximately 3000 base pairs in size. The genomic organization of the various hepadnaviruses is similar, and there is extensive nucleotide homology among them. The mammalian hepadnaviruses differ from the avian hepadnaviruses in that the avian hepadnaviruses do not contain the X region.

HBV DNA can be found either free or integrated in the host chromosome of the hepatocyte. Free HBV DNA represents intermediate forms of replication for the viral genome and can be detected during acute infections and some chronic stages of HPV infection. Integrated sequences are usually found during chronic virus infection and in HCC. The replication mechanism for the hepadnaviruses, first discovered by Summers and Mason for DHBV[111] and later confirmed for HBV, is different from that of other DNA viruses. The replication cycle involves a reverse transcription step resembling that of the retroviruses in that it goes through an RNA copy of the genome as an intermediate in replication. The hepadnaviruses differ from the retroviruses, however, in that retrovirus virions contain RNA and the intermediate form of replication is integrated DNA. The virions of the hepadnaviruses contain DNA and the intermediate replication form is RNA. Also, integration of the hepadnavirus genome as a provirus is not a necessary intermediate step for viral genome replication as it is for a retrovirus. The similarity between the retroviruses and the hepadnaviruses extends to the overall genomic organization, in which all of the genes are encoded on only one strand. The order of the genes within the retroviruses (gag, pol, and env) is similar to their counterparts for the hepadnaviruses (core, polymerase, and surface antigen). Other subtle differences in the transcriptional programs used to generate the messenger RNAs for these different viruses exist. A further similarity between these viruses is that some members of each group of these viruses encode transcriptional regulatory factors. For HTLV-1, described later in this chapter, the X region encodes the transcriptional activator tax as well as the rex gene product involved in messenger RNA transport to the cytoplasm. The X genes encoded by the mammalian hepadnaviruses similarly encode a protein that has been extensively studied and shown to have a variety of activities, including the ability to function as a transcriptional activator. The function of X in the life cycle of the mammalian hepadnaviruses, however, is still not well understood. Although there have been studies claiming that the X protein has oncogenic properties, the evidence implying a direct role for the X protein in HCC is far from compelling.[110]

Primary infection with HBV results either in a subclinical infection or acute hepatitis B, depending on the age of the individual, among other factors. In adults, 95% of such infections resolve, with clearance of virus from the liver and the blood and with lasting immunity to reinfection. The remaining 5% of infections do not resolve but develop into a persistent hepatitis with a viremia that usually lasts for the life of the host and can have a variety of pathologic consequences. Many of these persistent infections have little associated hepatocellular injury. Approximately 20% to 25% of persistently infected individuals do develop hepatocellular injury, either chronic persistent hepatitis (in which case the inflammation is limited to periportal areas) or chronic active hepatitis (where there is inflammation and hepatocellular necrosis extending outside of the portal areas). Chronic active hepatitis has significant potential for progression to cirrhosis, hepatic failure, and cancer.

HBV and Hepatocellular Carcinoma

An etiologic role of HBV in HCC is now established. There is a striking correlation between the worldwide geographic incidence of HCC and the prevalence of HBsAg chronic carriers, and important evidence for the role of HBV in HCC was provided by the prospective epidemiologic studies of Palmer Beasley in Taiwan.[108] The classic studies from Beasley demonstrated that chronic HBV carriers in Taiwan had more than 100 times the risk of noncarriers for the development of HCC. In areas such as Taiwan that are endemic for HBV, infection with the virus occurs in early childhood, and there is an interval of approximately 30 years before the development of HCC.

Despite the strong epidemiologic evidence establishing HBV as the major cause of HCC worldwide, a mechanistic role for HBV in HCC is not fully understood. Usually in HBV-positive liver cancers, viral DNA sequences can be found integrated into the host cellular DNA. Different tumors display different patterns of integration, indicating that the insertion of the viral DNA into the host chromosome is not site specific. In a given tumor, however, all cells have the same pattern of HBV DNA integration, indicating that the integration event preceded the clonal expansion of the tumor. This clonal pattern of HBV DNA integration supports the etiologic role of HBV in HCC.

The HBV integrated genomes are often highly rearranged within tumors, displaying a variety of deletions, inversions, and point mutations. Although occasional integrated genomes do retain one or more viral genes intact, there does not appear to be a consistent pattern in which one gene is regularly preserved intact. This indicates that the continued expression of a specific viral gene is not required for the maintenance of the malignant phenotype in an HBV-positive liver cancer.

There are two hypotheses to explain how HBV causes cancer, one involving a direct role of the virus in carcinogenesis and the other indirect, as a consequence of persistent liver injury caused by the immune response to infected hepatocytes by cytotoxic T cells. The direct models imply an oncogenic role for an HBV either through the integration of the viral genome or from the oncogenic activity of a viral gene product. The indirect models do not require a direct genetic contribution by the virus or its gene products to the transforming event.

Mechanisms by which HBV DNA integration could directly contribute to tumorigenesis could be either (1) proto-oncogene activation as a result of the insertion of the viral DNA or (2) the inactivation of tumor suppressor alleles by such integration. Indeed, there is compelling evidence that insertional activation in WHV-induced hepatomas is important in hepatocellular carcinogenesis in the woodchuck model. Approximately 20% of the tumors show WHV DNA inserted into the N-myc locus.[112] This gene, normally silent in adult liver, is strongly upregulated by this insertion, and this activation can be seen early in the oncogenic sequence—even in premalignant lesions. Whereas insertional activation of N-myc clearly plays a major role in WHV oncogenesis, a similar claim cannot be made for HBV. Human hepatomas do not harbor N-myc rearrangements. An extensive search for comparable events in HBV-associated human HCC have, however, turned up only rare examples of integration in loci that might contribute to the tumorigenesis described (i.e., insertions near loci for retinoid receptors, erb-A, or cyclin As).[110] In conclusion, although insertional mutagenesis or specific oncogene activation may be important in individual cases of HCC, there is little evidence that it is of general mechanistic importance for HCC in humans.

There is also no strong evidence that HBV encodes a transforming protein. The best candidate may be the viral X protein, a small regulatory protein that is encoded by the oncogenic mammalian hepadnaviruses but not by the non-oncogenic avian hepadnaviruses. Indeed, transgenic mice with high levels of hepatic expression of X develop HCC with increased frequency.[113] Tumors in these mice do not begin until midlife, suggesting that additional genetic changes are necessary for cancer development. The X protein has no homology to known oncogenes or cellular genes involved in signaling or growth control. X has been extensively studied from a functional standpoint, but its precise role in the hepadnavirus life cycle remains unclear. The X protein can stimulate cytoplasmic signal transduction pathways (e.g., the ras-raf MAP kinase pathway), can also function as a nuclear transcriptional activator, and can interfere with cellular DNA repair by binding DNA repair proteins.[110] The relationship of all of these activities to the putative oncogenic function of X is unproven. It may be that the role of the HBV X gene product in tumorigenesis in the transgenic mouse lines that have been derived is an indirect one, possibly due to liver injury and triggering hepatocellular regeneration from the overexpression of the X protein. It should be noted further that the X protein is not always expressed in HBV-positive HCCs.

Despite the absence of strong data to support a direct oncogenic role for HBV in HCC pathogenesis, there is mounting support for a more indirect model, in which neither the HBV genome nor any of its products make a direct genetic contribution to the transformation of the infected cell. Instead, HBV-induced cellular injury, a consequence of the immune or inflammatory responses to HBV infection, results in liver cell regeneration that, over time, can lead to cancer. Cellular proliferation in liver regeneration increases the chances for errors in DNA replication, leading to mutations that can contribute to the loss of normal cellular growth control. Those cells with an appropriate set of genetic mutations can then undergo clonal expansion and ultimately progress to HCC. In this indirect model, HBV promotes oncogenesis chiefly by provoking cellular proliferation in response to immune-mediated injury. Thus no direct genetic contribution is made by viral sequences acting in cis or viral gene products acting in trans. Significant experimental support for the indirect model for HBV-induced carcinogenesis has come from important experiments in HBV transgenic mice.[114-116]

Even though the tumorigenic mechanisms of HBV-induced carcinogenesis remain unclear, the overwhelming epidemiologic data clearly establish HBV as the principal cause of most cases of HCC worldwide. An effective vaccine to prevent HBV infection is predicted to prevent the majority of HCC. Vaccines expressing the surface antigens produced by recombinant techniques in yeast or in Chinese hamster ovary cells have been developed commercially, are highly immunogenic, and can protect against HBV infection.[117] The efficacy of protection against HBV infection has been established in large clinical studies of high-risk individuals. The reduction in the levels of HCC following a reduction in the HBV carrier rates among the vaccinated populations has provided confirmation of the role of HBV in HCC.[118] A universal HBV vaccination program has been

recommended by the World Health Organization, with the intended goal of eradicating HBV.

Hepatitis C Virus

Hepatitis C virus (HCV) is a human flavivirus, a positive-strand RNA virus that is an important cause of morbidity and mortality worldwide. HCV carries a very high rate of chronicity after infection, with over 70% of those infected going on to develop chronic liver disease. HCV is believed to be the leading infectious cause of chronic liver disease in the Western world. It is also etiologically responsible for many cases of HCC worldwide. Between 30% and 70% of HBV-negative HCC patients are seropositive for HCV. In the United States, it appears that as many as 40% of the cases of HCC may be associated with HCV. HCV positivity conveys about an 11.5-fold increased risk for the development of liver cancer.[119]

HCV was first cloned in 1989 from the infectious sera of individuals with posttransfusion hepatitis.[120,121] Much of our knowledge of this virus derives from molecular genetic and biochemical studies because, until recently, there were no suitable tissue culture systems or animal models for the study of this virus. Nonetheless, there have been major advances in our understanding of the molecular biology of this important human pathogen.[122] HCV is a single positive-stranded RNA virus with a 9.4-kb RNA genome that contains a single ORF encoding a polyprotein of 3011 amino acids. This large polyprotein is then posttranslationally cleaved to produce several mature structural and nonstructural proteins. The HCV virus is inherently unstable, giving rise to multiple types and subtypes. This genome instability is due to the dependence of the virus on the virally encoded RNA-dependent RNA polymerase to perform the RNA-to-RNA copying of the genome. There is no DNA intermediate in the replication of the genome, excluding the possibility of viral genome integration as a mechanism for HCV-associated carcinogenesis. Furthermore, the polymerase lacks proofreading capability, and there is a substantial level of base misincorporation, accounting for the marked heterogeneity in viral isolates even from a single infected individual. There is a high degree of variability in the viral envelope glycoproteins, which has led to the hypothesis that changes in these genes alter the antigenicity of the virus over time, permitting the virus to escape immune recognition by the host. This variability allowing the virus to escape the immune system is important to the pathogenesis of the virus in establishing a persistent infection. A characteristic feature of an HCV infection is repeated episodes of hepatic damage, resulting from the reemergence of a newly mutated genotype. This genomic heterogeneity, due to the ability of the virus to rapidly mutate, has proved problematic in attempts to develop an effective vaccine to HCV.

It is unclear whether HCV contributes directly to hepatocarcinogenesis. As noted earlier, HCC does not replicate through a DNA intermediate and therefore cannot integrate into host chromosomes, causing insertional mutagenesis. The virus encodes several nonstructural (NS) proteins that are involved in viral genome replication and in altering the cell environment to allow a persistent infection. For instance, one of these proteins, NS5A, can affect interferon signaling and cellular apoptosis through interactions with specific cellular proteins. Interactions of some of the HCV NS proteins with cellular proteins involved in cellular tumor suppression pathways have been described, and there have been a few reports suggesting some oncogenic properties for the viral NS proteins in transfection experiments.[122] To date, however, there is no compelling body of evidence suggesting that HCV encodes a protein that directly contributes to HCC development. Instead, as with HBV, the bulk of the data suggests that the role of HCV in hepatocarcinogenesis may be indirect, through persistent infection, chronic inflammation, and cirrhosis.

Human Retroviruses and Cancer

Human T-Cell Leukemia Viruses

The first substantiated reports of a human retrovirus were published in 1980 and 1981 from Robert Gallo and his colleagues at the NCI[123,124] and soon after from Yoshida and his colleagues in Japan.[125] These isolates were from human T-cell leukemia cell lines. The human T-cell leukemia virus type 1 (HTLV-1) is recognized as the etiologic agent of adult T-cell leukemia (ATL). A causal relationship between HTLV-1 and ATL was initially suggested by epidemiologic studies showing geographic clustering of ATL, a pattern that is consistent with an infectious agent. A second human retrovirus, referred to as HTLV-2, was initially isolated in 1982 from a cell line established from a patient with an unusual form of hairy cell leukemia.[126] However, studies have not established an association of HTLV-2 with any human malignancy.

ATL was first described by Takatsuki and his colleagues in 1977,[127] before the virus was discovered. It is a malignancy of mature CD4-positive lymphocytes and is endemic in parts of Japan, as well as in the Caribbean and in parts of Africa. Clinically the tumor resembles mycosis fungoides and Sezary syndrome but is more aggressive than these other two syndromes, with a median survival from the time of diagnosis of only 3 to 4 months. In addition to skin involvement, it affects visceral organs and there is often an associated hypercalcemia.

Serologic assays specific for HTLV-1 viral antigens revealed that virus infection is more widespread in

the endemic areas than is ATL.[128] It is estimated that an HTLV-1–infected individual has about a 3% lifetime risk of developing ATL. HTLV-1 infection is most marked in the southernmost islands of Japan and the Caribbean. Parts of Africa appear to have the next largest reservoirs of infection. The prevalence in the United States and in Europe is low in the general population, although it is quite high among intravenous drug abusers. A preleukemic disease in the form of a chronic lymphocytosis often precedes the development of acute leukemia or lymphoma. ATL usually occurs in early adulthood, and this is believed to be approximately 20 to 30 years after the initial infection in the subset of individuals who develop it.

HTLV-1 infection has been associated with a second clinical entity: HTLV-1–associated myelopathy/tropical spastic paraparesis (HAM/TSP), a chronic degenerative neurologic syndrome that primarily affects the spinal cord. Specific risk factors that may be important in determining the development of ATL or TSP in the HTLV-1–infected individual are currently not known. Transmission, when it occurs in childhood, is usually from the mother through breast milk and can result in ATL in a small percentage of patients as adults several decades later. The factors that contribute to disease progression in the few percent of HTLV-1–infected individuals who will develop ATL are not known. HAM/TSP, on the other hand, usually occurs in individuals through parenteral transmission by blood transfusion or intravenous drug use or through sexual transmission. It is generally believed that HAM/TSP is primarily the result of an autoimmune process against the central nervous system somehow initiated by the viral infection.

Epidemiologic studies have shown that about 2% to 5% of individuals seropositive for HTLV-1 will develop ATL. The virus is transmitted from mother to infants through mother's milk and in adults is transmitted through sexual contact and through contaminated blood. The latency period between the time of infection and the development of ATL can vary from a few years to as long as 40 years. There is some evidence to suggest that the virus's role in leukemogenesis may be direct, in that the virus alone appears to be sufficient to initiate a series of events that may lead to leukemia independent of subsequent environmental factors.

Molecular studies suggest a possible direct role of HTLV-1 as an etiologic agent in ATL. In the life cycle of a retrovirus, the provirus (i.e., the double-stranded DNA copy of the viral RNA genome) becomes integrated into the cellular genome at random positions as part of the life cycle of the virus. In the leukemic cells of an ATL patient, however, the viral sequences are found integrated in the same place in each cell, although the site of integration varies from leukemia to leukemia. This indicates that ATL is clonal and all of the leukemic cells must necessarily derive from a single cell, and that the viral infection must have preceded the expansion of the tumor.

HTLV-1 is also a transforming virus capable of immortalizing normal human umbilical cord blood lymphocytes (T-cells) in vitro. The mechanism by which HTLV-1 induces leukemogenesis is different from that of the other chronic leukemia retroviruses studied in animals, such as the avian leukosis virus or the murine leukemia virus.

The fact that the HTLV-1 provirus integration site varies from leukemia to leukemia is consistent with the HTLV-1 genome encoding a factor that is critical in the early stages of leukemogenesis. HTLV-1 and its relative HTLV-2 belong to a distinct group of retroviruses that has been referred to as trans-regulating retroviruses and includes the bovine leukemia virus, the biology of which is actually quite similar to that of HTLV-1 and HTLV-2. This group of retroviruses differs from the chronic leukemia viruses and the acute leukemia viruses as depicted in Figure 6-5 by the fact that they contain additional genes at the 3′ end of the genome. This region is called the X region and encodes trans-regulatory factors involved in transcriptional activation, translational control, and mRNA transport from the nucleus. Two unique regulatory genes, tax and rex, encoded by this region have been particularly well studied.[129] The tax gene serves as a master key for activating transcription from the viral long terminal repeat (LTR), and the rex gene is involved in the transport of specific viral messenger RNA species from the nucleus to the cytoplasm.

There is good evidence supporting a direct role for tax as a transforming gene in the causation of ATL. Tax can immortalize human CD4-positive T cells in an IL-2–independent manner, transform rodent fibroblasts in tissue culture, and induce tumors in transgenic mice.[129] Multiple transforming activities of Tax have been described that have been linked to its ability to either activate specific cellular transcription factors or affect the cell cycle through interactions with cell-cycle-inhibitors and inhibiting apoptosis and cellular DNA repair.

Tax transactivates the viral LTR promoter through its interaction with CREB/ATF-1, CBP/p300, and the Tax-responsive 21-bp repeat element (TRE).[129] In addition, the tax gene product has been shown to activate transcription of specific cellular genes, including lymphokines, the IL-2 gene, and the IL-2 receptor gene through the NFκB pathway.[130] It is felt that HTLV-1 may initiate the leukemogenic process through activation of specific cellular genes by tax. One mechanism by which HTLV-1 could induce cellular proliferation and immortalization could involve an autocrine loop through the tax-mediated stimulation of both IL-2 and its receptor. Tax-mediated activation of cellular genes may also involve paracrine mechanisms. Tax has also been shown to activate the expression of a group of nuclear oncogenes,

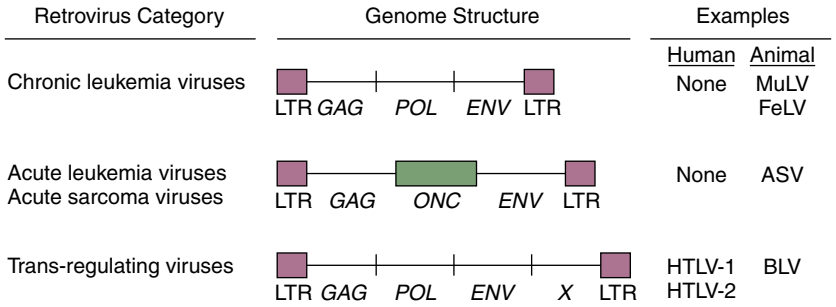

Figure 6-5 The genomic organization of different types of retroviruses The prototype retrovirus represented in the figure by the chronic leukemia viruses. It contains regulatory sequences at each end derived from the long terminal repeat (LTR) elements of the virus as well as the coding sequences for the viral proteins gag, pol, and env. The acute transforming retroviruses are defective viruses. Acquired onc sequences from the cellular genome replace critical viral gene segments. These defective viruses can therefore only replicate in the presence of a replication-competent helper virus. The trans-regulatory retroviruses contain sequences, 3′ to the env gene, that encode regulatory factors. This region has been referred to as the X region and encodes the tax and rex genes.

including c-fos, c-egr, and c-jun.[129] The mechanism by which Tax activates these various cellular promoters is through interactions with cellular transcription factors. The factors identified include CREB and the CRE modulator protein (CREM), the NFκB family of proteins, and the serum response factor (SRF).

Tax also binds and inactivates the inhibitory proteins of NFκB called IκB.[131,132] There is a complex of IκB proteins, most notably IκBα, that bind and retain NFκB in the cytoplasm until there is a signal for activation, when IκBα is targeted for proteolysis, releasing NFκB to translocate into the nucleus to activate transcription of its downstream effectors. Through binding IκB, Tax destabilizes the IκB/NFκB complex and activates NFκB. Thus the Tax mechanism of activation of genes under the control of NFκB appears to be two pronged, first, through the suppression of its cytoplasmic tether, IκB, and second through binding NFκB directly and bridging it with the basic transcriptional machinery.

In addition to its transcriptional activation functions, Tax also affects many aspects of the cell cycle. Tax can complex with p16INK4A, a cell cycle inhibitor, which binds and inhibits the activity of cell cycle–dependent kinase 4 (cdk4).[133] Cdk4 works with cyclin D to phosphorylate and inactivate the retinoblastoma protein (pRB). The consequence of Tax inactivation of p16INK4A is therefore the activation of cyclin D/cdk4 and the inactivation of pRB, which in turn leads to cell cycle activation, driving the proliferation of cells from G_1 to S. The pathway regulating pRB is commonly targeted by the DNA tumor virus oncoproteins, as discussed earlier in this chapter. In addition, Tax is capable of inactivating p53 functions,[134] inducing p21*CIP* expression,[135] and inhibiting apoptosis and DNA repair.[136] In addition, Tax can dramatically perturb mitotic regulation, causing micronuclei formation, cytokinesis failure, and chromosome instability.[137] HTLV-1 also encodes a protein on its minus strand called the HTLV-1 basic leucine zipper factor (HBZ) that may also be important to the leukemogenic activity of the virus. HBZ is expressed in ALT cells and promotes proliferation of T cells.[138]

The activities of Tax and HBZ are likely important for the direct role of HTLV-1 in the initiation and progression of leukemogenesis.[129]

HIV, AIDS, and Cancer

The human immunodeficiency viruses (HIV-1 and HIV-2) are members of a distinct subclass of retroviruses called lentiviruses.[139] Similar to HTLV-1, the HIVs also infect CD4-positive T lymphocytes. Beyond sharing a common cellular host for replication, however, the viruses are not closely related and do not share any serologic cross reactivity. HIV-1 and HIV-2 are associated with AIDS. These viruses themselves do not appear to play a major direct etiologic role in any specific human tumors. Patients with AIDS, however, do have a high incidence of specific tumors including KS and other cancers that are often caused by specific viruses.[140] Indeed, one of the earliest diagnostic features of AIDS in homosexual males can be KS, a tumor that was regarded as extremely rare before the current AIDS epidemic. The etiology of KS involves the Kaposi's sarcoma herpesvirus (KSHV or HSV-8) and is due to the uncontrolled proliferation of an activated microvascular endothelial cell, which is believed to be the cell of origin in KS (see earlier section on KSHV).

Other tumors often seen in AIDS patients include non-Hodgkin's lymphomas and papillomavirus-associated cancers, including anal squamous cell carcinomas and cervical cancer. Because of the immunodeficiency in AIDS patients, viral infections are common, and some of the tumors seen in these patients likely have a viral etiology. For instance, a high percentage of AIDS patients develop lymphomas, including central nervous system lymphomas. Some, but not all, of these lymphomas may be accounted for in part by the emergence of populations of B lymphocytes transformed by EBV. It is also possible that HTLV-1 may account for some

lymphomas in patients with AIDS. AIDS patients are often infected by papillomaviruses and HBV. The genital warts, anal and anal squamous cell carcinomas, and cervical cancers seen in these patients are due to the specific HPV types that are oncogenic in immunocompetent individuals.

Human Polyomaviruses and Cancer

SV40

There have been periodic reports dating back to the 1970s claiming the presence of SV40 DNA of SV40 in a variety of different human cancers, including osteosarcomas, mesotheliomas, pancreatic tumors, and brain tumors. A potential role of SV40 in some human cancers has been a very controversial area that has received scrutiny from investigators in the field and from the National Cancer Institute. I will not summarize all of these studies, but instead refer the reader to a recent review of this controversial subject.[141,142]

SV40 is a nonhuman primate virus that naturally infects Asian macaques. The major source of human exposure to SV40 was through contaminated poliovirus vaccines that were given between 1955 and 1963. SV40 is a highly oncogenic virus in rodent cells and has served as an extremely valuable model for determining the various mechanisms by which DNA tumor viruses transform cells and contribute to tumor formation. However, there is no epidemiologic evidence indicating a higher risk of cancers among the populations of individuals who received the SV40-contaminated vaccine.

There is also no compelling data that the virus is circulating among human communities. SV40 is closely related to the human polyomaviruses BK and JC, and much of the seroreactivity to SV40 seen in humans can be accounted for by cross reactivity with BK and/or JC virus. In addition, much of the data claiming an association of SV40 DNA with human tumors have been gathered by the use of PCR assays, which are error prone, and have been difficult to confirm. Furthermore, the PCR primers used in many of these studies would detect sequences that are present in many laboratory plasmid vectors, raising the possibility of laboratory contamination. Indeed, studies suggest that flawed PCR detection methodologies and laboratory plasmids might have contributed significantly to the positive claims for SV40 tumor associations.[143,144]

BKV and JCV

There have been periodic claims that the human polyomaviruses BK and JC are also associated with specific human cancers. Infections with both of these viruses are widespread in humans as measured by seroreactivity. They encode tumor (T) antigens similar in function to SV40 large T antigen and can functionally inactivate the p53 and pRB pathways. For JC virus, which is the cause of progressive multifocal leukoencephalopathy (PML), there have been reports of DNA and T antigen in brain tumors of patients with or without PML. This is a provocative association that will need confirmation and validation. A number of studies have found an association of BK virus with a variety of different types of cancers as well as precancerous lesions of the prostate. The presence and potential role of these viruses in the cancers with which they have been found will also need to be further explored.

Merkel Cell Polyomavirus

In 2008, Yuan Chang and Patrick Moore identified a new human polyomavirus by deep sequencing techniques that they called the Merkel cell polyomavirus (MCV) in human Merkel cell carcinomas (MCC).[145] MCC is a relatively rare cancer in humans that was first described in 1972 by Cyril Toker.[146] MCC is an aggressive tumor seen in immunosuppressed individuals and the elderly. MCV DNA is clonally integrated into the positive cancers, suggesting an etiologic role in the cancers. Furthermore, the expression of the virally encoded tumor antigens is required to maintain the cancer cells in tissue culture, strongly implicating the virus as the cause of these cancers.

Like the other human polyomaviruses, MCV is quite common, and initial infection occurs in childhood.[147] MCV can be found on the skin of healthy individuals[148] and appears ubiquitous in the human population. MCV DNA and its expression can be found in over 80% of MCCs, supporting an active role of the viruses in these cancers. Only a portion of the early region encoding the first half of the large T antigen as well as the small t antigen is expressed in the MCV-positive cancers, as recently reviewed.[149] Molecular biology research on MCV is a very active area of research to identify the mechanisms by which MCV transforms cells and contributes to cancer. There are also studies ongoing to determine whether MCV is associated with human cancers in addition to MCC.

Bacteria and Cancer

Helicobacter pylori and Gastric Cancer

Helicobacter pylori entered the scientific lexicon during the mid-1980s with the work of Robin Warren and Barry Marshal, who first cultured the bacterium and determined that it was the causative agent of most gastric and duodenal ulcers.[150,151] For their work, they shared the 2005 Nobel Prize in medicine, as well as upending the notion that gastric ulcers were mainly caused by stress and diet.

H. pylori (first known as *Campylobacter pyloridis*) is a gram-negative, flagellated spiral or curved bacillus that colonizes the stomach via attachment to gastric epithelial

cells. The complete genome was sequenced in 1997[152] and predicted to encode for approximately 1500 ORFs, many involved in adaptation for growth in the inhospitable acidic environment of the stomach. Infection is found in over 80% of the worldwide population, although a much smaller population develops gastric ulcers due to infection.

Two human cancers have been correlated with *H. pylori* infection: gastric cancer and MALT (*m*ucosa-*a*ssociated *l*ymphoid *t*issue) lymphoma of the stomach. The correlation was strong enough that *H. pylori* was categorized as a carcinogen by the International Agency for Research on Cancer (IARC). Gastric cancers are the fourth most common cancer worldwide. Since the isolation of the organism and the sequencing of its genome, a number of potential transformation mechanisms have been proposed, involving both epithelia and immune cell populations. There are a number of possible mechanisms related to *H. pylori*–induced transformation. One observation is that *H. pylori* produces excess free radicals, leading to host cell DNA damage and the accumulation of host cellular mutations.

A potentially oncogenic factor produced by *H. pylori* is the CagA protein. CagA is injected in gastric epithelial cells via type-IV secretion and has been shown to alter a number of signal transduction pathways.[153] One target of CagA is SHP-2, a tyrosine phosphatase implicated in some human cancers. CagA induces SHP-2 activation, leading to disruptions in cell adhesion and cell junctions and an increase in cell motility. Another factor produced by the bacterium is VacA, a secreted vacuolating cytotoxin protein that inhibits the ability of T lymphocytes to neutralize infection and allows the bacterium to evade the immune system and set up a chronic infection. Another proposed mechanism of *H. pylori*–induced transformation has been called a perigenetic pathway which refers to the effect that chronic inflammation has on host epithelial cells (reviewed in Ref. 154). Infection can induce TNF-α and IL-6, which can alter host cell adhesion and lead to migration of mutated cells.

Parasites and Cancer

Parasites were perhaps the first infectious agents to be potentially linked with human cancer. In 1900, Askanazy reported a link between *Opisthorchis felineus* infection and liver cancer, and Goebel published a report incriminating *Bilharzia* infections (schistosomiasis) with human bladder cancer.[155] Indeed, the Nobel Prize in medicine was awarded to Johannes Fibiger in 1926 for studies linking a nematode with tumors in rats; however, those studies could not be reproduced. Today there are two well-established associations of parasites with human cancer: schistosomiasis with bladder cancer and liver flukes with cholangiocarcinoma. The major burden for parasite-associated cancers is in developing countries.

Schistosomiasis and Bladder Cancer

Schistosomiasis, also known as bilharzia, is a parasitic disease caused by trematodes from the genus *Schistosoma*. *S. haematobium* is responsible for urinary schistosomiasis and can cause chronic infections that can lead to kidney damage and to bladder cancer. *S. haematobium* infections are a significant public health problem in much of Africa and the Middle East, second only to malaria among parasitic diseases. Bladder cancers associated with *S. haematobium* are squamous cell cancers and are histologically different from the transitional-cell carcinomas that are more commonly seen in the United States and Europe. The mechanism by which *S. haematobium* causes bladder cancer is unknown but most likely is a consequence of a persistent, chronic infection.

Liver Flukes and Cholangiocarcinoma

Opisthorchis viverrini and *Clonorchis sinensis* are liver flukes (a type of flatworm) that are associated with an increased risk of cholangiocarcinomas. Infections with these liver flukes come from eating raw or undercooked fish. They occur almost exclusively in East Asia and are rare in other parts of the world. Cholangiocarcinoma is more common in areas of endemic liver fluke infection (Hong Kong, Thailand). *O. viverrini* is endemic in northeast Thailand and is estimated to infect approximately 9 million people. *C. sinensis* infects approximately 7 million people in China and other parts of the Far East. Liver flukes usually enter the human gastrointestinal tract after ingestion of raw fish, and the parasites then travel via the duodenum into the host's intrahepatic or extrahepatic biliary ducts. Liver flukes cause bile stasis, inflammation, periductal fibrosis, and hyperplasia, with the subsequent development of cholangiocarcinoma.

Perspectives

Infectious agents play a major role in human cancer, either as direct or indirect carcinogens. In this chapter I have reviewed the association of a number of agents that have been generally accepted as playing a major role in human cancer. I have also discussed the controversy surrounding SV40 as a potential oncogenic agent. There are other agents that have been implicated in the literature but for which the data are not yet compelling. Individual infectious agents

contribute to carcinogenesis in different ways. Some, like HPV and cervical cancer or HTLV-1 and ATL and perhaps MCV and MCC, do so in a direct manner through oncogenic proteins encoded by the virus. Others, like the liver flukes and cholangiocarcinomas and *S. haematobium* and bladder cancer, likely do so through indirect mechanisms involving persistent infection and inflammation. The criteria that are generally used to determine whether or not an agent is carcinogenic must therefore necessarily involve a combination of epidemiology and molecular biology. Several questions arise. Are there additional unknown infectious agents associated with human cancer? If so, what cancers, and how can they be discovered? Certainly cancers in immunologically compromised individuals are good candidates for an infectious etiology. Also, advances in array technologies and bioinformatics searching tools should provide important platforms to examine such cancers. Another question is whether some very ubiquitous infectious agents might contribute to the initiation of some cancers, but do so in a hit-and-run fashion such that a molecular fingerprint is not left behind. How will the role of such agents in human cancers be discovered?

Environmental Carcinogenesis

Introduction to Cancer and the Environment

Environment, Genetics, and Cancer

Overall human cancer risk is determined by complex interactions between host genetics and environmental exposures. On exposure to a cancer-causing agent, a cascade of events is set into motion that converts normal cells into cancer cells. This process is referred to as *carcinogenesis*, and cancer-causing agents are referred to as *carcinogens*. Hundreds of confirmed and suspected environmental carcinogens have been identified. Environmental factors are generally believed to account for a significant portion of cancer mortality worldwide. In the context of the current chapter, we refer to the *environment* as any substance or agent that is normally present outside of the human body and that interacts with the human body to increase cancer risk. Genetically controlled host factors also contribute to cancer risk, primarily through modulation of responses to environmental agents. Understanding the causes of cancer and the underlying mechanisms that lead to cancer development provides a rational basis for developing prevention strategies. In this chapter, we discuss the major known environmental causes of cancer and, where applicable, underlying mechanisms. In addition, where known, significant gene-environment interactions are highlighted.

History of Chemicals and Cancer

The environmental contribution to chronic diseases such as cancer has been recognized for centuries.[1,2] In 1775, Dr. Percival Pott observed that chimney sweeps experienced an increased incidence of scrotal cancer, which was attributed to frequent and heavy exposure to soot. A century later, an excess of skin cancers was reported in coal tar workers in Germany and related to their occupational exposure. In the early 20th century, these observations were experimentally validated by Yamagiwa and Ichikawa, who demonstrated that multiple topical applications of coal tar to rabbit ears induced skin carcinomas. These studies were the first to demonstrate that a complex mixture was capable of inducing cancer. Sir Ernest Kennaway and others furthered these studies in the 1920s and 1930s. The group fractionated coal tar with the goal of isolating the principal carcinogenic agent. Fractions were screened for a characteristic blue-violet fluorescence spectrum, which was highly correlated with carcinogenic potency.[3] Ultimately, benzo[*a*]pyrene (B[*a*]P), which is composed entirely of carbon and hydrogen (Figure 7-1), was identified, synthesized, and shown to be a potent carcinogen in animal models. Collectively, these important early studies indelibly transformed the study of environmental carcinogenesis. In isolating a compound from coal tar that could induce cancer in animals, an occupational carcinogen exposure was linked to cancer incidence, and the utility of animal models of carcinogenicity in the interpretation of human epidemiologic associations was established.

Kennaway's studies in the early 20th century immediately preceded major progress in understanding the biochemical nature of genetic material and cellular replication. Beginning shortly after the discovery of benzo[*a*]pyrene, Avery and colleagues pursued experiments to reveal the identity of the transforming material of pathogenic *Streptococcus pneumoniae*. Results of their analyses showed that nucleic acids carried genetic information, although their findings were not widely accepted until the 1950s when Hershey and Chase published data demonstrating that DNA is the genetic material of viruses. Shortly thereafter, work with mutagenic mustard gas suggested that DNA was the target of carcinogens, and data published in the early 1960s revealed that mutagens covalently modify DNA.[1] Further, the carcinogenic potency of a series of hydrocarbons was positively correlated with the extent of their reaction with DNA. These and other studies provided compelling evidence for DNA as a target of carcinogens and gene mutation as a major mechanism whereby agents induce cancer. With this foundational knowledge, the list of known carcinogens has grown rapidly, along with a greater understanding of the mechanisms of cancer development associated with these agents.

CARCINOGEN CLASS	REPRESENTATIVE EXAMPLE
PAHs	3-methylcholanthrene  Benzo[*a*]pyrene  Dibenzo[*a*,*h*]anthracene Solvents	Benzene 
Mycotoxins	Ochratoxin A Alkyl halides	Vinyl chloride  Cyclophosphamide Aromatic amines	2-naphthylamine  Benzidine N-nitrosamines	NNK Heterocyclic amines	MeIQx Alkylating agents	bis(chloromethyl)ether 
Figure 7-1 Chemical structures of selected carcinogens.

Causes of Cancer

Epidemiology and Causal Criteria

The landmark findings of Kennaway, Avery, Hershey, Chase, and others in the early part of the 1900s guided a period of rapid advancement in the laboratory concerning the molecular basis of cancer. In contrast, the discovery of specific human carcinogens has been largely guided by epidemiologic studies of cancer incidence. The study of worldwide cancer incidence patterns, including analysis of cancer risk among migrant populations, has confirmed the critical role of environment in determining cancer risk. Studies of exposure cohorts and observational studies of cancer incidence have been especially crucial in the identification of the biologic, physical, and chemical agents capable of causing cancer. Similarly, epidemiologic studies have revealed numerous lifestyle choices and socioeconomic factors associated with increased risk of cancer.

Cancer risk is known to vary extensively worldwide.[4] For instance, liver cancer risk varies 20- to 40-fold internationally; the incidence is highest in eastern Asia and lowest in northern Europe and Central America. Prostate cancer rates are high in the United States, Canada, and Scandinavia, especially in comparison with the rates in China and other Asian countries. Similarly, breast cancer risk has historically been higher in the United States and European countries than in Asia, Africa, and South America. These observations suggest that (1) genetic differences among ethnic groups alter cancer risk and/or (2) differences in environmental exposures among geographic locations affect the risk of developing cancer.

Capitalizing on known ethnic variation in cancer rates, analysis of cancer risk in migrant populations has been undertaken and has yielded important information concerning the relative contribution of environment versus genetics in cancer etiology. In these studies, the rate of cancer in migrant cohorts is compared with the rate of cancer among people of the same ethnicity living in the country of origin and to the cancer rate of people in the destination population. For example, breast cancer incidence among Asian immigrants to the United States has been compared with that of women still living in their country or region of origin.[5] The breast cancer risk of Asian American women born in the East has been shown to rise with increasing number of years lived in the West. Ultimately, the risk of breast cancer among Asian American women approaches that of U.S.-born White women and is significantly higher than that of Asian women still living in the country of origin. Numerous studies of this kind demonstrate that even while in the first generation following relocation, immigrant populations assume a pattern of cancer risk in common with native populations rather

than with populations in their country of origin. These studies imply that environmental factors play a significant role in determining cancer risk. Similarly, studies of cancer risk in twins have suggested the importance of environmental factors in determining overall cancer risk.

Recent population-based evidence further underscores the overall importance of environmental factors in determining cancer risk. Cancers that were once associated with affluence and/or the Western lifestyle are on the rise in less developed countries. Rates of colon, breast, and lung cancers in developing countries have increased as their economies have transitioned.[4,6] Multiple factors likely contribute to this trend, including non-genetically controlled influences such as tobacco use, diet, and physical activity.

In addition to population-based evidence, case-control and cohort studies have been used to identify specific environmental agents and factors that are now considered to be human carcinogens. To assess the likelihood that a particular environmental exposure is causally linked to cancer, epidemiologic data are interpreted in the context of mechanistic data and other considerations. The strength of evidence for a causal role in cancer development is evaluated using criteria developed as a modification of Bradford-Hill's criteria (1965) for assessment of evidence of causation[7]:

1. Strength of Association: Large-magnitude effects on cancer risk are less likely than small-magnitude effects to be due to chance.
2. Temporal Relationship: To be causal, the environmental exposure must have happened in advance of the appearance of cancer.
3. Biologic Plausibility: Relationships that can be supported by laboratory evidence or a plausible mechanistic hypothesis are more likely to be causal relationships.
4. Dose-Response Relationship: Studies that demonstrate a gradient in disease outcome whenever a gradient in exposure has occurred provide stronger support for a causal relationship than those studies that do not demonstrate a positive correlation between dose and response.
5. Consistency: The most probable causal relationships are consistently demonstrated in multiple studies of the exposure-disease relationship.

Using these criteria, numerous cancer-causing agents and/or risk factors have been identified for further characterization.

Known Cancer Risk Factors

In a landmark paper published in 1981, Doll and Peto summarized available epidemiologic data to estimate the percentage of U.S. cancer deaths attributable to a variety of environmental and lifestyle influences. Their analyses suggested that as many as 60% of all cancer deaths could be attributed to two environmental factors: diet and tobacco use.[8] More than 30 years later, these estimates appear to remain valid; diet and tobacco use continue to be primary determinants of cancer mortality. Additional factors cited by multiple investigators and regulatory agencies as contributing to cancer risk include occupation, radiation, alcohol, pollution, infections, medications, and reproductive and socioeconomic factors.

Smoking

Tobacco use remains the single most important and avoidable factor in determining cancer risk.[9,10] Smoking is estimated to contribute to at least 30% of all cancer deaths. Lung, bladder, esophageal, pancreatic, uterine, oral, and nasal cavity cancers, among others, have all been associated with tobacco use. Approximately 90% of all lung cancer deaths can be attributed to smoking. Lung cancer risk is greatest for persons who begin smoking at an early age and continue smoking for many years, and the risk of tobacco smoke–induced lung cancer is directly proportional to the dose inhaled. Tobacco smoke is a complex mixture of chemicals, 55 of which are known or suspected human carcinogens (Table 7-1). On absorption in the lungs, these agents may act locally or at distal sites to (1) induce DNA damage and (2) alter cellular growth and proliferation. A synergistic effect has been noted in the case

Table 7-1 Carcinogens in Tobacco Smoke

Carcinogen Class	No. of Compounds	Example Compound
Polycyclic aromatic hydrocarbons	10	Benzo[*a*]pyrene 5-Methylchrysene Dibenz[*a*,*h*]anthracene
Aza-arenes	3	Dibenz[*a*,*h*]acridine
N-nitrosamines	7	4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) *N*-Nitrosodiethylamine
Aromatic amines	3	4-Aminobiphenyl
Heterocyclic amines	8	2-Amino-3-methylimidazo[*4,5-f*]quinoline
Aldehydes	2	Formaldehyde
Miscellaneous organic compounds	15	1,3-Butadiene Ethyl carbamate
Inorganic compounds	7	Nickel Chromium Cadmium Arsenic
Total	55

of combined tobacco use and heavy alcohol use. Despite antitobacco sentiment, approximately one fifth of U.S. citizens are still smokers, and smoking rates in countries such as China remain high; therefore, smoking-induced cancers are likely to continue to be prevalent worldwide.

Diet

The effects of diet on cancer risk have been attributed both to dietary chemical constituents and to overall energy consumption. As many as 14% to 30% of cancer deaths have been attributed to overweight and obesity. Overweight and obesity, as defined by the ratio of weight to height known as *body mass index* (BMI), are prevalent at epidemic proportions in the United States and other developed countries. Overweight and obesity have been associated with elevated risk of cancers of the colon, breast, endometrium, kidney, liver, pancreas, gallbladder, ovary, cervix, rectum, and esophagus as well as risk of non-Hodgkin's lymphoma and multiple myeloma. In addition, animal studies have consistently demonstrated that restricting calorie intake can significantly reduce cancer risk, whereas inducing obesity can significantly elevate cancer risk. Despite these findings, a complete understanding of the mechanistic basis for the effect of dietary energy balance status on cancer formation is not conclusively known.[11] Elevated steroid hormone production in adipose tissue has been proposed as the basis for obesity-induced endometrial and breast cancers; adipose-derived leptin, adiponectin, and proinflammatory molecules may affect cancer development more broadly. Recent studies have suggested that alterations in circulating insulin-like growth factor 1 (IGF-1) levels may account for some of the effects of altered dietary energy balance status on cancer risk.[12]

In addition to excess calorie intake, certain dietary constituents may affect cancer risk.[13] In the United States, cancer risk due to food additives is presumed to be quite low because the U.S. Food and Drug Administration (FDA) strictly regulates food additive use. In 1958, an amendment to the Food, Drugs, and Cosmetic Act of 1958, referred to as the *Delaney Clause*, was approved and stated that "the Secretary (of the FDA) shall not approve for use in food any chemical additive found to induce cancer in man, or, after tests, found to induce cancer in animals." Presumably, therefore, cancer risk due to food additive consumption is quite low. Nonetheless, inadvertent food contaminants such as the plasticizer bisphenol A remain a source of concern. Bisphenol A is a weak endocrine-disrupting agent that has been associated with a variety of health effects including increased cancer risk. Fungal toxins such as aflatoxins are food contaminants resulting from mold growth on foodstuffs. Several of these toxins have been shown to be extremely potent mutagens and in some cases potent carcinogens (e.g., aflatoxin B_1 [AFB_1]). Red meat consumption has been associated with elevated colorectal cancer risk, possibly due in part to the carcinogenic nitrosamine and heterocyclic amine content of preserved or heat-treated meats.

Although examples of carcinogenic dietary constituents can be identified, a possibly greater dietary determinant of cancer risk is consumption of anticarcinogenic fruits and vegetables. Consumption of fruits and vegetables has consistently been linked to reduced cancer risk for a variety of cancer types. Fruits and vegetables contain numerous antioxidant compounds, which may guard against oxidative DNA damage or other forms of carcinogenic assault. In fact, tea phenols such as epigallocatechin-3-gallate (EGCG), the turmeric component curcumin, grape-derived resveratrol, and lycopene from tomatoes are all proposed cancer preventive agents.[14] On the other hand, excess consumption of herbal health supplements is an emerging dietary concern due to their widespread use in the absence of proper validation or safety assessment. As an example, renal failure was noted in women who consumed weight-reducing Chinese herbal pills. The pills were inadvertently substituted with a nephrotoxic herb, *Aristolochia fangchi*, containing aristolochic acids. Aristolochic acids are mutagenic and carcinogenic, and a high rate of urothelial carcinoma was noted in the population of women who consumed these pills.[15]

Occupation

Many carcinogens have been identified at the cost of human exposure and cancer incidence that occurred as a result of industrialization. Human epidemiologic studies highlight the potency of chemical and physical carcinogens and how lack of understanding leads to lack of preparation and protection.[16-18] In the 1800s, high incidence of bladder cancer among workers in the aniline dye industry was recognized. Later, evidence was reported demonstrating that 2-napthylamine and benzidine were two carcinogenic agents responsible for this unusual cancer incidence. Also during the early 1900s, nearly 5000 workers were hired to apply luminous radium-containing paint to watch and instrument dials. Because of their occupational radiation exposure and a lack of precautionary practices, a large excess of bone cancers was noted among this cohort. Thousands of workers were exposed to vinyl chloride before its ability to induce angiosarcoma of the liver was recognized. Since the 1970s, strict workplace regulations and protective measures in the United States have largely prevented such dramatic incidents. The Occupational Safety and Health Administration (OSHA) was signed into existence in 1970 by the U.S. government with the goal of ensuring worker safety and health by improving the workplace environment. OSHA sets the legal limit for worker exposure to hazardous compounds in the United States. These limits are referred to as *permissible exposure limits* (PELs). PELs have been issued for approximately

Table 7-2 Environmental Carcinogens Associated with Occupation

Occupation	Carcinogen Exposure	Associated Cancer Type
Iron and steel founding	PAH, chromium, nickel, formaldehyde	Lung
Copper mining and smelting	Arsenic	Skin, bronchus, liver
Underground mining	Radon (ionizing radiation)	Lung
Aluminum production	PAH	Lung
Coke production	PAH	Lung, kidney
Painting	Chromium, solvents	Lung
Furniture and cabinet making	Wood dust	Nasal sinus
Boot and shoe manufacture	Leather dust, benzene	Nasal sinus, leukemia
Rubber industry	Aromatic amines, solvents	Bladder, leukemia
Nickel refining	Nickel	Nasal sinus, bronchus
Vinyl chloride manufacture	Vinyl chloride	Liver
Dye and textile production	Benzidine-based dyes	Bladder

PAH, Polycyclic aromatic hydrocarbons.

500 chemicals, a portion of which are known or suspected carcinogens. Also created in 1970, the Environmental Protection Agency (EPA) is charged with protecting human health and the environment. In addition to other roles, the EPA regulates the release of industrial pollution, including carcinogens. Before these institutions were in place, employment in a wide variety of settings was linked to elevated risk of numerous cancers (Table 7-2).

Despite regulatory measures, occupational exposure to carcinogens continues. In the U.S. President's Cancer Panel Report of 2008-2009,[19] members highlighted 14 types of environmental contaminants from industrial, manufacturing, and agricultural sources (polyhalogenated biphenyls, asbestos, chromium, perchloroethylene/trichloroethylene, particulate matter, mercury, formaldehyde, endocrine-disrupting chemicals, atrazine, DDT, nitrogen fertilizers, phosphate fertilizers, and veterinary pharmaceuticals) due to their cancer-causing potential and high probability of human exposure. The group estimated that millions of workers continue to be exposed to high levels of these and other agents each year. The families of exposed workers also experience higher than average exposure due to home contamination and may be at elevated cancer risk. As examples, chromium used in leather tanning, manufacture of dyes and pigments, wood preservation, and chrome plating is an established risk factor for lung cancer. Perchloroethylene, heavily used in dry-cleaning businesses, is classified as a probable carcinogen by the International Agency for Research on Cancer (IARC), and formaldehyde (a group 1 human carcinogen) is a synthetic starting material in manufacturing and a widely used disinfectant and preservative.

Causes of Cancer by Organ Site

Although an extensive list of known human carcinogens has been collected, the cause of many common cancers is still unknown. As shown in Table 7-3, gastric, liver, and cervical cancers are each clearly linked with biologic carcinogens: *Helicobacter pylori*, hepatitis B virus (HBV), and human papillomavirus (HPV), respectively. The vast majority of lung cancer cases can be linked to tobacco use, and mesothelioma incidence is strongly correlated with exposure to asbestos. In contrast, the causes of most brain, pancreas, and prostate cancers remain largely unknown. For many other cancer types such as bone cancers, relatively rare exposures have been causally linked to incidence, yet the associated attributable risk is quite low. The remainder of cases continues to be largely unexplained. In general, linking particular cancers to specific exposure events can be problematic, and further work is necessary to uncover the primary causes of a significant number of cancers. Limiting factors include the inability to accurately estimate exposure dose and duration and a lack of understanding of combinatorial effects in multi-exposure events and finally lack of adequate biomarkers of exposure.

Classes and Types of Carcinogens

Carcinogen Evaluation and Classification

The U.S. National Toxicology Program (NTP), the World Health Organization's International Agency for Research on Cancer (IARC), the U.S. EPA, and other agencies characterize and report the carcinogenicity of environmental agents and other factors (including drugs). Each entity independently evaluates the available evidence to rate the cancer-causing potential of a chemical, chemical mixture, occupational exposure, physical agent, biologic agent, or lifestyle factor. The most frequently referenced database is the IARC *Monographs on the Evaluation of Carcinogenic Risks to Humans*. IARC defines carcinogens as agents "capable of increasing the incidence of malignant neoplasms, reducing their latency, or increasing their severity or multiplicity." Agents are selected for evaluation on the basis of two factors: (1) evidence of potential carcinogenicity and (2) known exposure of humans. During the scientific review and evaluation of potential carcinogens, a working group is

Table 7-3 Exposures Associated with Human Cancers, as Identified by the IARC (Partial Listing)

Cancer Site	Carcinogenic Agents with Sufficient Evidence in Humans	Agents with Limited Evidence in Humans
Oral cavity	Alcohol, betel quid, HPV, tobacco smoking, smokeless tobacco	Solar radiation
Stomach	*Helicobacter pylori*, rubber production industry, tobacco smoking, x-rays, gamma radiation	Asbestos, Epstein-Barr virus, lead, nitrate, nitrite, pickled vegetables, salted fish
Colon and rectum	Alcohol, tobacco smoking, radiation	Asbestos, *Schistosoma japonicum*
Liver and bile duct	Aflatoxins, alcohol, *Clonorchis sinensis*, estrogen-progestin contraceptives, HBV, HCV, *Opisthorchis viverrini,* plutonium, thorium-232, vinyl chloride	Androgenic steroids, arsenic, betel quid, HIV, polychlorinated biphenyls, *Schistosoma japonicum*, trichloroethylene, x-rays, gamma radiation
Pancreas	Tobacco smoking, smokeless tobacco	Alcohol, thorium-232, x-rays, gamma radiation, radioiodines
Lung	Tobacco smoking, aluminum production, arsenic, asbestos, beryllium, bis (chloromethyl) ether, chloromethyl methyl ether, cadmium, chromium, coal combustion and coal tar pitch, coke production, hematite mining, iron and steel founding, MOPP, nickel, painting, plutonium, radon, rubber production, silica dust, soot, sulfur mustard, x-rays, gamma radiation	Acid mists, manufacture of glass, indoor emissions from household combustion, carbon electrode manufacture, chlorinated toluenes and benzoyl chloride, cobalt metal with tungsten carbide, creosotes, engine exhaust, insecticides, dioxin, printing processes, welding fumes
Skin—melanoma	Solar radiation, UV-emitting tanning devices	
Other skin cancers	Arsenic, azathiopurine, coal tar pitch, coal tar distillation, cyclosporine, methoxsalen plus UVA, mineral oils, shale oils, solar radiation, soot, x-rays, gamma radiation	Creosotes, HIV, HPV, nitrogen mustard, petroleum refining, UV-emitting tanning devices
Mesothelioma	Asbestos, erionite, painting	
Breast	Alcohol, diethylstilbestrol, estrogen-progesterone contraceptive and menopausal therapy, x-rays, gamma radiation	Estrogen menopausal therapy, ethylene oxide, shift work resulting in circadian disruption, tobacco smoking
Uterine cervix	Diethylstilbestrol (exposure in utero), estrogen-progestogen contraception, HIV, HPV, tobacco smoking	Tetrachloroethylene
Ovary	Asbestos, estrogen menopausal therapy, tobacco smoking	Talc-based body powder, x-rays, gamma radiation
Prostate		Androgenic steroids, arsenic, cadmium, rubber production industry, thorium-232, x-rays, gamma radiation, diethylstilbestrol (exposure in utero)
Kidney	Tobacco smoking, x-rays, gamma radiation	Arsenic, cadmium, printing processes
Urinary Bladder	Aluminum production, 4-aminobiphenyl, arsenic, auramine production, benzidine, chlornaphazine, cyclophosphamide, magenta production, 2-naphthylamine, painting, rubber production, *Schistosoma haematobium,* tobacco smoking, toluidine, x-rays, gamma radiation	Coal tar pitch, coffee, dry cleaning, engine exhaust, printing processes, occupational exposures in hair dressing and barbering, soot, textile manufacturing
Brain	X radiation, gamma radiation	
Leukemia and/or lymphoma	Azathiopurine, benzene, busulfan, 1,3-butadiene, chlorambucil, cyclophosphamide, cyclosporine, Epstein-Barr virus, etoposide with cisplatin and bleomycin, fission products, formaldehyde, *Helicobacter pylori*, HCV, HIV, human T-cell lymphotropic virus type 1, Kaposi's sarcoma herpesvirus, melphalan, MOPP, phosphorus-32, rubber production, semustine, thiotepa, thorium-232, tobacco smoking, treosulfan, X radiation, gamma radiation	Bischloroethyl nitrosourea, chloramphenicol, ethylene oxide, etoposide, HBV, magnetic fields, mitoxantrone, nitrogen mustard, painting, petroleum refining, polychlorophenols, radioiodines, radon-222, styrene, teniposide, tetrachloroethylene, trichloroethylene, dioxin, tobacco smoking (childhood leukemia in smokers' children)

Adapted from Cogliano et al. Preventable exposures associated with human cancers. *J Natl Cancer Inst* 2011;103:1835.
HBV, Hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *HPV,* human papillomavirus; *IARC,* International Agency for Research on Cancer; *MOPP,* mustargen-oncovin-procarbazine-prednisone chemotherapy; *UVA,* ultraviolet A light.

formed and charged with summarizing available data concerning anticipated exposure levels, human epidemiologic data, and studies of cancer-producing capacity in animals. Although the goal of the IARC *Monographs* has been to identify carcinogens regardless of an explanatory mechanism, information on mechanisms can also be used as supporting data. All agents evaluated by IARC are classified into one of five categories as shown in Table 7-4. As of the most recent report, 108 agents, groups of agents, or exposure scenarios are listed as "Carcinogenic to Humans" (a partial listing is shown in Table 7-5). An additional 64 are listed as "Probably Carcinogenic to Humans." These agents are extremely diverse in structure, potency, and mechanism.

Table 7-4 IARC Classification of Suspected Carcinogenic Agents

Group 1: Carcinogenic to humans: Sufficient evidence of carcinogenicity in humans exists or sufficient evidence of carcinogenicity in animals is supported by strong evidence of a relevant mechanism of carcinogenicity in humans.
Group 2A: Probably carcinogenic to humans: Limited evidence of carcinogenicity in humans exists but sufficient evidence of carcinogenicity in animals has been demonstrated. Alternatively, inadequate evidence in humans with sufficient evidence in animals may be supported by strong evidence that a similar mechanism of carcinogenicity would occur in humans.
Group 2B: Possibly carcinogenic to humans: Limited evidence of carcinogenicity in humans exists but inadequate evidence in experimental animals. Alternatively, this classification can be used for agents for which there are inadequate data in humans but sufficient evidence in animals or strong mechanistic data.
Group 3: Unclassifiable as to carcinogenicity in humans: Inadequate evidence in humans and animals exists. Alternatively, sufficient evidence of carcinogenicity may exist in animals but strong mechanistic data predict a lack of carcinogenicity in humans.
Group 4: Probably not carcinogenic to humans: Evidence suggesting a lack of carcinogenicity in humans and animals exists.

IARC, International Agency for Research on Cancer.

Types of Carcinogens

Carcinogens can be grouped into one of three categories according to their composition: (1) physical carcinogens, (2) biologic carcinogens, and (3) chemical carcinogens. The term *physical carcinogen* encompasses multiple types of radiation (e.g., ultraviolet [UV] and ionizing radiation). *Biologic carcinogens* refer to viral and bacterial infections that have been associated with cancer development (e.g., human papillomavirus [HPV] and hepatitis B virus [HBV]). Most carcinogens can be categorized as chemical carcinogens. As examples, heavy metals, organic combustion products (e.g., B[*a*]P), hormones, and fibers (e.g., asbestos) are considered to be chemical carcinogens. Note that in the discussion that follows, only selected carcinogens that are known to be carcinogenic in humans are described (see Table 7-5). For a more comprehensive listing of carcinogenic agents, including those listed in other IARC categories, refer to the WHO IARC monograph database (http://monographs.iarc.fr/ENG/Monographs/PDFs/index.php) and additional references.[20,21]

Physical Carcinogens

Examples of physical carcinogens include UV and ionizing radiation. *Radiation* refers to flow of energy-bearing particles; *ionizing radiation* refers to radiation that is of sufficiently high energy to remove an electron from an atom or molecule with which it collides. Exposure to ionizing radiation of various forms has been shown to cause multiple types of cancers. In addition, solar radiation is of sufficient energy to elicit photochemical damage to the skin, ultimately leading to cancer formation.

Table 7-5 Selected IARC Known Human Carcinogens

4-Aminobiphenyl	Hepatitis B virus
Arsenic	Hepatitis C virus
Asbestos	Human immunodeficiency virus type 1
Azathioprine	Human papillomavirus
Benzene	Human T-cell lymphotropic virus
Benzidine	Melphalan
Benzo[*a*]pyrene	8-Methoxypsoralen
Beryllium	Mustard gas
N,*N*-Bis(2-chloroethyl)-2-naphthylamine	2-Naphthylamine
Bis(chloromethyl)ether	Nickel compounds
Chloromethyl methyl ether	*N*′-Nitrosonornicotine (NNN)
1,4-Butanediol dimethanesulfonate	Phosphorus-32
Cadmium	Plutonium-239
Chlorambucil	Radioiodines
1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea	Radium-224
Chromium[VI]	Radium-226
Cyclosporine	Radium-228
Cyclophosphamide	Radon-222
Diethylstilbestrol	Silica
Epstein-Barr virus	Solar radiation
Erionite	Talc-containing asbestiform fibers
Estrogen-progestogen menopausal therapy	Tamoxifen
Estrogen-progestogen oral contraceptives	2,3,7,8-Tetrachlorodibenzo-*para*-dioxin
Estrogen therapy	Thiotepa
Ethylene oxide	Treosulfan
Etoposide	Vinyl chloride
Formaldehyde	X- and gamma (γ)-radiation
Gallium arsenide	Aflatoxins
Helicobacter pylori	Soots Tobacco Wood dust

IARC, International Agency for Research on Cancer.

The incidence of skin cancers such as melanoma, basal-cell carcinoma, and squamous-cell carcinoma has risen dramatically in recent years.[22] The risk of developing skin cancer is highest in equatorial regions and correlates with the number of blistering sunburns encountered during childhood. Correlative studies such as these, in addition to mechanistic studies at the cellular and organismal levels,

indicate that most skin cancers arise because of exposure to solar radiation. In particular, UV radiation in the 100- to 400-nm range appears to be causative. The health effects of UV radiation vary according to wavelength. Consequently, UV radiation is examined in three regions of wavelength: UVA, 315 to 400 nm; UVB, 280 to 315 nm; UVC, 100 to 280 nm. In contrast to UVC radiation, UVB and UVA can bypass the earth's atmosphere, including stratospheric ozone; therefore, UVA and UVB are believed to contribute to a much higher attributable risk of cutaneous carcinogenesis than UVC. Moderate UVB exposure results in an erythema response, and UVB is well absorbed by cellular molecules such as DNA, melanin, amino acids, carotene, and urocanic acids.[23,24] UVB is more potent in inducing skin tumors in hairless mice than UVA. However, exposure to UV light of any wavelength results in DNA damage and mutation in in vitro models, and UVA also induces tumors in hairless mice. For this reason, excess exposure to any wavelength of UV light is considered unsafe, and tanning beds have been placed on the IARC's list of human carcinogens.

For UV radiation to produce an adverse reaction in skin, photon energy must be absorbed by the target biomolecules such as DNA. Although melanin produced by resident melanocytes is a critical UV radiation absorption filter, unfiltered photons may generate oxidative stress and/or damage DNA. UV irradiation of DNA results in the formation of pyrimidine dimers and other photodamage such as DNA strand breaks and pyrimidine-pyrimidone photoproducts.[25] When these lesions are not repaired, DNA mutations can result. The hallmark UVB radiation-induced mutations are C→T or CC→TT transitions. Target genes for solar radiation–induced mutations include but are not limited to *TP53* (squamous-cell carcinomas [SCCs], basal-cell carcinomas [BCCs], melanoma), *CDKN2A* (melanoma), *BRAF* (melanoma), *NEDD9* (melanoma), and *PTCH* (BCCs, possibly SCCs). UV irradiation of skin keratinocytes also alters numerous cell signaling pathways such as growth arrest and DNA damage-response (i.e., *p53*, *GADD45*, mismatch repair genes), apoptotic (i.e., bcl-2, fas), and mitogenic (i.e., ras, ERK) signaling pathways.[26]

In addition to solar radiation, ionizing radiation in the form of x-rays, nuclear fallout, and therapeutic irradiation as well as energy deposition from radon gas also contribute to the incidence of human cancers. Epidemiologic studies of radiation workers and atom bomb survivors of Hiroshima and Nagasaki as well as the use of animal models have led to the characterization of ionizing radiation as a "universal carcinogen."[27] Ionizing radiation can induce tumors in most tissues and in most species examined because of its unique ability to penetrate tissues and induce DNA damage via energy deposition.[28]

Radon-222 is a radioactive gas that is produced by radioactive decay of uranium-238, which is found ubiquitously in soil, rock, and groundwater. Concern over accumulation of radon in indoor air, especially in underground spaces, has led to study of the health effects of inhaled radon. Radon decay results in the release of alpha particles (two protons and two neutrons), which do not deeply penetrate tissues but possess the capacity to damage DNA in areas of contact. Inhalation of radon has been associated with lung cancer incidence due to exposure of the bronchial epithelium to decay products.[29] Uranium miners have been shown to succumb to lung cancer at a much higher rate than the general population because of their exposure to radon in underground air supplies. At the reduced exposure level detected in homes, radon carcinogenic potential is low, although not insignificant. WHO officials consider radon to be "the second most important cause of lung cancer second to tobacco in many countries" (http://www.who.int/phe/radiation/backgrounder_radon/en/index.html).

Biologic Carcinogens

Biologic carcinogens also play an important role in human carcinogenesis. Approximately 20% of human cancers are associated with infectious agents including bacteria, parasites, and viruses. These are discussed in more detail in Chapter 6 and are not discussed further in this chapter.

Chemical Carcinogens

Chemical carcinogens can be classified into one of four groups according to their chemical nature: organic carcinogens, inorganic carcinogens, fibers, and hormones. The first experimental confirmation of the existence of organic chemical carcinogens came in 1915, when Yamagiwa and Ichikawa demonstrated that multiple applications of coal tar could induce skin tumors on the ears of rabbits.[30] It was later shown that the active carcinogenic agent was composed entirely of carbon and hydrogen. Since that time, numerous carbon-based carcinogens have been identified in studies using experimental animals and in epidemiologic studies of human populations. These organic compounds range from industrially produced and utilized solvents, to naturally occurring but chemically complex combustion products and mycotoxins, to simple alkyl halides such as vinyl chloride (see Figure 7-1).

Organic Carcinogens

Benzene

Benzene is a widely used solvent and is present in gasoline, automobile emissions, and cigarette smoke. Historically, high-level exposure to benzene was commonplace, and, in general, benzene exposure has been the cause of great concern due to its carcinogenic properties. Exposure to benzene

occurs in industrial settings such as in rubber production, chemical plants, oil refineries, and shoe manufacturing. Because benzene is a volatile aromatic solvent, inhalation exposures predominate.[31]

The carcinogenic properties of benzene have long been recognized; an increased risk of leukemia has been shown in workers exposed to high levels of benzene. Benzene exposure is associated with myelodysplastic syndromes. In addition, the strongest associations of benzene and cancer risk are found with risk of acute myeloid leukemia and non-Hodgkin's lymphoma. Benzene is a recognized clastogen and induces oxidative stress upon metabolic activation. Along with mutagenic effects, benzene is believed to alter cell-signaling pathways that control hematopoiesis in hematopoietic stem cells.[32] Workplace exposure restrictions have reduced human exposure to high levels of benzene. Current research is aimed at assessing risk associated with chronic low-level exposure scenarios.

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) are a diverse group of intensively studied organic compounds including benzo[*a*]pyrene. Many PAHs can be metabolically activated to become highly reactive, electrophilic mutagens. PAHs are converted to "bay region" diol epoxides as depicted in Figure 7-2. These diol epoxides covalently bind to DNA, forming a DNA adduct, and their overall reactivity is predictive of their carcinogenic potency.[2,33] For example, benzo[*a*]pyrene diol epoxide reacts extensively with the exocyclic amino group of guanine to produce mutagenic DNA adducts (Figure 7-3, and see section entitled Initiation and Mutational Theory of Carcinogenesis). In addition, certain PAH metabolites may act synergistically with bay region diol epoxide metabolites to promote tumor formation in a manner unrelated to DNA adduct formation.[34] PAHs are formed during combustion of organic matter such as coal, mineral oil, and oil shale. Therefore, PAH exposure occurs in the form of automobile exhaust, soot, coal tar, cigarette smoke, and charred food products. Many PAHs have been found to be carcinogenic in animal studies, and PAH exposure is associated in humans with lung, skin, and urinary cancers, among others. The carcinogenic potential of PAHs is highly variable. Examples of potent to moderately carcinogenic PAHs include 3-methylcholanthrene, B[*a*]P, dibenzo[*a*,*h*]anthracene, 5-methylchrysene, and dibenz[*a*,*j*]anthracene, whereas benzo[*e*]pyrene, dibenz[*a*,*c*]anthracene, chrysene, benzo[*c*]phenanthrene and fluoranthene are relatively weak or inactive carcinogens. Because humans are exposed to mixtures of PAH that are produced during combustion, estimates of carcinogenic potential associated with diverse exposure scenarios are highly variable.

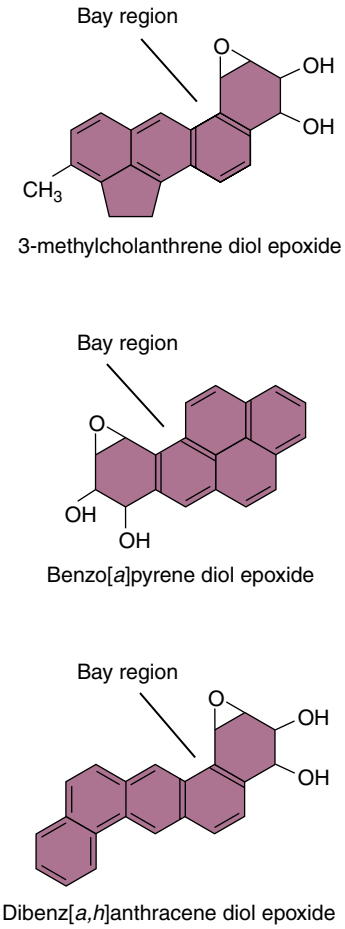

Figure 7-2 Selected polycyclic aromatic hydrocarbon (PAH) bay region dihydrodiol epoxides.

Aflatoxin B_1

One of the most potent liver carcinogens is the fungal metabolite aflatoxin B_1 (AFB_1). AFB_1 and other aflatoxins are produced by *Aspergillus* mold species, such as *Aspergillus flavus* and *Aspergillus parasiticus*. Exposure to aflatoxins occurs via consumption of contaminated nuts and grain, such as peanuts and corn, on which *Aspergillus* species grow. Humid conditions and poor storage contribute to the growth of these molds. In numerous epidemiologic studies, the incidence of hepatocellular carcinoma (HCC) has been correlated with aflatoxin intake. AFB_1 is highly mutagenic in in vitro assays. AFB_1 is converted to an epoxide metabolite responsible for its mutagenic and carcinogenic action. The DNA base targeted by activated AFB_1-epoxide is G (N7 position; see Figure 7-3), and the mutations induced are predominantly GC→TA transversions. Significantly, the *TP53* gene is mutated (GC→TA point mutation in codon 249) in a high proportion of human HCCs that arise in areas where aflatoxin exposure is high.[35,36] Evidence suggests that *TP53* mutation at codon 249 may occur as a result of combined exposure to HBV and AFB_1, and studies have shown elevated risk of HCC in individuals exposed

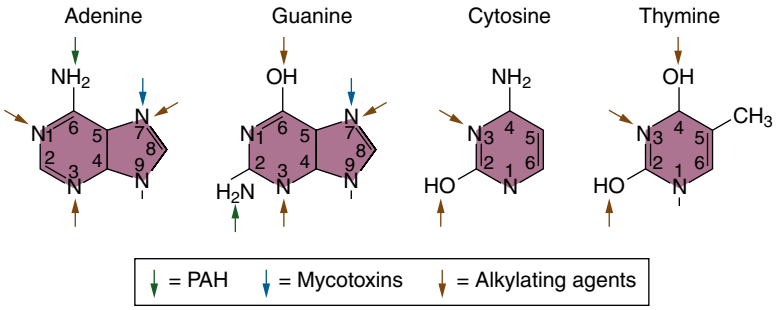

Figure 7-3 Sites of adduct formation associated with carcinogenicity of selected agents.

to both HBV and aflatoxin over individuals exposed to either agent alone.

Benzidine

Benzidine is a member of a large class of carcinogens referred to as *aromatic amines*. The carcinogenic nature of benzidine was discovered in the context of bladder cancer induction in workers in the dye industry.[37] In the past, benzidine-based azo dyes were synthesized in vast quantities in the United States and abroad. In the 1970s, their use was significantly curtailed because of health concerns. However, numerous workers were exposed to these carcinogens before regulation. On activation, benzidine and certain benzidine-based dyes can covalently react with DNA, and benzidine has been shown to induce chromosomal damage in vivo.[38] Benzidine is a bladder carcinogen in multiple species, including humans, dogs, mice, rats, and hamsters, although species differences in activation of the parent compound have made the study of benzidine-induced bladder cancer challenging.[39]

Nitrosamines and Heterocyclic Amines

Shortly after the identification of benzo[*a*]pyrene, *N*-nitrosodimethylamine was shown to induce liver tumors in rats. These results were provocative at the time because of the stark differences in physical properties between the PAHs and the water-soluble *N*-nitroso compounds. Since the initial discovery of *N*-nitrosodimethylamine, a wide variety of *N*-nitroso compounds have been shown to be powerful carcinogens in multiple experimental models and suspected carcinogens in lung and gastrointestinal cancers in humans.[40] Following metabolic activation, *N*-nitrosamines can react with DNA to initiate carcinogenesis. Exogenous and endogenous sources of *N*-nitroso compounds have been described. *N*-nitrosamines are present in smoked meats and in meats containing the antimicrobial and color-enhancing agent nitrite. In both cases, nitrogen oxides are formed, which react with the amines present in meat. Alternatively, the formation of *N*-nitroso compounds can occur endogenously because of low pH conditions in the gastric system or as result of the presence of intestinal bacteria that catalyze *N*-nitroso compound formation.

Heterocyclic amines are also formed in muscle meats on high-temperature processing. Most heterocyclic amines tested are mutagenic in in vitro assays, and several induce gastrointestinal tumors in rodents.[41,42] The two heterocyclic amines found most abundantly in cooked meat and best absorbed into the circulation are 2-amino-1-methyl-6-phenylimidazo-(4,5-*b*)-pyridine (PhIP) and 2-amino-3,8-dimethylimidazo-(4,5-*f*)-quinoxaline (MeIQx). At high temperatures, these heterocyclic amines are formed via reactions among creatinine, creatine, sugars, and amino acids.

N-Nitrosamine exposure is also associated with tobacco use[43]: 4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL), and *N*-nitrosonornicotine (NNN) are carcinogenic tobacco-alkaloid–derived *N*-nitrosamines present in unburned and burned tobacco products. PAHs and NNK are the most abundant pulmonary carcinogens in tobacco smoke. In contrast to PAHs, which induce SCCs, NNK induces adenocarcinoma of the lung in animal models. Furthermore, adenocarcinoma of the lung has become the most common lung cancer type in the United States. This fact may reflect changes in cigarette manufacturing in the past 30 to 40 years that have resulted in rising levels of NNK and falling levels of B[*a*]P. In addition, in smokeless tobacco products such as snuff, *N*-nitrosamines are prominent agents involved in the induction of oral cancer. These *N*-nitrosamines require metabolic activation for carcinogenic activity and form DNA adducts similar to other organic carcinogens discussed earlier.

Inorganic Carcinogens

Beryllium

In 1946, Hardy and Tabershaw reported "delayed chemical pneumonias" in workers exposed to beryllium. In that same year, Gardner and Heslington reported experimentally induced osteosarcomas in beryllium-injected rabbits. Subsequent studies in the 1950s demonstrated that inhalation exposure of rodents resulted in induction of lung tumors. Since that time, beryllium has been recognized as a human carcinogen capable of inducing lung cancer in exposed workers. Occupational exposures to beryllium include inhalation of beryllium-containing dusts during processing of ores,

machining of beryllium metal and alloys, and manufacturing of aerospace materials, ceramics, sports equipment, and electronics. Beryllium is weakly mutagenic in bacterial and mammalian mutagenesis test systems; however, it shows strong transformation capacity in Balb/3T3 and Syrian hamster secondary embryo cells.[44] In addition to genotoxic effects, beryllium has been shown to alter the expression of numerous cancer-related genes (i.e., *c-fos*, *c-jun*, *c-ras*, MAP kinases, DNA repair genes,). Despite these reports, the carcinogenicity of beryllium has recently been called into question.[45,46] Current occupational exposure levels are much lower than historical values, and previous reports of beryllium's effects may have been confounded by inadequate smoking history information.

Cadmium

Cadmium is a heavy metal present in soil, air, and water and is listed as a priority pollutant by the U.S. EPA. Occupational exposures to cadmium occur during the manufacture of nickel-cadmium batteries, pigments, and plastic stabilizers as well as electroplating processes, metal smelting, and electronic waste recycling.[47] In addition, cigarette smoke contains cadmium. Release of industrial cadmium waste into the environment is of particular concern because of its long biologic half-life. On absorption, cadmium can accumulate in the body because it is poorly excreted and effectively stored in liver and kidney as a result of binding to metallothionein. Furthermore, once absorbed, no effective detoxification pathways for cadmium exist. The half-life of cadmium in humans is estimated at 15 to 20 years.

Cadmium exposure has been linked to human lung cancer and may affect the risk of prostate and kidney cancers. Although the carcinogenicity of cadmium has been confirmed in rodent models, the precise mechanism is unknown.[47] Cadmium binds only weakly to DNA and is only weakly mutagenic in bacterial and mammalian assays, and high concentrations are required to induce oxidative stress. Cadmium may act via non-genotoxic mechanisms to activate proto-oncogenes and disrupt normal cellular processes. For example, cadmium has been shown to alter E-cadherin–mediated cell adhesion, inhibit DNA repair, and alter expression of numerous genes in vitro including *c-fos*, *c-myc*, metallothionein, and genes encoding heat shock proteins.

Arsenic

Arsenic is widely distributed in the environment, being found in the earth's crust in both inorganic [arsenite-As(III) and arsenate-As(V)] and methylated forms [monomethylated arsenic (MMA) and dimethylated arsenic (DMA)]. As(III), as well as MMA(III) and DMA(III), have been associated with skin, lung, urinary bladder, kidney, and liver cancers.[48] Human exposure to arsenic occurs via contaminated drinking water, diet, or contact with wood preserved with arsenicals; during mining of tin, gold, and uranium; and during application of arsenical pesticides. Signs of chronic exposure to arsenic in drinking water include altered skin pigmentation and hyperkeratosis of the palms of the hand and soles of the feet, which may ultimately lead to skin lesions and skin cancer.

Much attention has been given to assessing the health impact of arsenic contamination in drinking water sources. The current WHO guidelines for arsenic exposure recommend no more than 10 μg/L arsenic in water intended for human consumption. Since the 1980s, millions of people in China, India, Bangladesh, the United States, Chile, and Argentina have been exposed to arsenic in the drinking water far in excess of this limit. Already, numerous epidemiologic studies in Taiwan, the United States, Chile, and Argentina have demonstrated excess cancer risk in areas with known high exposure to arsenic in drinking water.[49] Unfortunately, identifying a safe level of arsenic in drinking water has been difficult because most epidemiologic studies show adverse effects at high doses; data concerning health risk at low exposures are unavailable. After intense debate, the limit in the United States was lowered to 10 μg/L in 2006.

For years, the study of arsenic and cancer was hindered by a lack of experimental evidence of carcinogenicity in animals. Only recently have studies of methylated arsenic and early life exposures provided adequate validation in vivo. As(III) and As(V) are transported into cells, As(III) more readily than As(V). On absorption, As(V) is reduced to As(III); As(III) can then be methylated. Historically, methylation of As(III) was considered to be a detoxification reaction, but recent evidence contradicts this dogma.[50] MMA(III) and DMA(III) are at least as cytotoxic, mutagenic, and clastogenic as As(III). Nonetheless, when methylated, arsenic is readily excreted in urine. DMA can be detected in urine shortly after exposure; also, because of the wide distribution of arsenic, exposure can be assessed via hair and fingernail deposits months or years after exposure. Therefore, methylated arsenic in hair and fingernail samples serves as a useful biomarker of exposure.

Numerous mechanisms of action have been proposed for arsenic carcinogenicity.[48] Arsenic exposure is known to generate reactive oxygen species. Like many transition metals, arsenic can participate in Fenton reactions that produce oxidative stress. Furthermore, arsenic may activate superoxide-generating NAD(P)H oxidase. In this way, arsenic is thought to induce DNA and protein damage that may initiate carcinogenesis. Arsenic has also been shown to elevate the total level of tyrosine phosphorylation in cells. Specifically, arsenic may alter phosphorylation-dependent epidermal growth factor receptor (EGFR) and mitogen-activated

protein kinase (MAPK) signaling. In addition, arsenic has been shown to alter NFκ signaling, apoptosis rates, cell cycle regulation, DNA repair, and genome stability. More recent evidence suggests that epigenetic dysregulation may underlie these adverse effects of arsenic exposure.[51]

Chromium

Chromium in the hexavalent state [Cr(VI)] is a human carcinogen. The carcinogenic properties of chromium have been identified via epidemiologic studies of exposed workers in industries such as chrome plating, welding, leather tanning, and stainless steel production. Exposure to chromium generally occurs via inhalation and primarily affects risk of lung cancer. Because of environmental contamination, consumption of chromium in drinking water is also possible; however, the health consequences of the low-level exposure are unclear.[52]

The oxidation state of chromium determines not only its bioavailability but also its cellular reactivity.[53] Cr(VI) readily enters cells via anion channels, whereas Cr(III) only slowly crosses the cell membrane. On entry to the cell, Cr(VI) is likely reduced, as Cr(VI) does not readily react with DNA in in vitro analyses. Chromium in lower oxidation states [Cr(III), Cr(IV), and Cr(V)] is more reactive; Cr(III) is believed to be the ultimate DNA reactive form. The reduced forms of chromium can also induce oxidative stress. In addition to or as a result of oxidative stress, chromium alters cell signaling pathways. Signaling molecules affected include NFκB, AP-1, p53, and HIF-1.

Fibers

Asbestos

The term *asbestos* refers to a group of naturally occurring silicate mineral fibers. There are numerous types of asbestos fibers that are classified according to their morphologic characteristics, including whether the fibers are curly (serpentine) or straight (amphibole). The shape and length-to-width ratio are important determinants of whether a particular asbestos fiber type will be carcinogenic.[54] This is likely because the size of the fiber determines the ability of the fiber to reach the deep lung tissues and penetrate the lung. Long (>4 μm) and thin (<0.5 μm diameter) fibers are the most carcinogenic. Extensive exposure to asbestos has occurred because the flame-resistant and durable characteristics of asbestos have led to its use as an insulating agent in schools, factories, homes, and ships, as construction material, and as a raw material for automobile brake and clutch parts. A large cohort of workers was exposed to high levels of asbestos when ship building peaked during World War II.

The toxic effects of asbestos exposure have been known for many years.[54] For example, more than 40 years ago, crocidolite asbestos exposure of South African miners was linked to mesothelioma incidence. Mesothelioma is a rare cancer of the membranous lining of the abdomen and chest. Numerous animal studies and in vitro experiments support the conclusion that asbestos can induce tumors. In fact, few cancer cause-effect relationships are as striking as asbestos and mesothelioma; most cases of mesothelioma can be related to asbestos exposure. In addition to mesothelioma, asbestos exposure has been associated with lung and laryngeal cancers. The initial accumulation of evidence of asbestos carcinogenicity was obscured by the differences in carcinogenicity of asbestos fibers of varying shape and by the long latency for the development of tumors following exposure. Since identification of asbestos as a cancer-causing agent, asbestos usage in the United States has greatly declined because of the introduction of a replacement material (fiberglass) and OSHA regulation of asbestos exposure. Nonetheless, mesothelioma rates have not declined in the United States in the past 15 years.

Numerous biologic hypotheses concerning the mechanism(s) by which asbestos induces tumors have been proposed.[55] Because long, thin fibers are the most carcinogenic, asbestos fibers may penetrate the lung and irritate the lining of the chest wall. The chronic inflammation and scarring would then contribute to tumor formation. Alternatively, the fibers may pierce spindle fibers during mitosis and thereby induce chromosome damage. Finally, asbestos fibers may induce oxidative stress and/or alter EGFR and MAPK cell signaling. Significantly, epidemiologic studies show that cigarette smoking acts synergistically with asbestos exposure to induce lung tumors. In addition to asbestos, exposure to other fibers such as plant-derived silica fibers (biogenic silica) has been shown to be carcinogenic.[56]

Hormones

The etiology of numerous cancers is believed to be influenced by hormonal or dietary factors, and hormones under certain conditions are considered to be known human carcinogens (see Table 7-5). As previously mentioned, overweight and obesity are associated with elevated cancer risk. This effect may be mediated by endocrine dysregulation such as altered adiponectin, leptin, insulin, and IGF-1 levels. In addition, prostate, ovarian, breast, testicular, and endometrial cancers are hormonally driven.[57,58] A role for hormones in cancer etiology was established when castration and ovariectomy studies revealed that hormone-dependent cancers could be prevented by removing the primary hormone-synthesis organs. As an example of the action of hormones in cancer formation, estrogen activates hormone-responsive receptors. Stimulation of these receptors, such as the estrogen receptors, can increase the cellular proliferation rate to promote tumorigenesis. Endogenously synthesized hormones and administered hormones have been shown to influence cancer formation. Hormone replacement therapy and estrogen-only birth control therapy have been associated

with increased risk of hormone-dependent cancers. An even more dramatic example of synthetic hormone-induced cancer is that of women who were exposed to estrogenic diethylstilbestrol (DES) in utero. DES was taken by pregnant women to prevent abortion; however, a large percentage of their female offspring developed clear-cell carcinomas of the vagina and cervix after the onset of puberty.

Mechanisms of Chemical Carcinogenesis

Multistage Nature of Carcinogenesis and the Multistage Model of Mouse Skin Carcinogenesis

In the early days of carcinogenesis research, it was noted that wounding of the skin of mice previously treated with mutagenic coal tar led to skin tumor formation. To explain these findings, a multistage model of carcinogenesis was proposed.[59] The model holds that tumors arise in cells that have first undergone a mutating event initiated by an electrophilic metabolite such as that formed from benzo[*a*]pyrene found in coal tar. Subsequently, cell proliferative stimuli promote the initiated cell population to expand, resulting in premalignant clonal outgrowths. Finally, additional genetic alterations accumulate in these lesions, leading to the development of a neoplasm that becomes invasive and ultimately metastatic. Over the years, this model has been refined to encompass the fundamental role of stem cells as the targets of initiation, the importance of stemlike characteristics in the plasticity of developing tumors, and the critical role of tumor microenvironment in carcinogenesis.[60] In addition, the mechanistic importance of DNA methylation changes and histone modifications in the initiation, promotion, and progression phases has been acknowledged.

Numerous animal models have been developed to study the multistep manner in which various epithelial and other tumors develop and progress. In one of the best-characterized models, the mouse two-stage skin carcinogenesis model, a subcarcinogenic dose of a mutating agent is delivered.[61] This is followed by multiple exposures to growth-promoting stimuli and the appearance of tumors on the dorsal skin (Figure 7-4). This model has provided an excellent paradigm in which to examine the carcinogenic potential of environmental agents and has been used to reveal the mechanistic bases of multistage carcinogenesis by environmental agents.

Initiation and Mutational Theory of Carcinogenesis

During the first stage of multistage carcinogenesis, DNA mutations result as a consequence of electrophilic carcinogen exposure, oxidative damage to DNA, DNA strand breaks, or other DNA insults. Mutations are believed to occur in multipotent stem cells and are inherited by daughter cells. Theodor Boveri first proposed the concept that cancer arises as a result of damage to genetic material at the turn of the 20th century. In the 1950s and 1960s, James and Elizabeth Miller, after observing that a wide variety of structurally diverse chemicals could induce cancer in animal models, suggested that chemical carcinogens required metabolic activation to electrophilic intermediates. These electrophilic intermediates could then covalently bind to proteins, RNA and DNA.

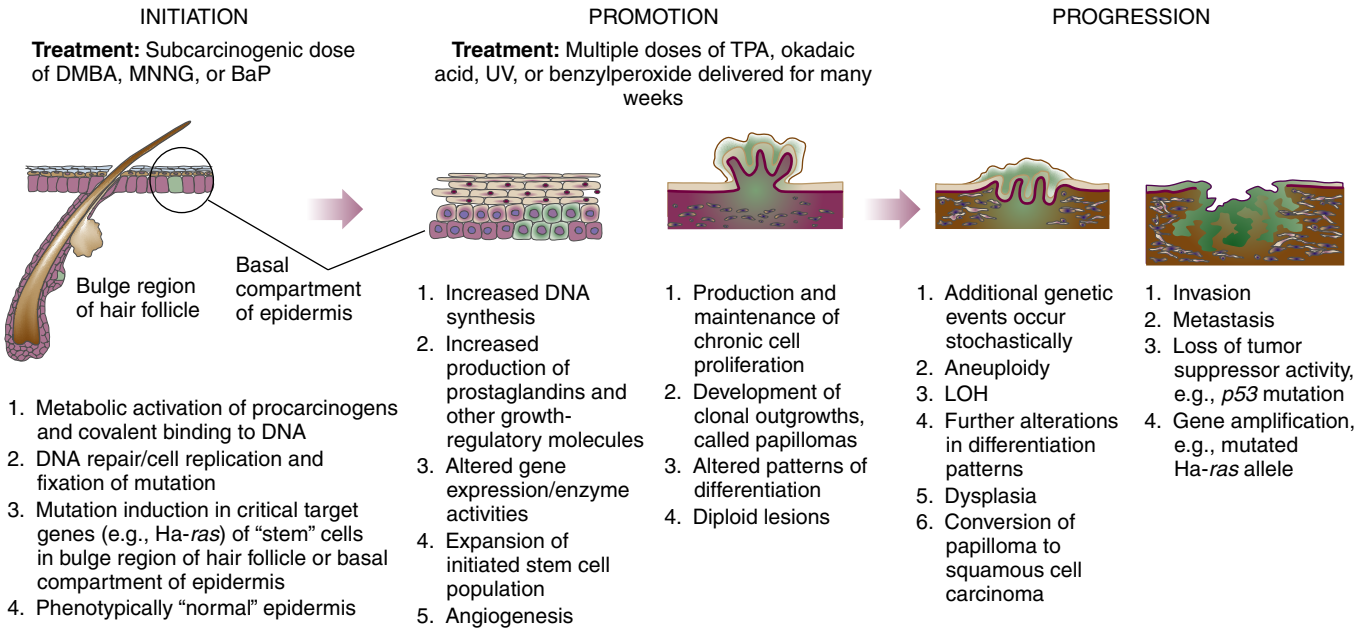

Figure 7-4 Multistage model of mouse skin carcinogenesis. *BaP,* Benzo[*a*]pyrene; *DMBA,* 7,12-dimethylbenz[*a*]anthracene; *LOH,* loss of heterozygosity; *MNNG, N*-methyl-*N*-nitro-*N*-nitrosoguanidine; *TPA,* 12-*O*-tetradecanoyl phorbol-13-acetate.

The term *electrophile theory of chemical carcinogenesis* was coined to describe their concept. The Millers' work was supported by data reported in 1964 by Brooks and Lawly, which demonstrated that the degree of covalent binding of carcinogenic PAHs to DNA correlated with carcinogenic potential.[62] Subsequently, many chemical carcinogens have been shown to bind and alter DNA integrity, thereby inducing mutations. Carcinogens that alter DNA to induce cancer in this manner are referred to as *genotoxic carcinogens*. The majority of carcinogens identified to date are genotoxic carcinogens.

DNA mutations occurring in proto-oncogenes and tumor suppressor genes are particularly critical to the initiation of carcinogenesis. These normal cellular genes are targeted during carcinogenesis and play critical roles in tumor formation. Proto-oncogene mutations are dominant, in that activation of a single copy of a proto-oncogene to an oncogene may be significant for carcinogenesis. Proto-oncogenes are discussed in greater detail in Chapter 2; however, a list of proto-oncogenes and the cancers with which they are associated is provided in Table 7-6. In contrast to proto-oncogenes, the normal cellular function of tumor suppressor genes is to negatively regulate cell growth. According to Knudson's two-hit theory, tumor suppressor genes require that both copies of the gene be lost or inactivated because tumor suppressor mutations are recessive in nature. For instance, inheritance of one mutated copy of *p53* is not significant until the second copy is lost ("second hit"), resulting in loss of heterozygosity (LOH). Examples of tumor suppressor genes and associated cancers are also provided in Table 7-6.

In the multistage mouse skin carcinogenesis model, initiation occurs via application of a genotoxic carcinogen (e.g., *N*-methyl-*N*-nitro-*N*-nitrosoguanidine [MNNG], 7,12-dimethylbenz[*a*]anthracene [DMBA], or B[*a*]P; see Figure 7-4). A subcarcinogenic dose of the initiating agent is applied to the shaven dorsal skin of the mouse. The critical mutations for tumor development are believed to occur in epidermal multipotent stem cells, a major population of which resides in the bulge region of the hair follicle. Although no phenotypically aberrant cells are apparent in the "initiated" skin, small populations of epidermal cells can be identified as early as 1 week after treatment with DMBA that contain signature mutations. The initiation stage is irreversible and cumulative. That is, the dose required for initiation can be divided and applied in portions over time or applied in a single dose with essentially the same result. In addition, commencement of the promotion phase can be delayed, because the DNA mutations induced by the initiating agent are permanent.

Table 7-6 Selected Proto-oncogenes and Tumor Suppressor Genes and Some Associated Cancers

Gene Type	Gene Name	Associated Cancer Type
Proto-oncogene	*C-MYC*	Leukemia, lung, colon
	ERBB-2	Breast, ovary
	ABL	Leukemia
	RASH	Bladder
	RASK	Lung, ovary, bladder
	RASN	Breast
Tumor suppressor	*APC*	Colon
	P53	Breast, colon, lung
	RB	Retinoblastoma, breast, bladder, lung
	$BRCA_1$	Breast, ovary
	$BRCA_2$	Breast

Adapted from Perkins AS, Stern DF: Molecular biology of cancer. Oncogenes. In: DeVita VT, Hellman S, Rosenbert SA, eds. *Cancer: Principles & Practice of Oncology*. 5th ed. Philadelphia, Pa: Lippincott-Raven Publishers; 1997.

In the mouse skin model, the most frequently mutated proto-oncogene following initiation with PAH is *Hras1* (reviewed in Ref. 61). Mutations at G^{38} of codon 13, in the case of B[*a*]P, and at A^{182} of codon 61, in the case of DMBA, lead to constitutive activation of the gene product of *Hras1*. These mutations can be detected in the resulting tumors, reflecting the clonal origin of the papillomas. In addition, the specificity of these mutations is directly related to the major sites of DNA adduct formation arising from the carcinogenic diol-epoxides of these two PAH carcinogens. In a variety of rodent models of multistage cancer (rat azoxymethane-induced colonic lesions, mouse diethylnitrosamine-induced liver foci, mouse urethane-induced lung adenomas), mutations in ras oncogenes frequently occur, highlighting the importance of ras, and oncogenes in general, in the development of cancer. Activating mutations in *Hras1* are believed to confer, at least in part, resistance to terminal differentiation of keratinocytes during tumor promoter treatment, thus conferring a selective growth advantage to these cells. Findings in animal models have established the irreversible and cumulative nature of tumor initiation and underscore the specificity of critical DNA mutations in proto-oncogenes or tumor suppressors induced by genotoxic carcinogens.

During carcinogenesis, numerous types of DNA lesions occur following exposure to carcinogenic agents. For example, in the case of electrophilic carcinogen attack, specific points within the DNA nucleotides are targeted for adduction (see Figure 7-3). As noted previously, B[*a*]P targets primarily the N^2 exocyclic amino group of guanine, whereas other PAHs may target adenine in addition to guanine (e.g., DMBA). As shown in Figure 7-3, alkylating agents target numerous sites within DNA bases. However, certain sites (e.g., 0^6 methylguanine and 0^4 methylthymine for methylating agents) may be the most important for carcinogenesis by this class of carcinogen. During replication, mispairing due to

DNA adducts or other DNA lesions may become fixed, and the ultimate effect depends on the location of the mutation. Mutations affect coding sequences, intronic signals, untranslated regions, or promoter elements; consequently, protein function or expression levels may be altered. Following DNA double-strand breaks, incorrect rejoining of DNA has been shown to cause rearrangement of DNA coding and promoter regions. In addition to these qualitative changes, quantitative changes in gene copy number (gene amplification or gene deletion) may also affect key cancer-associated genes.

Promotion

During the tumor promotion phase of carcinogenesis, growth stimuli and other factors promote clonal expansion of initiated cells. This stage is characterized by altered gene expression and proliferation of initiated cells, some of which maintain stemlike characteristics. Most tumor promoters are thought to exert their effects through cellular receptors or cell growth, differentiation, and/or apoptotic signaling pathways. Inflammatory mediators or other stromal factors may mediate these effects by providing a permissive environment for tumor growth. Promoting agents do not directly affect DNA but act primarily via non-genotoxic, reversible mechanisms.

Growth Factor Receptor Signaling Pathway Engagement

In the mouse two-stage skin carcinogenesis model, the promotion stage is elicited by multiple applications of promoting agents delivered over the course of weeks or months (see Figure 7-4). In this model, promotion must occur following initiation with a mutating agent. As opposed to initiation, the promotion stage is initially reversible, does not elicit DNA mutation, is prolonged in nature, and appears to be nonadditive. Typical skin tumor-promoting agents include the phorbol ester 12-*O*-tetradecanoyl phorbol-13-acetate (TPA); the phosphatase inhibitor okadaic acid; the organic peroxide benzoyl peroxide; and the anthrone derivative chrysarobin (see Figure 7-5 for the diversity of structures of chemical tumor promoters). In addition, UV light, repeated

abrasion, full-thickness wounding, and certain silica fibers possess the ability to function as tumor promoters. The endpoint of promotion in the mouse two-stage skin carcinogenesis model is the development of premalignant, clonal outgrowths referred to as *squamous papillomas*. These lesions (hyperplastic epidermis folded over a core of stroma) are still well differentiated and do not possess the ability to invade surrounding tissue. Once the cells of the papilloma acquire additional mutations that allow autonomous growth, the promotion stage is no longer reversible.

Promoting agents act primarily by altering gene expression.[63] The initial interaction of promoting agent with the cell depends on the nature of the promoter. In the mouse skin model, the receptor for TPA (the most frequently used promoting agent) has been identified as protein kinase C (PKC). Stimulation of PKC results in a cascade of events that allow for expansion of the initiated cell population. PKC-mediated signaling events include induction of ornithine decarboxylase (ODC) activity, activation of the MAPK pathway, and upregulation of ligands for the EGFR. EGFR activation leads to further activation of multiple signaling pathways involved in proliferation and survival. For instance, Akt and Stat3 signaling are believed to affect cell-cycle parameters via altered cyclin Dl expression.[64,65] Although the initial mechanism for other skin tumor promoters (e.g., okadaic acid, benzoyl peroxide, chrysarobin) is different from that of TPA, all tumors promoter ultimately elicit key biologic and molecular changes. These changes include induction of ODC, induction of growth factors and cytokines, production of eicosanoids, and increased DNA synthesis. Growth factors and cytokines known to be altered by tumor-promoting stimuli include TGF-α, TGF-β, IL-1, IL-6, and TNF-α, among others.

During tumor promotion, immune inflammatory cells play diverse and complex roles. Increasingly, cytokines are acknowledged as active players in the growth-promoting environment of developing neoplasia. These cells, along with fibroblasts and other cells present in the stroma, release signaling molecules such as EGF, VEGF, and FGF2 to facilitate proliferation and contribute to proinvasive capacity by affecting expression of matrix metalloproteinases and other proteases. In contrast, other immune surveillance cells can play tumor-antagonizing roles.

Examples of Tumor Promoters

Tumor-promoting agents have been identified for a number of rodent tissues other than mouse skin, indicating the generality of this phenomenon to other organs and species (reviewed in Ref. 66). Some examples of tumor promoters that act on organs other than skin include 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) (liver), butylated hydroxyanisole (BHA) (lung), sodium saccharin (urinary bladder), and bile acids (colon) (see Figure 7-5 again for chemical structures). Certain components of tobacco smoke can also act as tumor promoters.

Progression

The final stage of carcinogenesis is referred to as *progression*. The original tumor mass increases in size, additional mutations accumulate, and invasion and metastasis occur. Genome stability is compromised, and a mutator phenotype may develop to permit further accumulation of mutations. Crucial to progression of solid tumors is the ability of cancer cells to invade the surrounding stroma, enter the bloodstream, and extravasate to colonize distal sites. For cells to break away from the primary tumor, downregulation of cell adhesion, often by repression of E-cadherin expression, must occur. Subsequently, the cells must acquire mobility and ability to invade the surrounding stroma and blood vessel basement membranes. Invasion requires the action of degradation enzymes such as the matrix metalloproteinases (MMPs). These changes are collectively referred to as the *epithelial-to-mesenchymal transition* (EMT). Once established, the metastatic colony must develop adequate nutrition and oxygen supply via stimulation of angiogenesis.

The process whereby normal cells accrue an increasingly aberrant and invasive phenotype as a consequence of selection has been likened to evolutionary theory at the population level.[67] However, in addition to an accumulation of genetic mutations, tumor promotion and tumor progression can also involve heritable but non-genotoxic lesions. These changes, referred to as *epigenetic reprogramming*, involve altered DNA methylation patterns and changes to the histone code. In the case of DNA methylation, the promoter regions of tumor suppressor genes may become hypermethylated, thereby silencing gene expression. Alternatively, the expression of proto-oncogenes may be upregulated via hypomethylation. Recent proposals suggest that environmental agents elicit epigenetic changes and alter the risk of tumor promotion and/or progression.[68,69] Interestingly, epigenetic reprogramming may precede the neoplastic process in some cases, and modifications to the histone code may affect DNA damage response or DNA repair during initiation, promotion, or progression.[69]

During progression in the two-stage mouse skin carcinogenesis model, premalignant papillomas convert to SCCs (see Figure 7-4).[61] This conversion process is accompanied by additional genetic alterations, including the development of aneuploidy. Characteristic changes in gene expression such as elevation in gamma-glutamyltranspeptidase, $\alpha_6\beta_4$ integrin, and keratin-13 expression as well as loss of E-cadherin expression are also common. The histologic appearance of SCCs can be distinguished from papillomas by downward growth and loss of ordered differentiation of epidermal keratinocytes.

Multistage Environmental Carcinogenesis in Humans

The applicability of multistage carcinogenesis concepts to human cancer is supported by a number of observations. First, human environmental carcinogen exposure outside of occupational settings usually occurs in low doses repeatedly delivered over the course of months or years. Each individual dose alone is likely insufficient to produce cancer. In addition, it is unlikely that a single dose of a sole agent is the cause of most human cancers. Second, there is considerable evidence from human epidemiologic and experimental animal studies that certain human carcinogens such as tobacco smoke and UV light exhibit a strong tumor-promoting activity. Furthermore, many components of the human diet appear to influence cancer in humans through a tumor-promotion type of effect. Finally, histochemical and molecular examination of tumors at various stages indicates that human cancers develop via multiple steps. It has been postulated that human cancers require as many as four to six sequential genetic events for their development.[70]

Numerous human cancers, particularly those of epithelial origin, appear to develop in a multistage progression. For instance, regions of dysplasia and carcinoma in situ appear to precede invasive carcinoma when melanoma, head and neck squamous-cell carcinoma, and cervical cancer lesions are examined. Supporting the multistage nature of cancer development, genetic alterations have been shown to accumulate during tumorigenesis in these lesions. For example, during colorectal carcinogenesis, mutations in the adenomatous polyposis coli (APC) gene appear to initiate tumorigenesis.[71] A portion of the resulting dysplastic foci further accumulate mutations in the K-*ras* oncogene and other oncogene and tumor suppressor genes and progress from adenomas to invasive carcinomas. A similar pattern of accumulation of molecular abnormalities has been noted for squamous-cell lung carcinoma. As the severity of the histopathologic appearance of these lesions increases, the frequency of loss of heterozygosity events also increases.[72]

Examination of tumor DNA has also validated a role for environmental carcinogens in the etiology of human cancer. When tumor suppressor and oncogene gene sequences are examined, characteristic mutation spectrums can be identified and associated with specific carcinogen exposure. The mutation spectrum of the *p53* tumor suppressor gene has been intensively studied.[73] A database of more than 10,000 reports of *p53* mutations in human cancers has been collected. Depending on the cancer type, mutations are frequently reported at amino acids 130-142, 151-164, 171-181, 193-200, 213-223, 234-258, and 270-286, which are part of the DNA-binding domain of *p53*. Sixty-one percent of lung cancer samples have mutations at codon 157 in addition to mutations in codons 248 and 273. A large percentage of these mutations are the result of G→T transversions. In vitro analyses indicate that exposure of normal human bronchiolar epithelial cells to benzo[*a*]pyrene diol epoxide results in DNA adducts in *p53* in the same mutation hot spots as in lung cancer: codons 157, 248, and 273.[74] These results provide strong evidence for a link between chemical carcinogen exposure (B[*a*]P of cigarette smoke) and human lung cancer. In addition, aflatoxin B_1 exposure correlates strongly with liver cancer and *p53* mutation at codon 249, whereas sunlight exposure, which is known to induce CC→TT transition mutations, correlates with CC→TT tandem mutations at hot spots for skin cancer in *p53*.

Endogenous Defense Systems against Chemical Carcinogenesis

Various genetically influenced defense systems determine the ultimate outcome following exposure to an environmental carcinogen. Chemical carcinogens are often metabolized to less toxic derivatives and cleared from the body. Damage to cellular DNA may be repaired, or the damaged cell may be eliminated via apoptosis. Furthermore, the cell possesses a number of endogenous defense mechanisms against carcinogen-induced oxidative stress. Interindividual differences in the efficacy of these defense mechanisms are known to exist and influence host susceptibility to environmentally induced cancer.

Carcinogen Metabolism

Subsequent to absorption through the gastrointestinal tract, xenobiotics travel via the portal vein to the liver where first-pass metabolism occurs. Hepatic tissues are highly concentrated with metabolic enzymes specialized in chemical conversion referred to as *biotransformation*. In other cases, such as inhalation or dermal exposure, biotransformation enzymes at the site of exposure can begin immediately to convert the parent compound into metabolites. Biotransformation enzymes are theorized to have evolved primarily as natural defenses against environmental chemical exposure.

Phase I and Phase II Biotransformation Reactions

The reactions catalyzed by biotransformation enzymes have been categorized into groups referred to as *phase I* and *phase II* reactions because of their often sequential roles in the conversion of xenobiotics. Phase I reactions include oxidation, reduction, and hydrolysis reactions and, generally, expose functional groups that enable phase II biotransformation to proceed. Phase II biotransformation reactions catalyze

glucuronidation, sulfation, acetylation, methylation, and glutathione conjugation reactions, among others.[75] Numerous enzymes that catalyze these reactions have been identified and classified according to gene family (Table 7-7).

Phase I metabolites, in general, display minimally increased hydrophilicity. In contrast, phase II biotransformation reactions catalyze the addition of cofactor molecules to the parent compound, resulting in a significant increase in hydrophilicity. In certain instances, phase II conjugation reactions may also target the parent compound for export via specialized efflux pumps. Therefore, in general, phase II biotransformation reactions ultimately result in metabolites that are less toxic and more readily excreted. In contrast, phase I biotransformation of carcinogens often results in reactive metabolites capable of covalent modification of cellular macromolecules. It is important to note, however, that these are generalizations. Examples of phase I–mediated detoxification have been noted, and phase II–mediated chemical activation has been documented.

According to the Millers' electrophilic theory of carcinogenesis, all mutagenic compounds must be inherently chemically reactive or converted via biotransformation to a reactive form. Carcinogens that do not require metabolic activation are referred to as *direct carcinogens;* indirect carcinogens require metabolic activation. The conversion of the parent compound to a reactive state converts a procarcinogen to an ultimate carcinogen. Ultimate carcinogens, like direct carcinogens, are electrophilic and attack nucleophilic groups in DNA to initiate carcinogenesis, as discussed in the section titled Initiation and Mutational Theory of Carcinogenesis. Although categorizing biotransformation reactions according to the phase I versus phase II nature of the metabolism is useful, the endpoint of carcinogen exposure is often determined by a combination of oxidation, reduction, and conjugation reactions.

PAH Biotransformation

PAHs are widely studied substrates for cytochrome P450 (CYP450)-mediated biotransformation. CYP450s, a class of enzymes present in the endoplasmic reticulum of most cells, have been implicated in numerous carcinogen activation reactions. In humans, the CYP450 family consists of more than 50 genes. which are grouped on the basis of sequence similarity into families (1, 2, 3, . . .), subfamilies (A, B, C, . . .), and individual CYP450s (1, 2, 3, . . .) (e.g., CYP450 1A1, 1A2, 1B1, etc.).[64] CYP450s catalyze oxidation, reduction, oxygenation, dealkylation, desulfuration, dehalogenation, and hydroxylation reactions. CYP450-mediated reactions can detoxify direct carcinogens or activate indirect carcinogens.

Once absorbed, certain PAHs can be biotransformed into electrophilic mutagens via the sequential action of phase I enzymes (Figure 7-6[23]). First, PAH double-bond oxidation is catalyzed by CYP450 enzymes (e.g., CYP1A1). For example, in the case of B[*a*]P, CYP450-mediated oxidation forms the epoxide intermediate, benzo[*a*]pyrene-(7*R*,8*S*)-epoxide. Next, microsomal epoxide hydrolase (mEH) catalyzes hydrolysis of arene oxide to a *trans* dihydrodiol. Finally, a CYP450-catalyzed oxidation reaction forms the ultimate carcinogen (i.e., benzo[*a*]pyrene-7,8 diol-9,10-epoxide), a diol-epoxide metabolite. In human lung tissue, both B[*a*]P epoxidation steps are catalyzed primarily by CYP1A1. Studies using CYP1B1-deficient mice highlight the importance of this p450 enzyme in PAH activation. These mice are resistant to DMBA-induced carcinogenesis, due to a lack of conversion of DMBA from procarcinogen to ultimate carcinogen.[76]

PAHs can be detoxified by glutathione *S*-transferases (GSTs). GST-mediated glutathione conjugation of PAH epoxides can deactivate the ultimate carcinogen, prevent activation to reactive diol epoxides, or accelerate clearance of PAHs following exposure. In this way, GSTs act as an endogenous defense system against PAH-induced carcinogenesis.

Aflatoxin Biotransformation

Metabolism plays a critical role in determining the carcinogenicity of the mycotoxin AFB_1. AFB_1 must first be activated to the ultimate carcinogen, *exo*-8,9-AFB_1-epoxide (see Figure 7-6). This reaction is predominantly catalyzed by CYP450 3A4 in humans.[35] Alternatively, CYP450s can metabolize AFB_1 to inactive products such as AFM_1, AFQ_1, or AFB_1 *endo*-8,9-epoxide (AFBO).

Glutathione conjugation catalyzed by GSTs plays a critical role in protecting against mutagenic and carcinogenic effects of AFB_1 metabolites. Generally, GSTs facilitate xenobiotic clearance by catalyzing glutathione conjugation of a variety of electrophilic substrates.[77] In humans, cytosolic GSTs are categorized according to gene sequence similarity into at least six classes: Alpha (A), Mu (M), Omega (O), Pi (P), Theta (T), and Zeta (Z). Individual GST family members demonstrated unique, though overlapping, substrate specificity.

Subsequent to activation, GST-mediated glutathione (GSH) conjugation can detoxify the AFB_1 epoxide, and this reaction is a major factor underlying the substantial species variation in sensitivity to AFB_1-induced carcinogenesis. For example, rats are highly sensitive to AFB_1-induced hepatocarcinogenesis, whereas mice are comparatively resistant. In line with this observation, mice express mGSTA3-3, which demonstrates high activity toward AFBO, whereas rat GST-mediated deactivation of AFB is significantly less in comparison. Mutational studies of recombinant mGSTA3-3 indicate that the high activity of this protein toward AFBO is due to multiple, critical amino acid residues in the substrate binding site that are not present in homologous rat GSTA3-3.[78]

Table 7-7 Selected Phase I and Phase II Biotransformation Enzymes

Enzyme Classification	Reaction Catalyzed	Gene Family	Class/ Subfamily	Isoforms
Phase I	Oxidation, others	Cytochrome P450	CYP_1	CYP_1A_1
				CYP_1A_2
				CYP_1B_1
			CYP_2	CYP_2A_6

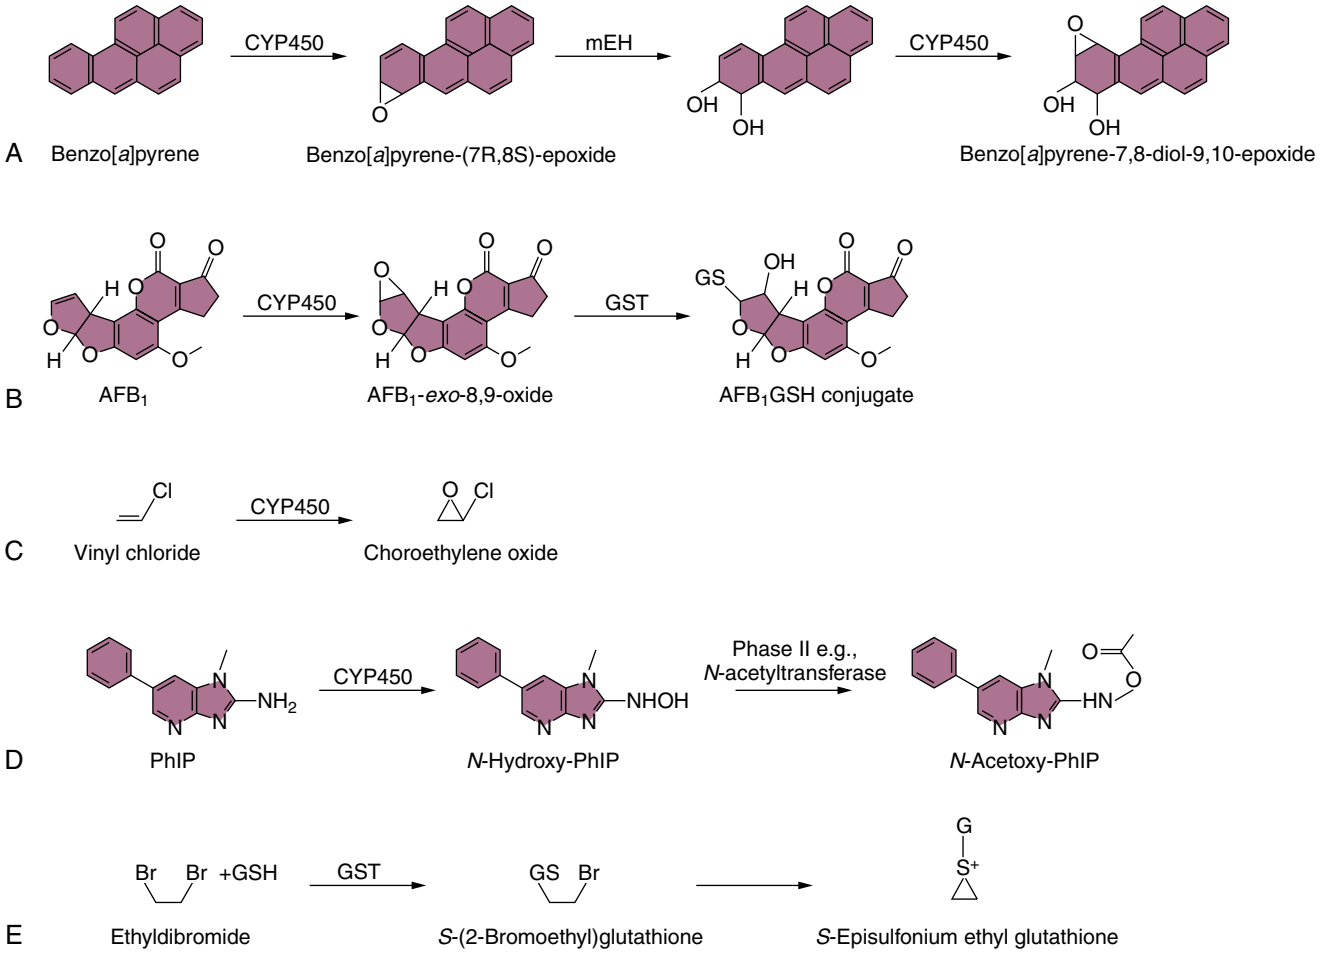

Figure 7-6 Biotransformation either activates or deactivates the ultimate carcinogen **(A)** Sequential action of cytochrome P450 (CYP450) and microsomal epoxide hydrolase (mEH) activates B[*a*]P. **(B)** CYP450 activates while glutathione *S*-transferase (GST)-mediated conjugation of glutathione (GSH) deactivates aflatoxin B_1 (AFB_1). **(C)** Vinyl chloride is activated to its epoxide metabolite by CYP450. **(D)** The 2-amino-1-methyl-6-phenylimidazo-(4,5-*b*)-pyridine (PhIP) is first metabolized by CYP450, then activated by *N*-acetyltransferase. **(E)** GST mediates activation of ethyldibromide.

Vinyl Chloride Biotransformation

Vinyl chloride is the starting material for the production of polyvinyl chloride, used in the fabrication of products such as PVC pipe. The mutagenicity of this liver carcinogen is dependent on metabolic activation by CYP450, and detoxification is mediated by mEH.[18] As shown in Figure 7-6, vinyl chloride is a relatively simple compound. In the presence of oxygen and NADPH, CYP450 2E1 catalyzes formation of a highly unstable epoxide moiety across the central carbon double bond. This epoxide, chloroethylene oxide, is the ultimate carcinogen capable of covalently binding DNA. Chloroethylene oxide can be detoxified via the action of mEH as noted previously or by GST-mediated glutathione conjugation.

Benzidine Biotransformation

Benzidine, an aromatic amine bladder carcinogen, must also undergo metabolic activation to initiate carcinogenesis.[38] CYP450 enzymes catalyze the activation of benzidine via *N*-oxidation. Subsequent to *N*-oxidation, *N*-acetyltransferase (NAT)-catalyzed *O*-acetylation forms electrophilic *N*-acetoxy derivatives capable of attacking DNA. In contrast, *N*-acetylation is also believed to compete with *N*-oxidation and, therefore, is considered a detoxification reaction when it occurs before the formation of the *N*-OH metabolites. *N*-glucuronidation of oxidized benzidine catalyzed by UDP-glucuronosyltransferase (UGT) is a second detoxification mechanism, because *N*-glucuronidation facilitates excretion. Therefore, in the case of benzidine biotransformation, phase II reactions activate and detoxify the carcinogen.

Heterocyclic Amine Biotransformation

Heterocyclic amines, found in cooked meat and fish, are initially activated to genotoxic metabolites via CYP450-mediated oxidation to the *N*-hydroxyl derivative (see Figure 7-6).[42] In particular, this reaction is catalyzed in the liver predominantly by CYP450 1A2 (CYP1A2). The hydroxylated heterocyclic amine metabolites are then further activated by acetyltransferases and sulfotransferases to the ultimate

carcinogen, a highly reactive electrophile. GSTs and UDP-glucuronosyl transferases are thought to deactivate the ultimate carcinogen and permit elimination. Therefore, during the biotransformation of heterocyclic amines, phase II enzymes activate and detoxify the carcinogen.

Ethylene Dibromide (1,2-Dibromoethane) Biotransformation

An additional example of phase II–mediated carcinogen activation is that of the halogenated aliphatic ethyldibromide.[79] Ethylene dibromide is a potent mutagen used as an industrial solvent, gasoline lead scavenger, and fumigant. Following glutathione conjugation of the parent compound, *S*-2-bromoethyl glutathione spontaneously forms an episulfonium ion (see Figure 7-6). This sterically strained molecule is the reactive ultimate carcinogen and primarily attacks the N^7 position of guanine. Again, although GSTs commonly detoxify xenobiotics, glutathione conjugation of ethylene dibromide leads to carcinogen activation.

DNA Repair

A second form of endogenous defense against environmental carcinogenesis is DNA repair. Various forms of carcinogen-induced DNA damage, such as DNA adducts, DNA crosslinks, and double- and single-strand breaks, have been reported following exposure to various carcinogenic insults. To maintain genomic integrity, DNA repair genes have evolved.[80] More than 125 DNA repair enzymes and DNA damage response genes have been identified. The importance of these genes is highlighted by inherited syndromes (e.g., xeroderma pigmentosum [XP], Fanconi anemia, Bloom syndrome, and ataxia-telangiectasia) wherein DNA repair defects render the individual more susceptible to cancer development. These DNA repair proteins can be generally categorized according to the repair pathways in which they function or according to their ability to signal for or regulate DNA repair (see Chapter 4). The predominant human DNA repair pathways include base excision, nucleotide excision, base mismatch, and DNA strand break repair. Simpler, direct repair pathways have also been reported. In cases where DNA damage is excessive, crosstalk may activate apoptotic pathways. In this case, programmed cell death can be viewed as a protective host response.

Defense against Oxidative Stress

Numerous carcinogens, including UV light and heavy metals, are thought to act by inducing oxidative stress and oxidative DNA damage. Endogenous defense systems have evolved to detoxify reactive oxygen species such as hydroxyl radical and superoxide anion. These defense systems range from the free radical scavengers glutathione and vitamin E, to glutathione synthesis enzymes, to antioxidant enzymes such as glutathione transferases, peroxidases, superoxide dismutase and catalase, to DNA repair enzymes that are specialized for repair of oxidative DNA damage.

Host Susceptibility to Environmental Carcinogenesis

As described in the preceding sections, biotransformation of carcinogens, DNA repair, and other cellular events play roles in defending cells against carcinogenic insults. Sequence variation in the genes involved in these cellular processes has been described and is expected, in some cases, to alter cancer risk. In addition, susceptibility to certain carcinogens may vary according to other clinical factors such as developmental stage, disease status, or co-exposure to additional environmental agents. The combined and interacting effects of carcinogen exposure, genetic background, and clinical susceptibility determine the individual's ensuing risk of developing cancer.

Genetic Susceptibility

For years researchers have sought to define the relationship between toxicant exposure outcome and the mediating effects of genetic polymorphisms. Genetic polymorphisms are defined as genetic variations occurring with 1% or greater prevalence in a human population. Polymorphisms can occur in the form of large deletions, small deletions, small insertions, and individual base changes, especially single-nucleotide polymorphisms (SNPs). These polymorphisms can occur in exons, introns, and promoter regions and produce a wide variety of effects ranging from changes in the protein function, to expression-level alterations, to changes in protein stability. The physiologic relevance of genetic variation may be a function of the severity of the alteration and the level of carcinogen exposure. Thus, genetic variation may be most important in the context of low-level exposure, because high-level carcinogen exposure may overwhelm any differences in effects that may result from genetic variation.

Biotransformation Enzyme Polymorphisms and Cancer Risk

Although genetic variation can influence cell signaling, cellular differentiation, apoptosis rate, cellular proliferation rate, or other biochemical processes during chemical carcinogenesis, historically more emphasis has been placed on identification of genetic determinants of carcinogen metabolism and DNA repair. SNPs occur in GST gene exons, introns, and promoter regions, and two-gene deletion polymorphisms have been described.[81] The *GSTM1* and *GSTT1* genes are deleted in about 50% and about 20% to 60% of

the population, respectively. Polymorphisms have also been described for CYP450, NAT, and mEH genes. A number of these alterations have been shown experimentally to affect either the expression level or catalytic activities of their corresponding proteins.[82]

One of the most studied biotransformation enzyme/cancer risk relationships is the relationship between *GSTM1* deletion polymorphism and lung cancer risk. *GSTM1* detoxifies PAHs such as those in cigarette smoke, and meta-analysis of epidemiologic data suggests that *GSTM1* deficiency is a moderate risk factor for lung cancer.[71] Similarly, *GSTM1* deletion may increase the risk of colon and bladder cancers.[72,73] However, some studies of *GSTM1* genotype and cancer phenotype have reported inconsistent outcomes; therefore the relative contribution of this polymorphism requires further investigation. Studies of *GSTM1* deletion polymorphism in the context of other carcinogen-response gene polymorphisms may be critical.

GWAS and Cancer Risk

More recently, genome-wide association studies (GWAS) have largely supplanted single-gene studies as the preferred method for probing the relationship between genetic background, carcinogen exposure, and disease risk.[83] GWAS allow high-throughput scans of the entire genome in cancer case and control groups without prior hypotheses concerning which genes or gene regions may contribute to cancer susceptibility. Numerous groups have attempted to identify the primary genetic determinants of cancer risk using this technique. Their work has revealed that multiple, common alleles each makes a small contribution to the heritability of cancer susceptibility, with no single gene or gene pathway dictating cancer risk.

Clinical Susceptibility

The relatively modest findings derived from GWAS and earlier epidemiologic studies illustrate the complex nature of predicting cancer risk phenotype based on genotype alone. Additional factors such as carcinogen dose and tissue-specific expression of biotransformation genes must be taken into account in the context of low-penetrance phenotypes. In addition, it is well known that developmental stage of the individual, concurrent diseases, co-exposures to other dietary and environmental chemicals, and the frequency, dose, and timing of carcinogen exposure affect the clinical susceptibility to cancer development. Co-exposures to other agents can alter expression or activity of phase I and phase II enzymes and confound the genotype-phenotype relationship. In addition, in case-control and cohort studies, accurate estimates of carcinogen dose are virtually impossible because of recall bias, lack of adequate exposure monitoring technology, effects of dosing frequency or timing, and other confounding factors that influence clinical susceptibility.

Researchers have begun to realize the importance of developmental stage in determining the physiologic response to carcinogen exposure. Accumulating evidence suggests that exposures during the critical periods of organogenesis and tissue differentiation may permanently affect disease risk later in life.[84] Although gene mutation in stem cells or other critical cell populations may contribute, epigenetic reprogramming is believed to be the primary mechanism whereby early life exposures affect health outcomes in childhood or adulthood. During development, epigenetic programs are in constant flux and open to environmental cues. Exposure to agents that affect DNA methylation or histone modification may permanently "reprogram" the response to carcinogens within the affected tissue. The strongest evidence for epigenetic reprogramming of cancer susceptibility comes from studies of reproductive tract and breast cancers. As an example, in utero exposure to the xenoestrogen DES is associated with a significantly increased risk of vaginal clear-cell carcinoma. Studies in animal models show that DES exposure alters DNA methylation patterns. Therefore, the stage at which an individual is exposed to environmental agents could be a critical determinant of susceptibility. Even a brief exposure to epigenetic reprogramming agents during development could potentially alter host susceptibility to carcinogenesis. Despite these inherent challenges in assessing co-exposures, temporal effects, and multiple genetic factors, the ultimate goal is to achieve cancer risk modeling that takes into account both inheritance of polymorphisms in genes encoding carcinogen defense pathways and other clinical factors that affect susceptibility.

Cancer Prevention

Because a significant fraction of cancer risk appears to be attributable to environmental factors, cancer prevention should be an attainable goal. Multiple approaches to cancer prevention have been proposed and include chemoprevention and, more simply, exposure reduction. As new products and pollutants are introduced into the environment, vigilance in hazard identification should largely prevent population-wide health crises such as those that led to the discovery of many occupational carcinogens in the 1970s and earlier. In addition, careful analysis of current dietary and other environmental exposures will increase the understanding of existing hazards. Finally, understanding of the underlying molecular mechanisms associated with the carcinogenic process will allow for the design of effective chemoprevention strategies.

Hazard Identification

Assays

An important aspect of cancer prevention is hazard identification. To effectively prevent human exposure to carcinogens, the carcinogen must be recognized as such. Hazard identification occurs via multiple avenues under the direction of numerous institutions. Academic institutes, corporations, and government agencies all contribute to the identification of carcinogenic agents. Initial screening is often conducted using short-term, in vitro techniques. Several widely used assays have been developed and measure the mutagenicity of suspected carcinogens.

Ames Assay

The Ames assay of mutagenicity utilizes *Salmonella typhimurium* bacterial strains with unique growth requirements to detect mutagenicity of test compounds.[85] In these assays, histidine-synthesis–deficient *Salmonella* strains are initially grown in the presence of exogenous histidine and are subsequently exposed to test compounds. Mutations in histidine-synthesis genes revert the bacterial strain to a histidine-independent status, which can be detected by growth in minimal-histidine media. Only those bacteria that have acquired specific mutations in histidine-synthesis genes are able to form colonies. Because bacterial strains cannot activate procarcinogens via CYP450 biotransformation, inclusion of mammalian metabolic enzymes is an important feature of this "reversion" assay.

HPRT Assay

The hypoxanthine-guanine phosphoribosyltransferase (HPRT) assay uses cultured human somatic cells to detect mutagenic agents. The normal function of HPRT in cells is to recycle nucleotide bases from degraded DNA. To detect mutations in the HPRT gene, cells are first exposed to the test compound and then exposed to a toxic nucleotide analogue, 6-thioguanine (6TG). When HPRT is nonmutated and functioning, 6TG is incorporated into DNA, triggering cell death. However, when HPRT is inactivated by mutations, no 6TG is incorporated, and the cells remain viable. Therefore, the number of surviving cells after a defined period of cell growth following 6TG exposure reflects the mutagenicity of the test agent.

Additional In Vitro Carcinogen Identification Assays

In addition to the HPRT and Ames assays, several other direct and indirect in vitro assays for the detection of genetic damage have been developed. Assays of changes at the chromosomal level in human cells include (1) the chromosome aberration assay, wherein metaphase chromosomes are examined for abnormalities; (2) the sister chromatid exchange (SCE) assay, wherein exchanges of identical pieces of chromosomes in duplicated sister chromatids are examined in metaphase cells; (3) the micronucleus assay, wherein the number of chromosome fragments referred to as *micronuclei* are counted; and (4) the comet (or single-cell gel electrophoresis) assay, wherein DNA strand breaks in individual cells are visualized using fluorescence microscopy.

In Vivo Assays

Two-year bioassays in rodents are currently used extensively for carcinogen identification. Whole-animal assays are conducted to determine the carcinogenic potential of an agent when delivered over the lifespan, in a more physiologically relevant model. Of the approximately 200 agents classified as human carcinogens, almost all have been shown to cause cancer in rats or mice, highlighting the utility of animal studies in the identification of carcinogens. Rodents are administered the test compound via the exposure route most relevant to human scenarios at two doses: the maximum tolerated dose (MTD) and one half the MTD. The compound is administered for a majority of the lifespan of the animal, and tumor incidence at all sites is recorded. Generally, the rat is recommended for the first 2-year carcinogenicity study. These data are then supplemented with additional short- or medium-term in vivo studies or with a 2-year carcinogenicity study in another rodent species such as the mouse. Short- and medium-term testing may include the use of transgenic or "knockout" mouse models wherein an oncogene is overexpressed or a tumor suppressor gene allele is missing, although the validity of using these genetically altered models is still under debate.

The costly nature of in vivo screens (more than 800 rodents and histopathological analysis of more than 40 tissues) limits their utility.[86] Only approximately 1500 chemicals have been adequately examined. Recent effort has been directed toward developing predictive models for more thorough or higher throughput screening of new drugs and other agents. For example, the vast majority of known carcinogens is mutagenic or genotoxic; therefore, several groups have proposed an expanded battery of DNA-based tests, including tests of DNA adduct formation, DNA strand breaks, and DNA repair. In addition, toxicogenomic strategies for the identification of gene expression profiles that are predictive of genotoxic and non-genotoxic carcinogenicity have been proposed.

Non-genotoxic Carcinogens

The identification and analysis of non-genotoxic carcinogens are less straightforward than are those for genotoxic agents. These agents are identified in the context of the 2-year rodent bioassay. Agents that are identified as carcinogenic in these in vivo assays but do not directly interact with DNA

are classified as non-genotoxic carcinogens.[87] Non-genotoxic carcinogens characteristically induce tumors in only one or a few species and only after a threshold dose is achieved. Non-genotoxic carcinogens are not detected in in vitro assays of mutagenicity such as the Ames or HPRT assays. Many of these non-genotoxic carcinogens possess properties similar to tumor promoters, suggesting, together with a lack of genotoxicity, that they work mechanistically differently from classical, genotoxic carcinogens. Considerable debate is ongoing concerning the best way to identify and regulate such compounds (see subsequent sections).

Risk Assessment and Regulation of Carcinogen Exposure

As carcinogen exposure scenarios are identified, an assessment of predicted exposure dose and the expected degree of health hazard is conducted. This informs an estimation of overall cancer risk associated with the observed exposure. Estimating cancer risk helps investigators determine when and if behavior modifications should be enforced. This process of predicting cancer risk in a given exposure scenario is referred to as *risk assessment*, whereas the response to predicted risk is referred to as *risk management*. The EPA is responsible for risk assessment in areas of known or suspected exposure of the population to carcinogens and makes recommendations for risk management to minimize health consequences due to environmental contamination.

Risk assessment concerning mutagenic carcinogen exposure assumes that no threshold dose exists. That is, no safe exposure level can be identified because any exposure dose could, in theory, induce a mutation in a critical target gene, thereby elevating cancer risk. Extrapolation of a safe level of human exposure to non-genotoxic carcinogens is more complex and requires multiple assumptions. For instance, it is assumed that an agent found to be a non-genotoxic carcinogen in rodents would be toxic to humans and that the no observable adverse effect level (NOAEL) in rodents could be applied to humans. Such decisions are greatly enhanced by mechanistic information so that judgments can be made concerning potential threat to human health. In 2005, the EPA released new risk assessment guidelines that acknowledge the different mode of action for non-genotoxic carcinogens and provide for this deviation during risk-management decision making.

Prevention Strategies

The goal of risk assessment and risk management is to prevent cancer by anticipating and circumventing carcinogen exposure. However, the etiology of certain cancers is still unknown. In many cases, risk assessment is impossible or risk management measures are unavailable. Furthermore, some carcinogen exposures are unavoidable, or avoidance is not practically feasible. For instance, therapeutic radiation and certain chemotherapy drugs are known carcinogens; however, the risk-to-benefit ratio still favors voluntary exposure, despite health risk. In these instances, prevention tactics are needed to counteract the carcinogenic process, especially in the absence of effective treatment options. Several approaches to prevention have been taken in recent years with varying degrees of promise.[88]

Vaccination

Vaccination is among the most promising of approaches for biologic carcinogens such as HBV, HPV, and *Helicobacter pylori*.[89] The development of vaccines to block initial infection with carcinogenic bacteria or virus would presumably prevent or reduce associated cancers. As an example, HPV vaccines have been developed to limit the spread of the virus and reduce the incidence of cervical cancer. In addition to this traditional use of vaccination, the use of vaccines against oncoantigens has also been proposed to prevent cancer via stimulating immune mechanisms to attack small cancerous lesions. Oncoantigens, which are tumor-associated molecules, are used to stimulate persistent immune memory mechanisms. When the antigen is later detected via immune surveillance, an effective adaptive immune response is mounted. In theory, the immune system is primed to detect and destroy any cancer cells expressing the oncoantigen. The success of vaccines in the prevention of tumors in animal models has been documented; however, the utility of such vaccines to prevent human tumors must still be validated.

Chemoprevention

Chemoprevention strategies for reducing the incidence of cancer have also been proposed. For instance, chemicals that upregulate biotransformation enzymes (in particular, phase II enzymes) have been investigated as chemopreventive agents.[75,90] Because most phase II biotransformation reactions reduce chemical reactivity of the parent compound, the rationale for inducing phase II enzymes or their cofactors is to reduce the mutagenicity of initiating agents. For instance, oltipraz administration has been shown to attenuate AFB_1 toxicity in rats. Oltipraz elevates GST activity, likely via activation of antioxidant response elements within GST promoter regions. Oltipraz may also inhibit the activation of aflatoxin by CYP450. The challenge associated with enzyme induction as a chemopreventive approach is that not all phase II biotransformation reactions are detoxification reactions. Because humans are exposed to a wide variety of carcinogens, induction of biotransformation enzymes may

be simultaneously beneficial and detrimental. Therefore, the decision to use of this type of chemopreventive agent must weigh multiple factors such as carcinogen target organ, agent distribution, and exposure scenario.

In addition to agents that induce the expression of detoxification enzymes, agents that combat or prevent oxidative stress are potential chemopreventive agents. Oxidative stress is believed to contribute to the formation of multiple cancer types; consequently, treatment with antioxidant agents may block carcinogenesis. In this regard, selenium, α-tocopherol, EGCG, and lycopene are potent antioxidants under study for chemopreventive properties. Similarly, inflammation is believed to contribute to formation of numerous cancer types. Agents such as cyclooxygenase-2 (COX-2) inhibitors (i.e., celecoxib) as well as other nonsteroidal antiinflammatory drugs (NSAIDs) have been proposed as chemopreventive agents to combat procarcinogenic inflammation. In addition, hormonal agents have been proposed for the chemoprevention of cancers of reproductive organs such as breast and prostate cancers.[91] For instance, selective estrogen receptor modulators (SERMs) have been proposed to prevent breast cancer by blocking the action of procarcinogenic estrogen. Tamoxifen, an antiestrogenic agent, was first approved for the treatment of advanced breast cancer but also reduced the risk of contralateral breast cancer occurrence. Tamoxifen has since been approved as a chemopreventive agent in high-risk patients.

Summary and Conclusions

Cancer is known to develop over many years and is determined by the interaction of host genetic factors as well as environmental exposures. Environmental factors appear to play a major role in determining cancer risk. Of the known cancer risk factors, smoking and diet account for a significant proportion of cancer deaths. There are many types of environmental carcinogens including biologic agents (e.g., viruses), chemicals (e.g., PAH), and physical agents (e.g., solar radiation). The linkage between environmental exposure and cancer in humans is strong in some cases (e.g., asbestos and mesothelioma of the lung), whereas in other cases the environmental etiologic factors are less well understood (e.g., breast and prostate cancers). Epidemiology studies, together with studies in model systems, especially animal model systems, provide the evidence used to determine the relative risk of specific environmental exposures. Categorizing cancer risk from environmental agents is an ongoing process conducted by the NTP and the IARC. Study of genetic polymorphisms in various genes involved in the carcinogenic process is leading to a better understanding of the overall risk associated with environmental exposures and identification of high-risk populations to target prevention strategies. Research on the underlying mechanisms associated with environmental carcinogenesis provides the basis for early detection and identification of target molecules for chemoprevention and/or intervention strategies. Carcinogens are known to target oncogenes and tumor suppressor genes through DNA damage and/or to alter cellular signaling pathways in bringing about the changes associated with cancer formation in specific tissues. Ultimately, environmental carcinogenesis occurs via the stepwise accumulation of genetic alterations leading to invasive and metastatic lesions. Finally, although many regulatory mechanisms exist to protect the public, diligence is required to guard them from future unintended carcinogen exposures. It will remain prudent to closely monitor the environment for potential human carcinogens.

Animal Models: Flies, Fish, and Yeast

The molecular pathogenesis of human cancer is a complex process that often requires the cooperation of genetic mutations within many cellular pathways that ultimately lead to tumorigenesis. Simple model organisms with conserved genes and developmental pathways offer systems with which to dissect the role of individual genes and their contribution to the development of cancer in vivo. From single-celled yeasts to vertebrate fish such as the zebrafish, each model system provides its own unique strengths with which to identify new genes and to elucidate genetic interactions required for the development of cancer.

Why Use a Simple Model Organism?

Cancer develops as a result of disruption of the normal physiological processes of cell growth, differentiation, and proliferation. Genes involved in these processes encode transcription factors and other regulatory proteins controlling the cell cycle, apoptosis, and survival. Many of these genes, found in the simplest eukaryotes, are conserved with higher species. Over several decades the development of tools for forward genetic analysis based on phenotype in simple organisms has led to yeasts *(Saccharomyces cerevisiae)*, the fruit fly *(Drosophila melanogaster)*, and more recently the zebrafish *(Danio rerio)* emerging as the key simple organisms for investigating cancer genetics (Figure 8-1).

In addition to their individual strengths for investigating conserved pathways there are three main practical reasons to use a simple model organism: time, space, and tractability. Yeasts such as *Saccharomyces cerevisiae (S. cerevisiae)* and *Schizosaccharomyces pombe (S. pombe)* are single-cell organisms. They have comparatively few genes and little intronic DNA. They replicate rapidly by budding *(S. cerevisiae)* or fission *(S. pombe)* and can be maintained in large numbers in both haploid and diploid states, facilitating the isolation and investigation of recessive mutations. Yeast cell numbers double every 100 minutes (given adequate nutrition), and these organisms are safe and cheap to maintain. The whole organism can be readily visualized by light microscopy, and the incorporation of fluorescent proteins allows subcellular localization of specific proteins in real time. Similarly, *Drosophila melanogaster* has a life cycle of 10 days, and large numbers of animals can be maintained in a small space. This multicellular organism can be used to examine cell-cell interactions and the roles of non-cell autonomous gene function in the development of cancer. Although *Drosophila melanogaster* does not develop cancer in its classical form and lacks the closed blood system of vertebrates, ingenious genetic techniques have been applied to model pathways involved in the development of cancer and invasive metastases in this organism, which has the added advantage of being both multicellular and tractable to single-cell resolution.[1] The zebrafish is relatively new to the field of well-characterized model organisms but has rapidly gained popularity. As a vertebrate with a closed vascular system (and beating heart), it provides an ideal intermediate model system between studies in invertebrates and small mammals such as the mouse. In contrast to the mouse, zebrafish development occurs rapidly outside the mother in transparent embryos, allowing direct visualization of the evolving systems and easy analysis of incorporated fluorescent markers. Its small size and high fecundity allow it to be easily maintained. The ability to directly visualize development in the embryo is particularly beneficial given that proto-oncogenes often have a crucial role during embryonic development.

Genetic Conservation and Synteny

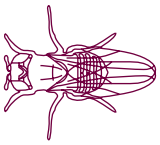
It has long been recognized that simple organisms carry genes that have functional equivalents in humans. Conclusive evidence for this phenomenon was determined when human DNA sequences expressed in yeast cells rescued the phenotypic defects arising from mutations in yeast or *Drosophila* genes, allowing the homologous human DNA sequence to be cloned.[2] Conservation of a given gene through evolution suggests that its protein product performs essential functions

SACCHAROMYCES CEREVISIAE

~7000 genes
~12 million bases

Key features

- Single cell
- Viable as haploid
- Phenotypic variation during cell cycle
- Use of selectable markers
- Ease of plasmid insertion and homologous recombination
- Rapid replication and large cell number
- Few genes and little intronic DNA
- Sequenced genome



DROSOPHILA MELANOGASTER

~15,000 genes
~132 million bases

Key features

- Multicellular but discernible at the single-cell level
- Rapid development
- Sequenced genome
- Short life cycle
- "Tumor" development
- Easy assessment of noncell autonomous function
- Polytene chromosomes
- Large living libraries of mutants
- Sequenced genome

DANIO RERIO

~20,000 genes
~1547 million bases

Key features

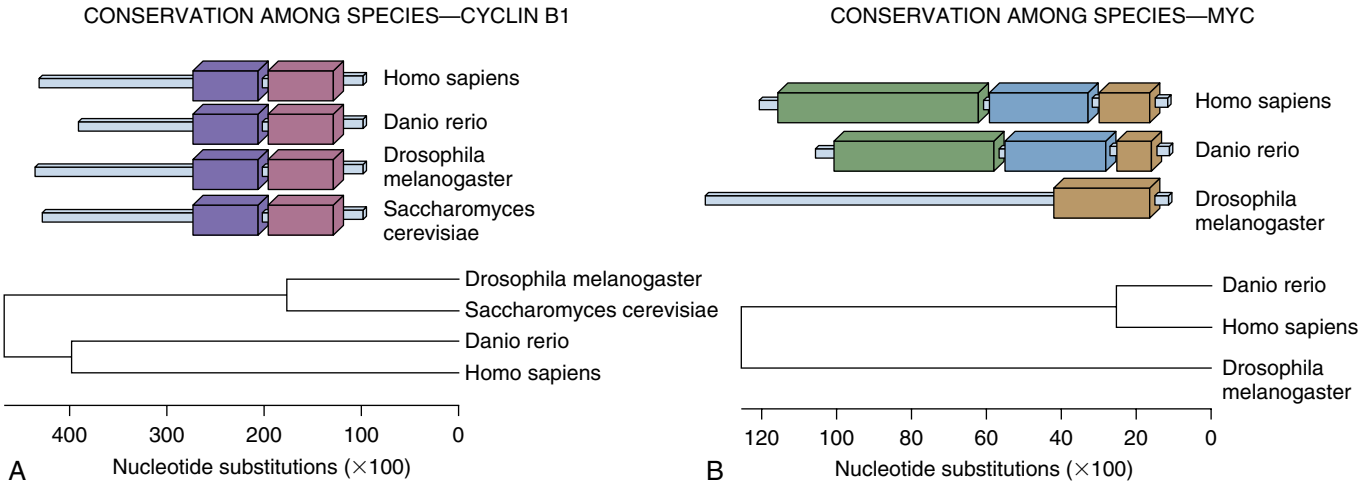
- Vertebrate
- Transparent embryos
- Large numbers of progeny
- Rapid ex-utero development
- Develop true human-like cancers
- Morpholino technology for transient gene knockdown
- Genome editing for targeted gene deletion
- Lines can be maintained as frozen sperm
- Transgenesis is well developed
- Sequenced genome

Figure 8-1 Model organisms (the budding yeast—*Saccharomyces cerevisiae*; the fruit fly—*Drosophila melanogaster;* and the zebrafish—*Danio rerio*) and their key attributes as models for dissecting the molecular basis of cancer.

that are similar across species. The more highly conserved the gene, the more important or critical the function of its product. For example, the amino acid sequence of the fission yeast ribosomal protein of the small subunit 14(rpS14) is 75% identical to the human RPS14. This suggests that from the millions of random mutations arising over millions of years of evolution, only 75% diversification of the amino acid sequence occurred, presumably because the majority of mutations resulted in deleterious effects on the fitness of the organism. Similarly, the most critical functional domains of a protein can be implied by determining the regions that are most highly conserved among species (illustrated in Figure 8-2). The genetic complexity of higher eukaryotes, however, indicates that not all genes are conserved. Indeed, even with the now-vast repositories of bioinformatics that house sequence data for hundreds of genes and species, it is not always straightforward to identify a single gene that is the functional ortholog of a human gene in a simple organism. As a result, in simple organisms there are often fewer genes performing a particular function than in humans. An example of this is the number of functionally conserved BCL2 family members in the intrinsic apoptosis pathway seen in worms and zebrafish (with none identified in yeasts).[3-5] This is further complicated in zebrafish, where whole-genome duplication that occurred in teleost fish more than 150 million years ago[6] has resulted in the presence of two or three copies (paralogs) of a large number of individual genes.[6] Several methods permit determination of which copy of such genes is functionally homologous to the human gene. The analysis of genetic synteny using bioinformatic approaches has demonstrated that zebrafish orthologs of human genes can usually be found in chromosomal locations in the fish that reflect their location on conserved human chromosomal regions.[7] In many cases divergence in promoter sequences leads to tissue-specific activities of different teleost orthologs of a single mammalian gene (see Figure 8-2, C).

Forward Genetics, Reverse Genetics, and Transgenesis

Simple model organisms, with their rapid development and large numbers, lend themselves well to the identification of new oncogenes, tumor suppressors, and novel therapeutic targets important in cancer. This is generally accomplished using classical (and variations on classical) genetic screens. Forward genetic screens are based on Mendelian inheritance of genes and the observation of a phenotype in cells or organisms where a gene has been disrupted (Figure 8-3). The methods by which genes are disrupted and the assays used to screen for phenotypes are wide ranging, and some are species specific. Early screens looked for naturally occurring phenotypes of simple processes, such as inability of yeast to grow at a certain temperature, as a method of assaying genes involved in cell division. To increase the number of mutated organisms (mutants) with a phenotype of interest, methods of inducing mutations in genes, either chemically with retroviruses or with transposons ("jumping genes"), have been employed. Large numbers of organisms



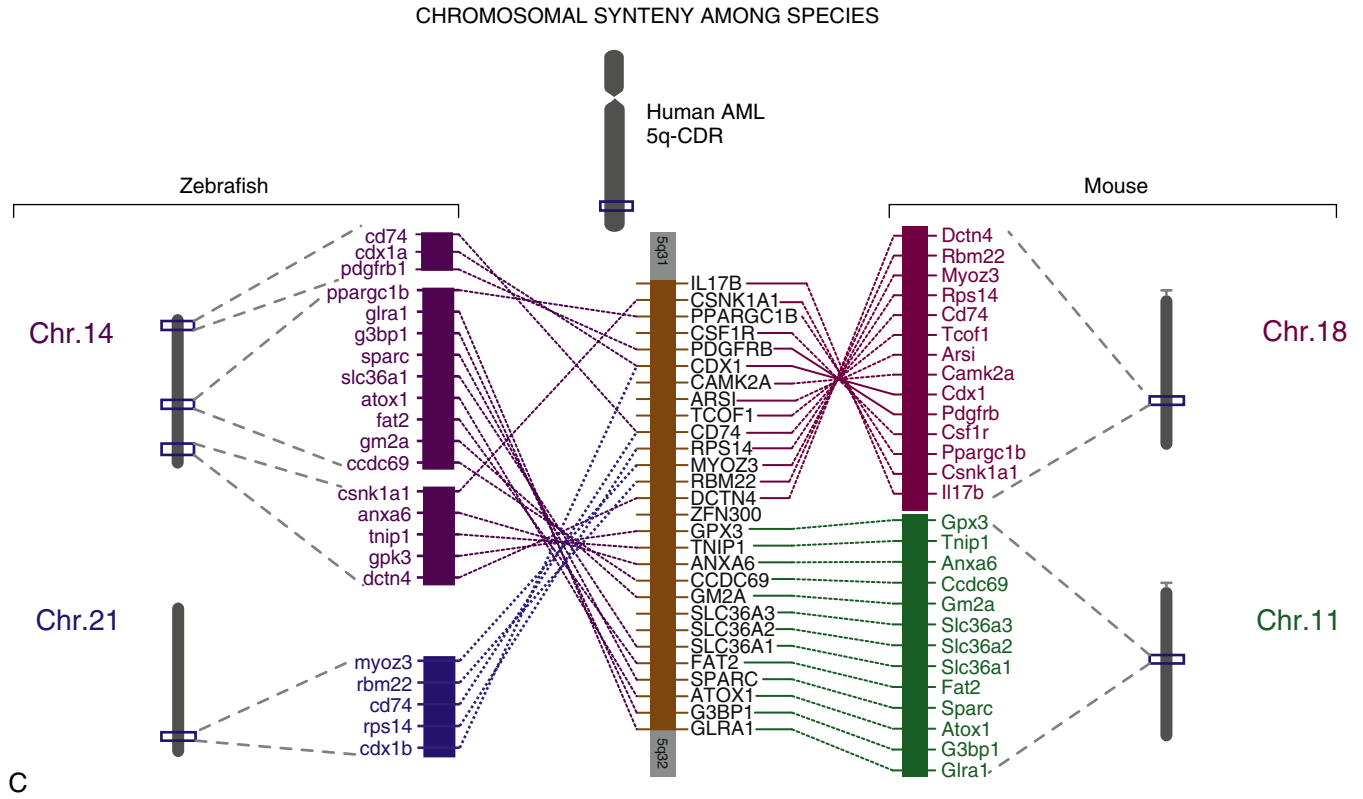


Figure 8-2 Conservation among species for (A) cyclin B1 and (B) the Myc oncogene. Each colored block represents a conserved protein domain. The phylogenetic trees below demonstrate common ancestries and the approximate number of nucleotide substitutions that have occurred leading to the divergence of the proteins for each of the given species. **(C)** The syntenic relationships among zebrafish chromosome 14 and 21, mouse chromosomes 18 and 11, and the region on the long arm of human chromosome 5 that is found to be critically deleted in myelodysplastic syndromes and acute myeloid leukemia with isolated loss of chromosome 5. *AML*, Acute myeloid leukemia; *CDR*, critically deleted region.

are screened to ensure that every gene within the genome has been mutated at least once—this is known as saturation of the genome. Forward genetic approaches allow unbiased isolation of phenotypically mutant organisms, after which the gene causing the mutant phenotype can be identified. The forward genetic screen remains the most powerful strength of model organisms as a cancer model, in particular for the discovery of novel tumor suppressors. Tumor suppressors are genes whose normal functions are to regulate uncontrolled or abnormal growth, or the growth of cells whose genetic integrity has been compromised. Because the cancer-causing effects of these genes can only be fully recognized when they are absent or nonfunctional, forward screening of large numbers of simple organisms is an attractive means to identify such genes in vivo. Historically, a potential drawback of such forward screens, particularly in

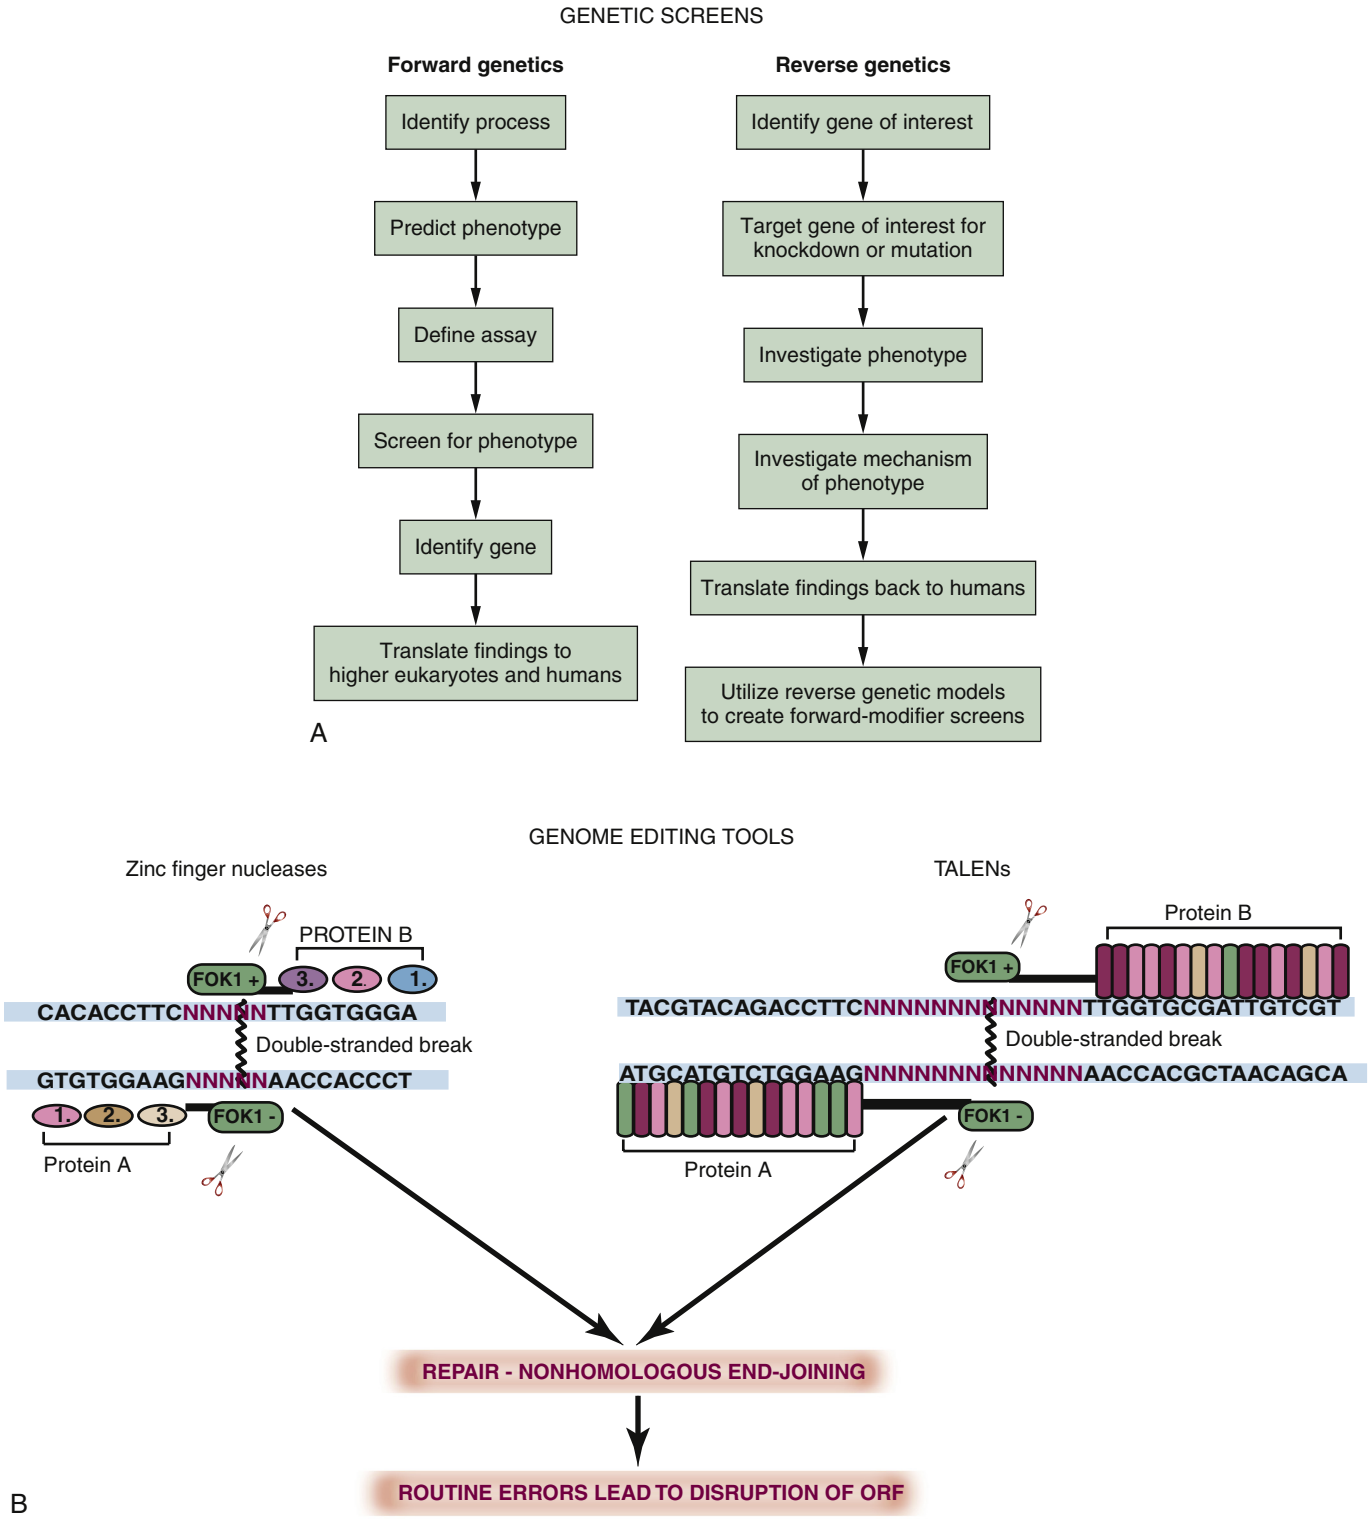

Figure 8-3 **(A)** Flow diagram illustrating the steps involved in forward and reverse genetic screens. **(B)** Schematic of the mechanism by which zinc finger *(left)* and tal effector endonucleases *(right)* function as genome editing tools. Zinc fingers are composed of two half-sites with three separate zinc finger domains in each. Each triplet is fused to the cleavage portion of the chimeric endonuclease FokI. Binding of the zinc fingers to the DNA target site results in FokI alignment for dimerization and cleavage of double-stranded DNA. Tal effector nucleases function in a similar manner. Each half-site is made of 14-16 tal effector repeats. Depending on two critical residues, these repeats will bind an A, C, T, or G, allowing a high level of specificity of DNA binding and subsequent ligation. Repair of the double-stranded break by nonhomologous end joining results in the introduction of insertions, deletions, or substitutions that result in mutant protein generation. *ORF,* Open reading frame; TALENs, transcription activator–like effector nucleases.

the zebrafish, where there is somewhat greater genetic complexity, is that identification of the genetic mutation causing the phenotype can sometimes be time consuming and technically challenging: something of a "needle in a haystack" search. This is especially true if the mutation occurs in a regulatory or noncoding region of the genome or in telomeric regions of chromosomes where increased amounts of crossing over during meiosis further hamper conventional positional cloning techniques. However, the past decade has seen the emergence of massive parallel sequencing technologies that are now being used to facilitate rapid fine mapping of genetic mutants derived from phenotypic screens.[8,9] These technologies allow hundreds of genes to be sequenced simultaneously, covering the entire genome in such a way that regions of the genome linked to the mutant phenotype can be identified when the fish have been crossed to a strain of a different genetic background. The rapidly decreasing costs and increasing efficiency and availability of these technologies will likely fuel a new wave of studies in coming years, accelerated by advances in deep sequencing for positional cloning.

In addition to forward genetic modeling, it is also possible to disrupt specific known genes (such as known oncogenes or tumor suppressors) to investigate the phenotype produced. This process is termed *reverse genetics*. The most common reverse genetic studies are carried out using transient knockdown techniques. These include RNA interference (RNAi) in flies and antisense oligonucleotides ("morpholinos") in frogs and fish. These techniques are particularly useful in determining epistatic relationships among genes giving rise to a particular phenotype, as several genes can be knocked down simultaneously. More recently, there have been a number of advances in the field of genome editing technologies that have made the generation of stable knockout lines at virtually any site within the genome accessible to researchers using simple organisms.[10,11] This is beneficial because it allows specific domains within a protein to be targeted for mutation and allows propagation of mutations through the germline for studies in later stage juveniles or adult organisms. This is achieved by the creation of synthetic restriction endonucleases that fuse the cleavage portion of FokI, a naturally occurring bacterial restriction endonuclease, to a site-specific DNA binding domain generated using synthetic zinc fingers (ZFNs) or transcription activator–like effector nuclease (TALEN) repeats. Two DNA sequences are targeted, one on either side of the region of the genome where a mutation is desired (see Figure 8-3, *B*). Because FokI requires dimerization to induce cleavage at its target site, this produces site specificity and minimizes off-target mutations. Novel technologies allowing the generation of large numbers of TALENs are likely to make the use of this form of genome editing widespread not only in simple organisms but also in mammalian models and cell culture systems.

Forward and reverse genetic models may be used in combination. Reverse genetics in simple organisms may add tools for the investigation of the genetic interactions of a known gene by permitting the development of modifier screens where the mutant is subjected to forward genetic screening to identify genes that enhance or suppress its phenotype. In this way modifier screens may provide novel therapeutic targets in human cancers.

Another genetic tool used in simple model organisms is transgenesis. To obtain a transgenic organism, specific DNA sequences are typically introduced into the genome of an organism and expressed under the control of a specific promoter sequence to guide the cellular, temporal, and spatial localization of transgene expression. For example, in zebrafish, the introduction of the mouse *Myc* gene under the control of the *rag2* lymphocyte-specific promoter leads to expression of *Myc* in the thymus and the subsequent development of T-cell leukemia/lymphoma.[12,13] Adding the coding sequence of green fluorescent protein to the integrated construct has the additional advantage of permitting spatiotemporal visualization of the development of cancer in this system. A prime example is the recent use of dopamine β-hydroxylase promoter to drive MYCN and activated ALK expression in transgenic zebrafish to produce neuroblastoma,[14] demonstrating the power of this model for detailed studies to reveal cellular mechanisms underlying synergy between oncogenes that are also activated together in human malignancies. Transgenic approaches are easily performed in yeasts, which undergo efficient homologous recombination into their chromosomes, allowing site-specific integration of the transgene. Using this tool in yeasts facilitates reverse genetics by replacing the normal functioning gene with a mutated or nonfunctional form (which may be genetically engineered or even derived from a different species).

Drug Screens

Simple organisms can also be used for drug discovery in a variety of ways. Yeast can be manipulated to express a gene or protein of interest at a higher level than normal, or a heterologous human gene under control of a yeast-specific promoter. A differential effect of a drug on the normal-versus-mutated gene can also be assessed (e.g., attempting to find drug targets selective for certain oncogenes).[15] More recently, drug screens using whole organisms, including both flies and zebrafish, have been successful in uncovering potential novel therapeutic anticancer drugs and for revealing previously unsuspected anticancer activities of existing drugs.[16,17]

Conditional Models

Only a small number of human cancers can be attributed to the presence of an underlying inherited cancer predisposition mutation; thus the majority of human cancers arises from a series of somatic mutations acquired over time. Because many human oncogenes and tumor suppressors play a critical role in embryologic development, germline mutations affecting key genes of this type in all tissues frequently lead to death during development. Although investigation of the embryologic phenotype in model organisms continues to provide crucial information on gene function, the study of genetic interactions in specific tissues and in specific cancer models provides additional information on how the mutated gene contributes to tumorigenesis in vivo.

Over the past 20 years, genetic tools have been developed to engineer targeted conditional expression or (in some cases) knockout of a specific gene. There are three main conditional systems that facilitate directing gene expression to a specific cell type at a specific time. The first is based on an enzyme from P1, which is a bacteriophage that infects the bacterium *Escherichia coli*. This virus produces an enzyme called *Cre recombinase* that cuts DNA whenever it sees two identical 34-base-pair sequences known as Lox-P sites. The enzyme removes the DNA between the two Lox-P sites, and the sites are ligated together. In model organisms, this system can be used by driving the expression of Cre with a promoter that is only expressed at a certain site (tissue specific) or with a promoter that is activated by exposure to a specific stimulus such as heat shock or a particular drug (e.g., estrogen). Lox-P sites can be introduced into a transgene such that on Cre activation, the transgene is expressed (or removed) in a specific tissue. Fluorescent proteins can also be incorporated into transgenes to allow visualization of where the transgene is expressed and where the Lox-P sites have been removed (Figure 8-4). In a similar fashion, Flp recombinase is an enzyme made by the 2-μm plasmid of *Saccharomyces cerevisiae*. This recombinase acts in a similar way to Cre recombinase, recognizing two 34-base-pair sequences termed *Frt sites*. This system has been extensively employed in flies, where instead of simply excising the intervening DNA sequence between two Frt sites, Flp recombinase results in the crossing over and exchange of genetic material between arms when Frt sites are located on opposite arms of the same chromosome. This allows, for example, the expression of mutant tissue in an otherwise wild-type background[18] (see Figure 8-4). Tissue-specific overexpression of a gene can also be achieved by using the yeast transcription factor Gal4 driven by a tissue-specific promoter and its upstream activating sequence (UAS) driving the gene of interest. UAS can also drive a fluorescent protein–colored marker to allow spatial localization of cells expressing the gene of interest (see Figure 8-4).

Yeast

Genetic Tools and Functional Genomics

Recovery of the genes responsible for a mutant phenotype observed in a forward genetic screen and harnessing the power of reverse genetics is made possible in yeast by the ease with which the organism can be transformed with DNA using plasmid vectors or polymerase chain reaction (PCR) products and by the subsequent ability of the yeast to undergo the process of homologous recombination. Homologous recombination is a conserved DNA repair process that allows recognition of homologous DNA sequences at sites of double-stranded DNA breakage. This recognition allows double-stranded breaks to be repaired by using the other intact copy (located on the sister chromosome) as a template. This physiological mechanism is hijacked when vector-derived DNA is designed to carry homology arms with sequences identical to the genome location where incorporation is desired. The yeast homologous recombination machinery then recognizes the homology arms and inserts the vector DNA sequence (chosen by the researcher) into the desired location. In this way, any gene can be replaced by another stretch of DNA. This could be a mutated or null allele or a normal allele to replace a mutated one. In addition, mutant or wild-type alleles can be coupled with genes encoding positive or negative selection factors to allow the identification of yeast strains that have undergone homologous recombination (such as an antibiotic or growth factor requirement). The application of these techniques is widespread, including the development of targeted gene "knockouts" such as those used in the yeast genome deletion project. An example of this is shown in Figure 8-5. Molecular profiling of the effects of different growth conditions has been facilitated by the addition in the yeast genome deletion project of two unique 20-nucleotide tags that flank each knockout cassette. Using these tags as "barcodes" and starting with equal quantities of each deletion strain, gene chips have been developed to hybridize and quantify each tag (and thus knockout strain) in any given growth condition.[19]

Because the yeast genome is relatively small and contains little noncoding DNA, it has been possible to derive plasmid libraries for all genes found in yeast that are of a manageable size. This is done by cutting the whole genome with restriction enzymes that recognize a particular DNA sequence and then inserting each of these smaller cut pieces of DNA into a plasmid vector. These DNA libraries are useful to identify the gene causing a phenotype or to address the phenotype resulting from the overexpression of certain genes (e.g., which can also be used in a drug screen).

One complication of examining genotype-phenotype relationships is that for some genes loss of function and/or

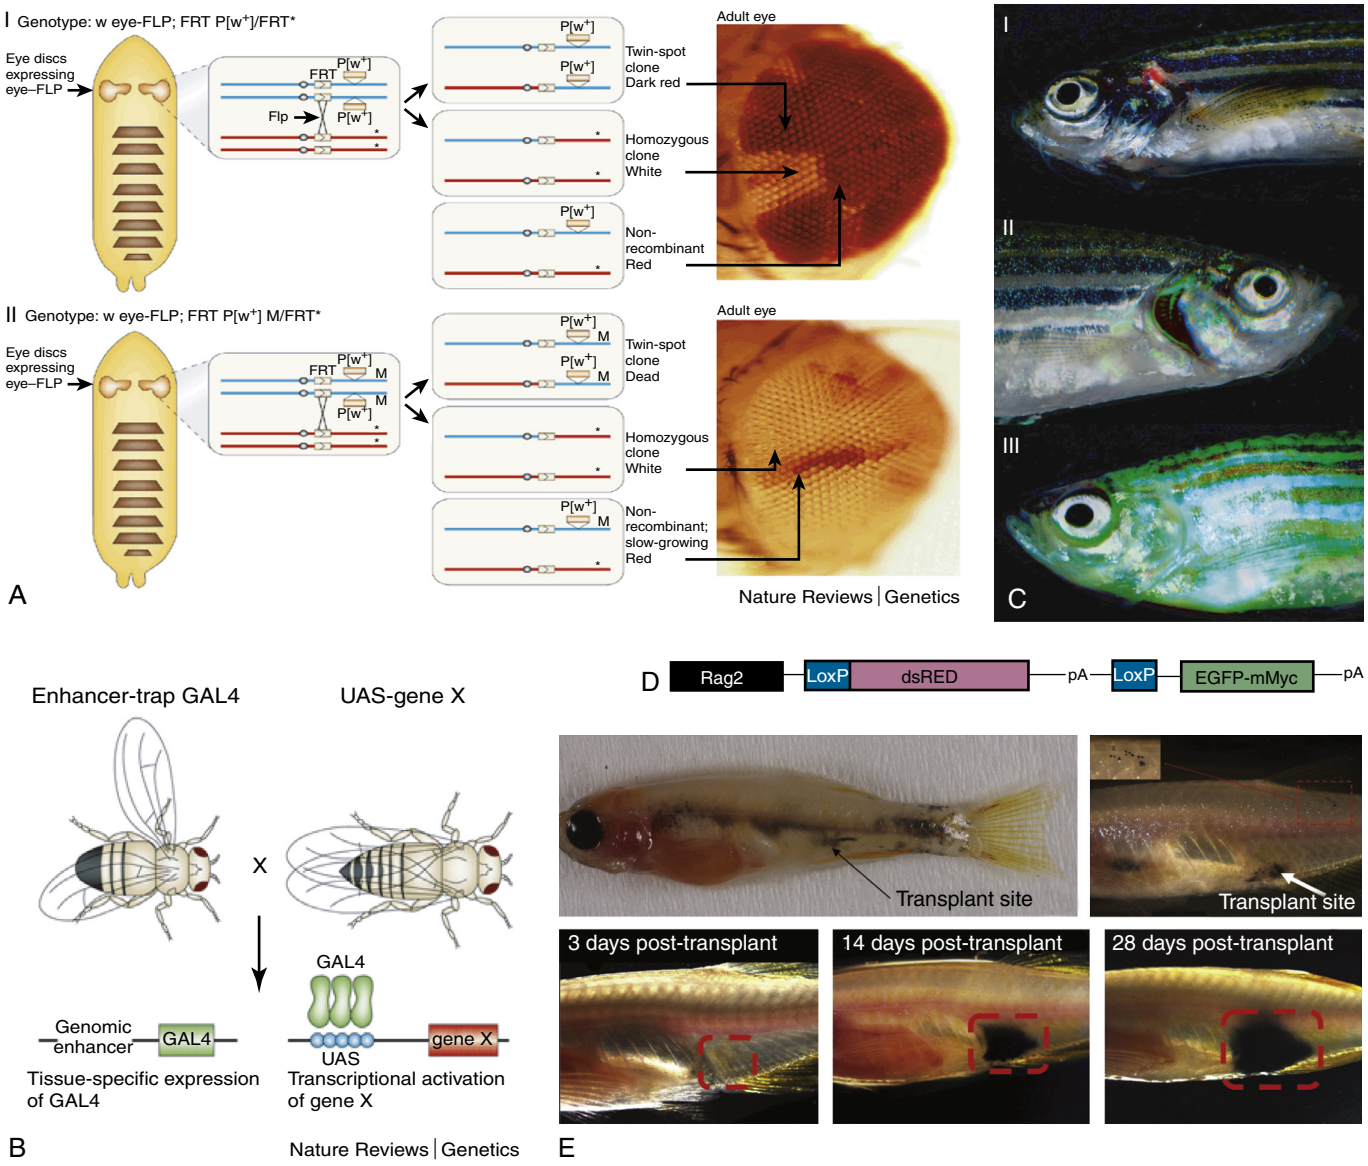

Figure 8-4 **(A)** Flt/FRP system/twin-spot clones. By placing the FLP recombinase gene under the control of the eyeless enhancer (which drives expression specifically in the eye-antennal imaginal disc), Flp/FRT-mediated recombination can be targeted to this disc to generate homozygous mutant clones in the eye in flies that are otherwise heterozygous. *(I)* The non-mutant chromosome (the asterisk indicates a mutation) is marked by a mini-white transgene, but there is no selection against the twin-spot clones or nonrecombinant cells, and both the mutant clones *(white)* and the twin-spot clones (*darker red*, because they carry two copies of white+) are relatively small. *(II)* The effects of incorporating a Minute mutation (M) onto the nonmutant FRT chromosome. The mutant clones now occupy almost all of the eye, because they outcompete the slow-growing nonrecombinant cells (which are M/+), whereas the twin-spot clones die. **(B)** Gal4/UAS system. The yeast transcriptional activator Gal4 can be used to regulate gene expression in *Drosophila* by inserting the upstream activating sequence *(UAS)* to which it binds next to a gene of interest (gene *X*). The *GAL4* gene has been inserted at random positions in the *Drosophila* genome to generate "enhancer-trap" lines that express *GAL4* under the control of nearby genomic enhancers, and there is now a large collection of lines that express *GAL4* in a huge variety of cell-type and tissue-specific patterns. Therefore, the expression of gene *X* can be driven in any of these patterns by crossing the appropriate *GAL4* enhancer-trap line to flies that carry the *UAS*–gene *X* transgene. This system has been adapted to carry out genetic screens for genes that give phenotypes when misexpressed in a particular tissue (modular misexpression screens). **(C,D)** Cre-Lox system. Zebrafish carrying the construct shown in **(D)**: *(I)* No cre activation—fish show red thymus, showing that the dsRED cassette has not been excised. *(II)* Following cre injection, the dsred stop cassette is removed, allowing expression of the cMyc-EGFP fusion oncogene. This fish has an enlarged green thymus indicating the development of T-cell acute lymphoblastic lymphoma. *(III)* In this older fish, the whole fish fluoresces green, indicating disseminated T-cell acute lymphoblastic leukemia. **(E)** Tumor transplantation experiment using the transparent "casper" fish. These images show the development of melanoma (derived from p53 null/BRAFV600E model) over time in the same animal. The tumor can be monitored externally without sacrificing the fish. *(**A** and **B**, Reprinted with permission from Macmillan Publishers Ltd:* Nat Rev Genet. *St. Johnston. **C**, Courtesy Hui Feng (unpublished data). **E**, Reprinted from White et al.,* Cell Stem Cell. *Copyright 2008, with permission from Elsevier.)*

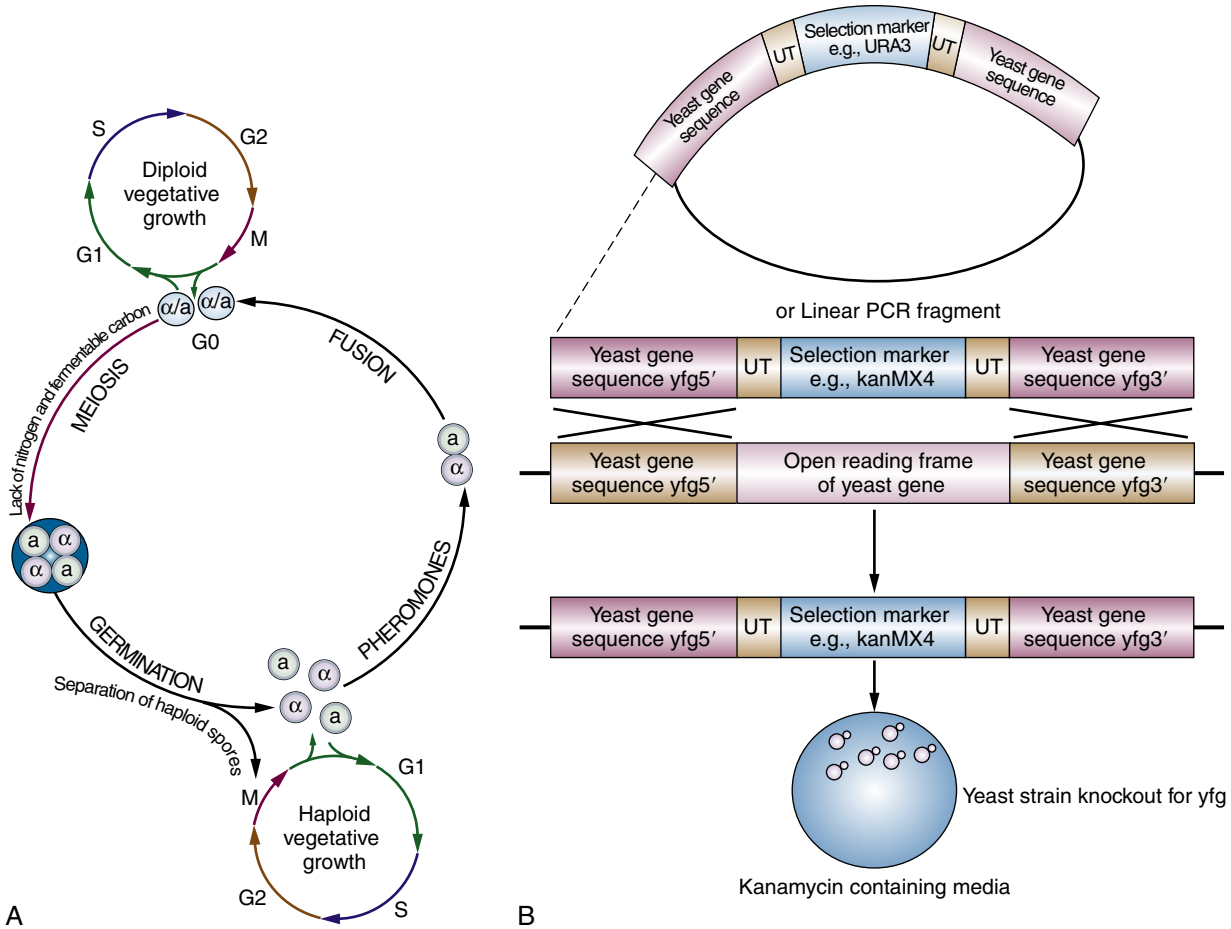

Figure 8-5 **(A)** A schematic representation of the budding yeast life cycle. Under adequate nutritional conditions diploid yeast cells undergo vegetative growth by mitosis *(top left)*. The cells cycle through G1, S (synthesis), G2, and M (mitosis) phases. When starved of nitrogen and fermentable carbon, sporulation occurs with formation of gametes by meiosis. The gametes are contained within a casing called an *ascus*. As the gametes germinate, the haploid spores separate. The a and α gametes secrete pheromones leading to fusion of an a to α gamete when they meet. If separated, however, haploid vegetative growth can also continue by mitosis *(bottom right)*. **(B)** Schematic representation of replacement of yeast gene *yfg* (your favorite gene) with a deletion cassette containing the selection marker KanMX4 conferring resistance to the antibiotic G418 (kanamycin). 40-50 bp of yfg gene sequence at the 5′ and 3′ ends are cloned with KanMX4 selection marker between, flanked on each side by 20-bp unique tags *(UT)*. The *yfg* sequences are recognized by the homologous recombination machinery in the yeast, and a proportion of yeasts will swap the genetic material encoding the gene for that encoding the selection marker. Yeasts that survive in media containing kanamycin have incorporated the deletion cassette and no longer contain a functional *yfg*. These strains can be isolated from mixed cultures by PCR using the flanking UT. *(Adapted by permission from Macmillan Publishers Ltd:* Nat Rev Genet. *Kumar A and Snyder M. Emerging technologies in yeast genomics. Copyright 2001.)*

gain of function do not show a phenotype. The likelihood is that these genes are either redundant or act in pathways whose physiological functions are buffered by other cellular pathways acting in parallel.[20] To decipher the interaction between two deleted genes (synthetic fitness or, more severely, synthetic lethality when the interaction causes lethality) or between a deleted gene and an overexpressed gene (known as synthetic dosage fitness or lethality), novel synthetic genetic array (SGA) screens have been employed.[21,22] Yeasts with the mutation of interest in the haploid state are mated to a pool of haploid yeast knockout strains of the opposite mating type. Selection markers are introduced to allow identification of double mutant strains, and their phenotype is assessed. Synthetic lethality screens have been further developed to incorporate the microarray technology using barcodes as described earlier—the synthetic lethality analyzed by microarray (SLAM).[20] SLAM has allowed analysis of double-mutant heterozygous diploid strains of yeast, as well as other genetic interactions such as chemical genetic interactions.[23]

Yeast screens have been devised to determine not just genetic but also protein-protein interactions. These can be in the form of two-hybrid screens, or more recently in the form of tandem affinity purification tagged (TAP-tag) analysis. The principle of the two-hybrid screen analysis is that transcription factors require two domains—a DNA binding domain (BD) and an activation domain (AD) in close proximity to one another—in order to bind to and cause transcription of their target gene. Part of the Gal4 transcription factor (either the BD or the AD; for this example the BD) is fused to the protein of interest, for example, the MYC oncoprotein. A library of other proteins is then fused

to the Gal4 AD. If any of the library proteins interacts with MYC, then the Gal4 transcription factor will bind and cause transcription of target genes. The target gene can be engineered to be a selection factor that will only allow yeast to grow in the presence of its expression in selective culture conditions, and its identity can be confirmed by subsequent sequencing.[24] In TAP-tag analysis, a tandem affinity purification protein tag is introduced into the open reading frame (ORF) of each yeast gene to create the expression of a fusion protein. This protein tag is specially designed to allow efficient affinity purification of the tagged protein of interest along with other proteins bound or associated with it. The resultant interacting proteins can then be resolved by a variety of methods, the most accurate of which is mass spectrometry.[25,26]

The Cell Cycle

The fundamental processes of cell growth and division are governed by the tightly regulated processes that maintain the cell cycle. The cell cycle is an ordered set of events by which cells grow and divide to produce two identical daughter cells. It is divided into four phases, as shown in Figure 8-5. Two features of cancer cells in mammalian systems are controlled (at least in part) by cell cycle maintenance: altered growth and genomic instability. Based on a number of features, yeasts provide the ideal system for study of the cell cycle.[27] The budding yeast *Saccharomyces cerevisiae* has been the most highly investigated. *S. cerevisiae* is able to survive in both haploid and diploid states. In the presence of sufficient cell nutrients, diploid cells undergo division by mitosis and growth by budding. The size (or presence) of a bud can be visualized by light microscopy and permits determination of cell cycle status in individual cells. Each diploid cell contains a copy of each of the two mating types—Mat**a** and Matα—determined by the MAT locus. When diploid cells are starved of nitrogen and fermentable carbon, they undergo sporulation and commence formation of **a** and α gametes. Here the cells undergo division by meiosis, followed by differentiation of the subsequent haploid progeny. The haploid progeny immediately fuse with a cell of the opposite mating type to produce a diploid cell—a process determined by a mating pheromone that is specific to each mating type (**a** or α). Therefore the cell cycle and mating machinery are integrally linked.[28,29] In addition, yeast cells that have arrested at different parts of the cell cycle (usually under specific conditions such as high temperature) have disrupted genes critical to progression through the cell cycle and cell growth, which may be potential oncogenes and/or tumor suppressors. The study of mutant yeast strains with abnormalities in the cell cycle has led to the identification of genes orthologous to human oncogenes and tumor suppressors.

CDC2 and CDC28

In 2001, the power of yeast as a genetic tool for studying the cell cycle and its implications in cancer were recognized with the award of the Nobel Prize in medicine to Paul Nurse and Leland Hartwell. They not only elucidated many of the critical genes involved in regulating the cell cycle but also demonstrated the genetic and biochemical conservation that makes study in this and other simple organisms so powerful. Two of the critical genes identified by these investigators continue today to provide insight into how cancer cells evade normal growth and cell cycle regulatory mechanisms. The *CDC28* gene was discovered in the early 1970s by Leland Hartwell in an early genetic screen to identify *S. cerevisiae* strains that conditionally blocked cells at different stages of the cell division cycle (cdc). The presence of Cdc28 was found to be essential for cells to initiate both the nuclear and cytoplasmic events required for cell division. Before the Cdc28-dependent step, yeast cells are able to undergo either sexual replication or entry into the cell cycle, and thus the Cdc28 step in G1 came to be known as the start of the cell cycle in the budding yeast. The *CDC28* gene was cloned in 1980, and by 1985 Cdc28 was shown to have protein kinase activity.[30]

Paul Nurse uncovered a critical regulator of the cell cycle in *S. pombe*. Using the observation that in budding yeast, cell size is coordinated with progression through the cell cycle, a number of "wee" (meaning small) mutants were identified. "Wee" mutants progressed through the cell cycle more rapidly than normal before sufficient time for normal growth had passed, resulting in the generation of the small phenotype. The second "wee" mutant isolated, *wee2*, was shown to map the same locus as *cdc2* and later, in 1982, was shown to be functionally homologous to the *CDC28* gene in budding yeast. The cloning of the human *CDC2* gene in 1987 confirmed the utility of this system for investigating the role of specific genes in humans.[27] In more recent years, *cdc2* and *CDC28* have been renamed *CDK1* (cyclin dependent kinase 1) as part of the CDK family of kinases, which (along with other roles in cell cycle, transcription, and differentiation) associate with cyclins, allowing intricate control of the cell cycle. CDK1 associates in particular with cyclin B and is involved in the control of mitosis (reviewed in Refs. 31 and 32). Since then, abnormal expression of CDK1 has been found in a variety of human cancers and is now known to be required for efficient phosphorylation of the Bloom syndrome DNA helicase (BLM).[33] Homozygous mutation of the BLM leads to Bloom syndrome—a condition in humans

that predisposes to multiple forms of cancer as a result of genomic instability.

Ploidy, Genome Instability, and Cancer

The study of Leland Hartwell's temperature-sensitive cell division mutants led to the analysis of genes essential for cell cycle progression and their roles in determining the fidelity of genetic replication. Several cell cycle mutants demonstrated markedly increased rates of chromosome loss, recombination, or mutation. From this evidence, the DNA damage checkpoints and DNA repair pathways active during the cell cycle were first identified. One such mutant carried a mutation in *POL3*, a gene now known to encode the catalytic subunit of DNA polymerase subunit δ. This polymerase forms part of a proofreading enzyme whose role is to limit errors occurring during DNA replication by removing any incorrectly incorporated nucleotides via intrinsic exonuclease activity. Homozygous mutations in *POL3* are embryonic lethal (in yeasts and mammals), but heterozygous mutations within the catalytic domain result in a mutator phenotype. The mutator phenotype—where a mutation in one gene predisposes to the development of additional mutations—is known to contribute to the development of cancer in mammals, and thus heterozygous mutations in *Pol3* result in increased rates of cancer in mice. However, in bacteria it is known that the presence of a mutator phenotype results in reduced fitness of the bacterium. This occurs because with each division, an increase in the number of deleterious mutations occurs, ultimately reducing its ability to grow and divide. This continues until such time as an "antimutator" mutation occurs that decreases the number of de novo mutations, allowing this subpopulation to have the growth advantage. It is possible that such a process also occurs in humans, contributing to the clonal evolution of tumors over time. Herr et al. recently tested whether this phenomenon was active in eukaryotic cells using budding yeast, with the hypothesis that a critical threshold of mutations could be tolerated before a yeast became incapable of further cell division.[34] The authors identified several mutations within conserved residues of *Pol δ* that exacerbated the mutator phenotype observed in a yeast strain also carrying a mutation within the mismatch repair gene *MSH6 (msh6Δ)*. In addition to confirming their hypothesis that a threshold number of mutations can be tolerated within a eukaryotic cell, the authors identified occasional yeast colonies that grew in the presence of apparently otherwise synthetic lethal gene mutation combinations. Assessing these "error-induced extinction" (eex) mutants, they determined that indeed these yeasts had developed antimutator phenotypes, with a third of cases having additional antimutator mutations within the *POL3* gene itself as the mechanism of their escape. This elegant study highlights evidence that supports some recent clinical observations in cancer, such as the remarkable success of inhibition of the poly(ADP) ribose enzymes (PARP). PARP1 and PARP2 enzymes are an integral component of the repair of single-stranded breaks as cancer therapies. In the presence of mutations in genes involved in homologous recombination, such as BRCA1 and BRCA2, found in breast cancers among others, PARP inhibition results in selective tumor killing.[35] The likely mechanism of this is the synthetic lethality of tumor cells that arises from the breaching of the critical threshold of mutations sustainable by an individual cell. However, it does raise the concern that the clonal evolution of cells resistant to this mechanism of killing is likely to be problematic when using this therapeutic strategy in some cases.

Flies

Why Use a Fly?

Drosophila melanogaster has been used as a model organism in developmental biology and genetics for a century, and the resultant generation of a vast array of tools make it one of the most comprehensively genetically tractable systems for study. Several features of the fruit fly have led to its popularity as a genetic model, most critically the small number of genes contained within the four fly chromosomes, relatively little redundant DNA, and large numbers of human homologs that have been identified following the complete sequencing of both the fly and the human genomes. In addition, fruit flies develop large polytene chromosomes in the salivary gland. These chromosomes are produced in the last larval stage (the third larval instar) when large amounts of glue proteins are required for pupation. The large amount of protein production is achieved by genome amplification by a process called *endoreduplication*—DNA replication without division. When stained by standard G-banding, the resolution of endoreduplicated chromosomes is an order of magnitude greater than that seen of human chromosomes, as there are multiple copies of each gene. This in turn facilitates the identification of genes that have been deleted. Although wild-type flies do develop tumors, the similarities of these spontaneous growths to mammalian cancers are limited. However, forward genetic analysis has uncovered cancer-like proliferations in the developing fly larva that provide an excellent platform for the investigation of tumorigenesis in this multicellular organism. Early in embryogenesis, cell fate is assigned, leading to the formation of certain adult structures, which develop in the larva via saclike invaginations of specialized epithelium (known as imaginal discs). There are 15 imaginal discs—seven bilaterally symmetrical pairs and

one germ cell imaginal disc. Imaginal discs consist of a single layer of cells that can be easily visualized in the developing larva. In addition, both brain and blood cell neoplasia can be seen in mutant fruit flies.[36] Not all aspects of human cancer can be modeled in a fly, however. In particular, flies lack a closed vascular system, and thus angiogenic properties of tumors cannot be investigated. Despite this, genes known to regulate the angiogenic properties of human tumors, such as vascular endothelial growth factor (VEGF), have fly homologs that have been implicated in tumor development in flies.

Another feature of the fruit fly that makes it an attractive model to study is the availability of large banks of mutant flies. Mutagenesis in flies has been performed using x-rays, chemical agents to induce point mutations, and P-element–mediated insertional mutagenesis. P-elements are transposons or sequences of DNA that can move around or "jump" within the genome. When transposons insert into the genome at the beginning of a coding sequence, that gene's transcription is disrupted, generally creating a null allele. Identification of the disrupted gene is much easier than with a chemically induced point mutation, because the sequence of the P-element is known and can be "tagged," and PCR primers can be used to facilitate gene identification. To determine which flies carry the P-element, its sequence can also be modified to carry a marker, such as rosy eyes. "Jumping" of the P-element requires the function of another gene, transposase, and thus the disrupted gene will be fixed unless the transposase is present. The transposase gene can be bred into flies carrying a P-element to induce the latter to move and is usually carried on what is known as a "balancer" chromosome with another mutation that is easily identifiable, such as curly wings.

Genetic Tools

The first tumor suppressors identified by forward genetics in flies exhibited only one or two features of cancer. The phenotypes observed were of hyperplasia or neoplasia in a single tissue affecting 100% of flies with the mutations and, unlike in human cancers, there did not appear to be a requirement for the development of additional mutations to cause tumorigenesis. Because these initial tumor suppressor genes were not homologous to those found in humans, the fly became less popular as a model organism to study cancer. However, this soon changed, as highly conserved signaling pathways were subsequently identified in flies and humans and more sophisticated genetic techniques to study gene interactions became available.[37] These included genetic screens to identify second-site modifiers of known tumor suppressors; the discovery of a *Drosophila* homolog of C-terminal src, dcsk, isolated by Stewart et al. in a screen for dominant modifiers of the lats tumor suppressor[38]; and the dissection a number of second-site modifiers of the transcription factor E2F.[39,40]

More recently, the use of the conditional Frt/Flp and Gal4/UAS systems has been invaluable in cancer research in the fly. Focusing on the fly's greatest strength—that it offers the ability to investigate cell-cell interaction at a single-cell level—the introduction of mosaic clone analysis for the first time underpinned the role of the microenvironment and non–cell-autonomous cues in the life of an individual cell.[41] The utility of this tool has been used to dissect the cell-autonomous and non–cell-autonomous roles of the *Drosophila myc* gene.[42-44] Similarly, the interactions between oncogenes and tumor suppressors have been evaluated in mosaic clones, demonstrating cooperation between many known oncogenes and fly tumor suppressors.[45-48]

The normal processes by which cells migrate during different developmental processes have been studied extensively in the fruit fly. Different processes use different modes of migration, requiring alterations in cell polarity, cell shape, and the adhesion of cells both to other cells and to the extracellular matrix. Disruption of genes and signaling pathways employed in normal migration processes has been shown to be involved in the ability of cancers to invade local tissues and metastasize to distant regions. This area of research is in its infancy, but the extensively delineated normal processes will undoubtedly assist in the investigation of mechanisms by which cancer cells evade their local environment in this model.[18]

Numerous ingenious second-site modifier and overexpression screens have also been developed in *Drosophila*, the complexity of which are beyond the scope of this chapter but are extensively reviewed elsewhere.[1,18,49]

Malignant Neoplastic Tumor Suppressors in *Drosophila:* scribble and Others

Many fly mutant genes were classified as tumor suppressors in early embryonic screens for larval tissue overproliferation. However, subsequent characterization of a number of those genes demonstrated mechanisms of tissue expansion that did not represent features normally ascribed to cancer cells, and thus these genes are no longer considered true tumor suppressors. Despite this, the recent identification of the tumor suppressor *scribble* was through a screen designed to identify maternal effect mutations that disrupted aspects of normal epithelial morphology.[45] It was noted that *scribble* mutants, in addition to disrupting epithelial morphology in the embryo, also led to epithelial defects in the monolayer epithelium of the female germ cells (follicle cells), in which clones of mutant cells were expressed among wild-type cells.[45] A further screen for additional mutant clones affecting the follicle

cell epithelium led to the identification of another mutant with a phenotype almost indistinguishable from that of the *scribble* mutants. Mapping of this mutation revealed it to be an allele of a previously identified tumor suppressor called *lethal giant larvae (lgl)*. It was also noted that mutant clones of another known tumor suppressor, *discs large (dlg)*, led again to a very similar phenotype in follicle cells. In normal tissues, the role of the Scribble protein is in maintenance of cell polarity and cell-cell adhesion, by controlling the localization of other proteins within epithelial cells in order to maintain correct spatial orientation. Bilder et al. postulated that given such similarities in phenotype *scribble* may be a tumor suppressor like *lgl* and *dlg* and also that *lgl*, *dlg*, and *scribble* might interact to form the necessary machinery to maintain cell architecture and cell proliferation in fly epithelium.[45] The identity of *scribble* as a tumor suppressor was confirmed by investigation of the epithelium of the third-instar larvae imaginal discs, which demonstrated cellular overproliferation with loss of apicobasal polarity and disordered architecture. In addition, overgrowth of brain tissue was observed in *scribble* mutants—another feature common to the *lgl* and *dlg* mutants. Epistatic relationships among the three genes have also been demonstrated by the ability to enhance the phenotype of *scribble* mutants by an additional heterozygous mutation of either *dlg* or *lgl*. Following the discovery of *scribble* and its properties as a tumor suppressor in flies, a further screen set out to use the fly as a method of studying the metastatic properties of tumors. Until this point, individual tumor suppressors and oncogenes that had been studied in flies apparently lacked the capability to proliferate without the microenvironment in which the malignant cells reside. This is perhaps not surprising, given the premise that a single genetic lesion is rarely sufficient to promote tumorigenesis, but that it creates a mutator phenotype predisposing to the additional mutations required for cancer to develop; and that in an organism such as the fly, the likelihood of that secondary mutation occurring is low within its short natural lifespan. The screen that was developed investigated the interaction of activated *ras* (ras^{v12}) and known and unknown additional mutations. The system allowed for the development of clones of malignant cells that expressed ras plus additional mutations in the normal microenvironment within the eye disc, using the Frt/Flp system, the Gal4/UAS, and the Gal80 suppressor to localize expression. The results demonstrated that the combination of a ras^{v12} mutation and *scribble* mutation led to circulating tumor cells within the fly hemolymph open circulation and the development of widespread metastatic tumor formation. In these metastatic tumors, basement membrane integrity was breached (as in mammalian metastatic tumors), and overexpression of the junctional adhesion protein E-cadherin suppressed the metastatic behavior of the tumors. This is also in keeping with mechanisms of metastasis in human epithelial tumors, where E-cadherin is frequently downregulated.[50] These studies unequivocally demonstrate the utility of the fly as a cancer model with unique properties for uncovering novel genetic interactions and potential therapeutic targets. Recent studies on the human *SCRIBBLE* gene have shown that it is downregulated in cervical cancer[51,52] and the majority of invasive breast cancers[46] and interacts with the adenomatous polyposis coli gene, leading to altered expression in many cases of colon cancer.[53]

Archipelago

The archipelago *(ago)* gene was identified in a screen to distinguish mutant clones in the eyes of fruit flies that provided a proliferative advantage over their wild-type neighbors. The screen identified several known tumor suppressors as well as three alleles of a novel gene the authors named *archipelago*. *ago* mutant clones showed increased proliferation compared to wild type and only a small amount of compensatory apoptosis. *ago* encodes an F-box protein. F-box proteins are involved in the recognition of other proteins, such as *myc* and *cyclin E*, which are targeted for degradation by a series of enzymes that catalyze the addition and polymerization of the small protein ubiquitin. These specificity factors are termed *E3 ubiquitin ligases*. Polyubiquitination directs the protein to the proteosome for degradation. The F-box protein exists in a complex with other enzyme components required for ubiquitin activation (E1) and ubiquitin conjugation (E2). In *ago* mutants, all three alleles were found to be mutated in the domain of the protein known to be involved in substrate recognition (known as the WD repeats). This led to the hypothesis that the mutant *ago* was unable to recruit a protein substrate for degradation, and this in turn was responsible for the observed phenotype. Because of the proliferative phenotype, the authors hypothesized that a positive regulator of the cell cycle may be involved in the observed phenotype and investigated expression levels of the cyclins. Levels of cyclin E protein were found to be increased without a corresponding increase in cyclin E mRNA, suggesting a post-transcriptional mechanism. *Cyclin E* complexes with *Cdk2* (cyclin-dependent kinase 2), and degradation of this complex promotes the transition from the G1 to S phase of the cell cycle. In the presence of excess cyclin E, cells are driven to replicate their DNA prematurely, leading to genomic instability. Therefore Ago appears to be the F-box protein that directs ubiquitination and subsequent degradation of cyclin E, and the failure to degrade cyclin E is responsible for the proliferative phenotype observed. Elevated cyclin E levels are seen in a variety of human cancers, including breast and ovarian cancer. The human *AGO* ortholog *FBW7* (also known as

hAGO, *hCDC4*, and *FBXW7*) was shown to be mutated in 4 cancer cell lines, including 3 of 10 ovarian cancer cell lines and 1 T-ALL cell line.[54] A further report confirmed the role of human *FBW7* and *Drosophila ago* as part of a complex of proteins responsible for E3 ubiquitination known as an *SCF complex* and showed reduced levels of FBW7 mRNA in breast cancer cell lines where cyclin E levels were elevated.[55] Subsequent investigation has shown that a small number of primary ovarian cancers have mutations in *FBW7*.

Fish

In 1995, Christine Nusslein-Volhard won the Nobel Prize in medicine for her work on the delineation of the embryonic axes of the developing fruit fly. Notably, half of her acceptance speech was dedicated to a different organism, the zebrafish.[56] The major appeal of the zebrafish over other organisms as a cancer model is that it is allows investigation of vertebrate tumor biology but remains amenable to embryonic and forward genetic study in a manner quite unfeasible in other vertebrates. The transparent zebrafish embryos undergo extrauterine fertilization and development. The embryos can be maintained in the haploid state, and gynogenetic diploid (diploid fish derived from maternal sister chromatids—or half-tetrads) are viable to adulthood and fertile. Each female fish is capable of producing up to 200 eggs per clutch, and in vitro fertilization from frozen sperm is also possible. Embryonic development is rapid, with the completion of somitogenesis in only a few days, and adult fish are able to reproduce from 3 months of age. Although the speed of forward genetic screening is slower than in flies or yeast, zebrafish is the model of choice for large-scale forward genetics in a vertebrate organism.[57,58] The addition of a beating heart and closed circulation in zebrafish provides the ability to dissect additional facets of cancer biology, such as abnormal angiogenesis. In contrast to flies and yeast, fish get cancer in the wild, with macroscopic characterization and microscopic histopathologies similar to those seen in other vertebrates, including humans. Exposure to carcinogens has confirmed that teleost fish are susceptible to cancer in virtually all organs and tissue types.[59] Several transgenic models have now been developed using tissue-specific expression of human or murine oncogenes, resulting in the development of human-like cancers. These have provided the platform for a second generation of zebrafish screens, which critically include modifier screens for genes or drugs that can affect the onset or progression of oncogene-induced tumors that are genetically based on human molecular oncogenesis. Such modifier screens provide important information for dissecting disease biology and causative pathways, as well as for the identification of new drugs and therapeutic targets. An example of such pathway interactions was demonstrated in zebrafish overexpressing the activated oncogene BRAF in fish melanocytes. These produced pigmented nevi, but when mated to a p53 mutant line, developed fulminant malignant melanoma.[60]

Gene inactivation by homologous recombination as described in yeast, flies, and mice has yet to be successfully performed in the zebrafish, but the challenge of reverse genetics has been met by several other genetic technologies. Transient gene knockdown is possible in zebrafish embryos using morpholinos. Morpholinos are chemically modified antisense oligonucleotides directed either at the translational start site of a gene, blocking protein production, or at a splice site resulting in inappropriate RNA splicing and the formation of nonfunctional proteins. Injection of the morpholino into single-cell–stage embryos results in gene knockdown that is stable for around 4 days, allowing observation of the effects of gene inactivation on embryonic development. This allows rapid assessment of whether gene function in fish creates a phenotype similar to that in mammals.

To provide specific germline gene knockout models, two major technologies have traditionally been employed. Both are based on traditional forward genetic mutagenesis techniques. The first, targeting induced local lesions in genomes (TILLING), combines chemical mutagenesis using *N*-ethyl-*N*-nitrosourea (ENU) with an enzyme derived from celery named CELI, which cuts DNA at positions of base pair mismatch. Using this enzyme, pools of genomic DNA from multiple mutagenized fish can be amplified by PCR to identify mutations in a gene of interest. An alternative method is large-scale viral insertional mutagenesis. This technique was pioneered in the laboratory of Dr. Nancy Hopkins and involves the use of a murine retrovirus that inserts randomly into the genome.[61] Both of these technologies are labor intensive and require a large amount of aquarium space. However, novel sequencing technologies that allow rapid identification of mutations are now being used at the Sanger Centre in Cambridge, UK, to sequence ENU mutagenized fish and generate a library of gene-inactivating mutations for every zebrafish gene (http://www.sanger.ac.uk/Projects/D_rerio/zmp). In parallel, the use of targeted genome editing technologies described earlier and shown in Figure 8-3, *B*, is becoming widespread throughout the zebrafish communities.[10] The major advantage of TALEN and zinc-finger nuclease–based strategies for targeted gene knockdown is that they are easily accessible to even small laboratories and, because the location of the double-stranded break is known, this should facilitate strategies to allow homologous recombination to be successfully achieved in this organism.

Although in recent years the fish of choice for modeling tumorigenesis has been the zebrafish, several other teleost

fish have been used for genetic study. The fully sequenced genome of the pufferfish (*Takifugu rubripes*) is particularly of benefit to zebrafish researchers, because there is less evolutionary divergence between fish genes than between those of fish and mammals, and there is less intronic DNA in the pufferfish than in the zebrafish. By comparing the gene localization and sequence in the pufferfish, the few remaining gaps in the now essentially complete zebrafish genome sequence can often be bridged.

One potential drawback when observing tumorigenesis in zebrafish is their stripes. The presence of pigment in the skin of the zebrafish means that after around 5 to 10 days postfertilization (dpf), direct visualization of the developing fish is hampered by the presence of pigment cells. Chemicals such as phenylthiourea are routinely used to delay the onset of pigmentation, but these cannot be used indefinitely, and thus adult fish are not transparent. To facilitate the visualization of adult tissues, a novel pigment mutant has been developed. This mutant fish, aptly named *casper*, is derived from a compound homozygous fish carrying a mutation in the *mitf* gene along with the mutant fish *roy orbison* (whose gene mutation is unknown). This fish remains transparent throughout its life. Thus, fluorescent transgenic markers and in vivo tumor development can be visualized without the necessity to sacrifice the animal (see Figure 8-4, *E*).[62] Furthermore, this model greatly facilitates the study of cell autonomy and transplantation, because transplants into these hosts can be visualized directly in real time.[62,63]

Leukemia Models and Therapy Using Transgenic Zebrafish

The role of the zebrafish as a cancer model combining the attributes of vertebrate biology and model organism genetics came to fruition with the development of T-cell acute lymphoblastic leukemia (T-ALL) in transgenic zebrafish expressing the mouse *c-Myc* oncogene under the lymphoid-specific promoter *rag-2*. The *c-Myc* oncogene was fused to a cDNA encoding the enhanced green fluorescent protein (EGFP), allowing real-time visualization of the leukemic cells. In common with mammalian hematological malignancies, it was possible to sublethally irradiate a recipient wild-type zebrafish and transplant EGFP-positive tumor cells from the *c-Myc*–induced leukemia from another fish by injecting them into the immunosuppressed recipient fish peritoneum. These fish went on to develop leukemia with the same pattern as the donor fish, with initial homing of T lymphoblasts to the thymus gland followed by subsequent infiltration of surrounding tissues and finally dissemination and death.[13] This seminal work demonstrated not only the ability of fish to develop human-like cancers in response to mammalian oncogenes, but also a feasible fish-tumor model system for modifier and drug screens to alter the leukemia phenotype or onset.

Capitalizing on the similarities between human and zebrafish T-cell leukemia as well as the similarities between normal and malignant T-cell development, Ridges and colleagues recently showed the utility of the zebrafish as a model in which to perform in vivo drug screens relevant to human cancers.[64] Based on the fact that treatment of zebrafish embryos with dexamethasone, a drug active in human T-ALL, resulted in a loss of normal thymocytes, the authors used a zebrafish with a green fluorescent thymus to screen a large library of compounds. They identified compounds that led to loss of thymocytes and subsequently prioritized drugs for further assessment by determining whether they had global effects on cell cycle within the fish (which are likely to be generally toxic) and whether the compound had effects in the c-Myc–induced leukemia model. The authors were able to identify one compound (Lenaldekar) that demonstrated specific antitumor effect in human leukemia cells and were able to show that this compound functioned by inhibiting the PI3Kinas/AKT/mTOR pathway, as well as having a tumor-specific effect on cell cycle at the G2/M phase. This study places the zebrafish as a novel in vivo model system in which to identify drugs for cancer treatment.

Zebrafish Screen for Genomic Instability Mutants

Many inherited human syndromes predisposing to cancer (such as Fanconi anemia and Bloom syndrome) are characterized by disruption of genes critical for DNA repair and maintenance of genomic stability. Karyotypic abnormalities are a common finding in the majority of cancers that progressively accumulate over time, highlighting a role for genomic instability in cancer progression. To identify novel genes predisposing to genomic instability and the development of cancer, a forward genetic screen in zebrafish was designed. The screen design used several unique facets of zebrafish genetics. First, wild-type male fish were treated with the mutagen ENU to induce potential *g*enomic *in*stability (gin) mutations per sperm. These fish were mated to fish homozygous for a pigment mutation known as *golden* (gol). Golden embryos in the homozygous state have a characteristic gold-colored pigment in the developing eye, in contrast to wild-type or heterozygous fish, where the pigment is black. In heterozygous golden mutants, an additional recessive mutation predisposing to genomic instability will induce patches of golden pigment as second inactivating mutations occur in the remaining normal golden allele. The number and size of patches of golden tissue can be quantified. This

assay is known as the *mosaic eye* assay.[65] For this assay to effectively identify recessive gin mutations, fish need to be homozygous for the gin mutation (gin/gin) and heterozygous for the gol mutation (gol/+). The progeny from the initial matings are heterozygous for both (gin/+ and gol/+). To obtain this configuration, early-pressure parthenogenesis was used. This technique uses ultraviolet (UV)-irradiated sperm to fertilize the double heterozygous fish, leading to potentially haploid embryos. To maintain a gynogenetic diploid state, the second meiotic division is inhibited by using early pressure applied by a French press. Because of crossing over at the cell cycle stage meiosis I, genes that are nearer to the ends of the chromosomes (telomeric) compared with those nearer to the centromere (centromeric) are more likely to have undergone crossing over; therefore telomeric genes are more likely to be in the heterozygous state. The golden locus is known to be telomeric, and 89% of embryos generated in this way were heterozygous for gol, allowing assessment of genomic instability in the mosaic eye assay. Twelve genomic instability mutants were identified in the screen, all leading to an increased incidence of a variety of cancers in the adult fish in the heterozygous state, but more markedly in the homozygous state. In addition, some of the mutations interacted with one another to produce more severe phenotypes in the double heterozygous state.[66] To date, only preliminary mapping of the mutations has been completed, but identification of the genes causing the observed cancer-predisposing genomic instability phenotypes will likely shed some valuable information on tumor formation in mammals, including humans.

Conclusion

This chapter provides the reader an overview of the immense utility and strengths of simple model organisms as tools to dissect the molecular pathogenesis and improve the targeted therapy of human cancer. Model organisms can tell us more about things we know a little of, and reveal to us things of which we know nothing—which is especially important given the emerging complexity of genetic alteration in human cancers. Useful additional Internet resources are provided in Table 8-1.

Genetic Mouse Models of Cancer

The study of many different organisms has contributed to our understanding of cancer at the molecular, cellular, and organismal levels. Considerable effort is focused on the rational design and use of mouse models, including spatially and temporally controlled genetic modifications to recapitulate human cancers. Long before the development of genetically engineered animal models, research on mice, rats, rabbits, and chickens led to major discoveries directly related to cancer, including the discovery of oncogenes and the biochemical purification of tumor suppressor proteins.[1-4] In addition, many key regulators of proliferation, differentiation, and cell death have been characterized by studying developmental processes in mice. The knowledge of pathways that regulate organ development is an important framework on which to build our understanding of all aspects of tumor initiation, progression, and metastasis.

In this chapter, we discuss mouse models of cancer, emphasizing the techniques used to create genetically engineered mouse models and the application of these models to cancer research. Several fundamental discoveries resulting from the use of mouse models are also highlighted, as well as the important role of these models in the future of cancer research.

Basis for Mouse Models of Cancer

Our understanding of the genetic alterations in human tumors and the ability to manipulate the mouse genome has allowed for the development of models of human cancer.[5-8] Mice are the preferred model organism with which to study the complex processes of tumor development and progression for many reasons, including their short generation time, small size, availability of inbred strains, and the close genetic relationship between mice and humans. Fish, flies, and worms have also been successfully used to investigate tumorigenesis, and the unique genetic tools available in these species have allowed for a range of informative experiments to be performed.[9-12]

Observational and correlative studies of human cancer combined with in vitro experiments on human cancer cell lines have contributed a great deal to the foundation of our knowledge of tumorigenesis. The dissection of cancer development and progression in humans is greatly limited by the difficulty in accessing lesions at various stages of development and the inability to test gene function in vivo except by pharmacologic means. The interrogation of gene function in vitro is limited to genes that control the intrinsic processes of cancer cells, including proliferation, differentiation, and cell death. Moreover, the complex interactions between different cell types within the tumor are poorly recapitulated in vitro, and the selective pressure of in vitro growth may significantly alter the genotype and phenotype of cultured cells. For all these reasons, animal models in which the entire developmental progression of the disease from tumor initiation to metastatic outgrowth occur in vivo are of paramount importance.

The underlying genetic heterogeneity of the human population, the existence of subtypes of different malignancies, and the genetic and genomic heterogeneity within tumors of the same type complicate studies of human tumor gene expression and mutational analysis. The induction of tumors with specific oncogenic alterations in mice on inbred backgrounds can overcome many of these limitations. Mouse models also offer the ability to assign causality to genetic alteration and to assess the roles of certain genes and pathways in vivo.

Mouse Models of Cancer

Modeling human cancer in mice has evolved as techniques to modify the mouse genome have been developed. Combinations of the approaches described in the following sections have been used to model many human cancers. The plethora of options to create these models has been used to address many fundamental questions in tumor biology.

Spontaneous and Mutagen-Induced Tumor Models

Mice spontaneously develop a spectrum of cancers. The observation that different inbred strains of mice develop cancer at different frequencies gave early support to the idea that the genetic background of a mouse (or person) can predispose them to cancer. Spontaneous tumor formation is often assessed in non-genetically engineered mouse lines to determine whether the specific gene mutation influences the prevalence, progression, or types of cancers that arise (Figure 9-1, *A*).

Many known or suspected carcinogens have been used to create mouse models of cancer (see Figure 9-1, *B*). These models rely on the treatment of mice with chemical or physical mutagens, which most often leads to the development of genetically undefined cancers. Carcinogen-induced cancer protocols can be used with genetic techniques to create combined carcinogen/genetic models of human cancer.

Xenograft and Orthotopic Models

The transplantation of human and mouse tumor cells into recipient mice has been used extensively to investigate tumor development in vivo (see Figure 9-1, *C* and *D*). Human tumor cell lines can be injected orthotopically into the organ from which the tumor originated, intravenously (to mimic the metastatic spread of cancer cells) or subcutaneously (to simply allow the tumor to grow in vivo). Mouse tumor cell lines can be transplanted into syngeneic immunocompetent recipients, whereas human cell lines must be transplanted into immunocompromised recipients. This in vivo tumor growth requires many of the proper tumor-host interactions, including the development of vasculature and recruitment of supportive stromal cells. However, these procedures often involve the injection of high numbers of cells and do not recapitulate the series of events that lead to human cancer. Nonetheless, the ability to manipulate tumor cell lines in vitro before transplantation and the speed and reproducibility of tumor growth are major advantages of these approaches.

Genetically Engineered Mouse Models

Gene expression and genomic analyses of human cancers have uncovered many of the important genetic changes in different tumor types. The knowledge gleaned from these studies coupled with the ability to create germline and somatic alterations in the mouse genome has allowed the creation of genetically defined mouse models of cancer that approximate human cancer at the genetic and histologic levels. Transgenic overexpression was the first genetic technology used to create mouse tumor models[13-15] (Figure 9-2, *A*). Tissue-specific promoters can be used to drive the expression of genes of interest in the desired cell type or tissue, and the tumorigenic consequences can be determined. More elaborate transgenic approaches also allow transgene expression to be controlled temporally.

An interesting system for the delivery of genes to somatic cells in vivo uses avian retroviral vectors. Transgenic

	SPONTANEOUS	CARCINOGEN-INDUCED	XENOGRAFT TRANSPLANT	ORTHOTOPIC TRANSPLANT
	Wait for untreated mice to get tumors with age.	Expose mice to known or suspected carcinogens.	Inject human tumor cells into mice. Often cells are injected subcutaneously.	Inject tumor cells into their tissue of origin.
Pros	Tumors arise in proper tissue environment.	Use carcinogens known to promote tumor formation in humans.	Use human tumor cells. Tumor cells can be manipulated in vitro prior to injection. Rapid generation time.	Use human or mouse tumor cells. Tumor cells can be manipulated in vitro prior to injection. Tumors arise in proper tissue environment.
Cons	Long latency, unspecified tumor development. Unknown genetic alteration in tumors.	Unknown genetic alteration in tumors. Unsynchronized and variable tumor development.	Incompatibility between human and mouse growth factors. Requires the use of immunocompromised recipients. Often use tumor cell lines. Injection of high numbers of cells. Growth in inappropriate tissue.	Not all tissues are amenable to orthotopic injections. Often use tumor cell lines. Injection of high numbers of cells.

Figure 9-1 Non–genetically engineered mouse models of cancer **(A,B)** Mice develop tumors spontaneously or in response to carcinogen exposure. **(C,D)** Transplantation of human or mouse tumor cells into recipient mice provides a rapid method to study cell growth and progression in vivo.

expression of the cell surface receptor for the RCAS virus (tva) allows the specific and stable infection of a cell type of interest[16] (see Figure 9-2, *B*). The viral vectors can be engineered to express a gene of interest, and the effect of these genes on tumorigenesis can be determined after in vivo infection of the tva-expressing permissive cell type.

Techniques to alter the germline of mice allow the deletion or alteration of genomic loci (see Figure 9-2, *C* and *D*). These alterations can also be induced in cell-type and temporally regulated fashions. Such powerful approaches allow mouse models to be created that mimic the loss of tumor suppressor genes and activation of oncogenes that occur in different human cancers, resulting in mouse models that closely resemble the human disease. These genetically engineered mouse models are being used in a myriad of research settings to further our understanding of tumor biology.

Techniques to Modify the Mouse Genome

Different genetic strategies can be used to overexpress, alter, or reduce the expression of genes that affect tumor incidence or progression. Genetic mouse models begin to recapitulate the selected human cancer when the genetic alterations are consistent with those detected in human cancers and when those alterations produce a tumor lesion that appears histologically similar to the human disease. Transgenic overexpression, induced and germline gene deletion, and conditional expression of activated oncogenes allow most of the genetic alterations found in human cancers to be modeled in mice.

Transgenic Mice

Transgenic mice have an extra copy of the gene of interest controlled by a ubiquitous or tissue-specific promoter (Figure 9-3, *A*). The use of a cell-type–specific promoter provides spatial control over the expression of the transgene. A normal or mutant form of a gene can be overexpressed to ascertain its effect on tumor development. In addition to gene overexpression, transgenic mice can also be used to reduce gene expression or protein function. The expression of dominant negative or viral proteins that interfere with endogenous protein function has been used to assess the effect of disrupting certain pathways on in vivo tumorigenesis. In addition, RNA interference (RNAi) can be used to reduce the expression of a gene of interest in mice (see Figure 9-3, *B*).[17,18]

Traditional transgenic mice constitutively express the transgene in the chosen cell type, potentially disrupting organ development or tissue homeostasis. Therefore, systems have

	Transgenic gene overexpression	RCAS viral-based gene expression system	Germline genetic alteration	Spatial and temporal control of oncogenes and tumor suppressors
	Tissue-specific expression of a gene of interest	Specific in vivo gene transfer to cells expressing the viral TVA receptor by an avian retrovirus	Deletion or alteration of gene of interest in the germline.	Alteration of gene of interest in a cell-type-specific and temporally controlled manner to assess its role in tumorigenesis
Pros	Recapitulates overexpression or amplification of genes in human tumors. Tissue-specific expression.	Transfers genes into somatic cells. Can control timing of tumor initiation. Confines expression to cell type of interest. Can express multiple genes.	Model familial cancer syndromes. Tumors arise in proper tissue environment.	Can control timing of tumor initiation. Confine expression to cell type of interest. Intact immune system. Tumors arise in proper tissue environment. Known genetic alterations.
Cons	Transgene expression is affected by integration site. Inability to recreate gene mutation or true gene loss.	Requires production of TVA transgenic mouse lines. Virus can only infect dividing cells. Potential effect of viral insertion into the genome.	Unknown additional genetic alteration required for tumor formation.	Requires production of genetically altered mouse lines. Requires prior knowledge of oncogenic lesion in specific tumor type.

Figure 9-2 Genetically modified mouse models of cancer **(A,B)** Transgenic gene expression and **(C,D)** the alteration of endogenous loci allow induction of tumors in mice with genetic alterations analogous to those in human cancer.

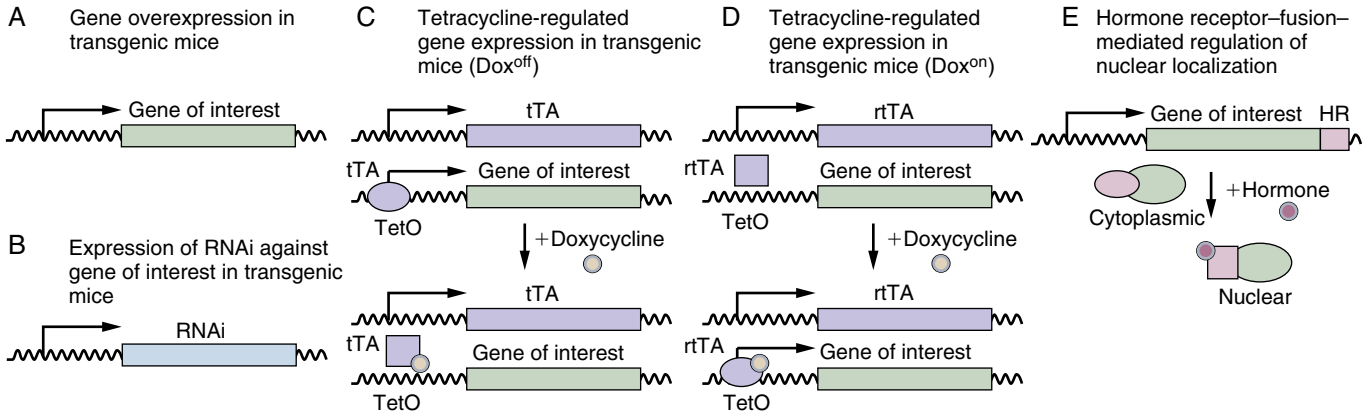

Figure 9-3 The toolbox for the transgenic control of gene expression and protein function in genetically modified mice (A,B) The use of tissue-specific promoters allows the expression of a gene or interfering RNA of interest in the desired tissue. **(C,D)** Regulation of gene expression by the tetracycline system adds a level of temporal control based on a change in conformation of the tetracycline transactivator (tTA) or reverse tetracycline transactivator (rtTA) in the presence of doxycycline. **(E)** The expression of hormone receptor (HR)-fusion proteins allows the nuclear translocation of proteins of interest only in the presence of the hormone.

been developed to allow the temporal control of transgene expression or function. Two complementary systems rely on a tetracycline-dependent transactivation to control the spatial and temporal expression of the gene of interest[19-21] (see Figure 9-3, *C* and *D*). The tetracycline transactivator (tTA) drives the expression of genes under the control of the bacterial tetracycline-dependent operator (tetO). The transactivation function of the tTA is blocked when tetracycline derivatives, often doxycycline, are present (see Figure 9-3, *C*). The reverse tTA (rtTA) works analogously to tTA, except that the expression of the tetO-controlled gene is induced only in the presence of doxycycline (see Figure 9-3, *D*). Exposure of mice with cell-type–specific expression of the tTA or rtTA transgene and a tetO-controlled gene of interest to doxycycline can be used to turn gene expression on and off. These systems have allowed investigators to control tumor initiation and evaluate the requirement for continued oncogene expression during tumor maintenance and progression.[22-28]

The fusion of oncogenes and tumor suppressors to hormone receptors has also been used to regulate protein function by controlling their subcellular localization (see Figure 9-3, *E*). In-frame fusion of a gene of interest to the estrogen receptor (ER) or a truncated progesterone receptor (APR) creates a fusion protein that is sequestered in the cytoplasm until the cell is exposed to the appropriate hormone that induces its nuclear import (see Figure 9-3, *E*). Modified ERs (ER(TAM) and ER(T2)) have been created that translocate to the nucleus in the presence of 4-hydroxytamoxifen but not natural ER ligands, thus reducing background translocation.[29,30] These acutely switchable protein alleles have been used to determine the execution point for various nuclear proteins, including oncogenes and tumor suppressors.[31-33]

Gene-Targeted Mice

The ability to alter endogenous loci within the mouse genome has dramatically affected every field of biology.[34] Homologous recombination in embryonic stem cells allows the specific deletion or alteration of genomic loci (Figure 9-4, *A* and *B*). This technique was initially used by cancer biologists to make germline deletions of several genes implicated in human cancer.[35-38] These conventional "knockout mice" lack the gene of interest in every cell in the animal. Germline deletion of some genes results in embryonic lethality, necessitating the analysis of heterozygous mutant mice or the use of conditional deletion strategies. Several tumor suppressor genes are mutated in the germlines of families, predisposing them to cancer, and mice with heterozygous deletion or mutation of these genes can serve as useful models to study tumor development under these sensitizing genetic conditions.[39-43]

The ability to delete genes specifically in a chosen cell type is comparable to the use of tissue-specific promoters to drive transgene expression (see Figure 9-4, *C*). Using bacteriophage-derived Cre recombinase, it is possible to delete genomic regions flanked by loxP nucleotide sequences (these loci are referred to as *floxed*).[34,44] FLPe recombinase is used less frequently but can also be used to recombine loci flanked by FRT sequences (see Figure 9-4, *C*).

The development of mice that express Cre recombinase in defined cell types and the creation of floxed alleles of many important cancer genes have allowed researchers to investigate the role of these genes in the development of various types of tumors in a highly controlled manner. Cre recombinase can also be used to induce chromosomal translocations analogous to the translocations that are pathognomonic of certain hematopoietic cancers[45,46] (see Figure 9-4, *D*).

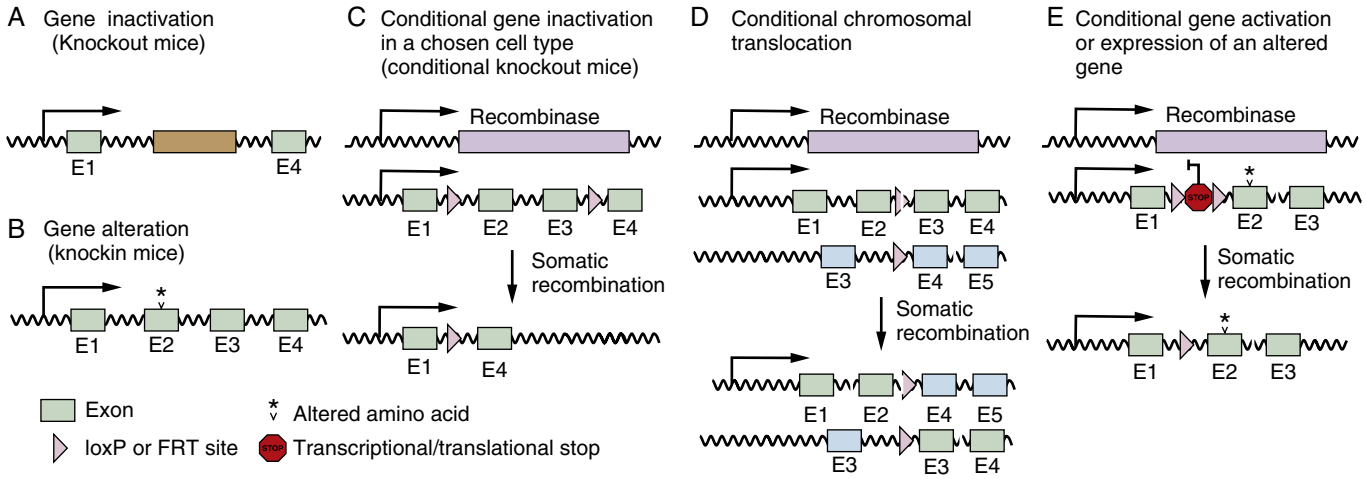

Figure 9-4 The toolbox for the deletion or genetic modification of endogenous genes in mice Genetic alteration of endogenous loci to inactivate **(A),** alter **(B)** or conditionally activate **(D,E),** or inactivate **(C)** genes. Homologous recombination allows the deletion or alteration of gene coding sequences. **(C-E)** The expression of a recombinase (Cre or FLPe) from a tissue-specific promoter or virus allows the spatially restricted deletion **(C),** translocation **(D),** or induced expression **(E)** of a targeted allele.

The expression of activated oncogenes is an important aspect of mouse models of human cancer. To express a mutated oncogene at its physiologic level from its endogenous promoter (as is the case in most human cancers), mice have been engineered with a floxed transcription/translation stop cassette in the first exon of a chosen mutant oncogene. These oncogenes remain silent until Cre-recombinase removes the stop cassette, allowing the expression of the mutant oncogene in the chosen cell type (see Figure 9-4, *E*).

Specific promoters direct the expression or deletion of genes to a desired cell lineage, and sophisticated systems can also allow the timing of gene alteration to be controlled. In these situations, however, every cell of the chosen cell type undergoes the same oncogenic event, which is in stark contrast to the initiation of human tumors where a single cell likely incurs the oncogenic alteration. Although inducing these genetic changes in a single cell may not be the most appropriate approach in experimental research, the use of viruses to deliver Cre recombinase to a subset of cells may be an acceptable medium. In these systems, viruses (often adenoviral or lentiviral vectors) are used to deliver Cre to a fraction of the cells in the organ of interest in mice that are genetically poised to express or delete genes of interest. These viral vectors have been used to initiate multifocal non–small-cell and small-cell lung cancer, hepatocellular carcinoma, ovarian cancer, and various brain tumors.[47-51]

Rational creativity may be the underlying theme of these mouse models. Table 9-1 contains a selection of mouse models that use a variety of different genetic techniques to model different tumor types. As our knowledge of the genetic alterations in human cancers increases, our ability to control their expression in mice will also expand with the application of additional orthogonal systems.

Applications of Mouse Models to Cancer Biology

Combinations of the methods described in the preceding sections have been used to address several important questions in cancer biology, including oncogene addiction and the cooperation and interdependence of various oncogenes and tumor suppressors.

Cross-Species Comparisons

The comparison of tumors from different species has highlighted the central role for several oncogenic and tumor suppressor pathways. Mutations in *p53* are found in about half of human tumors, but *p53* is also mutated in tumors in the soft-shell clam, *Mya arenaria*, underscoring the importance of this tumor suppressor and the conservation of critical alterations across diverse phyla.[52,53] Cross-species comparison of gene expression and genomic changes in tumors from mice and humans has also yielded valuable insight into the important genetic changes in cancer.[54-58] The genetic changes in human tumors are often complex and are overlaid on the considerable allelic variation among individuals. Although possible, pinpointing the important somatic changes or genomic alterations can become unwieldily complex.[59] By comparing the overlapping genomic and genetic changes in mouse and human tumors of the same type (and even tumors containing several of the same oncogenic events), the minimal critical genetic changes can be established. In addition, these changes can be functionally validated in the mouse models that aided in their identification.

Table 9-1 Examples of Genetically Modified Mouse Models of Cancer

Tumor Type	Genetic Modification	Mouse Model	Common Alterations in Human Cancer	Reference
Breast cancer (Chapter 36)	Transgenic expression of an oncogene	MMTV-*HER2*	*HER2*, *C-MYC*, and/or *cyclin D1* amplification; germline *BRCAL* or *BRCA2* mutations; *p53*, *RB1*, and/or *PTEN* loss	93,94
Prostate cancer (Chapter 38)	Transgenic expression of the SV40 large T-antigen to block tumor suppressors	Pb-*T antigen*	*RB*, *p53*, *PTEN*, and/or *NKX3.1* loss; active K-RAS, active H-RAS	95
Acute lymphoblastic leukemia (Chapter 26)	Tetracycline-regulated oncogene expression (Dox off)	*EμSRα-tTA; tetO-cMYC*	Immunoglobulin *locus-MYC* translocation	24
Melanoma (Chapter 42)	Tetracycline-regulated oncogene expression (Dox on) in the absence of a tumor suppressor locus	*Tyr-rtTA; tetO-Hras^{G,2V}; Ink4a/Arf$^{-/-}$*	*INK4a/ARF* loss; N-RAS activation, B-RAF activation; *PTEN* loss; *MITF* amplification, *NEDD9* amplification	26
Pancreatic B-cell adenocarcinoma (Chapter 35)	Estrogen receptor–oncogene fusion regulated by tamoxifen and transgenic expression of a prosurvival gene	pIns-*cMycER^{TAM}*; RIP$_7$-*Bclx$_L$* with tamoxifen	*MEN$_1$* loss	32
Glioblastoma (Chapter 40)	Avian virus delivered oncogene in the absence of a tumor suppressor locus	Nestin-*tva; Ink4a/Arf$^{-/-}$* with RCAS-EGFR*	*INK4a/ARF* loss; *EGFR* amplification; *p53* loss, *RB$_1$* loss; *CDK4* amplification	16
Colon cancer (Chapter 34)	Mutation of a tumor suppressor gene	*APC$^{min/+}$; APC$^{Δ716/+}$; APC$^{1638N/+}$*	*APC*, *SMAD4*, and/or *p53* loss; active K-RAS, active N-RAS	96-98
Small-cell lung cancer (Chapter 32)	Deletion of two tumor suppressor genes with viral-Cre	*P53$^{flox/ftox}$; Rb$^{flox/ftox}$* with viral-Cre	*RB$_1$* loss and *p53* loss; *N-Myc* or *L-MYC* amplification	50
Acute myeloid leukemia (Chapter 28)	Conditional chromosomal translocation	*Mll$^{loxp/+}$; Enl^{loxp}/+; Lmo2$^{Cre/+}$*	Many different translocations, including the *MLL-ENL* translocation	44
Pancreatic ductal adenocarcinoma (Chapter 35)	Conditional activation of an endogenous oncogene and expression of a point mutant tumor suppressor gene	*Kras$^{LsL-G12D/+}$; p53$^{LsL-R172H/+}$;* Pdx1-Cre	Active K-RAS; *p53* loss, *SMAD4* loss	99
Non–small-cell lung cancer (Chapter 32)	Conditional activation of an endogenous oncogene and deletion of a tumor suppressor gene with viral-Cre	*Kras$^{LSL-G12D/+}$; p53$^{flox/flox}$* with viral-Cre	Active K-RAS; *p53* loss; *EGFR* activation and amplification	100
Head and neck squamous-cell carcinoma (Chapter 33)	Progesterone-regulated conditional activation of an endogenous oncogene and deletion of a tumor suppressor gene	*Kras$^{LSL-G12D/+}$; TGFβRII$^{flox/flox}$; K5-CrePR$_1$* with RU486	*p53* loss, *Ink4a/Arf* loss, *cyclin D$_1$* amplification, active K-RAS, active H-RAS	101

Oncogene Addiction

Mutation or overexpression of oncogenes can initiate tumor development. The use of tetracycline-regulated expression systems has documented the requirement for continued oncogene expression for growth and survival of established tumors and metastases.[22-28] Although most tumors undergo dramatic cell death and regress after oncogene inactivation, the regression is not always complete, and tumor subclones that escape the requirement for the initiating oncogene can recur (Figure 9-5).[55] Interestingly, in a model of MYC-induced hepatocellular carcinoma, MYC reactivation after tumor regression results in the development of tumors that are clonally related to the initial primary tumor, indicating that dormancy can also be a result of oncogene inactivation.[25] These dramatic results validate the future use of these models to predict the outcome of altering specific pathways predicted to influence tumor survival or progression. Clinically, pharmacologic oncogene inactivation can successfully reduce tumor growth, supporting the concept of oncogene addiction. In particular, a subset of non–small-cell lung cancer with mutant EGFR,[60,61] gastrointestinal stromal tumors with active/mutant c-Kit,[62] and chronic myeloid leukemia with the BCR-ABL translocation[63] have been successfully treated with small molecules targeting these driving oncogenes.

Oncogene Cooperation and Codependence

The hypothesis of a multistep model of tumorigenesis mediated by multiple genetic alterations raises the interesting question of how these genes cooperate to promote tumor development. In vitro studies in immortalized cell lines and primary fibroblasts were initially used to show the cooperativity of different oncogenes.[64] The tumor suppressor networks, the relationship between oncogenes and their target genes, and the cooperation of different genetic changes in promoting tumor initiation and progression have also been studied in vivo using genetic methods.[65-67]

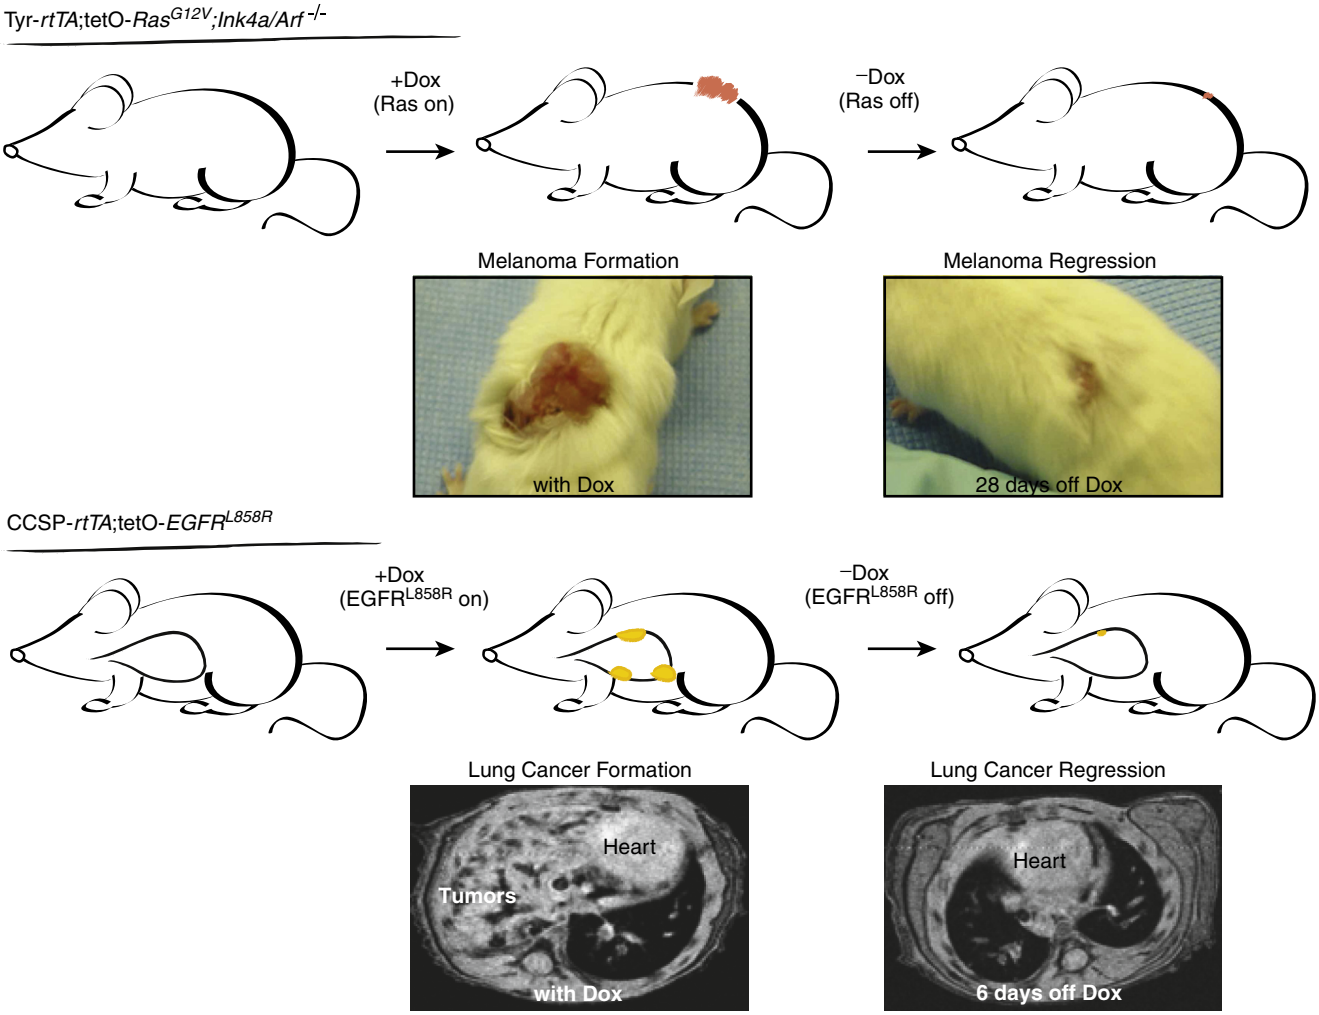

Figure 9-5 Oncogene addiction of mouse tumors predicts the outcome of therapeutic blockade of oncogene expression or activity
Melanocyte-specific oncogenic Ras expression leads to the formation of melanoma, which regresses when Ras is no longer expressed. Lung epithelial expression of an active point mutant of EGFR produces lung adenocarcinoma development. The maintenance of these lung tumors relies on the continued expression of the oncogene. *Melanoma images are courtesy Joseph Gans and Lynda Chin, Dana-Farber Cancer Institute, Harvard University. Lung adenocarcinoma images are courtesy Katerina Politi and Harold Varmus, Memorial Sloan-Kettering Cancer Center.)*

Genetic epistasis experiments in mice have identified several critical targets of specific oncogenes that mediate different aspects of tumorigenesis.[33,65,68] Moreover, genes that enhance or reduce the effect of tumor suppressor gene mutation and oncogene expression have also been identified.[66,67,69]

Future Directions of Cancer Models

The most advanced genetically engineered mouse models of human cancer reflect their human counterparts at the genetic and histologic levels. These mouse models are now poised to lead the way to the discovery of new genes and pathways dysregulated in cancer and aid in the development and screening of potential therapeutics.

In Vivo Screens

Transposon and retroviral insertional mutagenesis, short-interfering RNA (siRNA) libraries, and advances in the analysis of gene expression and genomic alteration allow mouse models to be used as tools in the discovery of new cancer genes and pathways. Each of these approaches has been used to identify genes that promote tumorigenesis.[70-79] Unlike chemical or physical mutagens, insertional mutagens allow the identification of mutated genes. By using these mutagens in sensitized backgrounds (e.g., loss of a tumor suppressor or expression of an oncogene), the genes that regulate tumor initiation, invasion, or metastasis can be identified. Whole-genome or focused siRNA and shRNA library screens for genes that influence transformation have been conducted in vitro[74-76] and in vivo.[80-82] Genes discovered by these methods can be confirmed in the

same tumor model in which they are found, and these unbiased approaches have begun to contribute to the identification of genes and pathways that are potential therapeutic targets.

Validation of Pharmaceutical Targets and Preclinical Trials

The development of new therapeutics requires carefully designed preclinical studies in models that most closely approximate human disease. Xenograft tumor models are the mainstay of current preclinical testing. Although several obstacles must be overcome before genetic mouse models can fully reach their potential in pharmacologic and biotechnological settings, these models may more accurately reflect the therapeutic response of patients.[7,8,83,84] The use of genetically defined mouse models may prioritize potential therapeutic compounds and stratify patients based on the mutational status of their tumors.[85] These efforts should accelerate the translation of novel therapies into the clinic.

Biomarkers for Early Tumor Detection

The detection of cancer at an early stage is of paramount importance, as patients diagnosed with early-stage disease invariably have a better prognosis. Unfortunately, there is a dearth of sensitive and reliable screening tests for most solid tumors. Here again, mouse models on inbred backgrounds with controllable and reproducible disease, coupled with advances in proteomic and molecular imaging technologies, may allow new diagnostic markers to be identified.[86]

Identification of the Cell of Origin

Spatial and temporal restriction of genetic alterations in mice also allow the initial events that are triggered by oncogene expression to be investigated and the cells that respond to these initial genetic lesions to be identified. Specific genetic manipulation in defined cell types can identify the cell type in a given tissue that is susceptible to oncogenic transformation.[87,88] Alternatively, analyzing the cells that respond after in vivo oncogene activation may identify the cells of origin.[89] The appeal of these approaches is not solely to identify tumor-initiating cells but also to allow their subsequent manipulation and the identification of critical pathways dysregulated in these cells.

Recruitment and Function of Immune, Vascular, and Stromal Cells in the Tumor Environment

It has become increasingly clear that tumor growth and progression are greatly influenced by surrounding nontumor cells, including various immune cell types, vascular cells, stromal fibroblasts, and myofibroblasts.[90,91] Mouse models in which each of these tumor cell populations can be manipulated independently allow the function of each cell type to be identified.[92] Moreover, molecules that regulate the recruitment, survival, and function of these cells within the tumor can be characterized in mouse models in vivo. The secreted and cell-surface molecules used by these cells to communicate with each other and with the tumor cells will lead to the identification of important regulators of tumor growth, angiogenesis, invasion, and metastasis.

Conclusions

Genetically engineered mouse models of human cancers are an important component of the arsenal of experimental systems that will allow the in vivo dissection of tumor biology over the next several decades. The versatility of mouse models that recapitulate human cancer will lead to timely identification and validation of therapeutic targets that will ultimately influence human health.

Cancer Stem Cells and the Microenvironment

Accumulating evidence suggests that most if not all tumors are maintained by a subpopulation of cells that display stem cell properties including self-renewal and lineage differentiation. Cancer stem cells (CSC) have been isolated from a number of human malignancies by using cell surface markers and enzymatic activity of cytoplasmic proteins. Subsequent characterization of these CSCs in mouse xenograft models revealed that these cells can mediate metastasis and contribute to treatment resistance and relapse. Furthermore, recent studies suggest that the CSCs are regulated by the components of tumor microenvironment through complex networks of cytokines and growth factors. Importantly, these components have a direct influence on CSC properties and thus may represent attractive targets for development of novel therapeutics. This chapter highlights advances in elucidating the networks between CSC and the tumor microenvironment and efforts to target these CSC regulatory networks.

Identification of Cancer Stem Cells

Embryonic and tissue-specific stem cells display two distinct properties: (1) self-renewal, or the ability of the cell to undergo several symmetric or asymmetric divisions while maintaining an undifferentiated cell pool; and (2) differentiation, or the ability to generate distinct cell types. Tissue-specific stem cells are distinguished from embryonic stem cells in that their differentiation is primarily limited to cell types of a particular organ. Tissue-specific stem cells have the capacity to self-renew as well as to differentiate into committed progenitors and terminally differentiated cells with specialized functions. There is increasing evidence that a similar hierarchy governs many human malignancies, including tumors of the hematopoietic system and solid organs. CSCs are operationally defined by their ability to initiate tumors in mice on serial passage, a demonstration of self-renewal, as well as their ability to differentiate into the non–self-renewing cells forming the tumor bulk.[1-3] Human CSC assays have used immunocompromised mice whereas mouse CSCs have also been identified via transplantation studies in syngeneic hosts.[4,5] In fact, these early studies on normal organ development and tumors suggested that the tumors are indeed organ-like structures resembling their normal counterparts in that they are both comprised of heterogeneous cell populations.

According to the CSC hypothesis, tumors are hierarchically organized whereby self-renewing CSCs drive tumorigenesis while differentiated cells form the tumor bulk.[6] The CSC model fundamentally differs from the traditional or "stochastic" model of carcinogenesis in which any cell may have equal malignant potential. Based on the stochastic model, most therapeutic strategies have been selected for their ability to cause tumor shrinkage by targeting rapidly cycling cells, whereas the CSC model predicts that targeting and elimination of self-renewing cancer stem cells will be necessary to significantly improve outcome and ultimately cure patients with cancer.

Despite the fact that the heterogeneity of tumor cells has been widely acknowledged, the CSC model was difficult to validate until appropriate mouse models were developed. The development of biomarkers to identify CSCs, as well as validation of in vitro and mouse models, has facilitated the isolation and characterization of these cells from both murine and human tumors. Bonnet and Dick were the first to describe the hierarchical organization of acute myeloid leukemia (AML) and the existence of CSCs[7] in that disease. The team isolated such cells from AML and demonstrated that a small subset of cells characterized by $CD34^+/CD38^-$ phenotype that made up less than 0.01% of tumor cells could transfer human AML into NOD/SCID mice, whereas the remaining cells that lacked this phenotype failed to do so.[7] Using similar techniques, CSCs have subsequently been isolated from many human

*Disclaimer: Max S. Wicha has financial holdings and is a scientific adviser for OncoMed Pharmaceuticals, is a scientific adviser for Veristem, and has research support from Dompe.

malignancies, including those of the brain, breast, colon, prostate, pancreas, lung, and liver.[3,8-14]

Examples of Cancer Stem Cells

Uchida and colleagues described a phenotype, $CD133^+$ $CD34^-CD45^-$, that is characterized by the expression of a cell surface antigen—Prominin-1 (CD133), a five-transmembrane glycoprotein—and lack of CD34 and CD45 to isolate human central nervous system stem cells.[15] Brain tumors displayed a cellular hierarchy reminiscent of their normal counterparts, in which $CD133^+$ tumor cells but not $CD133^-$ cells were able to form tumors in NOD-SCID mouse brains and neurospheres in in vitro cultures.[15]

A subpopulation of breast cancer cells that displayed stem cell properties was characterized by expression of the cell surface markers ESA (EpCam) and CD44 in the absence of CD24 expression.[3] As few as 200 $EpCam^+CD44^+/CD24^-Lin^-$ cells were able to generate tumors in immunocompromised NOD/SCID mice, whereas 100-fold more cells that did not express these markers isolated from the same tumors were nontumorigenic.[3] Furthermore, the tumor-initiating populations regenerated tumors that recapitulated the heterogeneity of the initial tumor.[3] Subsequently, both normal and malignant mammary stem cells were isolated by virtue of their increased expression of aldehyde dehydrogenase (ALDH), which can be accessed by Aldefluor assay.[2] Interestingly, $CD44^+/CD24^-$ and $ALDH^+$ identify overlapping but not identical cell populations.[2,16] Furthermore, these markers can be used to isolate CSC populations from established breast cancer cell lines, as well as primary tumor xenografts.[2,17]

In the normal prostate, $CD133^+$ cells have been shown to display properties of stem cells,[18] whereas the $CD44^+/\alpha2\beta1^{hi}/CD133^+$ phenotype (about 0.1% of the total tumor cells) marked prostate cancer stem cells.[19] As few as 500 cells with this phenotype were able to form tumors in mice, whereas 5×10^5 cells that lacked this phenotype failed to generate tumors.

Distinct pulmonary epithelial cells located at the bronchioalveolar ductal junction displayed functional stem cell properties in mouse models.[20] These cells, characterized by the $Sca1^+/CD34^+/CD45^-/Pecam^-$ phenotype, were able to generate lung epithelium after tissue damage, suggesting that these cells possess self-renewal and lineage differentiation properties. Furthermore, in K-Ras–induced mouse lung adenocarcinoma, a $Sca1^+/CD34^+/CD45^-/Pecam^-$ phenotype identified lung cancer stem cells capable of initiating tumors when transplanted into syngeneic mice.[20] In addition, human lung cancers contain a rare population of cells that express CD133[8] and ALDH1.[21] These cells are able to initiate tumors as well as to generate differentiated cells in mouse xenografts.

Tumor-initiating cells have also been isolated in colorectal tumors. Ricci-Vitiani and co-workers and O'Brien and colleagues, isolated $CD133^+$ human colon cancer cells and injected them subcutaneously or under the renal capsule of NOD-SCID mice.[12,13] Both groups demonstrated that $CD133^+$ cells not only were capable of forming tumors, but also generated tumors that recapitulated the cellular heterogeneity of the initiated tumors. In contrast, $CD133^-$ cells lacked these properties, suggesting that the capabilities of self-renewal and lineage differentiation are required for tumor initiation as well as generating non–self-renewing cells that constitute the tumor bulk.

Human pancreatic carcinomas contain a subpopulation of cells with a $CD44^+/CD24^+/ESA^+$ phenotype (0.2% to 0.8%) that were 100-fold more tumorigenic than those that did not express these markers.[11] These pancreatic CSCs also displayed activation of developmental pathways such as sonic hedgehog.

Human liver cancer stem cells characterized by the expression of CD133 demonstrated self-renewal potential, increased colony-forming ability, and tumor formation in mouse xenografts.[14] In addition, liver tumor cells that express CD90 (Thy1), glycosylphosphatidylinositol-anchored glycoprotein, and CD44 have been shown to be able to initiate tumors that are capable of metastasis in immunodeficient mice.[23]

The Origins of Cancer Stem Cells

The use of transplantation models to identify and characterize tumor-initiating cell populations has been criticized because these studies involve introducing cells into an environment that may differ from that found in de novo tumor initiation. However, several recent studies have used in situ lineage tracing directly to address this concern. These studies have demonstrated the generation of CSCs from tissue stem cells in mouse models of skin, gut, and brain.[24-26] Expression of the Wnt target Lgr5 marks intestinal stem cells and by using lineage tracing Schepers et al. demonstrated that Lgr5 expression also identifies a subpopulation (5-10%) of growing intestinal adenomas in mice. These $Lgr5^+$ cells self-renew to generate additional $Lgr5^+$ cells as well as other $Lgr5^-$ lineages.[24] Driessens and associates employed a similar genetic lineage tracing approach to mark individual skin papilloma cells and traced lineages derived from these cells at different stages of tumor progression in mice. Interestingly, a majority of labeled cells displayed limited proliferative potential, whereas a fraction of tumor cells were long lived and gave rise to progeny that formed the tumor bulk.[25]

Patients with glioblastoma have a median survival of about 1 year because of therapeutic resistance and recurrence after tumor resection. In order to understand the nature of cells that are responsible for relapse, Chen and colleagues used a genetically engineered mouse model of glioblastoma to demonstrate that repopulating tumor cells were nestin-positive cancer stem cells located in the subventricular zone.[26] These nestin-expressing glioblastoma cells were resistant to chemotherapy and repopulated the tumor after therapy. Together, these studies provide strong support for the cancer stem cell model by demonstrating cellular hierarchies in tumors that develop in situ without the requirement for transplantation.

Regulation of Cancer Stem Cells by the Tumor Microenvironment and Cytokine Networks

Although the preponderance of cancer research has focused on genetic alterations that initiate and drive cancer, there is substantial evidence that malignant transformation and tumor progression are also highly influenced by the tumor microenvironment. This research has suggested that tumors are in effect "organ-like structures" composed of different cell types whose interaction is required to drive and promote tumor growth and metastasis. In normal tissues, a small number of stem cells have the capacity to self-renew as well as to differentiate into multiple lineages. A similar hierarchy governs many human malignancies, including the tumors of the hematopoietic system and solid organs. Analogous to the regulation of normal stem cells by their "niche," CSCs are regulated by, and in turn, regulate, cells within the tumor microenvironment. Cells recruited to the microenvironment, including mesenchymal stem cells (MSCs), tissue-associated fibroblasts, and endothelial cells, interact with CSCs via growth factor and cytokine networks (Figure 10-1). Furthermore, immunomodulatory cells, including T cells and macrophages, exert both inhibitory and stimulatory effects on CSCs and their progeny. In addition, chronic inflammation characterized by increased generation of inflammatory cytokines such as IL-1, IL-6, and IL-8 may also regulate CSCs during carcinogenesis.[27-29] The interaction between CSCs and their microenvironment provides new targets for therapeutic intervention.

Emerging evidence also implicates CSCs in tumor metastasis and therapeutic resistance,[30-33] and therefore understanding the pathways that regulate this cell population is of clinical importance. As is the case with their

Figure 10-1 The tumor microenvironment Elevated levels of cytokines/growth factors produced by tumor cells enhance the proliferation and survival of cancer stem cells, induce angiogenesis, and recruit tumor-associated macrophages, neutrophils, and mast cells, which secrete additional growth factors, forming a positive feedback loop that promotes tumor cell invasion and distant metastasis.

normal counterparts, CSCs are regulated by intrinsic as well as extrinsic signals originating in the tumor microenvironment.[34] Epigenetic and genetic changes that occur during carcinogenesis modulate these regulatory signals within the tumor microenvironment.[35,36] Stem cell regulatory pathways frequently dysregulated in tumors include the Notch, Hedgehog, Wnt, PI-3K, NFκB, and Jak/STAT pathways.[16,37-40] Although these pathways are activated in some tumors via mutation of key regulatory elements, they are more often activated by signals from the tumor microenvironment.[41,42] Bi-directional paracrine signaling networks coordinately regulate tumorigenic cell populations, including cancer stem cells.[37,43-45] Tumor cells in turn produce factors that attract and regulate the diverse variety of cell types constituting the tumor microenvironment.[43,45] Interestingly, many of the pathways activated during tumor formation resemble those that mediate normal wound healing, including cytokine loops that in turn are regulated by the transcription factor NFκB.[37] In addition, immunomodulatory cells may manifest stimulatory or inhibitory effects on tumor progression.[46,47] Diverse cell populations within the tumor microenvironment may impinge on these pathways to regulate the CSC population. Elucidation of these networks is of clinical importance because it may allow for the identification of novel therapeutic targets and the development of strategies to target CSC populations.

Cellular Components of the Tumor Microenvironment That Influence Cancer Stem Cells

During tumor progression, tumor cells recruit a diverse collection of cells that make up the microenvironment, and through iterative interactions both the tumor cell and its microenvironment co-evolve.[42] For example, because of increased oxidative stress in the prostate tumor microenvironment, stromal cells acquire the ability to mimic other cell types such as mesenchymal and vascular stem cells.[48] Although early studies suggested that some of the cells in the tumor microenvironment harbored mutations,[22] more recent evidence suggests that mutations are limited to the tumorigenic cells, which through paracrine interactions modify the epigenetic program of nontumorigenic cells in the tumor microenvironment.[22,41,49,50] The cells in the microenvironment in turn interact with and generate epigenetic changes in tumor cells.[41,42] This reciprocal interaction is illustrated by changes in the tumor microenvironment that occur during the evolution of preinvasive ductal carcinoma in situ to invasive carcinoma of the breast, which involves sequential epigenetic changes in both the tumor as well as the stromal microenvironment.[41,42] Human bone stromal cells were able to induce aggressive mouse prostate tumors that acquired an EMT phenotype associated with resistance to radiation therapy.[51]

In human breast cancers, mesenchymal cells are recruited from the bone marrow[43] or from the normal breast stroma.[45] As is the case in breast cancer cells, ALDH expression is elevated in MSCs that are recruited from the bone marrow. These MSCs interact with breast CSCs through cytokine loops involving IL6 and CXCL7.[43] These cytokine loops stimulate the self-renewal of breast CSCs.[43] Immunohistochemical analysis has confirmed the existence of such MSC–breast CSC interactions in biopsies obtained from breast cancer patients.[43] In addition, MSCs have the ability to differentiate into adipocytes as well as tumor-associated fibroblasts that also interact with and influence tumor cells.[52]

The activation of fibroblasts and myofibroblasts was originally described in a study of wound healing by Gabbiani and Majno, who observed morphological changes in activated myofibroblasts compared to quiescent tumor- and wound-associated fibroblasts.[53] Based on the similarities between the wound healing process and cancer, both of which involve infiltration of inflammatory cells and activation of cytokine networks, it was proposed that malignant tumor cells are "wounds that don't heal."[54] It appears that the persistence of a wound healing environment promotes the persistence and/or expansion of CSCs. In an experimental mouse model, acute wounding in the mammary gland by dermal incision accelerated breast tumor growth and metastasis.[55] Although the exact mechanisms remain unknown, paracrine signals from evolving tumors induce epigenetic changes in the surrounding stromal fibroblasts.[56] Indeed, the gene expression profile of tumor-associated fibroblasts resembles that of wound-activated fibroblasts, and this profile is associated with poor prognosis.[57,58] Growth factors such as TGF-β may be involved in these epigenetic changes, leading to activation of fibroblasts.[59] In addition, cytokines such as SDF-1 (aka CXCL-12) produced by breast carcinoma–associated fibroblasts (but not normal fibroblasts) may promote the proliferation of tumor cells, which express the SDF-1 receptor CXCR4.[60] The level of expression of SDF-1 in serum has been associated with poor survival in breast cancer patients.[61,62] Other growth factors such as hepatocyte growth factor (HGF), produced by mammary stromal cells, may also have a profound effect on developing mammary tumors, possibly inducing the stem cell compartment.[63] HGF provides a co-stimulatory signal to the Wnt pathway during colon carcinogenesis.[64] Other important growth factors produced by activated fibroblasts include the fibroblast growth factors (FGFs). Cancer stem cells can use oxidative stress to drive stromal fibroblasts to produce necessary nutrients for their survival.[65] It has recently been shown that estrogen regulates

the breast CSC population through a paracrine mechanism involving FGF9.[66] Additional factors produced by stromal cells in the tumor microenvironment activate a number of pathways including IGF, PDGF, Wnt, NFκB, Notch, Hedgehog, and matrix metalloproteinases (MMPs) regulating tumor proliferation, invasion, and metastasis.[67-72] These pathways also have been implicated in regulating CSCs in a number of human malignancies.[37,40,73-76]

Immunomodulatory cells may also exert inhibitory and stimulatory effects on CSCs, and the ultimate balance of these effects may profoundly influence tumor growth/progression. The importance of the immune system is illustrated by recent studies elucidating the mechanisms by which macrophages recognize and destroy CSCs. Recent studies in human leukemia and lymphoma have suggested that tumor cells express the antigen CD47, which serves as a "don't eat me" signal to tumor-associated macrophages.[77] At the same time, these cells express calreticulin, recognized by these macrophages as an "eat me" signal.[78] Administration of a blocking antibody to CD47 induced macrophage phagocytosis of tumor cells in vitro and in mouse models. Importantly, it was demonstrated that leukemic stem cells as well as bulk tumor cells could be targeted by this approach.[78,79] Interestingly, CD47 is widely expressed in a number of solid tumor CSCs, and targeting of this molecule suppresses tumor growth and metastasis in mouse tumor models.[80]

Endothelial cells may also play an important role in the tumor microenvironment by directly interacting with tumor cells as well as by their role in blood vessel formation. Endothelial cells constitute an important component of normal hematopoietic and neuronal stem cell niches.[81,82] In addition, cytokines produced by endothelial cells directly regulate cancer stem cells.[83,84] More than 40 years ago, Judah Folkman proposed that angiogenesis, the process of new blood vessel formation, was required for tumor growth and metastasis.[85] The role of tumor angiogenesis has been demonstrated in preclinical models of many cancers, including those of the breast.[86] This has led to the development of a number of anti-angiogenic agents as cancer therapeutics. Angiogenesis is a complex process involving interactions among multiple cell types. Bone marrow–derived endothelial progenitor cells are attracted to tumors, where they differentiate into mature endothelial cells and capillaries.[87,88] These newly formed blood vessels carry oxygen and nutrients to growing tumors, facilitating progression and metastasis (see Figure 10-1). Interestingly, the tumor vasculature is vastly different from the normal vasculature, as illustrated by the finding that more than 1000 genes are differentially expressed, including FGFRs, MMPs, and JAK3.[83] Although preneoplastic lesions lack angiogenic capacity, transition from hyperplasia to neoplasia requires induction of angiogenesis, a process that may be regulated by NFκB.[89,90]

Tumors may also generate a vasculature by a process termed *vasculogenic mimicry* in which CSCs transdifferentiate into vessel-forming cells that resemble endothelium. Recent reports have demonstrated that glioblastoma CSCs are multipotent and can differentiate into endothelial cells, generating their own vasculature.[91,92] Although many pro-angiogenic factors have been identified, vascular endothelial growth factor (VEGF) is the primary mediator of this process,[93] and as a result it has been the principal target of anti-angiogenic therapies. A humanized monoclonal antibody targeting VEGF, bevacizumab, as well as two multikinase VEGF inhibitors, sorafenib and sunitinib, are currently approved for clinical use. These anti-angiogenic agents have shown utility in a number of tumor types, including renal and colon cancers.[94,95]

Bevacizumab was initially approved for use in metastatic breast cancer on the basis of reports demonstrating that it prolonged time to tumor progression.[96] However, more recent studies (AVADO and RIBBON1) have suggested that this effect is limited and that the addition of bevacizumab to cytotoxic chemotherapy failed to increase patient survival.[97] These results are consistent with reports in mouse models that anti-angiogenic agents may accelerate local breast cancer invasion and distant metastasis.[98,99] In mice bearing human breast cancer xenografts, these agents increase the CSC population through the generation of tissue hypoxia[100] and activation of HIF1α-Wnt signaling. Anti-angiogenic agents may also stimulate CSC expansion by increasing HGF production by tumor stromal cells.[101] These studies provide a rationale for the addition of CSC targeting agents to anti-angiogenic agents to improve clinical efficacy.

Cytokine Networks Can Promote Cancer Stem Cell Self-Renewal

The link between inflammation and cancer is an old concept that was first proposed by Virchow in 1864, when he observed that inflammatory cells frequently infiltrate the tumor stroma.[102] Considerable clinical evidence suggests links between inflammatory states and cancer development, including the well-documented association of ulcerative colitis, hepatitis C, and chronic pancreatitis with cancers of the colon, liver, and pancreas, respectively.[102] States of chronic inflammation as assessed by serum C reactive protein or β amyloid are correlated with risk of breast cancer recurrence in women after primary therapy.[103] This chronic inflammatory state may be mediated by cytokines including IL-1β, IL-6, and IL-8.[27] Genetic polymorphisms in these cytokine genes predispose affected individuals to cancer.[104] These inflammatory cytokines stimulate CSC self-renewal, which then may promote tumor growth and metastasis.[44,105]

IL-6 and IL-8 have been implicated both in chronic inflammation and in tumor growth.[106,107] Within the tumor microenvironment, many cell types, including mesenchymal cells, macrophages, and immune cells, secrete both IL-6 and IL-8.[106] In patients with advanced breast cancer, the serum levels of both of these cytokines have been associated with poor patient outcome.[108,109] In a variety of preclinical models, IL-6 has been shown to promote tumorigenicity, angiogenesis, and metastasis.[44,110-112] IL-6 has been shown to be a direct regulator of breast CSC self-renewal, a process mediated by the IL-6 receptor/GP130 complex through activation of STAT3.[37] Using mouse xenografts, we have recently demonstrated that bone marrow–derived MSCs are recruited to sites of growing breast cancers by gradients of IL-6.[43] IL-6 is a key component of a positive feedback loop involving these MSCs and CSCs.[43] Furthermore, Sethi and colleagues recently demonstrated that IL-6–mediated Jagged1/Notch signaling promotes breast cancer bone metastasis.[73] These studies identify IL-6 and its receptor as attractive therapeutic targets to deplete CSCs.

Using gene expression profiling we previously demonstrated that the IL-8 receptor CXCR1 is highly expressed on breast CSCs[105]. Interestingly, cytotoxic chemotherapy induced cell death in differentiated cancer cells that resulted in increased production of IL-8, which in turn stimulated breast CSCs via activating CXCR1. A small-molecule CXCR1 inhibitor, reparaxin, significantly reduced CSC in breast cancer xenografts, inhibiting tumor growth and metastasis. Based on these preclinical studies, a clinical trial using reparaxin combined with established chemotherapy has been initiated.

The production of inflammatory cytokines including IL-6 and IL-8 is regulated by the NFκB signaling pathway.[113] The NFκB pathway plays a crucial role in inflammation and carcinogenesis. The NFκB family is composed of five related transcription factors: p50, p52, RelA (p65), c-Rel, and RelB.[114,115] In resting cells, NFκB proteins are predominantly located in the cytoplasm where they associate with the IκB family of proteins; activation of NFκB by diverse signals results in ubiquitin ligase–dependent degradation of IκB, which results in nuclear translocation of NFκB protein complexes. The transcription of a number of cytokines, including IL-6 and IL-8, is activated by NFκB.[113] In addition, a positive feedback loop maintains a chronic inflammatory state in tumor cells. Interestingly, this loop involves the microRNA let7, as well as Lin28, a factor involved in embryonic stem cell self-renewal.[37] This feedback loop is maintained by IL-6 through its activation of Stat3, which in turn activates NFκB and its downstream targets Lin28 and let7. The specific role of IL-6 in maintaining this inflammatory loop in BCSCs has been recently demonstrated.[37,40] NFκB may play an important role in normal breast physiology as well as carcinogenesis. In a HER2/neu mouse model of mammary carcinogenesis, suppression of NFκB in mammary epithelium reduced the mammary stem cell compartment, resulting in a delayed generation of HER2-neu–induced tumors, which displayed reduced angiogenesis and infiltration by macrophages.[90] NFκB has also been implicated in the regulation of mouse mammary stem cells during pregnancy. Elevated levels of progesterone during pregnancy induce the production of RANK ligand (RANKL) by differentiated breast epithelial cells. RANKL in turn stimulates breast stem cell self-renewal via activation of NFκB in these cells.[116,117] The increased incidence of aggressive breast cancers associated with pregnancy[118] may result from activation of these pathways in breast CSCs.[116,117]

Epidemiologic studies demonstrate that obesity is associated with a significant increase in postmenopausal breast cancer,[119,120] which may be related to the known link between obesity and inflammation.[121-124] Patients with type 2 diabetes mellitus (T2DM) have elevated levels of circulating proinflammatory cytokines including TNF-α, IL-6, and C-reactive protein.[125] In addition, these elevated levels of proinflammatory cytokines have been linked to NFκB activation.[126] The diabetes drug metformin reduces levels of circulating glucose, increases insulin sensitivity, and reduces insulin resistance-associated hyperinsulinemia. Interestingly, in preclinical mouse models, metformin has been shown to selectively inhibit CSC self-renewal, reducing the proliferation of these cells in breast tumors.[127]

Summary

As organ-like structures, tumors are composed of diverse cellular compartments and networks that play important roles in tumor progression. Accumulating evidence suggests that these cellular components and cytokine networks also regulate CSCs, which in turn drive tumor growth and metastasis. One can reframe Paget's "seed and soil" hypothesis of tumor metastasis[128] in a modern context. The "seeds" are the cancer stem cells, and the "soil" is the rich microenvironment composed of diverse cell types that interact with tumor cells via growth factor and cytokine networks (see Figure 10-1). These networks regulate CSCs and their progeny, which propagate CSC as well as generating non–self-renewing cells that constitute the tumor bulk. Studies in preclinical models have demonstrated that targeting of regulatory pathways such as IL-6, IL-8, and NFκB can effectively reduce the CSC populations in breast cancer as well as other tumor types.

Regulation of the Cell Cycle

Basic Principles of Cell Cycle Progression

The essential function of cell cycle control is the regulated duplication of the cells' genetic blueprint and the division of this genetic material such that one copy is provided to each daughter cell following division. The cell cycle can be divided conceptually into four individual phases. The "business" phases include *S phase* or synthesis phase, which is the period during which DNA is replicated, and mitosis (*M phase*), where DNA is packaged, the cells divide, and DNA is distributed to daughter cells. S phase and M phase are separated by Gap phases (G phase) to provide the cell with a proofreading period to ensure that DNA replication is completed and packaged appropriately prior to division. Separating M phase from S phase is the first Gap phase (G_1 phase) and separating S phase from M phase is the second Gap phase (G_2 phase). G_0 or *quiescence* occurs when cells exit the cell cycle because of the absence of growth-promoting signals or the presence of prodifferentiation signals. Ordered progression through each phase is intricately regulated through both positive and negative regulatory signaling molecules and is the basis of normal organismal development. The consequences of deregulated growth control include failed or altered development and/or neoplastic/cancerous growth. Over the past two decades, a detailed picture of the major regulators of cell cycle control in both model organisms and higher eukaryotes has evolved. In this chapter, we describe the major regulators of cell division control and introduce current concepts regarding their participation in cell growth.

The Cyclin-Dependent Kinases

Cell cycle progression is positively regulated by a family of protein kinases referred to as the *cyclin-dependent kinases* (CDKs). In yeast, the organism in which early groundbreaking work defined many major cell cycle regulators, a single CDK regulates cell division: CDC2 (*Schizosaccharomyces pombe*, fission yeast) and CDC28 (*Saccharomyces cerevisiae*, budding yeast). In contrast, multicellular organisms use a distinct CDK whose activity promotes transition through each cell cycle phase (Figure 11-1). CDKs are binary enzymes. The catalytic subunit, the CDK, coordinates adenosine triphosphate (ATP) and transfers phosphate to appropriate substrates. As a monomer, the CDK has no enzymatic activity; activation requires association with a specific allosteric activator called a *cyclin*. CDK subunits associate with specific cyclins (Table 11-1) during distinct phases of the cell cycle and, as active protein kinases, trigger transition through cell cycle phases. Although some CDKs can form complexes with multiple cyclins, in most cases active complexes rely on specific partnerships.

Homology among CDKs, at the level of primary amino acid sequence, is in the range of 30% to 40%. The most highly conserved sequence, which contributes directly to cyclin binding, is the PSTAIRE sequence (CDK1, CDK2) or PV/ISTVRE (CDK4, CDK6) where letters refer to individual amino acids comprising this sequence (e.g., P = proline).[1]

Cyclins associate with the CDK subunit through a conserved domain within the cyclin called the *cyclin box*. The crystal structure of cyclins has revealed that the cyclin box comprises two sets of five α helices that share little primary homology, but share significant homology with respect to structural and folding topology.[2] Sequences N- and C-terminal to the cyclin box share little if any homology and contribute to substrate-specific interactions and to posttranslational regulation of cyclin protein accumulation (e.g., protein degradation).

Posttranslational Regulation of CDKs

Regulation of CDKs by Phosphorylation

Cyclin binding to the CDK contributes to kinase activation by inducing a conformational change wherein a C-terminal

CDK, Cyclin-dependent kinase.

domain of the CDK, referred to as the *T loop*, is directed out of the substrate binding cleft.[3] In the absence of cyclin binding, the T loop occludes substrate interactions. The cyclin-induced alteration, however, is not sufficient for complete CDK activation. T-loop displacement is ensured by direct phosphorylation of a conserved threonine residue within the T loop (Thr161, CDK1; Thr160, CDK2; Thr172, CDK4) by the CDK-activating kinase, CAK (Figure 11-2). In mammalian cells, CAK itself is a cyclin-dependent kinase composed of CDK7 and cyclin H.[4] CAK is constitutively active and contributes to CDK activation following cyclin binding via phosphorylation of the T-loop threonine.

Shortly after the identification of CDK7/cyclin H as CAK, CDK7/cyclin H was shown to be the previously identified activity referred to as *TFIIH*,[5] demonstrating that CAK (CDK7/cyclin H) not only contributes to CDK activation but is also implicated in transcriptional regulation. TFIIH phosphorylates multiple serine/threonine residues located in the carboxyl-terminal domain (CTD) of the largest subunit of RNA polymerase II (RNAPII), thereby contributing to increased transcriptional initiation.[5,6] CDK7 is also conserved in budding yeast. However, in yeast, CDK7 does not contribute to CDK activation. Rather, it is solely a

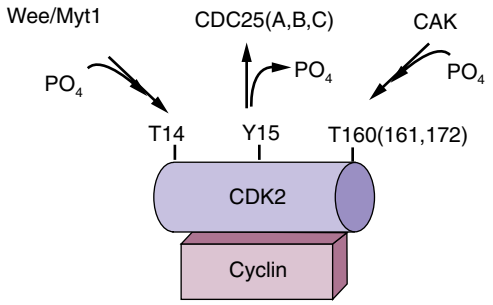

Figure 11-2 Regulation of cyclin-dependent kinase (CDK) CDKs are binary enzymes composed of a catalytic subunit, CDK, and a regulatory subunit, cyclin. Activation requires phosphorylation of a C-terminal threonine by the CDK-activating enzyme, CAK. In contrast, phosphorylation of N-terminal threonine and tyrosine residues inhibits adenosine triphosphate (ATP) binding and thus CDK activity.

regulator of RNA polymerase activity. Bona fide CAK activity in yeast is contributed by a distinct protein, CAK1.[7,8]

CDK phosphorylation is not solely an activating event. Phosphorylation of N-terminal threonine and tyrosine residues near the ATP binding pocket is inhibitory. Phosphorylation of threonine 14/tyrosine 15 is catalyzed by two enzymes, Wee1 and Myt1 (see Figure 11-2). Although Wee1 is a cytosolic enzyme, Myt1 is localized to endoplasmic reticulum structures.[9] The significance of the differential localization of Wee1 versus Myt1 remains to be established. Threonine 14/tyrosine 15 is located adjacent to the ATP binding pocket of CDKs, providing a structural basis for how phosphorylation of these residues prevents ATP binding.[10] Both threonine and tyrosine residues are conserved in CDK1-3, but only the tyrosine residue is present in CDK4-6. Although phosphorylation of CDK1-2 contributes to the timing of their activation during a normal cell cycle, the CDK4/6 enzymes appear to be subject to this inhibitory phosphorylation only when cells incur DNA damage.[11]

In mammalian cells, the removal of N-terminal inhibitory phosphates is catalyzed by any one of three highly related dual-specificity protein phosphatases: CDC25A, CDC25B, or CDC25C.[12] In contrast, yeast cells harbor a single CDC25 isoform that carries out all relevant functions. CDC25 isoforms are expressed in a cell cycle–dependent manner, and the A-B-C designation corresponds to their order of expression during the cell cycle. CDC25 A is expressed first, with its expression peaking at the G_1/S boundary. CDC25B expression follows that of CDC25A, with the highest levels detected during S phase. Finally, CDC25C is expressed during late G_2 and mitosis. From this expression pattern, substrate specificity was inferred, with CDC25A targeting the G_1 CDK_S (CDK4/6 or CDK2-cyclin E), CDC25B regulating the S-phase CDKs (CDK2-cyclin A), and CDC25C regulating mitotic CDKs (CDK1-cyclin B). Consistent with this hypothesis, inhibition of CDC25A resulted in increased CDK2-cyclin E tyrosine phosphorylation.[13] Also consistent

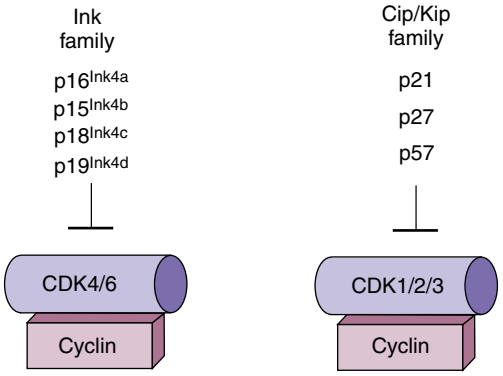

Figure 11-3 Regulation of cyclin-dependent kinases (CDKs) by polypeptide inhibitors Two distinct families of CDK inhibitors (CKIs) regulate CDK activity. The Cip/ Kip family binds with varying affinities to all CDK/cyclin complexes, but have the greatest inhibitory activity toward CDK2. The Ink4 family (inhibitor of CDK4/6) binds specifically to CDK4/6 and has no capacity to directly regulate other CDKs.

with substrate specificity being determined by the timing of expression, CDC25 enzymes do not exhibit any specificity toward distinct CDK substrates in vitro. However, timing of expression is not the sole determinant. Deletion of CDC25B or CDC25C, or even the combined deletion does not impair mouse development or cell proliferation in vitro.[14] It appears from this analysis that CDC25A expression is sufficient to drive cell cycle expression.

CDK Regulation by Small-Polypeptide Inhibitors

In addition to CDK regulation via phosphorylation, CDKs are subject to direct regulation by small-polypeptide inhibitory proteins referred to as *CDK inhibitors*, or CKIs (Figure 11-3).[15] These regulators bind directly to and inactivate CDK-cyclin complexes. There are two families of CKIs that have distinct biochemical activities. The *Ink4* (inhibitors of CDK4) family proteins bind exclusively to G_1 CDKs CDK4 and CDK6. Binding can directly inhibit an active CDK4/6-cyclin complex, or Ink4 protein can bind to monomeric CDK4/6 and prevent cyclin association. The second family, *Cip/Kip* family proteins, bind to a broad range of CDK-cyclin complexes but functionally appear to be negative regulators of CDK2 complexes.

Ink4 Family

The Ink4 family of proteins consists of four members: $p16^{Ink4a}$, $p15^{Ink4b}$, $p18^{Ink4c}$, and $p19^{Ink4d}$. All four proteins bind exclusively to and inhibit D-type cyclin-dependent kinases CDK4 and CDK6. The founding member of the Ink4a family was discovered as a protein that interacted with CDK4 in co-immunoprecipitation experiments,[16] subsequently identified as MTS1.

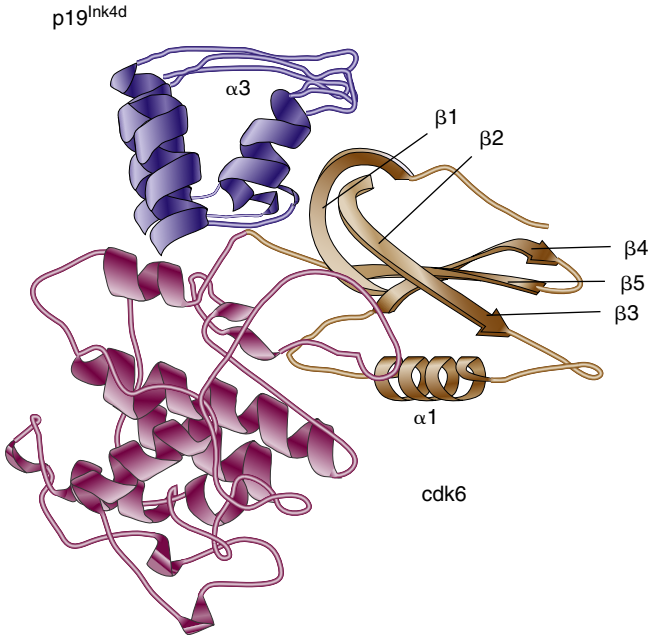

Figure 11-4 Three-dimensional structure of the $p19^{Ink4d}$/Cdk6 complex $p19^{Ink4d}$ is dark blue, apart from helix α3, which is light blue. The C-terminal domain of Cdk6 is dark brown, whereas the N-terminal domain, which undergoes extensive movement, is light brown.

Ink4 proteins are homologous in primary structure, sharing the presence of four or five ankyrin repeats, which are responsible for protein-protein interactions with CDK4/6. Each repeat consists of an extended strand connected by a *helix-loop-helix* (HLH) motif to the next extended strand. The crystal structure of the $p19^{Ink4d}$-CDK6 complex has been solved and provided valuable details about the mechanism of CDK inhibition by Ink proteins (Figure 11-4).[17] α-Helices and β-turns of $p19^{Ink4d}$ ankyrin repeats form a "cap" over the N-terminal domain of CDK6 and induce its spatial movement away from the C terminus. This event inhibits productive ATP binding but does not interfere with the formation of CDK-cyclin complex. As expected from their structure, all four Ink proteins exhibit similar biochemical activities toward CDK4 and CDK6. Interestingly, a short peptide that was derived from one of the ankyrin motifs had the ability to bind and inhibit CDK4, implying the importance of these domains in Ink4 functionality.[18]

Despite similar biochemical activities and comparable tertiary structures of Ink proteins, their regulation is distinct. $p16^{Ink4a}$ is not expressed in most tissues. Rather, it is induced in response to expression of oncogenic or transforming proteins and during cellular senescence. Several oncogenes as well as tumor suppressors regulate $p16^{Ink4a}$ expression. For example, overexpression of Ras increases $p16^{Ink4a}$ levels in primary rodent cells.[19] Inactivation of the retinoblastoma susceptibility protein, Rb, or tumor suppressor p53 can also promote $p16^{Ink4a}$ expression.[20] In contrast, $p15^{Ink4b}$ expression is regulated by growth-inhibitory factors

(anti-mitogens) such as TGF-β. Only $p18^{Ink4c}$ and $p19^{Ink4d}$ expression seems to be regulated during various phases of the cell cycle, with expression peaking during S phase.[21] The expression patterns of Ink4 proteins are also differentially regulated during development.

The structure of the genomic Ink4a locus is unique. Transcription through this locus gives rise to two biochemically distinct proteins, $p16^{Ink4a}$ and $p19^{ARF}$, as a result of alternative exon utilization.[22] Although $p16^{Ink4a}$ regulates CDK4/CDK6 activity, thereby indirectly regulating the Rb tumor suppressor, $p19^{ARF}$ regulates the p53 tumor suppressor.[23] $p19^{ARF}$ acts by attenuating Mdm2-mediated degradation of p53 and is known as an activator of the p53 pathway. Therefore, loss of $p19^{ARF}$ leads to impairment of p53 signaling. Elimination of the Ink4a/ARF genetic locus in mice makes the animals highly prone to tumor development.[24]

Cip/Kip Family

The Cip/Kip family of CKIs includes three members: $p21^{Cip1}$, $p27^{Kip1}$, and $p57^{Kip2}$. Unlike the Ink4 family of CKIs, Cip/Kip inhibitors bind to and efficiently inhibit various CDKs. Members of the Cip/Kip family are highly homologous and share approximately 50% of their sequences. The amino terminus of both $p21^{Cip1}$ and $p27^{Kip1}$ contains an RXL (where X is typically basic) sequence that is responsible for binding to cyclins and is called the *cyclin-binding motif*. Cip/Kip inhibitors also contain a domain that is responsible for the binding to CDKs (N-terminal in $p21^{Cip1}$ and $p27^{Kip1}$).[25] The crystal structure of the $p27^{Kip1}$/cyclin A/cdk2 complex (Figure 11-5) revealed that $p27^{Kip1}$ binds CDK2 at its N terminus and inserts into the catalytic cleft, thus mimicking ATP.[26] On cyclin A/CDK2, $p27^{Kip1}$ binds to the groove of the cyclin box. Because both Ink and Cip/Kip proteins occupy almost the same binding sites on CDKs, binding is mutually exclusive. For example, in vitro, $p15^{Ink4b}$ inhibits binding of $p27^{Kip1}$. However, in cells, which protein gets to the CDK first is often determined by the coordinated cellular localization of the inhibitors and cyclin-CDK complexes.

$p27^{Kip1}$ is responsible for induction and maintenance of the quiescent state. $p27^{Kip1}$ expression is induced in response to growth factor withdrawal and on contact inhibition in cell cultures.[27] $p27^{Kip1}$ levels are decreased on addition of the mitogens by various mechanisms described in subsequent paragraphs. Overexpression of $p27^{Kip1}$ in cells leads to cell cycle arrest in G_1 phase. Unlike $p27^{Kip1}$, $p21^{Cip1}$ is present at high levels in cycling cells, keeping CDK activities under tight control. $p21^{Cip1}$ levels are induced in response to DNA damage and genotoxic stress as a result of activation of p53. Similar to $p21^{Cip1}$ and $p27^{Kip1}$, induction of $p57^{Kip2}$ can mediate cell cycle arrest in G_1 phase. In addition, $p57^{Kip2}$ also participates in the M-to-G_1 transition through activation by p73.[28] Abrogation of p73 or its downstream effector $p57^{KIP2}$ perturbs mitotic progression and transition to G_1 phase.[29]

Transcriptional Regulation by the E2F Transcription Factors

E2F was originally identified as a cellular DNA binding activity that regulated expression of the viral E2 promoter.[30,31] Since this seminal work, molecular analysis has revealed that the E2F activity is encoded by a family of DNA binding proteins, which includes transcriptional activators and repressors. Mammalian cells encode eight known E2F proteins (E2F1-8; Figure 11-6). Further complication

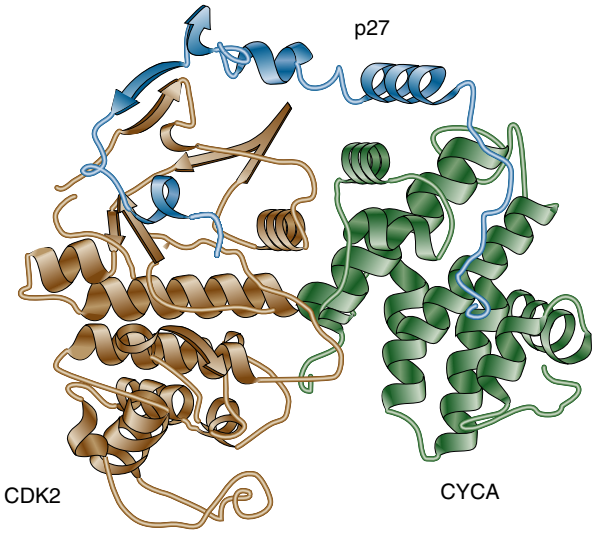

Figure 11-5 Cyclin A/CDK_2/$p27^{KIP1}$ complex Crystal structure of the inhibited ternary cyclin A/CDK_2/$p27^{Kip1}$ complex.

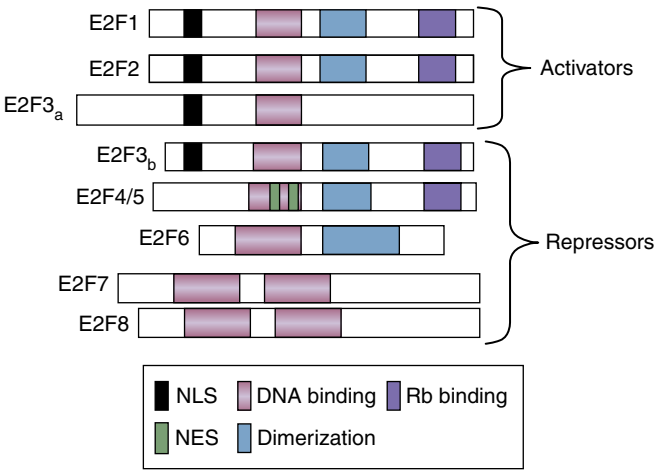

Figure 11-6 E2F family of transcription factors There are eight members of the E2F family of transcription factors. $E2F_5$ are classified as transcriptional activators or repressors. Functional domains are indicated by differential shading.

ensues from the fact that E2F associates with DNA as a heterodimer; the two known heterodimeric partners for E2F are DP1 and DP2. Indeed, the founding member, E2F1, can drive S-phase entry in the absence of growth factor stimulation.[32] The ability of E2F1 to drive S phase derives from its role in the regulation of genes whose protein products play essential roles in S-phase progression. Established E2F targets include components of DNA replication complexes (MCMs) and S-phase cyclins (E and A).[33] E2F family members were initially considered requisite regulators of S-phase entry. E2F1, E2F2, and E2F3 accumulate during G_1 phase and play critical roles in promoting expression of S-phase targets. Strikingly, E2F4 through E2F7 function as transcriptional repressors;[34] E2F3b, an alternatively spliced isoform of E2F3, is also a transcriptional repressor. The E2F repressors function to maintain cells in a quiescent or resting state. In addition to DP1, E2F complexes are further modulated by members of the retinoblastoma protein (pRb) family (pRb, p107, p130; Figure 11-7). The Rb family member functions to recruit chromatin-remodeling enzymes, such as histone deacetylases, to E2F complexes. As a consequence, increased activity of E2F1 through E2F3 requires dissociation of "pRb" from the E2F/DP1 heterodimer. As illustrated in the following sections, the G_1 CDK/cyclin kinase triggers this through direct phosphorylation of the associated pRb family member.[35]

In addition to the regulation of S-phase entry and progression, E2F transcriptional activators can trigger apoptosis or cell suicide. The mechanisms whereby E2F induces cell death remain unclear. However, pro-apoptotic genes have been identified as E2F target genes. Examples include the $p19^{ARF}$ protein, which is a known regulator of the p53 tumor suppressor. In addition, E2F can increase expression of pro-apoptotic proteins Puma, Noxa, and Bim and repress the anti-apoptotic Bcl2 family protein, Mcl1.

Two new E2F family members recently identified, E2F7 and E2F8, provide an important constraint against excessive E2F1 activation. Unlike the other mammalian E2Fs, E2F7 and E2F8 have two DNA-binding domains and do not require a DP partner to bind to DNA and as such are classified as atypical E2F family members.[36] These atypical E2Fs bind to the consensus E2F recognition sequence and can repress expression from a subgroup of cell cycle–regulated E2F targets. An E2F7 and E2F8 double knockout is an embryonic lethal resulting from massive apoptosis; this phenotype can be bypassed by removing E2F1 or p53.[37] Our current level of understanding underscores E2F7 and E2F8 as a distinct arm of the E2F network involved in repression of transcription during S-G_2 and control of the E2F1-p53 apoptotic axis.

G_1 Regulation/Restriction Point Control

During the first Gap phase or G_1, cells prepare for DNA replication. They must synthesize proteins necessary to replicate their genome, and once these are made, assemble the various components of the DNA replication machinery on chromatin at so-called origins of replication. This is

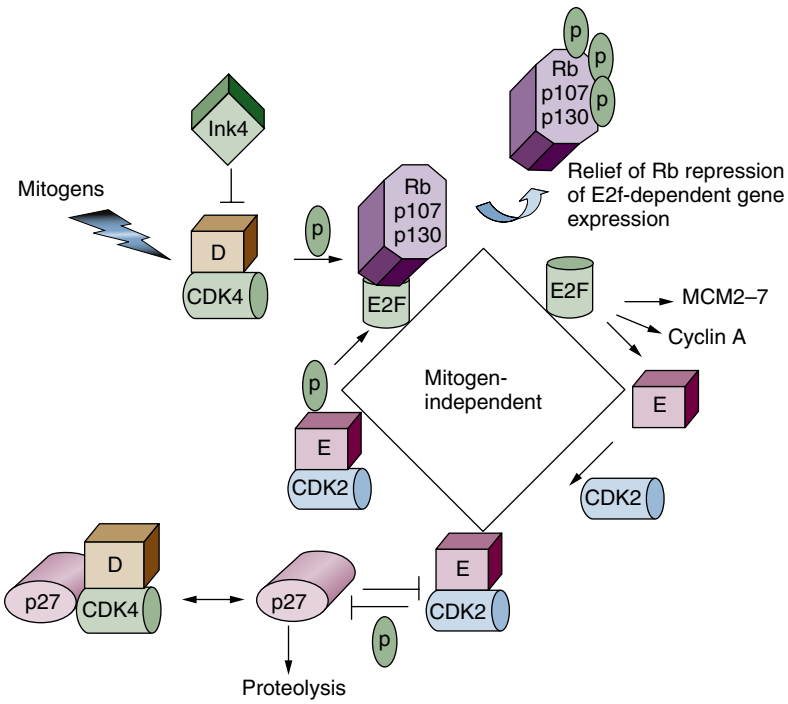

Figure 11-7 Restriction point control Progression through G_1 phase requires growth factor–mediated (mitogenic) signals. Mitogens promote the activation of the initial cyclin-dependent kinase (CDK; cyclin D/CDK4) complex, which phosphorylates Rb family proteins (inactivating signal). The CDK4 enzyme also binds to Cip/Kip CDK inhibitors (CKIs), thereby sequestering these proteins to facilitate CDK2 activation. Rb phosphorylation releases the transcription activating E2FS (E2F1-E2F3), which promote transcription of downstream targets such as cyclin E, A, and MCM proteins. Cyclin E binds to CDK2, and this active complex maintains Rb in an inactive state. Active cyclin E/CDK2 also targets its own inhibitor ($p27^{Kip1}$) for proteolysis via site-specific phosphorylation. The complete activation of CDK2, first by cyclin E and then by cyclin A, marks passage through the restriction point. Once past this point, cells no longer require growth factor stimulation for progression through the remainder of that cell division.

coordinated with nutrient and growth factor availability to ensure that the cell is in an environment that supports cell division. The G_1 phase of the cell cycle is unique in that it represents the only time wherein cells are sensitive to signals from their extracellular environment. These signals are in the form of adhesion to substratum and growth factors. Cells require growth factor–dependent signals up to a point in late G_1 referred to as the *restriction point* ("start" in yeast).

Progression through G_1 phase is driven by the collective activities of two distinct CDKs. The first is CDK4 or CDK6 in combination with a D-type cyclin. Mammalian cells encode three distinct D cyclins (D1, D2, D3), which are expressed in a tissue-specific manner. Whereas CDK4 and CDK6 are constitutively expressed, D cyclins are expressed in response to growth factor signaling. Following accumulation of active cyclin D/CDK4 or CDK6, the CDK2 kinase in combination with cyclin E accumulates to facilitate the transition from G_1 to S phase.

A key protein that regulates G_1-phase progression in the mammalian cell cycle is retinoblastoma protein, Rb. The Rb family consists of three members, Rb, p107, and p130. In quiescent cells, Rb proteins associate with E2F transcription factors to repress E2F-dependent transcription. E2F targets include genes responsible for regulation of cell cycle and DNA replication, such as cyclins E and A (see Figure 11-7). Rb activity is regulated at the level of posttranslational modification, specifically phosphorylation. Hypophosphorylated Rb is active and binds to E2F, thereby silencing E2F-dependent activity. Hypophosphorylated Rb family proteins therefore play a central role in maintaining cells in a resting or quiescent state. Quiescent cells reenter the cell cycle in response to mitogenic growth factors. Growth factor signaling induces the expression of D-type cyclins at transcriptional and posttranslational levels,[38] leading to activation of cyclin D–dependent kinases CDK4 and -6 and subsequent Rb phosphorylation. Cyclin D/CDK4 or -6 complexes also have a kinase-independent function. They sequester $p21^{Cip1}$ and $p27^{Kip1}$ CDK1s from CDK2 kinases and allow activation of basal CDK2/cyclin E kinases, which further phosphorylate Rb family proteins. Phosphorylation of Rb promotes its dissociation from E2F, allowing transcriptional activation of E2F targets such as cyclin E. The E2F-dependent spike in cyclin E, and thus CDK2/cyclin E activity, represents the transition from mitogen-dependent to mitogen-independent cell cycle progression (or passage through the restriction point). In addition to maintaining Rb proteins in a hyperphosphorylated (inactive) state, the activation of cyclin E/CDK2 promotes proteasome-dependent degradation of its own inhibitor $p27^{Kip1}$ (described in a subsequent section). These changes, which include cyclin D/CDK4/6 and cyclin E/CDK2 activation, Rb phosphorylation, and destruction of $p27^{Kip1}$, render cells with decreased mitogen dependency and are irreversibly committed to enter S phase of the cell cycle.

Regulation of DNA Replication (S Phase)

Early experimentation, which relied on techniques wherein two cells (generally one human and one rodent cell) in distinct phases of the cell cycle are fused together (one cytoplasm containing the two distinct nuclei), revealed that chromosomes were competent for duplication in G_1 and S phases. For example, fusing an S-phase cell with a G_1-phase cell could enforce replication of a G_1 cell; in contrast, fusion of a cell in G_2 phase with an S-phase cell could not enforce replication of G_2 chromosomes. It was inferred from these experiments that S-phase cells contained a factor that triggered replication initiation and that G_1 chromosomes were prepared or "licensed" for this initiating activity. Research efforts have shed light on the molecular basis of regulated replication initiation.

Although DNA is actively replicated during S phase, cells must prepare DNA for replication during the preceding G_1 phase. During G_1 phase, *origins* (chromatin positions where DNA polymerase complexes initiate replication) must first be established or "licensed." Licensing refers to the formation of the pre-RC (pre-replication complex) at origins of replication (Figure 11-8). Initially, the origin of replication complex (ORC) must be associated with chromatin to act as a landing pad on which the pre-RC is formed. Unlike most components of the pre-RC, ORC remains constitutively bound to DNA. In budding yeast, ORC acts as a sequence-specific DNA binding complex; however, in fission yeast and mammalian cells, no sequence specificity has been elucidated for ORC. The next step is the recruitment

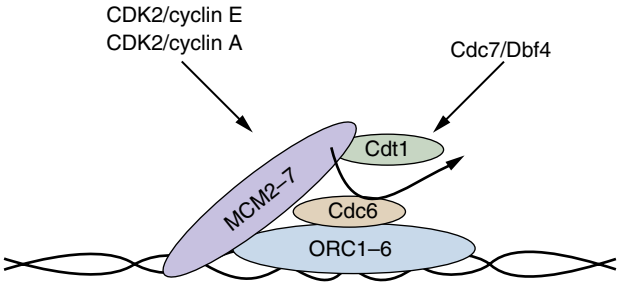

Figure 11-8 Prereplication complex Prereplication complexes (pre-RCs) form during mid- to late G_1 phase, and once they are formed, origins of replication are considered licensed for replication. Origins are recognized first by the hexameric origin of replication complex (ORC1-ORC6), which serves as a landing pad for recruitment of the remaining components. Following ORC recognition, Cdt1 and CDC6 function in a concerted fashion to recruit the MCM2-MCM7 complex, which is considered the replicative helicase. At the beginning of S phase, additional factors (MCM10, CDC45, and polymerases) are recruited and replication can initiate in a fashion dependent on the CDK2 and CDC7 kinase activities.

of *Cdc6* to the ORC. Cdc6 subsequently recruits the MCM complex and Cdt1. However, MCMs are not stably bound at this point. Stable loading of the MCM2-7 helicase complex requires ATP hydrolysis by CDC6, which also results in release of Cdt1.[39] At the G_1/S boundary additional factors are recruited, including *MCM10*, which functions to recruit *Cdc45* and subsequently, DNA polymerase α and primase.

Like G_1 phase, both the G_1/S transition and S-phase progression are driven by cyclin-dependent kinases (CDK2/cyclin E and CDK2/cyclin A, respectively), along with the activity of a distinct CDK-like protein kinase, *Cdc7/Dbf4*. The precise substrates that must be phosphorylated for the firing of origins remain to be conclusively identified. Substrates identified so far include ORC1, MCM2, MCM3, MCM4, and Rad18.[40,41] Not all origins fire simultaneously, but they are temporally regulated. Origins can be grouped generally into those that initiate at the beginning of S phase, "early," and those that fire toward the middle to end of S-phase, "late." The temporal control of firing most likely reflects local controls (chromatin structure modifications) and activation of the complex via phosphorylation.

Paradoxically, although origin firing requires CDK activity, CDK2 activity is also essential for inhibition of a second-round DNA replication (re-replication) within the same cell cycle. Although the precise mechanisms whereby CDK2 prevents replication are still under intense investigation, one way it achieves this goal is through direct regulation of Cdt1 levels. On release from the pre-RC, Cdt1 is subject to ubiquitin-mediated proteolysis. Ubiquitination of Cdt1 is in turn facilitated by CDK2-dependent phosphorylation, which targets it to ubiquitinating machinery.[42] In addition to Cdt1, MCM complexes dissociate from DNA during replication. Whether this dissociation reflects dislodgment from chromatin by polymerases or also reflects a CDK-dependent function remains to be established (Table 11-2).

When DNA is replicated, it is essential to retain memory of epigenetic marks in daughter cells. Histone methylation and acetylation during initiation of DNA replication contribute to this memory as well as proper replication. The histone methyltransferase PR-Set7 has been implicated in catalyzing histone monomethylation at lysine 20 (H4K20 me1) at replication origins, and this methylation is required for initiation of replication.[43] According to a model of epigenetic recruitment at the start of replication, histone acetylation plays a major role in DNA replication origin complex recruitment and H4K12Ac, H3K56Ac accompany the generation of the origin replication complex.[44]

DNA processivity factor proliferating cell nuclear antigen (PCNA) is loaded on both DNA strands during replication and also provides a link between replication and epigenetic memory. NP95 (also referred as UHRF1 and ICBP90) in mammals and VIM1 in *Arabidopsis thaliana* binds to hemimethylated DNA and DNMT1. NP95 recruits DNMT1 to replicating DNA. Another factor, LSH, has been shown to connect DNA methylation to replication in collaboration with NP95. Histone chaperones are required for proper recruitment of histones at DNA. H3.1-H4 chaperone chromatin assembly factor 1 (CAF1) interacts with PCNA, histone deacetylase (HDAC), and Lys methyltransferase. CAF1 regulates nucleosome assembly during DNA replication through proper deposition of H3.1-H4.[45] Another chaperone ASF1 assists CAF1 by supplying newly synthesized histones.[46] Histone methylation levels are transiently reduced during S-phase.[47] It has been recently proposed that TrxG and PcG proteins are associated with DNA during replication.[48]

G_2/M Transition Regulation

The Kinases of Mitosis

The transition from the second Gap phase (G_2) to mitosis (prophase, metaphase, anaphase, telophase) is regulated by CDK1 (formerly Cdc2) in association primarily with cyclin B.[49] Like other CDKs, CDK1 is relatively stable, and activation depends first on accumulation of cyclin B.

Table 11-2 Regulators of DNA Replication and Function

Cdt1	Associates with MCM2-MCM7 and, in concert with Cdc6, facilitates MCM loading on origins.
Cdc6	Functions to recruit and load the MCM complex in an ATPase-dependent manner.
CdC45	Associates with the MCM and is responsible for recruitment of DNA polymerase α, primase, and replication protein A.
MCM2-7	Minichromosome maintenance proteins. Hetero-hexameric complex composed of six distinct but related proteins (MCM2-MCM7). The MCM complex functions as the putative replicative helicase.
MCM10	Structurally distinct from MCM2-MCM7; functions to recruit CDC45.
Orc	Origin recognition complex. Hetero-hexameric complex that binds directly to DNA and functions as a protein landing pad on which the replication complexes form.
Origin	Functionally defined in mammalian cells as regions of chromatin where DNA replication initiates.
Cdc7/Dbf4	The Cdc7 protein kinase, like cyclin-dependent kinases (CDKs), requires an allosteric activator, Dbf4. The Cdc7/Dbf4 kinase phosphorylates components of the replication complexes to initiate DNA replication.
Pre-RC	The prereplication forms during G_1 and contains ORC1-ORC6, Cdc6, MCM2-7. Replication ensues at S phase on recruitment of DNA polymerase and phosphorylation by both the Cdc7/Dbf4 and CDK2-cyclin A protein kinases.

MCM, Minichromosome maintenance; *ORC*, origin of replication complex.

Mitotic cyclins accumulate during S phase and associate with CDK1; however, this complex is maintained in an inactive form via two mechanisms. In the first, Wee/Myt1-dependent phosphorylation of Thr-14/Tyr15 prevents ATP binding. The second mechanism relies on active transport of CDK1/cyclin complexes out of the nucleus. Onset of mitosis is triggered by dephosphorylation of CDK1 by a CDC25 isoform and increased nuclear transport/decreased nuclear exit of CDK1/cyclin complexes. Substrates for CDK1/cyclin B include APC20 (a component of the E3 ligase that ultimately degrades cyclin B), microtubule effectors, microtubule motor proteins, and tubulin itself.[50] From this and related work, it is clear that CDK1-dependent phosphorylation plays a significant role in the formation and regulation of cellular mitotic structures.

In addition to CDK1, a second family of kinases, called polo-like kinases (PLKs), also contributes to mitotic progression. In mammalian cells, there are five PLKs (PLK1-PLK5) with PLK1 being the human homolog of the founding member, Polo, from *Drosophila*.[51] PLKs are serine/threonine kinases. Structurally, they consist of an N-terminal kinase domain and a C terminus with one (PLK3) or two (PLK1-PLK3) "polo box" domains. Current models suggest that PLKs are not constitutively active kinases. Rather, PLK substrates are first phosphorylated by CDKs (e.g., CDK1/cyclin B). Phosphorylation by CDKs is thought to provide a docking site for the polo box domain. Binding of the polo box results in a conformation change in PLK resulting in its activation, whereupon it phosphorylates additional critical residues within the substrate. Alternative models suggest that PLKs are activated through phosphorylation by an upstream kinase, such as CDK1/cyclin B. Although CDK1 can indeed phosphorylate PLK1 in vitro, the functional significance of phosphorylation has not been established. Importantly, neither model is mutually exclusive, and both regulatory mechanisms could contribute to the regulation of PLK activity in cells.

Like CDKs, substrates for PLKs are still being elucidated. As alluded to in previous sections, many PLK substrates may also be CDK substrates. Substrates of PLK1 include CDC25C and Wee1. The consequence of PLK phosphorylation depends on the substrate. Whereas PLK-dependent phosphorylation of CDC25C promotes its activation during mitosis, phosphorylation of Wee1 promotes Wee1 destruction.

Entry into Mitosis

Entry into mitosis requires the nuclear accumulation of active CDK1/cyclin B kinase. During interphase, activity is low. During G_2, cyclin B accumulates as a consequence of increased gene expression and decreased protein degradation. Newly accumulated cyclin B is free to associate with CDK1. However, these complexes are maintained in the cytoplasm and are inactive as a consequence of the combined activities of Wee1 and Myt1. Activation of CDK1/cyclin B at the G_2/M boundary is triggered through CAK-dependent phosphorylation of Thr161 in the T loop and dephosphorylation of Thr14/Tyr15 by CDC25. The initial dephosphorylation is likely catalyzed by CDC25B. The activated CDK1/cyclin B then targets CDC25C and Wee1 to promote CDC25C activity and Wee1 destruction, respectively, thereby forming an amplification loop that drives mitotic progression. The accumulation of CDK1/cyclin B in the nucleus is facilitated by phosphorylation of cyclin B near its nuclear export signal, which thereby impedes nuclear exit. PLK1 contributes to mitotic entry and progression by facilitating these processes. PLK1 can phosphorylate cyclin B just outside the NES (serine 133), thereby preventing nuclear exit. Like the CDK1/cyclin B kinase, PLK1 can also phosphorylate both CDC25C and Wee1, again contributing to CDC25C activation and Wee1 destruction and thereby ensuring full CDK1/cyclin B activation.

Chromosome Cohesion

G_2 phase and the beginning of mitosis are denoted by a 4-N DNA content. Following DNA replication and prior to cell division (cytokinesis), cells must maintain the integrity and proximity of the recently duplicated chromosomes (sister chromatids). Before segregation, sister chromatids are held together or "glued" by a multiprotein complex called Cohesin.[52,53] The cohesin complex ensures that sister chromatids are recognized and properly aligned during metaphase. Once aligned, segregation ensues following proteolytic cleavage of cohesin components. Cohesin is composed of four subunits, Smc1/3 and Scc1/3. Smc1 and Smc3 heterodimerize in a head-to-head, tail-to-tail fashion to form a ring structure in an ATP-dependent manner. The Scc1/3 subunits associate with the Smc heads to complete the structure (Figure 11-9). The Scc1 subunit contacts both Smc1 and 3 and likely stabilizes the ring structure. Models suggest that the cohesin ring has a diameter of approximately 50 nm, sufficiently large to encircle two sister chromatids.[54] Cohesin is envisioned to function by binding and encircling DNA, thereby "gluing" sister chromatids together until released.

Exit from Mitosis

During mitotic prophase, chromosome structures are again altered by a complex called *condensin*, which serves to package chromosomes before mitotic division.[55] The mitotic spindle also forms during prophase. The mitotic spindle is a bilaterally symmetric microtubule organizing center shaped like a football. Each half of the spindle contains a *centrosome* and three distinct sets of microtubules (astral, kinetochore, and polar); the kinetochore microtubules are those

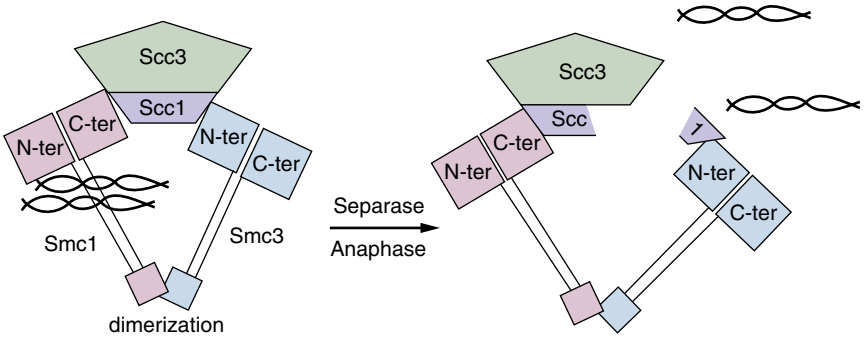

Figure 11-9 Chromosomes are held together by a complex called cohesin Smc1 and Smc3 form a protein ring that is held together by a dimerization "hinge" region that encircles chromatids. The Scc1 and Scc3 subunits interact with the Smc "heads," which retain intrinsic ATPase activity essential for separation of heads to allow DNA to enter. Once all chromatids are aligned during mitosis, Scc1 is cleaved by a protease called Separase to open the ring and allow movement to opposite spindles.

that attach to chromosomes at the kinetochores to facilitate movement to opposite poles before cytokinesis. PLKs are also implicated in the formation of mitotic spindles.[56] Loss-of-function experiments in multiple organisms (yeast to mammalian cells) result in the formation of monopolar spindles. During metaphase, the chromosomes align along the "metaphase plate" in preparation for cell division. Anaphase is marked by segregation of chromosomes to opposite poles. The proteolytic *cleavage* of the Scc1 protein by a protease called *separase* triggers the opening of the cohesin ring, thereby allowing chromosome segregation. Anaphase is also marked by the loss of CDK1 activity, which results from proteolytic destruction of cyclin B and cyclin A. The loss of cohesin and mitotic cyclins is coordinated by a multisubunit E3 ubiquitin ligase called the anaphase-promoting complex/cyclosome (APC/C; see subsequent sections).

Mitotic Checkpoint

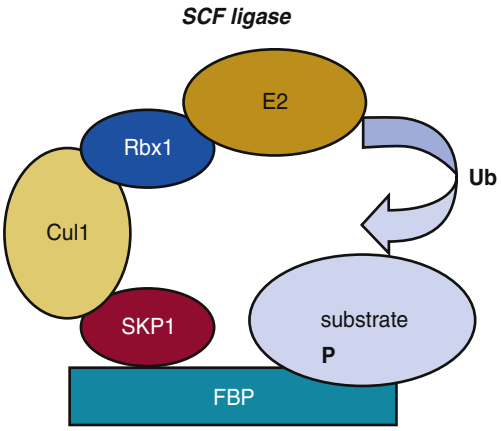
The primary goal of mitosis is to ensure that each daughter cell receives one chromosome complement after cellular division. During mitosis it means that a cell divides only after chromosomes are attached to the microtubules of the mitotic spindle. The *mitotic checkpoint*, or *spindle assembly checkpoint*, is activated as cells enter mitosis, in prometaphase, where it is triggered by *unattached kinetochores*, leading to the delay of anaphase onset. Thus, the role of the proteins that are involved in mitotic checkpoint signaling is to sense the attachment and/or tension at kinetochores.[57] These proteins are often found to be kinetochore-associated and comprise the mitotic checkpoint complex.[58] The mitotic checkpoint complex includes BubR1 and Mps1 kinases, CENP-E (*cen*tromere *p*rotein *E*), Mad (mitotic arrest deficiency proteins)-1 and -2, and others. The mission of mitotic checkpoint kinases is to signal regulatory proteins to inhibit the entry to anaphase. Models suggest that unattached kinetochores lead to phosphorylation of Mad1/2 proteins, which are then directed to the APC/C, resulting in the inhibition of its ubiquitin-ligating activity. This action ensures that chromosomes are accurately distributed to daughter cells. In human neoplasia, the mitotic checkpoint can be inactivated through mutations in components of MCC,[59] contributing to aberrant mitotic divisions and the appearance of aneuploid cells (genetic instability).

Regulated Proteolysis in Cell Cycle Control

Levels of cyclins and CKIs are tightly regulated throughout the cell cycle. This degree of regulation is achieved by coupling the rate of gene expression with regulated proteolysis, which occurs through the ubiquitin proteasome system. The ubiquitin polypeptide consists of 76 residues and is covalently attached to proteins destined for degradation. Attachment occurs through a reversible isopeptide linkage between the carboxy terminus of ubiquitin and lysine residue in the sequence of protein. The name *ubiquitin* derives from early observations of its ubiquitous expression. Indeed, ubiquitin is a highly conserved protein throughout evolution from yeast to humans.

Modification of proteins (*ubiquitination*) with ubiquitin polypeptides requires a conserved series of enzymes. This system includes the ubiquitin-activating enzyme (E1) that performs ATP-dependent activation of ubiquitin. There is only one known E1 enzyme encoded in the human genome. The E1 passes activated ubiquitin to the ubiquitin-conjugating enzyme (E2), of which there are more than 30.[60] In the final stage of ubiquitination, the E2 acts together with an E3, ubiquitin ligase, to attach mono- or polyubiquitin chains onto the target protein. The E3 ligase acts as the specificity factor that determines substrate recognition and thus comprises the largest group. Once a substrate is polyubiquitinated (four or more tandem ubiquitin molecules on a single lysine within the substrate) it is targeted to the 26S proteasome for degradation.

There are two primary E3 ubiquitin ligases involved in the cell cycle that regulate key cell cycle proteins such as cyclins and CKIs. Both sets of ligases belong to a broader E3 subfamily, either the Skp1-Cul1-F-box (SCF) protein ubiquitin ligases or the APC/C. These two systems are structurally similar. However, as one would expect, they target



FBP	Substrate
Skp2	p27, p21, p57
Fbw7	Cyclin E, Myc, Jun
b-Trepl	IkB, b-catenin, Cdc25a
Fbx4	Cyclin D1

Figure 11-10 The Skp1-Cul1-F-box (SCF) E3 ligase F-box protein, or FBP, acts as a specificity component of SCF E3 ligase that recognizes mostly phosphorylated substrates. Further assembly of SKP1-Cul1-Rbx1 components of SCF complex brings E2 ligases and substrates in close proximity for further ubiquitination. Examples of FBPs and their substrates are indicated in the table.

distinct substrates in a cell cycle–specific manner and are differentially regulated.

SCF Ligases

The SCF complex consists of variable and invariable components. The core components employed by all SCF ligases include a scaffold protein Cul1; a ring-finger protein, Rbx1/Roc1; and adaptor protein Skp1 (Figure 11-10). The variable component of the SCF ligase, which determines substrate specificity, is the F-box protein (FBP). FBPs bind Skp1 through an F-box motif initially identified in cyclin F and the substrate bringing the two within close proximity. There are approximately 70 F-box proteins reported in mammals.[61] F-box proteins are classified accordingly to various protein-protein interaction domains that they use to bind to substrates. WD40 repeats give the name to the FBXW class of F-box proteins—leucine-rich repeats (LRRs)—to the FBXL class and F-box proteins that recognize the substrates through other/unknown protein interaction domains belong to the FBXO (F-box only) class. Structurally, FBPs are organized in a fashion that allows them to recognize diverse substrates. Although substrate recognition by FBPs is generally regulated by phosphorylation of the substrate, recognition by one FBP, FBXL2, is determined at least in part by substrate modification with sugar moieties (N-glycans).[62] Thus, the activity of SCF seems to be constant, but the ability to bind to the target protein is regulated.

One of the most rigorously studied FBPs that is involved in cell cycle regulation is Skp2. Although discovered as cyclin A–associated protein, it has since been implicated in the degradation of CKIs: $p27^{Kip1}$, $p21^{Cip1}$, and $p57^{Kip2}$. Skp2 deletion in mice suggests that $p27^{Kip1}$ is a bona fide target for Skp2-mediated degradation, because these mice exhibited striking $p27^{Kip1}$ accumulation.[63] The binding of Skp2 to $p27^{Kip1}$ requires the phosphorylation of Thr187 by cyclin E/A/CDK2 in $p27^{Kip1}$. This binding occurs with high affinity only in the presence of another protein, called Cks1.[64] On binding of $SCF^{skp2/Cks1}$, phosphorylated $p27^{Kip1}$ is ubiquitinated and undergoes proteasome-dependent degradation in late G_1 and early S phases of the cell cycle. Fbw7, another FBP that has been implicated in the degradation of cell cycle key molecules, targets cyclin E, Myc, and c-Jun for degradation.[65] SCF complexes generally regulate proteins involved in G_1 to late S phase, at which point the APC/C is activated and regulates M-phase activities.

FBXO4 is an FBP that specifically directs ubiquitination of cyclin D1. FBXO4 dimerization requires GSK3β-mediated phosphorylation of FBXO4 Ser12, which triggers ligase activation at the G_1/S transition. 14-3-3ε facilitates FBXO4 dimerization, and 14-3-3ε interaction is dependent on Ser8, which is frequently mutated in human cancer, and phosphorylation of Ser12.[66] Recent work revealed the tumor suppressor function of FBXO4. FBXO4 mutations have been identified in human esophageal carcinoma and gastrointestinal stromal tumors.[67,68] Loss of FBXO4 results in cyclin D1 stabilization and nuclear accumulation throughout cell division. $FBXO4^{+/-}$ and $FBXO4^{-/-}$ mice succumb to multiple tumor phenotypes including lymphomas, histiocytic sarcomas, and, less frequently, mammary and hepatocellular carcinomas.[69]

APC/C Ligase

Structurally the APC/C ligase is similar to the SCF complex. The core components are Rbx1/Roc1-related ring-finger protein, APC11, a Cul1-related scaffold protein, APC2, and 11 additional proteins with required but essentially unknown functions.[70] Two components determine substrate specificity similar to SCF FBPs function: cell division cycle 20 (Cdc20) and Cdh1 (Figure 11-11). APC/C ligases recognize specific sequences in target proteins called the destruction box (D-box) and the Ken box. These short-peptide

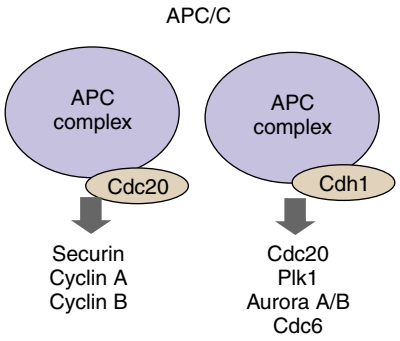


Figure 11-11 The anaphase-promoting complex/cyclosome (APC/C) APC/C ubiquitin ligase is a multiprotein complex that is active in the M through G_1 phases of the cell cycle. The subunits that are responsible for the recognition of substrates by APC are Cdc20 and Cdh1.

sequences are recognized by the Cdh1 and Cdc20 specificity adaptors and therefore facilitate recruitment of the active APC/C.

APC/C is active from anaphase through early G_1 phase. However, the regulation of APC/C activity is distinct from SCF ligases. The Cdc20 subunit of APC/C, APC/C^{Cdc20}, itself undergoes activating phosphorylation events by CDK1/cyclin B. APC/C^{Cdc20} can also be phosphorylated and activated by PLK1 and inactivated by PKA. The activity of APC/C^{Cdc20} is regulated by protein-protein interactions. Mitotic spindle checkpoint proteins Mad1/Mad2 bind to and inhibit APC/C^{Cdc20} function, thereby delaying the onset of anaphase. The substrates of APC/C^{Cdc20} ligase include securin, a protein associated with the mitotic protease separase that allows sister chromatid separation, cyclins A and B. When cyclin B is degraded, CDK1 activity declines, contributing to the activation of APC/C^{Cdh1}; active APC/C^{Cdh1} proceeds to fully ubiquitinate cyclin B molecules, eliminating CDK1 activity. The switch of Cdc20 specificity component of APC/C complex to Cdh1 in late M phase also leads to degradation of Cdc20 itself, Plk1, Aurora A/B kinases, and others (reviewed in).[70] APC/C^{dh1} remains active during early G_1 phase where it also ubiquitinates Skp2, permitting $p27^{Kip1}$ and $p21^{Cip1}$ accumulation, as described earlier.

Sumoylation

Sumoylation is another form of posttranslational modification that regulates the cellular localization of modified proteins. Small ubiquitin-like modifiers (SUMOs) are ubiquitin-like polypeptides that become covalently conjugated to cellular proteins in a manner similar to ubiquitination. Ras induces sumoylation and nuclear accumulation of cyclin D1, thereby inhibiting Rb phosphorylation.[71] The lysine residue, K33, of cyclin D1 is a key site for this newly identified regulation.[71]

Integration of Growth Factor Signals During G_1 Phase by the Ras Small GTP-Binding Protein

Growth factor–dependent signaling promotes the expression and accumulation of factors essential for cell growth (mass accumulation), cell survival, and cell cycle progression. With regard to the cell cycle, growth factor signaling converges on G_1-phase components. Entry to and progression through G_1 phase of the cell cycle requires activation of signal transduction pathways via extracellular growth factors. G_1 progression requires G_1 CDK/cyclin complexes to accumulate and become activated and conversely that CKIs be destroyed. Although this is accomplished through numerous pathways, the molecular basis for Ras-dependent signals in G_1-phase progression is understood with the greatest detail.

Extracellular growth factors promote the guanosine triphosphate (GTP) loading of Ras, its active form. Active Ras-GTP intersects with the cell cycle via the regulation of cyclin D1 expression and activation of the CDK4/6 kinase. Ras-GTP subsequently triggers the activation of multiple independent signaling pathways including canonical MAP kinase signaling Raf, mitogen-activated protein kinase-kinases (MEK1 and -2), and the sustained activation of extracellular signal-regulated protein kinases (ERKs or MAPK). This pathway contributes to cyclin D1 gene expression.[72] Ras-GTP triggers the activation of a second related, small-GTP binding protein, Rho; activation of Rho also plays a critical role in growth factor–dependent cyclin D1 expression during G_1 phase. A third pathway activated by Ras involves PI-3K and Akt (PKB). The activation of this pathway contributes to increased translation of a multitude of proteins, including cyclin D1 by virtue of the ability of Akt to regulate translation initiation.[73] Active Akt also inactivates glycogen synthase kinase-3β (GSK-3β) by site-specific phosphorylation. Active GSK-3β kinase phosphorylates cyclin D1, thereby promoting cyclin D1 ubiquitination and proteolysis.[74] Thus inactivation of GSK-3β is a critical step necessary for cyclin D1 accumulation during G_1 phase.

For cells to progress through G_1 phase, growth factor signaling must promote increased G_1 cyclin accumulation and suppress accumulation of the cell cycle inhibitor $p27^{Kip1}$. Active Ras also plays a central role in the regulation of $p27^{Kip1}$ in G_1 phase by decreasing the efficiency of $p27^{Kip1}$ translation and increasing the kinetics of $p27^{Kip1}$ proteolysis. Ras-dependent regulation of $p27^{Kip1}$ translation and degradation requires Rho signaling. The concerted increase in cyclin D1 accumulation and decrease in $p27^{Kip1}$ accumulation provides a threshold of CDK4/cyclin D1 activity that is necessary and sufficient for restriction point passage and commitment to S-phase entry.

Deregulation of G_1 Restriction Point Control in Cancer

In G_1 phase, cells make the decision to either progress through the restriction point and enter S phase or enter G_0. These decisions are based on extracellular signals that the cell receives and on the integrity of signaling machinery that detects these signals. Deregulation of G_1 progression is a frequent occurrence in cancer, through mutations or deregulated expression of CDKs, cyclins, or CKIs. Loss- or gain-of-function mutations in upstream regulators of the CDK kinases also occur in cancer. In this section, we discuss some alterations found in cell cycle regulators in cancer.

Cyclin D–dependent kinases are a primary point of control for the progression through G_1 phase and are linked to cancer progression. Cyclin D1 overexpression is a hallmark of breast and esophageal cancers.[75] In many cases this upregulation is due to cyclin D1 gene amplifications, but it can also result from increased transcription.[75] In addition to gene expression alterations, decreased cyclin D1 proteolysis is implicated in deregulated cyclin D/CDK4 activity in breast and esophageal cancers. Cyclin D1 overexpression also occurs as a consequence of chromosomal translocations. Amplifications encompassing the *CDK4* and *CDK2* genes have been reported in large B-cell lymphomas, lung tumors, and cervical carcinomas. Downstream targets of cyclin D/CDK4/6 kinases, Rb proteins, are also targeted in cancer. Mutations and deletions in the *Rb* gene are common events in tumors; inactivation of Rb alleviates a cell need for CDK4/6 kinase and thus relieves some cellular dependence on growth factor signals.[76]

As one might anticipate, Cip/Kip inhibitors can also function as tumor suppressor proteins in mouse model systems, and, consistent with this work, their expression is deregulated in human cancers. p53, the main transcriptional regulator of $p21^{Cip1}$, is often lost or mutated during tumorigenesis. Reduced $p27^{Kip1}$ levels alone or together with increased cyclin E expression are associated with poor prognosis in breast and ovarian carcinomas. Inactivation of $p16^{Ink4a}$ occurs frequently in lung, bladder, and breast carcinomas, as well as leukemia (reviewed in Ref. 24).

In addition to alterations in the expression and integrity of cell cycle genes in cancers, attenuation of their regulatory pathways also occurs. These include signaling pathways (Ras), transcription factors (myc), and components of ubiquitin ligases. Skp2, the specificity component of the SCF ligase for $p27^{Kip1}$, is upregulated in a variety of tumors, including colon, lung, breast, prostate, and lymphoma,[70] where it decreases $p27^{Kip1}$. Another F-box protein, Fbw7, which regulates degradation of cyclin E, is mutated in ovarian and breast cancers.

Altered functionality of cyclin D1 ubiquitin ligase can lead to increased cyclin D1 expression and ultimately to tumorigenesis. Cyclin ubiquitination requires both FBXO4 and a specificity co-factor, αB-crystallin.[77] αB-crystallin expression is lost or downregulated in breast cancer and melanoma cell lines, which correlates with decreased cyclin D1 proteolysis.[78,79] Primary esophageal carcinomas, which are known to frequently overexpress cyclin D1, exhibit hemizygous, missense mutations of FBXO4.[80]

Mutations and deregulation of the expression of regulators of mitosis are also observed in human malignancy. Increased accumulation of Cdc20 (APC/C) is observed in lung and gastric tumor cell lines. Mutations in *PLK1* are found in human cancer cell lines, and its attenuated expression is observed in colorectal, endometrial, and breast carcinomas.

Targeting the Cell Cycle as a Therapeutic Modality

Dysregulated cell division is a hallmark of cancer progression.[81] Therefore, the use of agents targeting the cell cycle machinery has long been considered as an ideal strategy for cancer therapy.[82] Cell cycle–based agents can be grouped into categories that reflect their molecular targets: CDK inhibitors, checkpoint inhibitors, and mitotic inhibitors. These drugs target the abnormal expression of CDKs, mitotic kinases/kinesins, or affect the cellular checkpoints, resulting in cell-cycle arrest followed by induction of apoptosis in cancer cells.

Targeting CDKs

The rationale for targeting CDKs in anticancer therapy is based on both their role in catalyzing cell division and, in certain cases, the frequency of their perturbation in human malignancy.[83] The rationale suggests that inhibition of CDKs would selectively block tumor growth without compromising normal cells, given that most normal tissues are postmitotic. During the past two decades, numerous CDK inhibitors have been identified as antitumor agents. These drugs have been classified as pan-CDK inhibitors or selective CDK inhibitors. First-generation CDK inhibitors such as flavopiridol, olomoucine, and roscovitine generally did not meet expectations following preclinical studies, showing low activity or no response in the clinical trials. Second-generation CDK inhibitors, such as aminothiazole SNS-032, pyrazole-3-carboxamide AT7519, and synthetic flavone P276-00, have recently been shown to be promising drug candidates in preclinical and clinical trials.

SNS-032, a potent and selective CDK 2, 7, and 9 inhibitor, is currently in phase I clinical study in B-cell malignancies including chronic lymphocytic leukemia, mantle-cell lymphoma (MCL), and multiple myeloma, providing data supporting the ongoing clinical trials. A phase I study of

pan-CDK inhibitor AT7519 was carried out in 28 patients with refractory solid tumors. Four patients showed stable disease and one had a prolonged partial response.[84] A phase II study to treat patients with relapsed or refractory multiple myeloma has been initiated. P276-00 is a highly specific inhibitor of CDK2. Confirmed stable disease has been observed in a phase I study in patients with advanced refractory neoplasms. Phase I/II studies are being performed to evaluate P276-00 efficacy in combination with gemcitabine in patients with pancreatic cancers or in combination with radiation in patients with squamous-cell carcinoma of the head and neck.

Other selective inhibitors such as CDK4/6 inhibitor fascaplysin, CDK4 inhibitor ryuvidine, CDK2 inhibitors purvalanol A and NU2058, and CDK5 inhibitor BML-259 are commercially available and broadly used in the research; however, they had not been entered into clinical trials. The highly selective CDK4/6 inhibitor PD 0332991 is a novel, orally administered inhibitor, which shows potential single-agent activity in clinical trials. PD 0332991 induces G_1 cell cycle arrest by blocking phosphorylation of Rb at CDK4/6-specific sites. Phase I study has been conducted in patients with Rb-expressing advanced solid tumors, relapsed MCL, or refractory non-Hodgkin's lymphoma. Dose-limiting toxicities relate mainly to myelosuppression.[85-87] A therapeutic response to PD 0332991 has also been seen in inoperable growing teratoma.[88] A phase II study of PD 0332991 in patients with recurrent Rb-positive glioblastoma is currently ongoing.

Targeting Cell Cycle Checkpoints

Targeting the S and G_2 checkpoints is also attractive for cancer therapy because loss of G_1 checkpoint control is a common feature of cancer cells,[89] making them more reliant on the S and G_2 checkpoints to prevent DNA damage–triggered cell death. Various molecules such as CHK1, CHK2, PP2A, Wee1, and cell division cycle 25 (CDC25) have been suggested as the key targets for checkpoint abrogation.[90] Numerous checkpoint inhibitors have entered into clinical trials, most of which focused on CHK1. Among all the checkpoint inhibitors, UCN-01 is most clinically advanced,[91-93] but after phase II trials it was discontinued because of dose-limiting toxicities and a lack of convincing efficacy. The newer, more specific inhibitors of CHK are still under investigation.[90,94]

Targeting Regulators of Mitosis

Critical mediators of mitosis that are also implicated in tumorigenesis include three distinct protein kinase families (CDKs, Aurora kinases, and PLKs) and specific mitotic kinesins. Overexpression/amplification of Aurora kinases has been observed in cancer cells and contributes to dysregulated spindle formation, compromised spindle checkpoint, and cytokinesis failure; collectively, these anomalies contribute to cellular aneuploidy.[95] Aurora kinase inhibitors are being pursued, and many of them are already in clinical development.

Like Aurora kinases, PLK1 is often overexpressed in human tumors but not in healthy, nondividing cells. This makes PLK inhibitors an attractive, selective target for cancer drug development. PLK inhibitors interfere with different stages of mitosis, such as centrosome maturation, spindle formation, chromosome separation, and cytokinesis. They induce mitotic chaos and severely perturb cell cycle progression, eventually leading to cancer cell death.[96] Numerous PLK inhibitors are being tested to evaluate their therapeutic potential in oncology.

Kinesins either have a single function or are functionally involved at different stages of the mitotic phase, making them potential anticancer targets.[97] Compounds that inhibit mitotic kinesins EG5 and centromere-associated protein E (CENP-E) have entered clinical trials. Additional mitotic kinesins are currently at varying stages of drug development, raising the possibility of kinesin as a successful target for cancer therapy.

Conclusions

Significant advances have been made in the understanding of the molecular basis of cell cycle regulation. Conceptually, it was anticipated that understanding the basic mechanisms and regulators would permit scientists to ask how they contribute to organismal development and/or cancer progression. Indeed, these questions are now being addressed through targeted deletion of individual genes in the mouse genome. G_1 cyclins and CDKs have been removed from the mouse genome by targeted deletion to evaluate the role of these molecules in organismal development and basic cell growth. Although genetic deletion strains in mice have revealed unique properties of each molecule, what has been most striking is the revelation that no one cyclin or CDK is absolutely essential for development.[98] Thus, although each mammalian CDK is considered to have distinct substrates, in an intact cell there is sufficient redundancy to permit loss of any one complex.

The identification of the critical regulators of cell division has also facilitated the development of antiproliferative therapies through the design of small-molecule inhibitors of the CDKs. Given that deregulated growth control is a fundamental property of cancer, the development of small molecules that inhibit the molecular machine that drives cell cycle transitions is a conceptually attractive therapeutic option. The continued investigation of components of the cell cycle machine will undoubtedly continue to contribute fundamental insights into cell growth control and potentially provide additional insights into diseases that alter growth properties.

Cell Growth

What Is Cell Growth?

Cell growth is the process by which cells accumulate mass and increase in physical size. On average, dividing animal cells are approximately 10 to 20 μm in diameter. Terminally differentiated cells have a wide range of sizes, spanning from tiny red blood cells (~5 μm in diameter) to motor neurons, which can grow to hundreds of micrometers in length.[1] For a typical dividing cell, water accounts for about 70% of the weight of a cell, and macromolecules, such as nucleic acids, proteins, polysaccharides, and lipids constitute most of the remaining mass (~25%—trace amounts of ions and small molecules make up the difference). The largest contribution to cellular dry mass is typically from proteins, which makes up about 18% of the total cell weight on average. There are many physical, chemical, and biological factors that affect the biosynthesis of macromolecules and therefore final cell size. Intracellular signaling networks that regulate metabolism and control macromolecule biosynthesis are particularly relevant to cancer. As discussed later, deregulation of the cellular circuitry controlling biomass accumulation is associated with a wide spectrum of human cancers.

There are many different examples in nature of how cells can grow. In some cases, cell size is proportional to DNA content. For instance, continued DNA replication in the absence of cell division (called *endoreplication*) results in increased cell size. Megakaryoblasts, which mature into granular megakaryocytes, the platelet-producing cells of bone marrow, typically grow this way. These cells cease division and then undergo multiple rounds of DNA synthesis, increasing from about 20 μm to approximately 100 μm in diameter as a result of the increased DNA content. It is unclear whether increased DNA content simply leads to an increase in total cellular material or whether cells actively grow to cope with the larger genome size. This growth strategy is found throughout nature in animals, plants, and single-celled organisms. By a different strategy, adipocytes can grow to approximately 85 to 120 μm by accumulating intracellular lipids. In contrast to endoreplication or lipid accumulation, some terminally differentiated cells, such as neurons and cardiac muscle cells, cease dividing and grow without increasing their DNA content. These cells proportionately increase their macromolecule content (largely protein) to a point necessary to perform their specialized functions. This involves coordination between extracellular cues from nutrients and growth factors and intracellular signaling networks responsible for controlling cellular energy availability and macromolecular synthesis.

Perhaps the most tightly regulated cell growth occurs in dividing cells, where cell growth and cell division are clearly separable processes. Dividing cells generally must increase in size with each passage through the cell division cycle to ensure that a consistent average cell size is maintained. (There are examples in the animal kingdom where cell division in the absence of growth serves an important evolutionary function, such as during the syncytial division stage of the early developing *Drosophila* embryo.) For a typical dividing mammalian cell, growth occurs in the G_1 phase of the cell cycle and is tightly coordinated with S phase (DNA synthesis) and M phase (mitosis). The combined influence of growth factors, hormones, and nutrient availability provides the external cues for cells to grow. It is hypothesized that once dividing cells reach a threshold size, cells irreversibly commit to at least one round of division; achieving adequate size is thus a prerequisite for DNA synthesis and mitosis. Deprivation of nutrients and other growth signals, as might be the case in the nutrient (and oxygen)-starved regions of a growing tumor, may encourage normal cells to exit the cell cycle into a resting or G_0 state. Therefore, mutations in signaling pathways that promote growth independently of growth factors and nutrient availability may provide tumor cells with a selective growth advantage. Efforts to identify intracellular signaling networks that control growth are therefore a mainstay of many cancer-focused research programs.

Biochemical Pathways That Control Cell Growth

The mTORC1 Pathway

Essential to connecting cell growth control with cancer pathogenesis was the identification of intracellular signaling molecules that coordinate signals from nutrient availability, growth factors, and hormones with autonomous cell growth. In cells, these inputs converge upon a Ser/Thr protein kinase called *TOR* (target of rapamycin), which has emerged as a central controller of eukaryotic cell growth.[2] TOR was discovered in the 1970s to be the molecular target of an antifungal macrolide produced by a soil bacterium *(Streptomyces hygroscopicus)* that was isolated on Easter Island (Rapa Nui). Today rapamycin is recognized for its immunosuppressive function, ability to prevent restenosis after angioplasty, and limited anticancer properties. Mechanistically, rapamycin binds an intracellular protein called FKBP12 (an immunophilin), and the rapamycin-FKBP12 complex binds potently and specifically to TOR. Extensive studies across multiple eukaryotic model systems, all spawned by the identification of TOR as the target of rapamycin, have unveiled a complex TOR-centric signaling network responsible for integrating numerous growth signals into a metabolic program that drives biomass production (i.e., cell growth).

About a decade after the discovery of TOR, biochemical studies revealed that TOR (named *mTOR* in mammals in which the *m* now officially denotes "*m*echanistic" TOR) associates into at least two distinct multisubunit protein complexes called *mTOR complex 1* (mTORC1) and *mTORC2*. Growth control by mTOR is largely attributed to the best understood mTOR complex—mTORC1. In addition to the catalytic mTOR subunit, mTORC1 contains Raptor (regulatory associated protein of mammalian target of rapamycin), PRAS40 (proline-rich AKT substrate 40 kDa), mLST8 (mammalian lethal with sec-13 protein), and DEPTOR (DEP domain containing mTOR interacting protein) (Figure 12-1). Of these interacting proteins, Raptor and PRAS40 are unique to mTORC1, whereas mLST8 and DEPTOR are shared with mTORC2 (discussed later). Raptor is both a regulator of mTORC1 catalytic activity and a scaffold for recruiting mTORC1 substrates. PRAS40 and DEPTOR inhibit mTORC1 activity by undefined mechanisms. The function of mLST8 is unknown, but it does not appear to be required for mTORC1 activity. Rapamycin-FKBP12 directly binds mTORC1 through a domain in the mTOR catalytic subunit called the *FRB domain* (*F*KBP12-*r*apamycin-*b*inding domain), and although the drug destabilizes the association between mTOR and Raptor, it does not dissociate any components of the complex. In fact, rapamycin's exact mechanism of action remains a mystery despite years of research.

It is now widely accepted that mTORC1 positively controls an array of cellular processes critical for growth, including protein synthesis, ribosome biogenesis, and metabolism, and negatively influences catabolic processes such as autophagy—all of which have roles in cancer pathogenesis. Elucidating the key downstream targets of mTORC1 driving these events is an intense area of research. Originally, much of the study of mTOR relied on experiments in which rapamycin was used acutely to inhibit mTOR (which we now know was mTORC1) in cultured cells. This led to extensive characterization of the best known mTORC1 substrates eiF-4E-binding protein 1(4E-BP1) and S6 kinase 1 (S6K1), both of which regulate protein synthesis.[3] In the unphosphorylated state, 4E-BP1 binds and inhibits the cap-binding protein and translational regulator eIF4E. When phosphorylated by mTOR, 4E-BP1 is relieved of its inhibitory duty, promoting eIF4E interaction with the eIF4F complex and the translation of capped nuclear transcribed mRNA. Following co-regulatory phosphorylation by mTORC1 and another kinase called *phosphatidylinositol 3-dependent kinase 1* (PDK1), S6K1 positively affects mRNA synthesis at multiple steps including initiation and elongation by phosphorylating several translational regulators. Although the preponderance of evidence indicates that S6K1 and 4E-BP1 are directly phosphorylated by mTOR, an unidentified phosphatase activity may also be involved in their regulation. For example, the rapamycin-sensitive phosphorylation site on S6K1 is rapidly dephosphorylated (i.e., within minutes) of exposure to the drug.

For many years studies using rapamycin were at odds with the model that mTOR is an essential controller of protein synthesis because rapamycin has only modest effects on translation in most mammalian cells. Rapamycin is an allosteric inhibitor that binds mTOR outside of the kinase domain; it was therefore suspected that rapamycin might incompletely inhibit mTORC1. In 2009, the first mTOR kinase inhibitors became available (discussed later), which, unlike rapamycin, are ATP-competitive inhibitors that target the ATP-binding pocket of mTOR.[4,5] The first studies employing mTOR catalytic site inhibitors confirmed what had previously been suspected: that rapamycin only partially inhibits mTORC1 activity. The mTOR catalytic site inhibitors exposed rapamycin-resistant functions of mTORC1 in translational control, and consequently the mTOR ATP-competitive inhibitors have more profound effects on mRNA translation and cell proliferation than does rapamycin. Researchers are now using these new-generation mTOR inhibitors to identify novel mTORC1 substrates (many of which are rapamycin resistant) and beginning to fill in the gaps between mTOR and the myriad cellular processes it regulates.[6,7]

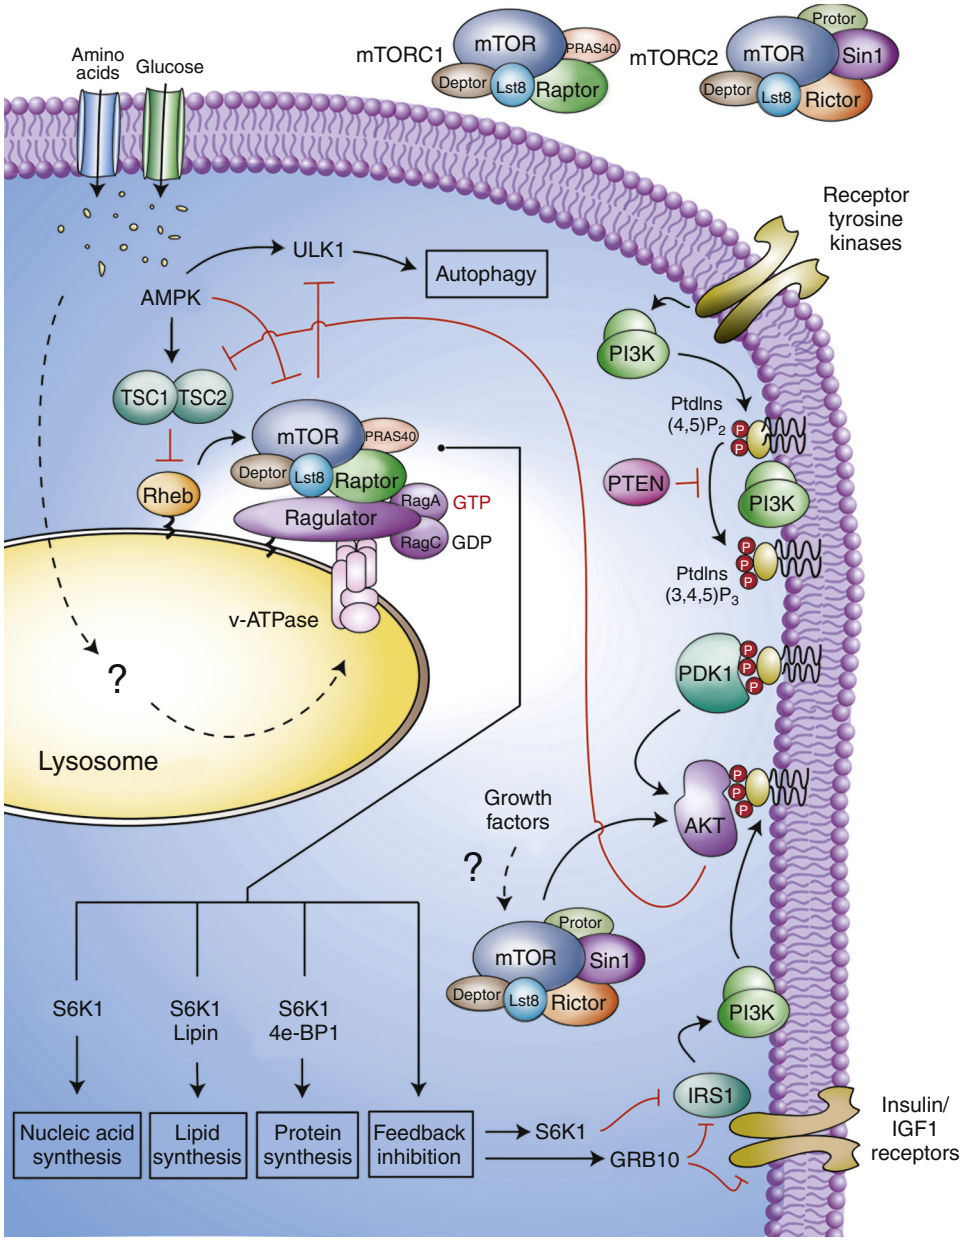

Figure 12-1 A simplified model of mTOR signaling in the active (i.e., nutrient-replete) state mTOR is the catalytic subunit of two distinct multisubunit complexes called mTORC1 and mTORC2 (described in the text). In nutrient-replete cells, the RAG-GTPase and Ragulator recruit mTORC1 to the lysosome, where it can be activated by the Rheb-GTPase. The RAG complex is active when RAGA or RABB (not shown) is in the GTP bound state and RAGC or RAGD (not shown) is bound to GDP. The active state is determined by an unknown amino acid- and glucose-sensing mechanism that exists inside the lysosome that signals through the v-ATPase to the Ragulator. The Ragulator possess guanine nucleotide exchange factor (GEF) activity toward RAGA/B and thereby triggers the switch that generates the mTORC1 lysosomal recruitment signal. The activation state of Rheb is controlled by the TSC complex, which senses energy availability (through AMPK) and growth factors (through AKT). In addition, AMPK can directly inhibit mTORC1 by phosphorylating Raptor, while AKT can activate mTORC1 by phosphorylating PRAS40 (not shown). When growth factors, energy, and nutrients are available, mTORC1 promotes anabolic processes such as protein, lipid, and nucleic acid biosynthesis and suppresses catabolic processes such as autophagy. mTORC1 activation also promotes feedback inhibition of growth factor signaling to maintain cellular homeostasis. In contrast to mTORC1, mTORC2 is poorly understood. The best-described mTORC2 function is to phosphorylate and fully activate AKT, suggesting that mTORC2 might also function upstream in controlling cell growth. However, AKT has many additional substrates that influence cell proliferation, cell survival, cell metabolism, and numerous other processes (not shown). Thus mTORC2 may have important roles in many other cancer-relevant pathways. *Black lines* represent positive regulatory signals; *red lines* are inhibitory signals. *Dotted lines* indicate undefined mechanisms.

In addition to synthesizing protein, growing and dividing cells need to synthesize lipids (to build the plasma membrane and the membranes of intracellular organelles) and nucleic acids (to make RNA and DNA). There is growing evidence that mTORC1 regulates lipid metabolism (and storage in the case of adipocytes) through SREBP1.[8] SREBPs are transcription factors that facilitate the expression of lipid and sterol biosynthesis enzymes. Several recent studies suggest that mTORC1 is an upstream regulator of SREBP1 activation. In addition

to driving lipid metabolism genes, SREBP1 can also increase the expression of genes involved in the pentose phosphate pathway, which produces important metabolites needed for both lipogenesis and nucleotide biosynthesis. How mTORC1 activates SREBP1 is still unclear, although it appears to function through multiple substrates including S6K1 and another direct mTORC1 substrate called Lipin1. In an mTORC1-dependent manner, S6K1 also controls pyrimidine biosynthesis by directly phosphorylating and regulating the activity of CAD (carbamoyl-phosphate synthetase 2, aspartate transcarbamoylase, dihydroorotase), which catalyzes the first three steps of de novo pyrimidine synthesis.[9,10] Thus, mTORC1 truly is a master controller of growth, as it significantly influences the intracellular synthesis of the major macromolecules required by growing (and dividing) cells: proteins, lipids, and nucleic acids.

Upstream Signaling to mTORC1

The connection between cell growth control by mTORC1 and cancer solidified with the identification of upstream mTORC1 regulators.[2,11,12] Building biomass requires adequate building material, sufficient energy, and favorable environmental conditions. Therefore, it is not surprising that mTORC1 activity is controlled by numerous factors such as amino acid and glucose availability, ATP level, mitochondrial activity, growth factor signaling, and oxygen levels, all of which affect cancer cell growth. The discovery that the TSC1 (hamartin) and TSC2 (tuberin) tumor suppressors function together in a complex (the TSC complex) to negatively regulate mTORC1 provided a key first step in unraveling the biochemical mechanism of how upstream signals control mTORC1 activity. The TSC complex contains GTPase-activating protein (GAP) activity, which suppresses the activity of a small GTPase called *Rheb*. Rheb directly activates mTORC1 by an unknown mechanism, and therefore by promoting Rheb-GTP hydrolysis, the TSC complex suppresses mTORC1 (see Figure 12-1). Mutation in either the *TSC1* or *TSC2* gene results in aberrant upregulation of mTORC1 activity and causes a tumor-prone syndrome called *tuberous sclerosis complex* (described later).

The TSC complex integrates many positive and negative signals responsible for modulating mTORC1 activity. For example, extracellular growth factors such as insulin and insulin growth factor 1 (IGF-1) can activate an intracellular signaling pathway that inhibits TSC2. Through activation of receptor tyrosine kinases, growth factors stimulate PI3K to phosphorylate membrane-associated phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P_2) to generate phosphatidylinositol 3,4,5-triphosphate PtdIns(3,4,5)P_3. PtdIns(3,4,5)P_3 serves as a docking site for the membrane recruitment and activation of the AKT kinase, one of the most versatile kinases in the human kinome. Among its many functions, AKT phosphorylates and inhibits TSC2 and thereby potentiates mTORC1 signaling.[13] AKT can also directly phosphorylate the PRAS40 subunit of mTORC1, which relieves a negative effect of this subunit on mTORC1 activity. The phosphatase and tumor suppressor PTEN, a major tumor suppressor in human cancer, balances PI3K activity by dephosphorylating PtdIns(3,4,5)P_3 and thus negatively regulates AKT activity. Other growth factor pathways such as the MAPK/ERK pathway and WNT pathway can also activate mTORC1 by inhibiting TSC as can proinflammatory cytokines such as tumor necrosis factor-α (TNFα) through the IκB kinase β (IKKβ).

Although extracellular growth factors provide the external (systemic) cues for growth, intracellular energy, oxygen, and nutrients must also be available.[2,11,12] An intracellular ratio of ATP to ADP and AMP is sensed by the AMP-activated protein kinase (AMPK). Under conditions of energy stress, high levels of ADP/AMP bind and activate AMPK, which suppresses anabolic processes and stimulates catabolic reactions. Active AMPK directly phosphorylates and activates TSC2 to suppress mTORC1 signaling when energy supplies drop. AMPK also directly inhibits mTORC1 by phosphorylating the Raptor subunit, emphasizing a theme that positive and negative regulators of growth often impinge on the mTORC1 pathway at multiple steps. Oxygen stress (i.e., hypoxia) inactivates mTORC1 through TSC, but by a different mechanism. In hypoxic conditions, hypoxia-inducible factor α (HIF1α) is stabilized, and its accumulation leads to a transcriptional response that promotes a metabolic shift away from oxidative phosphorylation toward oxygen-independent glycolysis, increased vascularization, and decreased mTORC1 activity by inducing expression of REDD1 and REDD2. REDD1/2 release TSC2 from an inhibitory interaction with 14-3-3 proteins. Notably, mTORC1 can also potentiate HIF1α by increasing its transcription and translation, possibly functioning as part of a feedback regulatory circuit. Finally, DNA damage can reduce mTORC1 activity in part by increasing expression of TSC2 and PTEN.

Nutrient Regulation of mTORC1

Amino acids signal mTORC1 activation independently of growth factors. In fact, amino acids may be the most critical activator of mTORC1, as their ability to stimulate TOR activity is conserved from yeast to human. However, elucidating the mechanism of amino acid regulation has lagged behind many of the other upstream signals because, unlike the other inputs, amino acids do not activate mTORC1 through the TSC-Rheb

axis. However, the mechanism behind amino acid regulation of mTORC1 is now beginning to be revealed.[14,15] The first major leap forward in unraveling the mystery of how amino acids regulate mTORC1 was the discovery in mammals of four small GTPases called the *RAG* GTPases (i.e., RAGA, RAGB, RAGC, RAGD). RAGA or RAGB (which are structurally similar to each other and functionally redundant) form heterodimers with RAGC and RAGD (which are also similar to each other and functionally redundant). In the presence of amino acids, RAGA/B are GTP bound, whereas RAGC/D are GDP bound. When starved of amino acids, the situation is reversed: RAGA/B are GDP bound and RAGC/D are bound to GTP. Active RAG heterodimers bind directly to mTORC1 through the Raptor subunit. Unexpectedly, the RAG GTPases do not directly activate mTORC1 activity, but rather redistribute mTORC1 from an unknown location in the cytoplasm to the lysosome. The RAGs are associated with the lysosome through interaction with a pentameric complex called the *Ragulator* (which contains the p18/LAMTOR1, p14/LAMTOR2, MP1/LAMTOR3, C7orf59/LAMTOR4, and HBXIP/LAMTOR5 subunits). The Ragulator is tethered to the lysosome through the p18/LAMTOR1 subunit, which is both myristoylated and palmitoylated. In addition, the Ragulator contains guanine nucleotide exchange factor (GEF) activity toward RAGA/B, indicating that it is also functionally involved in activating the RAG recruitment signal. Thus, when amino acids are present, the Ragulator loads RAGA/B with GTP, triggering mTORC1 recruitment to the lysosome, where it docks with the RAG/Ragulator. The mechanism that delivers mTORC1 to the lysosome remains unknown.

How amino acids signal to the Ragulator to activate the RAG recruitment signal is also unclear. Early work suggests that amino acids might actually signal mTORC1 recruitment to the lysosome from within the lysosome by an "inside-out" mechanism. This mechanism involves the vacuolar H^+-ATPase (v-ATPase), which senses intralysosomal amino acids by an unknown mechanism and relays that information to the Ragulator through an amino acid–sensitive direct interaction. The v-ATPase is composed of many individual protein subunits and hydrolyzes ATP to pump protons into the lysosome to acidify the lumen. The v-ATPase is required for amino acids to trigger RAG-dependent recruitment of mTORC1, but it is not required for the RAG GTPases to associate with the Ragulator. The exact pool of amino acids being delivered to the lysosome remains to be determined. Thus, the v-ATPase appears to function downstream of amino acids but upstream of the RAG GTPases by promoting Ragulator GEF activity and therefore RAGA/B GTP loading.

Why does mTORC1 need to localize to the lysosome? Because the RAG GTPases do not activate mTORC1, it is hypothesized that mTORC1 must be recruited to the lysosome to be activated. In line with this idea, Rheb is proposed to reside on endomembranes including the lysosome, and thus mTORC1 recruitment would bring the complex in close proximity to its activator. This model explains why mTORC1 cannot be activated by growth factors in the absence of amino acids: that is, growth factors activate lysosomally tethered Rheb, but in order for Rheb to promote growth, mTORC1 must be delivered to the lysosome, which requires amino acids. In fact, forcing mTORC1 and Rheb to interact by overexpressing Rheb, artificially tethering mTORC1 to the lysosome, or artificially tethering both mTORC1 and Rheb to the plasma membrane results in amino acid–independent mTORC1 activation. More recent work suggests glucose may also mediate RAG-dependent recruitment of mTORC1 to the lysosome.[16] Like amino acids, glucose stimulates interaction between the v-ATPase and the Ragulator, suggesting that amino acids and glucose availability may converge on a common mechanism of mTORC1 regulation inside the lysosome.

Whether additional amino acid–dependent mechanisms of mTORC1 regulation exist is an open question. Although the Rag-Ragulator mechanism controls mTORC1 localization and activation in response to general amino acid and glucose availability, there could be additional inputs from mechanisms in the cytoplasm that sense specific amino acids. For example, it has been proposed the leucyl-tRNA synthetase (which catalyzes the ligation of L-Leu to its cognate tRNA) can act as a direct sensor of intracellular leucine and in turn promote mTORC1 activation. The exact mechanism and significance of this input remain to be determined. Nevertheless, these emerging studies indicate that intricate mechanisms evolved to link mTORC1 growth signaling to nutrient availability—independently of growth factors—ensuring that growth does not occur unless the building materials and energy supply are sufficient to meet the metabolic demands of macromolecular biosynthesis.

PI3K-AKT Signaling, mTORC1, and Cancer

Conditions that inhibit growth, such as decreased energy, low oxygen, and insufficient nutrients, are associated with the harsh microenvironment of poorly vascularized tumor. The ability of cancer cells to overcome these adverse conditions would promote tumor growth, putting the desensitization of mTORC1 signaling in the spotlight as a potential mechanism cancer cells could exploit to enhance their viability. Whether mutations in the amino acid– and glucose-sensing pathway that activates mTORC1 exist in cancer is not known. Mutations in the growth factor inputs to mTORC1 are prominent in cancer. For example, mutations causing loss of PTEN function or oncogenic activation of

PI3K or AKT are associated with many aggressive human cancers (Table 12-1).[17-20] The findings that AKT promotes mTORC1 activity through TSC and PRAS40 suggest that cancers with elevated PI3K-AKT signaling may in part thrive because of an mTORC1-driven growth advantage. Activation of PI3K-AKT signaling also facilitates nutrient uptake by cells, which indirectly contributes to mTORC1 activity by localizing mTORC1 to lysosomes. Therefore, understanding the contribution and relevance of mTORC1 signaling in the progression of cancers with aberrant PI3K-AKT signaling is an important area of research.

Unlike tumor cells with PTEN loss, tumor cells that have lost TSC function are generally less belligerent. It is now accepted that this is due to negative feedback loops that suppress the PI3K-AKT pathway when mTORC1 activity is high.[2,6,7] For example, the mTORC1 substrate S6K1 can directly phosphorylate and inactivate the IRS1 and IRS2 proteins, two mediators of PI3K activation, which decreases PI3K-AKT activity. A second feedback mechanism occurs through the direct mTORC1 substrate Grb10, which is activated by mTORC1 and functions to inhibit both the insulin/IGF receptors and IRS proteins. Negative feedback mechanisms would normally keep cell growth and nutrient uptake in balance, but in the absence of TSC, negative feedback squelches PI3K and AKT activity, which is important for promoting cell survival and metastasis. This may be why tuberous sclerosis (discussed later), which is caused by mutations in TSC, generally does not develop into metastatic cancer. Because PTEN and PI3K are downstream of the insulin/IGF receptors and IRS proteins, cancers driven by loss of PTEN or PI3K activation are uncoupled from these particular mTORC1-driven negative feedback loops, explaining why they are typically associated with more aggressive cancer.

Table 12-1 mTOR Signaling in Disease

Disease	Linked Genetic Mutation and Clinical Pathology	Predicted Functional Link to mTOR Signaling
Tumor-prone Syndromes		
TSC (tuberous sclerosis complex)	*TSC1* or *TSC2;* hamartomas in multiple organs	TSC1/2 negatively regulates Rheb
LAM (lymphangioleiomyomatosis)	*TSC2;* abnormal proliferation of smooth-muscle–like cells in the lung	TSC1/2 negatively regulates Rheb
Cowden disease	*PTEN;* hamartomatous tumor syndrome	May promote AKT-dependent inhibition of TSC2 and mTOR phosphorylation
Proteus syndrome	*PTEN;* hamartomatous tumor syndrome	May promote AKT-dependent inhibition of TSC2 and mTOR phosphorylation
Lhermitte-Duclos disease	*PTEN;* hamartomatous tumor syndrome	May promote AKT-dependent inhibition of TSC2 and mTOR phosphorylation
PJS (Peutz-Jeghers syndrome)	*STK11/LKB1;* gastrointestinal hamartoma tumor syndrome	STK11 activates AMPK, a positive regulator TSC2
HCM (familial hypertrophic cardiomyopathy)	*AMPK;* myocardial hypertrophy	AMPK promotes TSC2 function
Cancer		
Prostate	*PTEN*	PTEN loss promotes AKT activation
Breast	*PTEN;* PI3K, *AKT,* or *Her2/neu* amplification/ hyperactivation	PTEN loss or gene amplifications promote AKT activation
Lung	*PTEN; HER* amplification	PTEN loss or gene amplifications promote AKT activation
Bladder	*PTEN*	Promotes AKT activation
Melanoma	*PTEN*	Promotes AKT activation
Renal-cell carcinoma	*PTEN*	Promotes AKT activation
Ovarian	*PTEN;* PI3K, *AKT,* or *Her2/neu* amplification/ hyperactivation	PTEN loss or gene amplifications promote AKT activation
Endometrial	*PTEN*	Promotes AKT activation
Thyroid	*PTEN;* PI3K, *AKT,* or *Her2/neu* amplification/ hyperactivation	PTEN loss or gene amplifications promote AKT activation
Brain (glioblastoma)	*PTEN*	Promotes AKT activation
CML (chronic myeloid leukemia)	*BCR/ABL* translocation	Promotes AKT activation

mTORC1 and Autophagy

Macroautophagy, or simply autophagy, is a catabolic process induced on nutrient limitation or stress in which autophagosomes form and fuse with the lysosome to create an autophagolysosome. The autophagolysosome is the final destination for proteins and organelles that are broken down into their basic components to be recycled as sources of cellular energy and metabolites during starvation. Autophagy has an important role in cell survival during times of energy crisis. Under normal growth conditions, autophagy also salvages and recycles cellular junk such as excess or damaged organelles. Newborn mice require autophagy to survive a brief starvation period immediately after birth, and defects in autophagy are associated with cancer, degenerative disorders, and aging.[21-23] A connection between mTORC1 signaling at autophagy first became apparent in yeast and mammalian cells in studies where rapamycin was found to induce autophagy. Genetic inactivation of TOR in *Drosophila* also induces autophagy and confirmed that mTORC1 not only positively controls anabolic processes, but suppresses catabolic processes opposing growth.

Recent studies have revealed that the regulation of autophagy by mTORC1 is at least partly direct and occurs in coordination with AMPK.[24,25] More than 30 autophagy *(ATG)* genes have been identified that control autophagy. In nutrient-rich conditions, mTORC1 associates with and directly phosphorylates ULK1/ATG1, the kinase subunit of a complex that is required for autophagy induction. Phosphorylation of ULK1 by mTORC1 inhibits its activity and reduces autophagic vesicle formation. In nutrient-deprived cells, AMPK not only inhibits mTORC1 by phosphorylating TSC2 and Raptor (as described earlier), but also directly activates ULK1 kinase activity. When mTORC1 activity decreases, ULK1 is dephosphorylated, allowing AMPK to now interact with, phosphorylate, and activate ULK1 to induce autophagy. This dual regulatory circuit emphasizes the tight balance between anabolic and catabolic processes.

Interestingly, prolonged autophagy, which delivers its cargo to the lysosome, eventually reactivates mTORC1. Thus, in nutrient-starved cells, autophagy may also be required to keep mTORC1 on in a minimally activated state to promote the synthesis of certain macromolecules essential for survival. The reactivation of mTORC1 also promotes the formation of nascent lysosomes that bud from the autophagosome. In fact, recent studies further suggest that mTORC1 may normally regulate lysosome formation through its ability to control that nuclear localization (and thus activity) of a transcription factor called *TFEB*. TFEB regulates the expression of many genes important for lysosome formation. Thus, the connections among nutrient and energy sensing, mTORC1 growth control, and protein/organelle turnover by autophagy and the lysosome are complex, and it will be interesting to determine if and how defects in these connections promote cancer.

Although the connections between mTORC1 and autophagy are being worked out, the strong connections between mTORC1 and cancer suggest that autophagy may have a role in tumorigenesis, and evidence supports this hypothesis.[21] For example, mice deficient for a pro-autophagy gene, called *beclin-1*, have an increased frequency of spontaneous tumor formation, suggesting that *beclin-1* is a tumor suppressor gene. How could inactivation of autophagy promote tumorigenesis? It is difficult to speculate at this time because little is known about Beclin 1, but perhaps some transformed cells rely on autophagy to remove damaged organelles or for complete self-disposal. In this model, mutations that prevent autophagy would promote cell survival. Interestingly, the Bcl-2 pro-survival oncoprotein, which has long been thought to inhibit apoptosis, binds and inhibits Beclin 1–dependent autophagy.[26] This suggests that the oncogenic activity of Bcl-2 might be linked to inhibiting nonapoptotic autophagic cell death. Contrary to having tumor suppressor capacity, autophagy could promote tumorigenesis in some cases. When cancer cells experience nutrient limitation, autophagy may provide the rations necessary to sustain the most essential bioenergetic cellular process. This may allow cancer cells to survive until angiogenesis is initiated or other deleterious mutations occur. Understanding the role of autophagy in different cancer cells will be important to designing mTOR-focused treatment strategies.

mTORC1 and p53

Mutation of the p53 tumor suppressor is one of the most common genetic abnormalities associated with human cancer. DNA or spindle damage, telomere shortening, various stresses, or oncogenic mutations will usually initiate a p53-dependent checkpoint that arrests cells in G_1 or trigger apoptosis (depending on the cell type and signals present). This has led to speculation that such a checkpoint mechanism involving p53 might communicate with the mTORC1 pathway to discourage growth when conditions are unfavorable. Early reports from work with cultured cells suggest that AMPK and p53 may communicate in some type of checkpoint mechanism to restrict growth in low-glucose conditions or when DNA is damaged, although it is unclear from this early work if and how directly mTORC1 regulation might be connected.[27] Mounting evidence also indicates that a communication link exists between p53 and the regulation of mitochondrial respiration, particularly in mediating a cellular switch to preferentially deriving energy from glycolysis rather than aerobic respiration—a hallmark characteristic of cancer cells.[28] It is well known that p53 and

the mitochondria, and to some extent mTOR, have roles in apoptosis. Because signals from the mitochondria are also thought to control mTORC1's ability to mediate growth, it seems likely that a complicated signaling circuitry involving both the p53- and mTOR-dependent pathway exists.

Beyond Cell Growth: Does mTOR Regulate Organ and Organism Growth?

The mTORC2 Pathway

The role of TOR in building cell mass is well documented and conserved in all eukaryotic organisms examined. However, extending a role for mTOR in controlling organ and organism growth is more complicated, because most tissues grow by mechanisms involving the collective coordination of cell growth, cell division, and cell death pathways. The finding that mTOR exists in a second complex called *mTORC2* does suggest that mTOR may have broad influence over cell growth, cell division, cell death, metabolism, and many other processes essential for building tissues and organisms. Many of these additional targets of mTOR activity, although not completely worked out yet, are likely to be important in cancer progression, and thus emerging therapeutic strategies are now aiming to more broadly target mTOR signaling by inhibiting both mTORC1 and mTORC2.

The second mTOR complex also contains mLST8 and Deptor, but instead of Raptor and PRAS40, mTORC2 contains the Rictor, mSin1, and PROTOR proteins (see Figure 12-1).[2] Understanding the function of mTORC2 initially eluded researchers because the complex is insensitive to acute rapamycin treatment, and thus rapamycin could not be used to probe for mTORC2 substrates. However, advances in RNA-interference technology allowed the specific depletion of Rictor from cells, leading to the discovery that mTOR, when outfitted with mTORC2-specific regulatory proteins, phosphorylates and activates the AKT kinase. Current models suggest that on recruitment to the membrane after growth factor stimulation, AKT is phosphorylated by mTORC2 in conjunction with PDK1, and this co-regulation is presumed necessary for full AKT activation. How mTORC2 activity itself is controlled remains to be worked out, but initial experiments indicate that growth factors also modulate mTORC2 activity by an unknown mechanism.

AKT activity influences cell growth, cell proliferation, cell survival, metabolism, and many other processes.[13] Thus, by coupling mTOR activity with proliferation and survival, the discovery of mTORC2, together with the well-known role of mTORC1 in controlling cell size, strengthens the argument that mTOR growth regulation extends beyond cell autonomous growth to organ and organism growth. Moreover, because of the widespread role of PI3K-AKT signaling in cancer (see Table 12-1), the finding that mTORC2 phosphorylates and activates AKT is a compelling additional link between mTOR and cancer. In fact, a number of studies now suggest that selectively targeting mTORC2 could also be a promising therapeutic strategy.[29,30] What is interesting about potentially targeting mTORC2 is that in many cases, loss of mTORC2 function (by genetic approaches) is less toxic to normal cells than targeting mTORC1 function. In contrast, mTORC2 activity is required for transformation, particularly when transformation is driven by loss of PTEN.[31] Thus, mTORC2 might be more essential to certain cancer cells than to many normal cells. The challenge of selectively targeting mTORC2 is that beyond the mTOR catalytic domain, the understanding of mTORC2 structure and regulation is only vague, and thus it is currently difficult to predict what type of targeting strategy might best achieve this goal.

In retrospect, it is not surprising that mTOR can also phosphorylate AKT, because the mTORC2 phosphorylation site on AKT (S473) is structurally similar to the mTORC1 site on S6K1 (T389), both of which are present in carboxy-terminal hydrophobic motifs. In fact, both S6K and AKT belong to a larger family of structurally related kinases called the AGC kinases.[32] The discovery of the mTORC2-AKT signaling module also sets up the peculiar situation whereby mTOR can regulate itself in a manner dependent on what proteins it interacts with. For instance, mTORC2-mediated phosphorylation of AKT is proposed to promote subsequent phosphorylation and inactivation of TSC2 and PRAS40 (as described earlier), which would place mTORC2 upstream of mTORC1 regulation. The extent to which normal and cancer cells rely on such regulation is under investigation. How other AKT substrates are regulated by mTORC2 is also largely unclear. In addition to AKT, mTORC2 can directly phosphorylate two additional AGC kinases called SGK and PKC. SGK is most similar to AKT, except that it lacks the membrane-targeting PH domain that brings AKT to its activation site at the cell membrane. SGK also has some overlapping functions with AKT, but currently the role of mTORC2-mediated SGK and PKC regulation in cancer is unknown.

Controlling Body Size

It is a remarkable feat for mammals to coordinate the development of their organs to appropriate sizes that are proportional to overall body size. The endocrine system is responsible for conducting this massively orchestrated systemic growth. The major hormone responsible for controlling postnatal growth is growth hormone (GH). GH is synthesized in the pituitary gland. After its release into the blood, circulating GH stimulates the release of insulin-like

growth factors (IGFs) from the liver. IGFs subsequently stimulate growth of bone and muscle, which are the two organs most relevant to determining body size.

The findings (1) that mTOR regulates cell growth, proliferation, and survival and (2) that both mTORC1 and mTORC2 are downstream of insulin/IGF signaling raise the question of whether mTOR is a master regulator of body size. The role of mTOR as a nutrient-sensitive regulator of eukaryotic cell growth (i.e., as part of mTORC1) is an ancient function conserved from yeast to humans. During the evolution of multicellular organisms, growth factor signaling was grafted onto the mTORC1 pathway, probably to modulate autonomous cell growth in conjunction with systemic nutrient availability and signals from other cells and tissues. The discovery that mTOR (as part of mTORC2) regulates AKT further suggests that additional pathways independent of mTORC1 may contribute to the regulation of cell growth, proliferation, survival, and metabolism. Many mTORC2 components are also conserved in yeast—although the protein sequences and downstream functions are more diverged compared to mTORC1, suggesting the cellular functions of mTORC2 may have also diverged. Because of mTOR's remarkable ability to integrate numerous signals and control many aspects of cell growth, it seems poised to be a master regulator of organ and body size control. Studying this in mammals has been difficult, however, because mice null for mTOR and the essential mTORC1 and mTORC2 regulatory subunits are embryonic lethal. In *Drosophila*, the fat body (which may be equivalent to the vertebrate liver) functions as a nutrient-sensing organ that can control body growth through a TOR-dependent mechanism.[33] Moreover, mice and flies deficient for S6K1 are viable but reduced in size because of smaller cells, implying a link between mTORC1 signaling and body size control.[34] Thus, limited evidence in model organisms suggests that mTOR could influence body size by systemic as well as cell-autonomous mechanisms. Interestingly, in humans a rare mutation in the p14/LAMTOR2 subunit of the Ragulator delays growth and causes immunosuppression and hypopigmentation.[35] As novel upstream regulators and substrates of mTOR are unveiled, it will be interesting to determine if genetic variation in components of the mTOR network has a role in determining organ and organism size.

Targeting mTOR Signaling as a Treatment for Cancer and Other Human Diseases of Cell Growth

With a role for mTOR signaling in cancer now firmly established, developing molecules that inhibit mTOR for therapeutic purposes is a significant focus of the pharmaceutical industry. As mentioned earlier, rapamycin (also known as *sirolimus*) is used clinically for immunosuppression (because of its ability to suppress T-cell proliferation), to prevent restenosis (by preventing the growth of vascular smooth muscle cells), and to treat certain cancers.[5,17,36] Analogs of rapamycin have also been developed for cancer therapy (CCI779/temsirolimus, AP23573, and RAD001/everolimus—collectively called rapalogues). Unfortunately, rapamycin as a broad anticancer drug has had limited success as a single-agent therapeutic, even against cancers with elevated PI3K-AKT signaling. The response to rapamycin is highly variable depending on the cancer, and only a few cancers, including mantle-cell lymphoma, renal-cell carcinoma, and endometrial cancers, have shown consistent positive responses. Temsirolimus was approved in 2007 to treat renal-cell carcinoma. Several trials are ongoing, although there is no clear biomarker predictive of rapamycin sensitivity.

A number of reasons have been proposed to explain rapamycin's general ineffectiveness as a cancer drug. One possibility (discussed earlier) is that inhibiting mTORC1 relieves strong negative feedback loops that function to suppress receptor tyrosine kinase (RTK) signaling and downstream PI3K-AKT activation (Figure 12-2). Therefore, treating cells with rapamycin boosts AKT signaling, which in turn could drive AKT-dependent cell proliferation and survival pathways—clearly an undesirable response. The MAPK-ERK signaling pathway is also triggered by mTORC1-S6K1 inhibition. Using rapamycin in combination with PI3K or MAPK pathway inhibitors might prove to be a better strategy. Second, it is now clear that rapamycin only partially inhibits mTORC1. For example, although rapamycin results in rapid dephosphorylation and sustained inactivation of S6K, phosphorylation of 4E-BP1 is only partially and transiently decreased.[37] Therefore, translation is largely insensitive to rapamycin. As more mTORC1 substrates are being discovered, it will be interesting to determine why substrates vary in their sensitivity to rapamycin.

It is often stated that rapamycin specifically targets mTORC1, implying that it does not inhibit mTORC2. However, the actual situation is more complex.[2,38] In cultured cells, rapamycin acutely affects only mTORC1, but prolonged exposure disrupts mTORC2 integrity, likely by blocking the assembly of new mTORC2 complexes. In some cell types this results in decreased AKT phosphorylation, but often there is no apparent change or increased AKT phosphorylation. Notably, any mTORC2 complexes that remain intact following rapamycin treatment are still susceptible to losing feedback inhibition. This likely explains the cell-to-cell variability in AKT phosphorylation following prolonged rapamycin treatment. For example, even if most mTORC2 complexes are

disrupted by rapamycin, what remains intact is hyperactive, and consequently AKT phosphorylation can appear insensitive to rapamycin or increase. Exactly what determines whether AKT phosphorylation in a particular cancer cell will show increased, decreased, or no sensitivity to rapamycin remains a mystery. Nevertheless, inhibition of mTORC2 following chronic exposure to rapamycin could explain the drug's effectiveness in certain cancers as well as some of its side effects. Dissecting the molecular mechanisms by which rapamycin functions and identifying biomarkers predictive of rapamycin sensitivity remains an important area of research.

Next-generation mTOR inhibitors are ATP competitive inhibitors (discussed earlier). Therefore, unlike the rapalogues (which are allosteric inhibitors), these drugs directly target mTOR kinase activity.[2,5] Consequently, the ATP competitive inhibitors more completely inhibit mTORC1 and also inhibit mTORC2. The mTOR ATP-competitive inhibitors are having a major impact in basic research, and several versions are being evaluated in clinical trials as anticancer drugs with the hope that they will outperform the rapalogues. Their tolerability remains to be seen, but early data are encouraging. Notably, losing feedback inhibition remains a challenge with these inhibitors because, despite the fact that they inhibit mTORC2 as well, the mTORC2 substrate AKT is also regulated by the PDK1 kinase, which increases activity following mTORC1 inhibition because the negative feedback is lost (see Figure 12-2). A related class of inhibitors is called the *dual-specificity inhibitors*, which target mTORC1, mTORC2, and PI3K. Dual inhibition is possible because the kinase domains of mTOR and PI3K are structurally similar, even though mTOR phosphorylates proteins and PI3K phosphorylates lipids. The dual-specificity inhibitors could have an advantage because by also inhibiting PI3K, they can mitigate the effects of losing the mTORC1-dependent negative feedback inhibition of PI3K-AKT signaling (see Figure 12-2). Because many

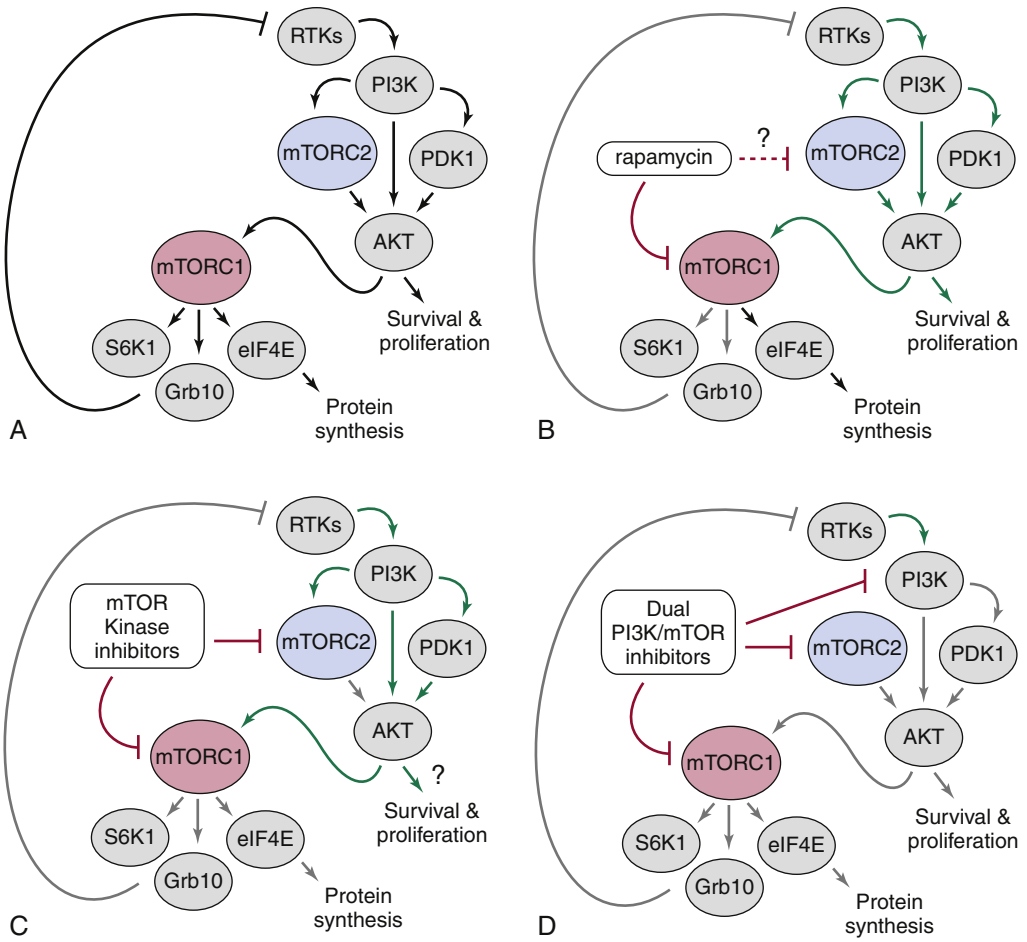

Figure 12-2 Model explaining how downstream signaling in cancer cells responds to currently available classes of mTOR pathway inhibitors **(A)** Simplified depiction of how the mTOR signaling circuitry is wired (described in the text). Note that PI3K is shown here activating mTORC2; however, exactly how growth factors activate mTORC2 is unknown. **(B)** Rapamycin (or the rapalogues) only partially inhibits mTORC1 and relieves strong mTORC1-dependent negative feedback inhibition of receptor tyrosine kinase (RTK)-PI3K signaling. Note that prolonged rapamycin treatment can inhibit mTORC2 in some cell types, but the therapeutic significance of this is unclear. **(C)** The mTOR kinase inhibitors are ATP-competitive inhibitors that target both complexes. However, these inhibitors also release PI3K from mTORC1-dependent feedback inhibition. **(D)** The dual-specificity inhibitors target both mTOR complexes and PI3K and thus may mitigate the consequences of losing feedback inhibition.

research studies and clinical trials are ongoing with both ATP-competitive and dual-specificity mTOR inhibitors, it should soon become clear to what extent they will be useful clinically.

Beyond the obvious rationale for targeting mTOR in human cancer, a variety of tumor-prone syndromes are also linked to mutations that impinge on mTOR (see Table 12-1).[18,39-42] These include tuberous sclerosis complex (caused by mutations in the *TSC1* or *TSC2* genes, a related disease called lymphangioleiomyomatosis or LAM (*TSC1* and *TSC2*), Cowden disease (*PTEN*), Bannayan-Riley-Ruvalcaba syndrome (*PTEN*), Proteus and Proteus-like syndrome (*PTEN*), Peutz-Jeghers syndrome (*LKB1*—an upstream activator of AMPK), and neurofibromatosis (*NF1*—a negative regulator of Ras-PI3K activity). Patients suffering from these syndromes are candidates for therapeutic intervention with mTOR inhibitors.

Tuberous sclerosis complex is characterized by benign tumors that can grow in the brain, kidney, heart, eyes, lungs, and skin and can be devastating and fatal depending on the degree of penetrance and location of the tumors. LAM usually affects women and results in abnormal growth of smooth muscle cells in the lungs that severely compromises respiration. The discovery that TSC negatively regulates mTORC1 propelled rapamycin into clinical trials to treat patients suffering from these diseases. Some features of tuberous sclerosis complex, such as the appearance of abnormally large astrocytomas in the brain, are reduced in size following rapamycin treatment, and everolimus is now FDA approved for treating this disease. Notably, the TSC complex may also have mTORC1-independent functions, and some studies have concluded that not all cellular phenotypes associated with losing TSC function are mTOR dependent. Although the rationale to use mTOR inhibitors to treat tuberous sclerosis complex and LAM is compelling, it will be important to consider the mTOR-independent roles of TSC when evaluating trial results.

Inactivation of PTEN can cause Cowden disease in addition to cancer. Cowden disease is characterized by hamartomas present in the skin, mucosa, gastrointestinal tract, bones, central nervous system, eyes, and genitourinary tract. Patients are at a high risk for breast and thyroid carcinoma. As described earlier, PTEN negatively regulates the PI3K-AKT signaling pathway, which can subsequently inactivate the TSC complex. Peutz-Jeghers syndrome is caused by inactivation of the LKB1 tumor suppressor and results in intestinal hamartomatous polyps and increased risk of intestinal cancer. LKB1 is a protein kinase that phosphorylates and activates AMPK. As discussed earlier, AMPK inactivates mTORC1 following energy depletion by promoting TSC function and by phosphorylating Raptor. Neurofibromatosis primarily results in tumors growing on nerve tissue but can also cause skin and bone abnormalities. The disease results from inactivation of NF1, a Ras-GTPase activating protein that, when absent, renders phosphorylation of TSC2 and S6K1 by AKT and mTORC1, respectively, resistant to growth factor (but not nutrient) withdrawal. Loss of NF1 leads to accumulation of Ras in the active GTP-bound state, suggesting that Ras, a well-known oncogene, also affects mTORC1 activity.

The links between signaling networks that control cell, organ, and organism growth through mTOR and the onset of human cancer suggest that therapeutic interventions targeting this pathway and its regulators could have promise. The potential for rapamycin and its analogs in treating cancer and other growth diseases captivated the pharmaceutical industry, and substantial investments in its development have led to extensive and ongoing clinical assessment. Despite years of research, rapamycin's mechanism of action remains enigmatic, and it is now clear that rapamycin only partially inhibits mTORC1. Effective use of the drug as an anticancer agent will require a deeper understanding of why only subsets of cancer cells are sensitive and whether there are efficacious combination therapies that can be exploited. Discovering that mTOR exists in at least two distinct complexes with differing sensitivity to rapamycin provided a strong rationale for developing novel inhibitors that target both complexes. Preclinical and clinical trials should soon inform the community of how efficacious these drugs will be. Other new potential avenues for developing mTORC1 pathway inhibitors include targeting the amino acid– and glucose-sensing pathway that delivers mTORC1 to the lysosome. However, it is possible that mTORC1 is so essential for maintaining normal cellular homeostasis that inhibiting it systemically will be too toxic to normal cells. Selectively inhibiting mTORC2 is an alternative strategy, at least in PI3K-driven cancers, as this could be less toxic to normal cells and leave mTORC1-dependent negative feedback loops largely intact. This, however, may prove to be a daunting task, as there is currently no obvious mTORC2 functional domain (outside the mTOR kinase domain) or essential upstream kinase that can be targeted. Because unique interacting proteins define the mTOR complexes, potential exists for developing mTORC2-selective inhibitors that might disrupt complex integrity or localization. Obtaining greater knowledge of the structure and function of the individual mTORC2 subunits will be essential for this endeavor. The discovery that prominent cancer pathways impinge on mTOR signaling has provided many new potential avenues for drug development, and ongoing efforts to develop mTOR inhibitors will undoubtedly affect the care of cancer patients.

The Metabolism of Cell Growth and Proliferation

Why Is Metabolism Important to an Understanding of Cancer?

At its heart, cancer is a disease of abnormal proliferation. Proliferation represents a distinct metabolic challenge: cells must replicate all of their proteins, lipids, and nucleic acids to generate a daughter cell. This process requires vast inputs of energy and raw materials. As a result, proliferating cells take up large quantities of nutrients in order to engage the biosynthetic reactions that support cell growth. Unsurprisingly, cancer cells exhibit many of the metabolic features that are characteristic of proliferating cells.[1] Given the logical association between metabolism and proliferation, it is not surprising that the study of cancer metabolism could yield diagnostic and therapeutic opportunities. Indeed, the propensity of cancer cells to take up high levels of glucose has been exploited clinically. For example, uptake of radioactive glucose analogs, measured by positron emission tomography, can be used to diagnose and monitor glucose-avid tumors.

Over the past decade, the study of cancer has become increasingly entwined with the study of cellular metabolism. Altered metabolism is a common feature of cancer cells, and most oncogene and tumor suppressor pathways directly regulate cellular metabolic pathways.[2] Moreover, cancer-associated metabolic alterations can in turn signal to alter the expression or activity of oncogenic pathways.[3] This chapter provides an overview of the metabolic changes associated with cancer cells, the genetic mechanisms that regulate tumor metabolism, and the clinical implications of altered cancer metabolism.

The Metabolic Requirements of Cell Proliferation

Proliferating and nonproliferating cells have very different metabolic requirements. Nonproliferating cells must maintain an ample supply of energy to fuel basic cellular processes, such as maintaining ion gradients and supporting transcription and translation, in addition to fulfilling their tissue-specific biological roles. This energy, usually in the form of adenosine triphosphate (ATP), is generated primarily in the mitochondrion. The basic building blocks of carbohydrates, lipids, and proteins (glucose, fatty acids, and amino acids, respectively) can be broken down in the tricarboxylic acid (TCA) cycle and the NADH generated by their oxidation used to produce ATP using oxidative phosphorylation (OXPHOS) (Figure 13-1).[4] This efficient conversion of nutrients into energy permits relatively low levels of nutrients to support the metabolic demands of quiescent cells.

In contrast, proliferating cells face the challenge of doubling all of the macromolecules in the cell in order to divide into two daughter cells. Cells must produce abundant nucleic acids, amino acids, and fatty acids in order to synthesize the DNA, proteins, and membranes that are necessary to replicate themselves. The process of synthesizing macromolecules, known as *anabolism* or *anabolic metabolism*, requires three main inputs that are critical for the process of cell growth:

1. *Substrates.* Extensive intracellular metabolic networks ensure that mammalian cells can generate many of the metabolic building blocks required for growth from relatively few inputs. For example, humans can synthesize 11 amino acids (which are consequently known as the nonessential amino acids) by rearranging the nitrogen and carbon backbones of other dietary inputs. (The other 9 amino acids are considered "essential" amino acids, as they cannot be synthesized in human cells.) In most cell types, glucose is the most important substrate for anabolic metabolism, because by-products of glucose breakdown (or catabolism) can contribute to the production of nonessential amino acids as well as nucleic acids and lipids. Most reduced nitrogen utilized for cell growth is taken into cells as glutamine. Glutamine plays a critical role providing nitrogen for nucleotide and nonessential amino

acid synthesis.[5] Like glucose, glutamine can also provide carbon units for fatty acid synthesis. Given their importance as central metabolites bridging both anabolic and catabolic pathways, glucose and glutamine are major fuels for cell proliferation and are discussed in detail later in this chapter. Cell proliferation requires numerous other substrates, including essential amino acids and a variety of vitamins and minerals, which will not be discussed (for more reading, see Ref. 6).

2. *Chemical energy*. Intramolecular bonds store large amounts of energy. Consequently, catabolism of macromolecules releases energy, which is harnessed either directly by driving the production of ATP or indirectly by reducing the electron carrier NAD^+ to NADH, which in turn fuels ATP production via OXPHOS. Conversely, macromolecular synthesis requires extensive energy input. Separately, protein translation and DNA replication consume significant amounts of ATP. In contrast to nonproliferating cells, a significant portion of the ATP required to sustain cell proliferation is produced by glycolysis, which is upregulated in rapidly dividing cells.

3. *Reducing equivalents*. Just as many catabolic reactions involve the oxidation, or removal of electrons from metabolites to electron carriers such as $NADP^+$ or NAD^+, several anabolic reactions require the input of electrons as reducing agents to forge intramolecular bonds. Reducing equivalents, primarily in the form of NADPH, carry these electrons for use in anabolic pathways. Fatty acid, nucleic acid, and nonessential amino acid synthesis consume large amounts of NADPH. The relative levels of $NADPH/NADP^+$ and $NADH/NAD^+$ often reflect the "redox" status of the cell—the extent to which the cell has more reduced electron carriers (higher $NAD(P)H/NAD(P)^+$ ratio) or more oxidized electron carriers (lower $NAD(P)H/NAD(P)^+$ ratio). Cellular redox balance is tightly controlled by many factors and can contribute to cancer growth, proliferation, and survival in numerous ways.[7] For proliferating cells, a large fraction of NADPH and NADH may be generated by glucose catabolism.[8]

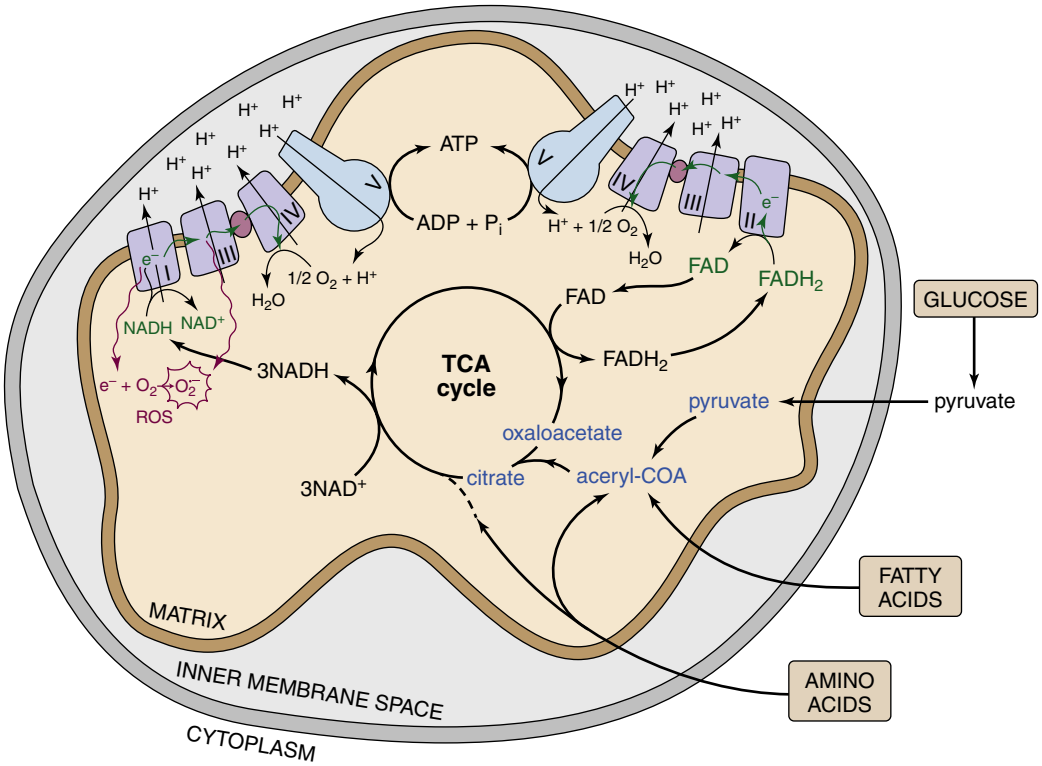

Figure 13-1 Mitochondria efficiently degrade metabolic fuels to generate ATP Metabolic fuels—carbohydrates, fats, and proteins—are broken down into their constituent units: glucose, fatty acids, and amino acids. These molecules are further degraded into metabolic intermediates that enter the tricarboxylic acid (TCA) cycle. Glucose-derived pyruvate, fatty acids, and many amino acids enter the TCA as acetyl-CoA, which condenses with oxaloacetate to form citrate. A series of biochemical reactions oxidize citrate back to oxaloacetate, while using the high-energy electrons released by these oxidation reactions to reduce the electron carriers NAD^+ and FAD to NADH and $FADH_2$, respectively. NADH and $FADH_2$ carry these electrons to complex I and complex II of the electron transport chain, regenerating NAD^+ and FAD. The high-energy electrons are passed through the electron transport chain (complex I-III-IV or complex II-III-IV), and their energy is used to pump protons from the mitochondrial matrix into the inner membrane space, generating an electrochemical gradient known as the *mitochondrial membrane potential*. Ultimately, the electrons reduce molecular oxygen to form water. The energy released by protons flowing down their electrochemical gradient through complex V/ATP synthase is harnessed to synthesize ATP from ADP and P_i. Reactive oxygen species (ROS) are formed when electrons leak out of the electron transport chain prematurely, combining with oxygen to form the superoxide radical ($O_2^{\cdot-}$). Although ROS is an inevitable by-product of oxidative phosphorylation, its production can be increased whenever flow through the electron transport chain is slowed, whether by heightened membrane potential or reduced oxygen concentrations. Metabolites are shown in *blue*. Electron carriers are shown in *green*.

Regulation of Cell Metabolism

During conditions of nutrient scarcity, anabolic programs are suppressed in favor of energy-generating catabolic pathways. Conversely, multiple cellular metabolic pathways must be coordinately rewired to support cell proliferation. Elevated nutrient uptake—particularly of glucose and glutamine—provides the substrates for cell growth. Rapid catabolism of glucose via glycolysis produces sufficient ATP and NADPH to support energy-dependent anabolic reactions while generating the metabolic intermediates that will be critical for macromolecular biosynthesis. Similarly, catabolism of glutamine will help maintain bioenergetics while ensuring adequate substrates for cell growth. Multiple regulatory mechanisms ensure that energy production and macromolecular biosynthesis are appropriately balanced with the metabolic needs of the cell.

Unicellular organisms are directly exposed to the environment and any fluctuations in nutrient availability that may occur. Consequently, these organisms have elegant mechanisms to sense the available nutrients and rewire their metabolism accordingly. Thus, for unicellular organisms, nutrient availability directly controls the signals that regulate growth and proliferation. If a unicellular organism is in an environment with abundant nutrients, these nutrients will directly activate signaling pathways that instruct the cell to engage anabolic metabolic pathways and to undergo cell division. Conversely, conditions of low nutrient availability will halt cell growth and division. Cells will engage catabolic pathways in order to produce energy to survive through the period of scarcity (Figure 13-2).

In contrast, metazoans have complex organ systems that maintain a relatively constant level of extracellular nutrients throughout the body. Cell-autonomous metabolic regulation would be catastrophic, as well-fed cells might undergo aberrant growth and proliferation. Thus, nutrient availability alone cannot determine whether cells engage anabolic or catabolic pathways; the metabolism of individual cells must be aligned with the needs of the organism as a whole. This coordination is largely achieved through extracellular growth factors that regulate nutrient uptake and utilization. Binding to receptors on the cell surface, growth factors stimulate intracellular signal-transduction cascades that regulate many facets of nutrient uptake and metabolism. In particular, growth factor signaling enables cells to take up high levels of nutrients such as glucose and glutamine and to engage in anabolic pathways supporting cell growth (see Figure 13-2).[9] In this manner, systemic signals can target individual cells (expressing the proper growth factor receptor) to induce specific activities, thereby ensuring that the behavior of individual cells is tailored to the needs of the entire organism. In the absence of growth factor signaling, metazoan cells are largely quiescent, maintaining homeostasis by the efficient degradation of the limited nutrients they are directed to take up. By engaging oxidative, catabolic pathways that preserve intracellular energy levels, these cells are able to survive and fulfill their allotted functions.

Most cells have the capacity to engage both anabolic and catabolic pathways, and the balance between the two—the balance that guards against inappropriate cell proliferation while maintaining cell survival—is carefully regulated by a number of factors. External signals such as growth factors instruct the cell to grow, activating anabolic reactions

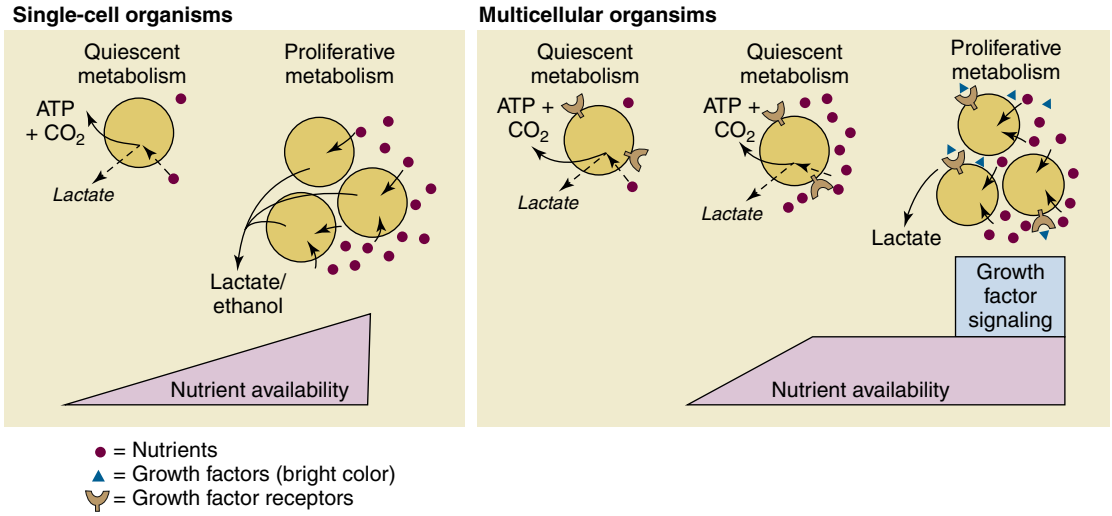

Figure 13-2 Proliferative metabolism is differentially regulated in single-cellular and multicellular organisms Quiescent cells in both single-cellular organisms and multicellular organisms engage in oxidative metabolism, efficiently converting available nutrients to ATP and carbon dioxide. In the presence of abundant nutrients, single-cellular organisms will engage in proliferative metabolism, consuming high levels of nutrients to produce biomass while excreting large amounts of lactate or other anaerobic fermentation products, such as ethanol. In contrast, the presence of abundant nutrients is insufficient to trigger proliferative metabolism in multicellular organisms, which require additional growth factor signals in order to engage proliferative metabolism. Once stimulated, these cells will undergo high rates of glycolysis to fuel cell growth.

and driving nutrient uptake accordingly. The activities of key metabolic enzymes that determine whether metabolites enter anabolic or catabolic pathways are regulated by post-translational modifications, most commonly phosphorylation triggered by growth factor signaling. Metabolites themselves function as critical allosteric regulators of metabolic enzyme activity, increasing or inhibiting flux through metabolic pathways according to the needs of the cell. For example, signals of abundant energy stores such as ATP and NADH can allosterically inhibit multiple enzymes that otherwise promote the channeling of metabolites into catabolic, energy-producing pathways. This allows for the diversion of metabolites toward anabolic processes when energy supply is plentiful. Similarly, both metabolic cues and growth factor signaling pathways can regulate the expression levels of metabolic enzymes. Through these mechanisms, cells carefully control the activation of anabolic or catabolic metabolic programs and ensure that during cell proliferation, metabolic pathways are coordinately rewired to support cell growth.

A major hallmark of cancer is the development of cell-autonomous regulation of cell growth.[10] Through multiple genetic events, including activation of growth factor signal transduction pathways (oncogenes) and loss of inhibitory signals (tumor suppressors), cancer cells circumvent dependence on external growth factor signaling. Constitutive activation of growth factor signaling pathways ensures that cancer cells are not subject to the normal regulation of metazoan cells. Consequently, cancer cells exhibit metabolic transformation, taking up high levels of nutrients and engaging in proliferative metabolism to support unchecked cell growth.

The Metabolic Profile of Cancer Cells

It is increasingly clear that cancer cells exhibit metabolic phenotypes that are similar to rapidly proliferating normal cells, with the major difference that the metabolic alterations in cancer cells stem from oncogenic cell-autonomous signaling, rather than the appropriate result of specific growth signals originating outside the cell. The characteristic metabolic features of rapidly proliferating tumor cells include elevated glucose uptake and glycolysis, increased glutamine uptake and utilization, and enhanced lipid and nucleotide biosynthesis. This section discusses the common metabolic signatures of tumor cells and how these metabolic alterations may support tumor growth.

Aerobic Glycolysis: The Warburg Effect

The most well-known and prevalent metabolic change associated with cancer cells is the enhanced uptake and metabolism of glucose, often referred to as the *Warburg effect*. In 1926, Otto Warburg noted that rapidly proliferating ascites cancer cells take up high levels of glucose and produce large amounts of lactate, even in the presence of oxygen. This finding was not intuitive: Work begun by Louis Pasteur had shown a clear inverse relationship between oxygen availability and the rate of glucose fermentation to lactate. The ability of eukaryotic cells to switch between anaerobic energy production through fermentation to aerobic energy production through oxidative phosphorylation depending on the presence of oxygen is known as the *Pasteur effect* (Figure 13-3). In cancer cells in the presence of oxygen, one might expect glucose to be metabolized to pyruvate, which would then be completely oxidized in the mitochondrion to produce ATP through the oxygen-dependent process of oxidative phosphorylation (see Figure 13-1). The surprising observation that cancer cells converted pyruvate to lactate despite abundant oxygen availability—the process of aerobic glycolysis—led Warburg to speculate that mitochondrial function is impaired in tumor cells, forcing a reliance on glycolytic metabolism.[11]

We now know that most cancers do not exhibit impaired mitochondrial energy production.[12] Moreover, research increasingly suggests that mitochondrial metabolic pathways are not simply catabolic and energy-producing; they may also play a critical role supporting anabolic biosynthetic pathways, as discussed later. These findings indicate that high aerobic glycolysis is not the secondary result of a metabolic failure, but rather a specific adaptation that promotes cell growth. Despite the centrality of the Warburg effect to cancer cell metabolism, there is still some debate as

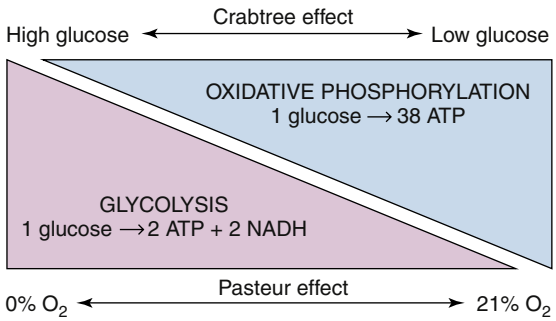

Figure 13-3 Normal, nonproliferating cells coordinate the balance between glycolysis and oxidative phosphorylation based on oxygen and glucose availability The Crabtree effect describes the inverse relationship between glucose availability and oxidative phosphorylation. In normal cells, abundant glucose promotes glycolytic metabolism and inhibits oxidative metabolism; conversely, low glucose availability stimulates mitochondrial oxidative phosphorylation to maximize ATP production from the available glucose. Similarly, the Pasteur effect summarizes the influence of oxygen tension on cellular metabolism: as cells adapt to low oxygen, they reduce their reliance on oxygen-dependent oxidative phosphorylation and increase their glycolytic rate to compensate. The Warburg effect appears to contradict these relationships, as highly proliferative cells undergo glycolytic metabolism even in the presence of abundant oxygen.

to how aerobic glycolysis confers a proliferative advantage to tumor cells.

The Paradox of the Warburg Effect

Glycolysis comprises a series of reactions that convert 1 molecule of glucose to 2 molecules of pyruvate, generating 2 molecules each of ATP and NADH (Figure 13-4). If oxygen is present, pyruvate is converted to acetyl-CoA in the mitochondrion, and acetyl-CoA is oxidized by the TCA cycle, producing 1 molecule of GTP and four pairs of high-energy electrons that will be used to fuel OXPHOS (3 molecules of NADH and 1 molecule of $FADH_2$). As the glycolytic reactions occur in the cytosol, the reducing equivalents of the NADH generated by glyceraldehyde-3-phosphate dehydrogenase (GAPDH) must be transferred to the mitochondrion in order for their energy to be harnessed into ATP. The malate-aspartate shuttle and the glycerol-3-phosphate shuttle transfer the electrons into the mitochondrion for oxidation by the electron transport chain. All together, this process of complete glucose oxidation produces 38 molecules of ATP. Thus, when oxygen is present, glucose can be efficiently converted to ATP while regenerating the NAD^+ required to maintain glycolysis.

If NADH is not oxidized to NAD^+, the subsequent depletion of NAD^+ will inhibit GAPDH and block glycolysis. To avoid this, under anaerobic conditions lactate dehydrogenase (LDH) reduces pyruvate to lactate, consuming NADH and producing NAD^+. In total, therefore, anaerobic glycolysis yields two molecules of ATP and two molecules of lactate that are secreted from the cell.

The paradox of the Warburg effect is that cells convert pyruvate to lactate even in the presence of oxygen. If glucose oxidation produces 19 times more ATP than anaerobic glycolysis, what benefit could a cell gain from choosing the less efficient route? And why would a cell that is growing rapidly throw away valuable carbon units in the form of lactate? Warburg's studies described an astonishing rate of lactate production in ascites tumor cells—cells produced up to

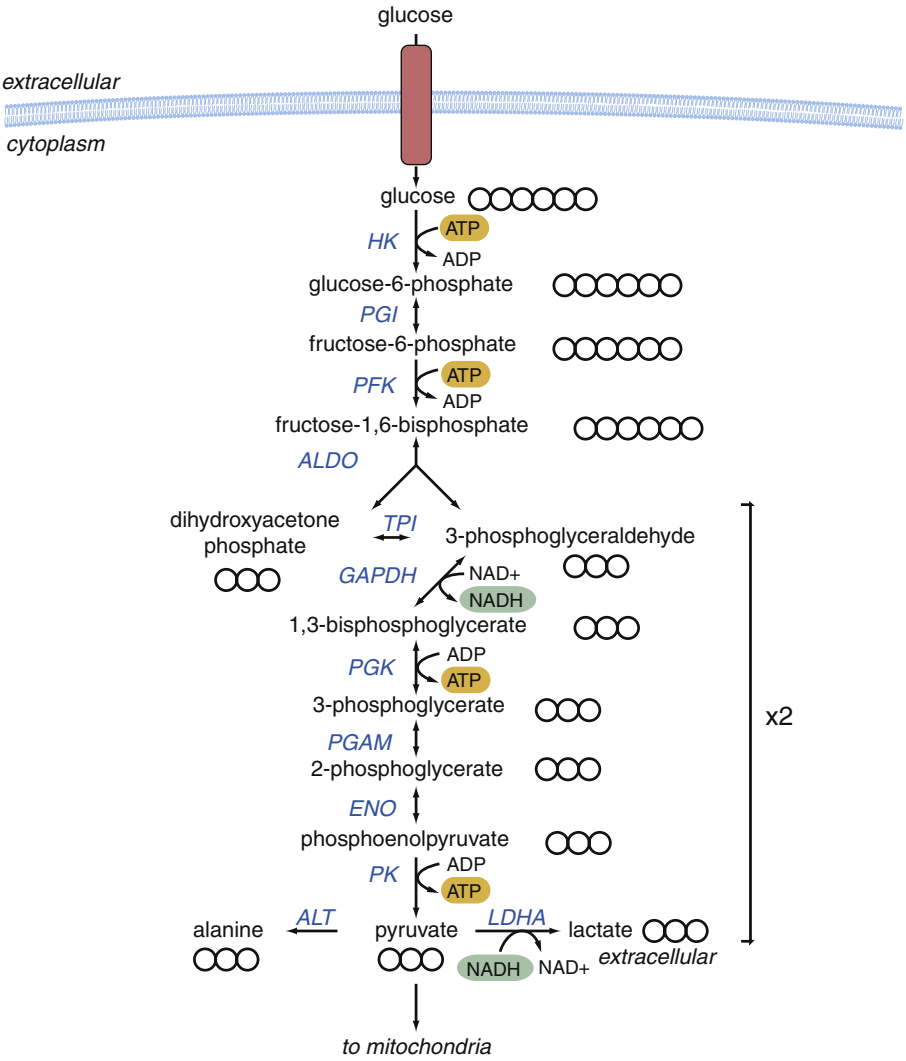

Figure 13-4 Glycolysis produces 2 ATP and 2 NADH for each molecule of glucose Glucose is metabolized to pyruvate through a series of biochemical reactions in the cytosol of the cell. This process yields a net of 2 ATP and 2 NADH molecules for each molecule of glucose. Pyruvate can be converted to lactate to regenerate the NAD^+ required to maintain flux through glycolysis, transaminated to alanine, or transported to the mitochondrion for further oxidation. Circles represent the number of carbons in each metabolite. Enzymes are shown in *blue;* reduced NADH is shown in *green;* ATP is shown in *orange*. *ALDO,* aldolase; *ALT,* alanine transaminase; *ENO,* enolase; *GAPDH,* glyceraldehyde-3-phosphate dehydrogenase; *HK,* hexokinase; *LDHA,* lactate dehydrogenase; *PFK,* phosphofructokinase; *PGAM,* phosphoglycerate mutase; *PGI,* phosphoglucose isomerase; *PGK,* phosphoglycerate kinase; *PK,* pyruvate kinase; *TPI,* triosephosphate isomerase.

30% of their dry weight in lactic acid per hour.[13] Although it is now known that this is a much higher rate than for most tumors, it is clear that aerobic glycolysis occurs at a high rate in many tumor cells. There are several potential explanations for how tumors could sustain such apparently wasteful metabolism and the benefits that rapid aerobic glycolysis might bestow:

1. *Aerobic glycolysis is a source of rapid ATP generation.* According to Warburg's calculations, the high rate of glucose consumption enabled cells to produce approximately the same amount of ATP through fermentation as through respiration.[11] Similarly, a series of studies demonstrated that stimulating cells to proliferate increased ATP turnover, as expected; however, the increased ATP demand was met entirely by increased glycolytic flux and not by any increase in ATP production by oxidative phosphorylation.[14] Thus, the relative inefficiency of ATP production may be counterbalanced by the high rate of glucose consumption. Furthermore, tumor cells may extract more than two molecules of ATP per molecule of glucose: Several studies demonstrate that cytosolic-mitochondrial NADH shuttles are active in tumor cells, indicating that tumors can oxidize GAPDH-derived NADH in the mitochondrion to produce ATP.[15-18] In addition, glycolysis generates cytosolic ATP very rapidly: The conversion of glucose to lactate can take mere seconds. This could benefit tumor cells undergoing high rates of protein, lipid, and nucleotide biosynthesis. Thus, as long as glucose supplies are not limited, high levels of glycolysis may provide an advantageously rapid and plentiful source of ATP.
2. *Adaptation to hypoxia.* Cells in solid tumors experience notoriously harsh and varied metabolic conditions as tumor growth disrupts the normal tissue architecture. Blood vessels inside the tumors are often dysfunctional or nonexistent. Consequently, tumor cells commonly experience periods of intermittent hypoxia. Survival in hypoxia requires metabolic adaptations, including increasing glycolysis and downregulating mitochondrial fuel oxidation.[19] A cell already primed with these metabolic adaptations would be more likely to survive inside a solid tumor. Indeed, cells cultured ex vivo from solid tumors often display high lactate production even when well oxygenated, suggesting that elevated glycolysis is a fundamental feature that either predisposes cells toward tumor formation or is selected for early in tumor development. It is worth noting that because hypoxia typically results from inadequate blood supply, cells rarely experience hypoxia without concomitant deprivation of nutrients such as glucose that are also provided by the vasculature. Thus, although glycolytic metabolism may increase the likelihood of survival during periods of intermittent hypoxia, sustained hypoxia will likely negatively influence cell growth regardless of metabolic adaptations.
3. *Acidification of microenvironment.* There is some evidence that the apparently wasteful secretion of lactate may itself confer a selective advantage to tumor development. Cells export lactate through the family of H^+-linked monocarboxylate transporters. By acidifying the microenvironment, lactate export may promote the death of normal cells and extracellular matrix degradation to enhance tumor invasion.[20] In support of this model, studies suggest that acidic conditions can stimulate tumor cell invasion in vitro, and in vivo interventions to increase pH can reduce spontaneous metastases.[21] Intriguingly, some studies suggest that lactate may also be used as a fuel source. Lactate exported from hypoxic cells can be used as a substrate for oxidative metabolism in normoxic cells within the same tumor, preserving glucose for the hypoxic cells while providing fuel for the normoxic cells.[22] Thus, lactate production may not be an unfortunately costly by-product of glycolytic metabolism, but may also serve pro-tumorigenic roles. Indeed, blocking conversion of pyruvate to lactate by suppressing LDH expression can impair tumorigenesis.[23] Clearly, the production of lactate is critical for cancer cell growth, whether by maintaining oxidized NAD^+ to promote glycolysis, acidifying tumor surroundings to promote cancer cell survival, or providing a means for efficient substrate allocation in a metabolically diverse microenvironment.

Glycolysis Provides Key Intermediates to Support Cell Growth

The preceding examples provide clues for how rapid aerobic glycolysis might provide a growth or survival advantage to tumor cells. However, we now know that aerobic glycolysis as Warburg described it—the conversion of glucose to lactate—is not the exclusive fate of glucose in cancer cells. Glucose is a major source of many of the building blocks of macromolecular biosynthesis, and it is clear that these various anabolic fates of glucose are an important component of the elevated glycolysis in cancer cells.

Glucose-Derived Metabolites Contribute to All Classes of Macromolecules

Glycolytic flux provides substrates for biosynthetic reactions that are required for the synthesis of lipids, nucleotides, and proteins (Figure 13-5). Glycolytic intermediates can be diverted to the pentose phosphate pathway to produce ribose 5-phosphate, which serves as the foundation for the de novo synthesis of purines and pyrimidines. The oxidative arm of the pentose phosphate pathway also generates NADPH,

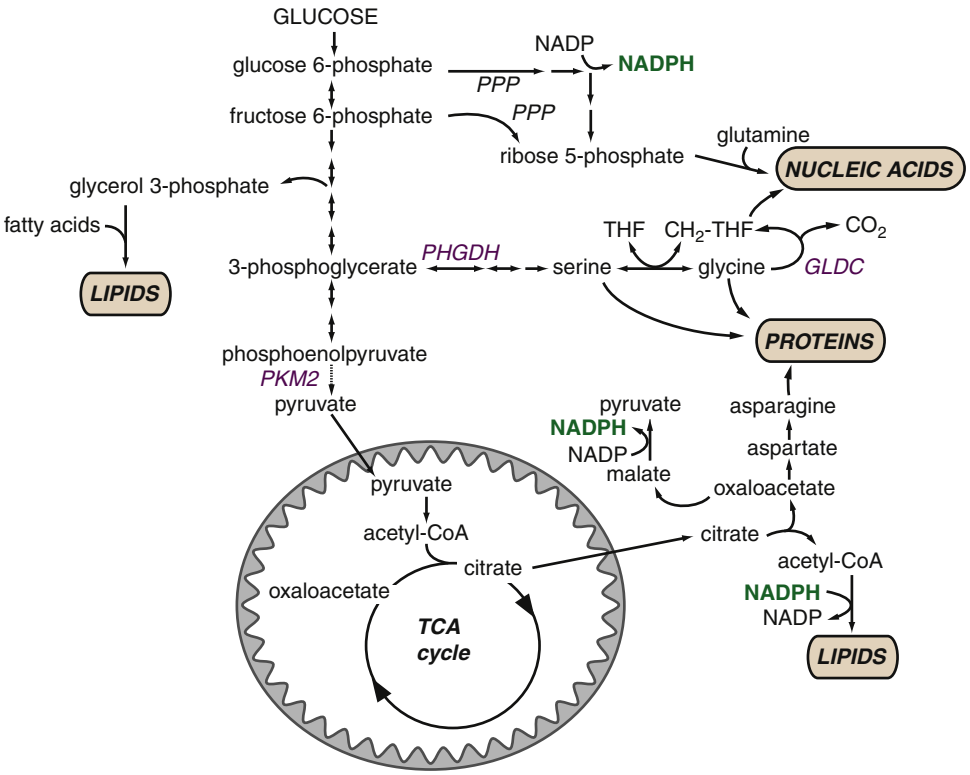

Figure 13-5 Glucose metabolism provides critical intermediates for cell growth Glycolytic intermediates provide the substrates for the pentose phosphate pathway (PPP) that generates the ribose 5-phosphate that is critical for nucleotide biosynthesis. The oxidative arm of the PPP, which utilizes glucose 6-phosphate, additionally generates NADPH. Glycerol 3-phosphate, which contributes the glycerol head groups for phospholipid biosynthesis, is formed from the intermediate dihydroxyacetone phosphate. 3-Phosphoglycerate provides the foundation for the serine synthesis pathway, which can further fuel glycine production for protein synthesis. This pathway also contributes to the pool of one-carbon units (CH_2-THF) that are used in nucleotide biosynthesis. Glucose-derived citrate provides the acetyl-CoA that represents the fundamental building block for the synthesis of the fatty acids that comprise cellular lipids. Key metabolic enzymes are shown in *blue;* NADPH required for biosynthetic reactions is shown in *green*. *CH_2-THF,* methylene tetrahydrofolate; *GLDC,* glycine decarboxylase; *PHGDH,* phosphoglycerate dehydrogenase; *PKM2,* pyruvate kinase M2 isoform; *PPP,* pentose phosphate pathway; *THF,* tetrahydrofolate.

which can provide reducing equivalents for nucleotide and fatty acid synthesis. Similarly, the glycerol required for phospholipid synthesis is derived from the glycolytic intermediate dihydroxyacetone phosphate. As the major component of mammalian cell membranes, phospholipid synthesis is critical for cell growth. Glycolytic intermediates can also contribute to amino acid synthesis: 3-Phosphoglycerate can be converted to serine and ultimately glycine.

A series of recent studies documenting tumors whose growth depends on diversion of glycolytic flux to anabolic pathways lends support to the hypothesis that glycolytic intermediates play a key role fueling tumor growth. Phosphoglycerate dehydrogenase (PHGDH), the enzyme that catalyzes the first step of the serine synthesis pathway that branches from glycolysis, is frequently amplified in melanoma and breast cancers, and flux into the serine synthesis pathway can support tumor cell growth.[24,25] Similarly, multiple tumor types display high levels of glycine decarboxylase (GLDC), which generates methylene tetrahydrofolate necessary for pyrimidine synthesis, and GLDC expression can promote cellular transformation and tumorigenesis.[26]

Macromolecular Synthesis, Not ATP, May Be the Major Purpose of Elevated Glycolysis in Cancer Cells

The importance of glycolytic intermediates as biosynthetic building blocks supporting cell proliferation was underscored by the observation that most proliferating cells express the M2 isoform of pyruvate kinase (PK), whereas quiescent cells express the PKM1 isoform.[27] Pyruvate kinase catalyzes the final ATP-producing step of glycolysis, converting phosphoenolpyruvate to pyruvate. Perhaps counterintuitively, PKM2 has less intrinsic activity than PKM1; PKM2 is also inhibited by growth factor signaling. These observations suggest that *inhibiting* the final step of glycolysis can be beneficial for cell growth. By slowing the final step of glycolysis, PKM2 enables accumulation of upstream glycolytic intermediates that can then be diverted into biosynthetic pathways. These findings indicate that proliferating cells do not undergo glycolysis for the sole purpose of ATP production; rather, they appear to selectively slow pyruvate production in order to maximize the flow of glucose carbons into anabolic pathways.

Expression of PKM2 may have the added benefit of reducing ATP production. Although ATP is required for anabolic reactions, NADPH is quantitatively more important. Biosynthesis of many macromolecules requires more reducing equivalents than energy from ATP.[1] Consequently, if all glucose were oxidized completely, ATP production would far outstrip NADPH production, thus greatly circumscribing potential cell growth. Furthermore, ATP is a potent inhibitor of phosphofructokinase-1, a key enzyme in the regulation of glycolysis, and so ATP produced in excess of biosynthetic demands would have the adverse effect of blocking glycolysis, further reducing NADPH production.

Although cancer cells preferentially reduce pyruvate kinase activity, the final step in glycolysis cannot be abrogated completely, as pyruvate fulfills many important metabolic roles. The pyruvate produced at this step has three fates: It can be transaminated to alanine, reduced to lactate to regenerate NAD^+, or imported to the mitochondrion, where it is converted to acetyl-CoA that can enter the TCA cycle. In many tumors, glucose consumption is high enough to support anabolic pathways while also maintaining pyruvate flux into the mitochondria and still resulting in high amounts of lactate secretion. It is likely that reducing pyruvate kinase activity slows glucose flux through glycolysis in order to increase the likelihood that glucose can be diverted into anabolic pathways rather than being completely and rapidly exported as lactate or oxidized in the mitochondria. Given the high rates of lactate produced from glucose (as much as 90% of glucose is converted to lactate and alanine in glioblastoma cells),[28] cancer cells still have appreciable pyruvate consumption. It is likely that despite the high percentage of pyruvate that is secreted as lactate, the rate of glycolysis is so high that sufficient pyruvate remains to fuel the TCA cycle.

The TCA Cycle as a Biosynthetic Hub

Just as glycolytic intermediates are harnessed to support anabolic pathways, proliferating cells rewire the TCA cycle to prioritize cell growth over ATP generation. In its traditional form, the TCA cycle begins with the condensation of pyruvate-derived acetyl-CoA with oxaloacetate to form citrate (Figure 13-6). A series of reactions in the mitochondrial matrix convert citrate back to oxaloacetate, releasing two carbons as two molecules of carbon dioxide and producing three

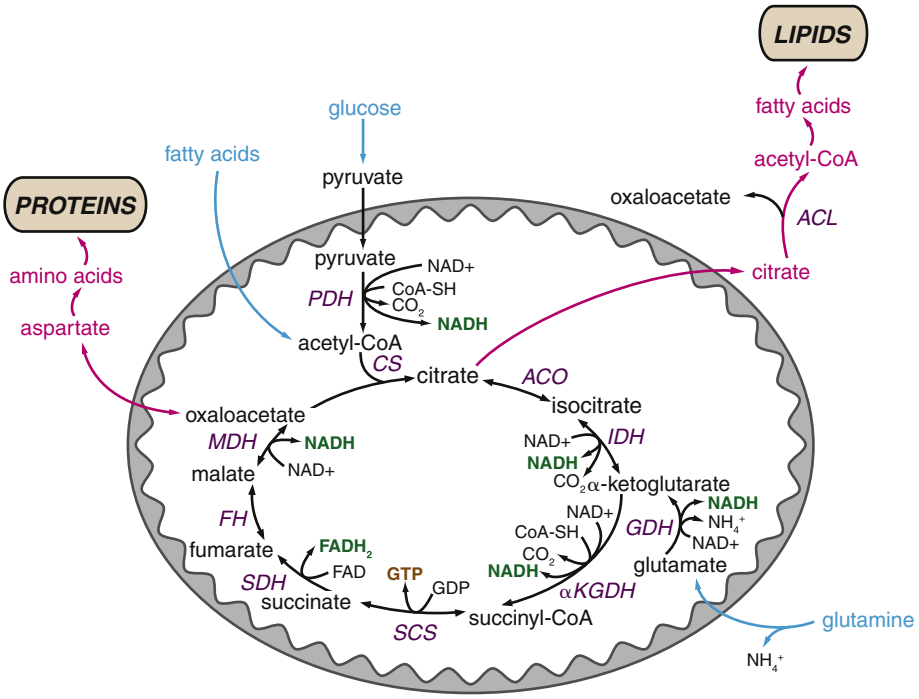

Figure 13-6 The tricarboxylic acid (TCA) cycle supports macromolecular biosynthesis Pyruvate derived from glucose enters the mitochondrion and is converted to acetyl-CoA by pyruvate dehydrogenase (PDH), and fatty acids are oxidized to produce acetyl-CoA units within the mitochondrion. Acetyl-CoA condenses with oxaloacetate to form citrate, which proceeds through the TCA cycle in highly oxidative tissues, releasing two carbons as carbon dioxide and regenerating oxaloacetate for further cycling. These reactions maximize ATP production from acetyl-CoA by reducing the electron carriers NADH and $FADH_2$ to fuel the electron transport chain. In proliferating cells, citrate is also exported from the mitochondrion to the cytosol, where it can provide the acetyl-CoA required for the synthesis of fatty acids and cholesterol. Similarly, oxaloacetate can form aspartate and other amino acids, contributing to intracellular amino acid pools for protein synthesis. Both of these reactions deplete TCA cycle intermediates; consequently, cells must replenish TCA cycle metabolites in order to regenerate the oxaloacetate necessary for citrate synthesis. Most cells use glutamine to fulfill this anaplerotic role: glutamine is converted to glutamate and then α-ketoglutarate, preserving TCA cycle flux. Metabolites that fuel the TCA cycle are shown in *light blue*. Metabolite efflux from the TCA cycle is shown in *pink*. Enzymes are shown in *dark blue*, reduced electron carriers in *green,* and high-energy triphosphates in *orange*. *PDH,* pyruvate dehydrogenase; *ACL,* ATP-citrate lyase; *ACO,* aconitase; *CoA-SH,* coenzyme A; *CS,* citrate synthase; *FH,* fumarate hydratase; *GDH,* glutamine dehydrogenase; *IDH,* isocitrate dehydrogenase; *αKGDH,* α-ketoglutarate dehydrogenase; *MDH,* malate dehydrogenase; *SCS,* succinyl-CoA synthetase; *SDH,* succinate dehydrogenase.

molecules of NADH and one molecule of $FADH_2$. NAD^+ and FAD are regenerated when NADH and $FADH_2$ donate their electrons to support oxidative phosphorylation. The cycle can continue by combining the recycled oxaloacetate with a new molecule of acetyl-CoA. In this manner, the oxidation of acetyl-CoA is used to maximize ATP production.

TCA Cycle Metabolites Are Required for Macromolecular Biosynthesis

In proliferating cells, citrate is not only oxidized in the TCA cycle but also can be exported to the cytosol where it is converted back to oxaloacetate and acetyl-CoA by the enzyme ATP citrate lyase (ACL). Cytosolic acetyl-CoA provides the substrate for the synthesis of fatty acids, cholesterol, and prostaglandins (Figure 13-7). Through this pathway, glucose acts as the major substrate for de novo lipogenesis; consequently, ACL inhibition blocks cell proliferation and inhibits tumor growth.[28-30]

Citrate is not the only TCA cycle metabolite that has an important biosynthetic role. Oxaloacetate and α-ketoglutarate can provide the carbon backbone for nonessential amino acids, which are used for protein and nucleic acid synthesis (see Figure 13-6). In this manner, multiple TCA cycle metabolites are diverted to other pathways that support cell growth.

Glutamine Plays Several Roles Supporting the TCA Cycle and Anabolic Metabolism

Although efflux of TCA cycle metabolites supports anabolic reactions, this results in depletion of TCA cycle intermediates from the mitochondrial matrix. Growing cells must draw on alternative sources to maintain the

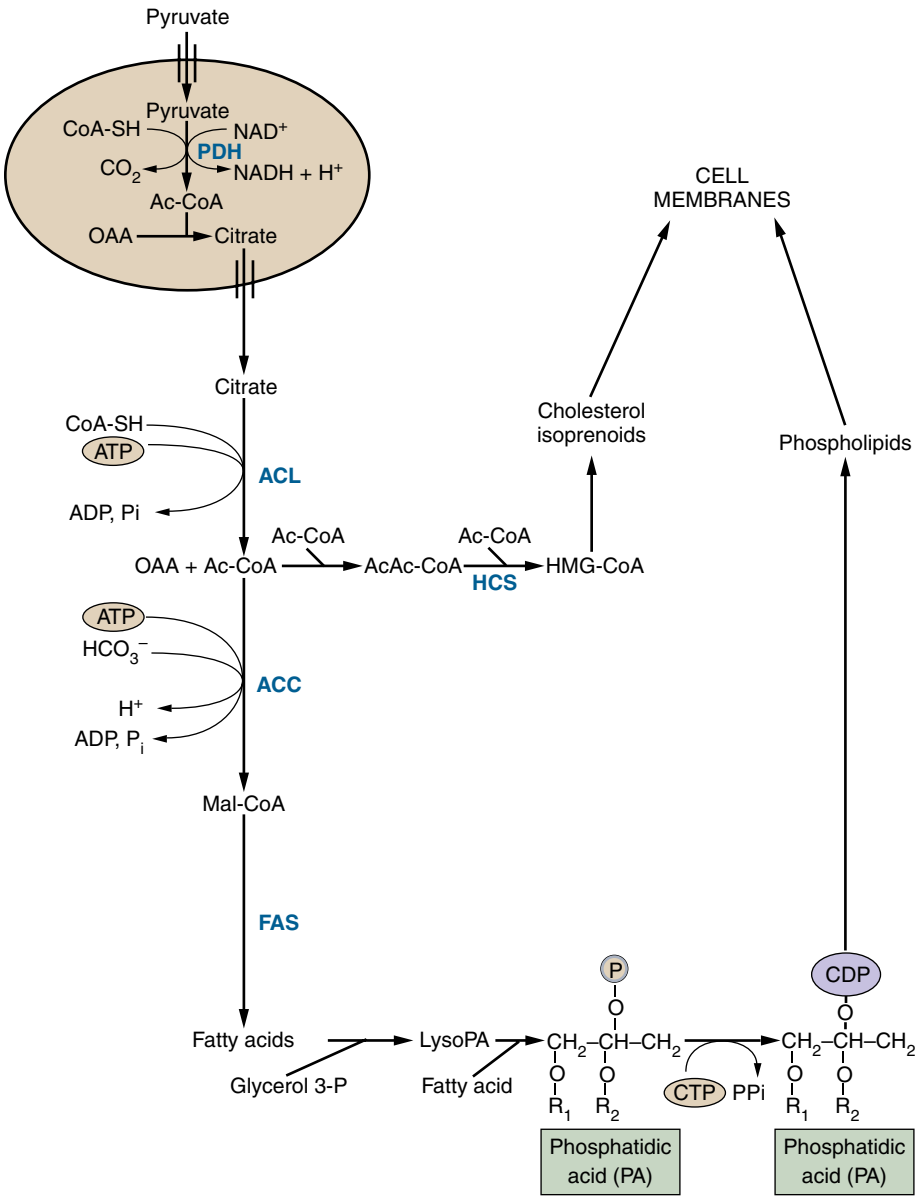

Figure 13-7 Glucose-derived acetyl-CoA fuels lipid and sterol synthesis Pyruvate derived from glycolysis can generate citrate in the mitochondrion. This citrate can be exported to the cytosol to provide acetyl-CoA for the synthesis of fatty acids, phospholipids, cholesterol, and isoprenoids, all of which are critical for membrane biogenesis and function. oxaloacetate required for citrate synthesis. Replenishment of TCA cycle intermediates, a process known as *anaplerosis*, is thus critical to maintain both a constant supply of metabolites for synthesis and appropriate ATP production through oxidative phosphorylation. Most proliferating cancer cells meet their anaplerotic needs through the catabolism of glutamine (see Figure 13-6). Glutamine is converted to the TCA cycle intermediate α-ketoglutarate through a metabolic pathway known as glutaminolysis. Tumor cells take up high levels of glutamine, often in great excess of any other amino acid, and studies using carbon labeling techniques have demonstrated that glutamine is the major source of carbon for the cellular oxaloacetate pool in cancer cell lines.[28]

By maintaining flux through the TCA cycle—and therefore delivery of electrons to the electron transport chain—glutamine plays a critical role maintaining mitochondrial bioenergetics in many cancer cells. Consequently, many cancer cell lines are absolutely dependent on glutamine for survival. Addition of cell-permeable TCA cycle analogs can rescue death of glutamine-deprived cells, highlighting the importance of glutamine as an anaplerotic substrate in cancer cells.[31,32]

Proliferating cells rely on glutamine to fulfill additional biosynthetic roles. First, glutamine provides an important source of nitrogen for synthesis of nonessential amino acids and nucleotides. Glutamine is required for two independent steps in purine nucleotide synthesis, and oxaloacetate-derived aspartate is required for a third (Figure 13-8). Similarly, two

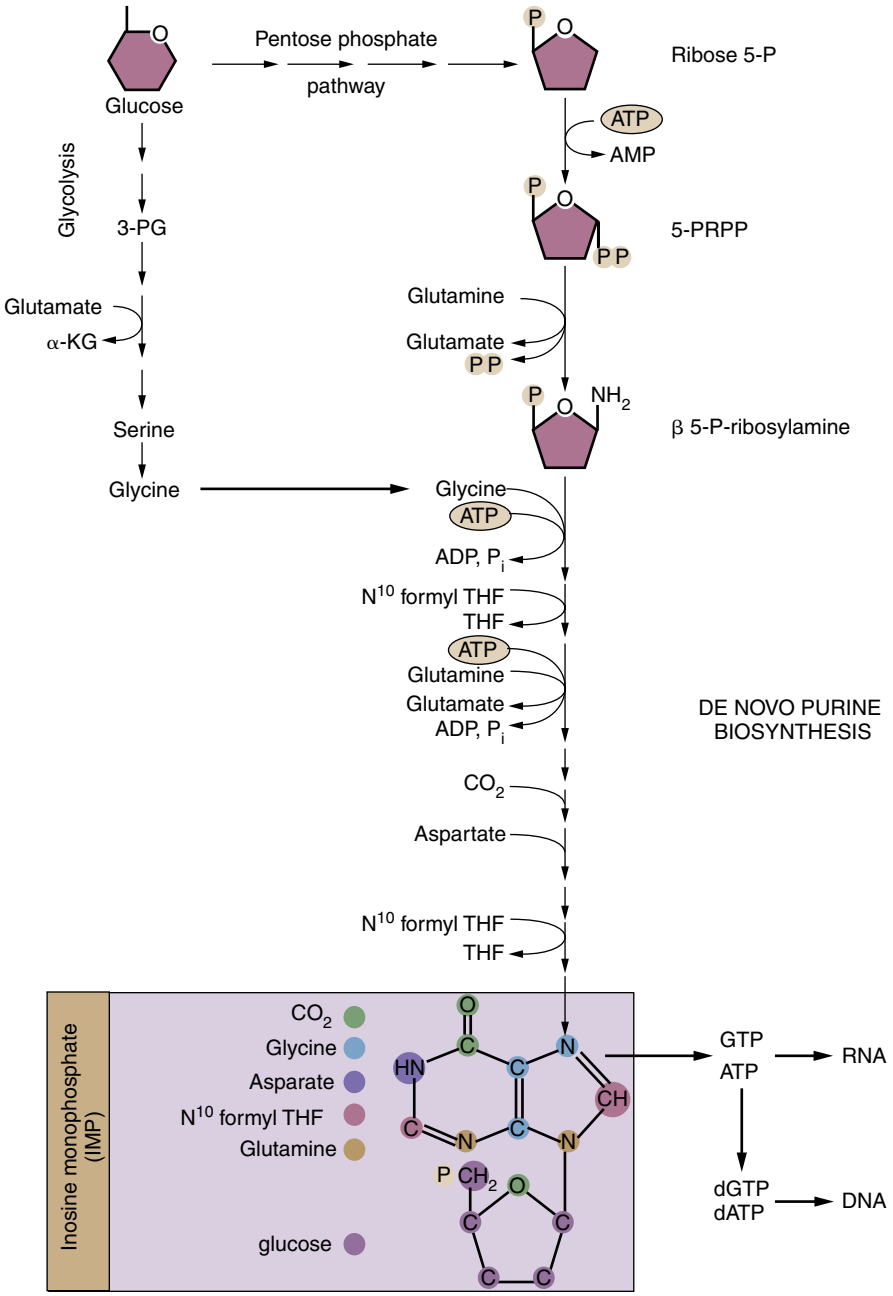

Figure 13-8 Nucleotide biosynthesis requires multiple metabolic inputs Nucleotide biosynthesis requires inputs from several metabolic pathways, highlighting why cells must coordinately regulate multiple metabolic pathways during proliferation. The de novo synthesis of purines (shown) and pyrimidines requires glucose, several amino acids, and one-carbon groups from folate metabolism. The origin of individual carbons and nitrogens on inosine monophosphate (IMP), the precursor to GTP and ATP, are color-coded in the purple box. *α-KG*, α-ketoglutarate; *N^{10} formyl THF*, N^{10} formyl tetrahydrofolate; *3-PG*, 3-phosphoglycerate; *β 5-P-ribosylamine*, β 5-phosphate-ribosylamine; *PRPP*, 5-phosphoribosyl pyrophosphate; *ribose 5-P*, ribose 5-phosphate; *P*, phosphate group.

steps of pyrimidine synthesis require glutamine. In all cases, glutamine donates nitrogen in the form of an amide group and is converted to glutamic acid, which provides a major source of nitrogen for amino acid synthesis. Transaminases can transfer the amine group from glutamic acid to α-ketoacids, which are themselves derived from the catabolism of glucose or glutamine, producing alanine, serine, aspartate, and ornithine. In turn, these amino acids act as precursors for the synthesis of glycine, cysteine, arginine, and asparagine. Likewise, two enzymatic reactions directly convert glutamate to proline. In this manner, glucose and glutamine contribute to the synthesis of every nonessential amino acid except for tyrosine, which is directly produced from the essential amino acid phenylalanine.

Intriguingly, cancer cells may convert up to 60% of glutamine carbon into lactic acid, an ostensibly wasteful secretion analogous to the Warburg effect.[28] One possible explanation for this behavior is that the conversion of glutamine to lactate produces NADPH, which is absolutely required for many anabolic reactions. NADPH is produced when malic enzyme converts glutamine-derived malate to pyruvate, which is subsequently reduced to lactate and secreted. In this manner, glutamine may contribute to all three needs of proliferating cells: Glutamine can provide the carbon and nitrogen for most metabolic building blocks, maintain ATP production to support bioenergetics, and generate reducing equivalents required for many anabolic reactions.

TCA Cycle Rearrangements Highlight the Role of TCA Cycle Metabolites as Biosynthetic Precursors

In proliferating cancer cells, the TCA cycle can behave more as a source of anabolic substrates rather than a bona fide cycle. A prime example of how the TCA cycle prioritizes biosynthetic reactions is the reductive carboxylation of α-ketoglutarate to isocitrate. During conditions of hypoxia or mitochondrial dysfunction, NADH accumulates from a combination of increased glycolysis and reduced oxidation of NADH by the electron transport chain. Depletion of oxidized NAD^+ poses a bioenergetic challenge for the cell: Both the conversion of glucose-derived pyruvate to acetyl-CoA and the production of oxaloacetate through the enzymes of the TCA cycle require NAD^+. Furthermore, during periods of acute hypoxia, pyruvate is converted to lactate at the expense of acetyl-CoA. Both of these events would strongly impair citrate production and thus cell growth. How, then, do hypoxic cells proliferate?

Several groups have demonstrated that under these conditions, the TCA cycle can partially function in reverse (for examples, see Refs. 33-35). Normally, isocitrate dehydrogenase (IDH) catalyzes the oxidative decarboxylation of isocitrate to α-ketoglutarate, consuming NAD^+ and producing NADH. When NAD^+ is limiting, both the mitochondrial and cytosolic isoforms of IDH can function in reverse, carboxylating α-ketoglutarate to isocitrate and producing oxidized $NADP^+$ (Figure 13-9). In this manner, cells can use glutamine-derived α-ketoglutarate to generate citrate, providing a mechanism to maintain anabolic reactions even under hypoxic conditions that characterize the tumor microenvironment.

Genetic Mechanisms Driving Cancer Cell Metabolism

Metabolic transformation is a common feature of tumorigenesis, occurring in many tumor types in diverse tissues. It is logical

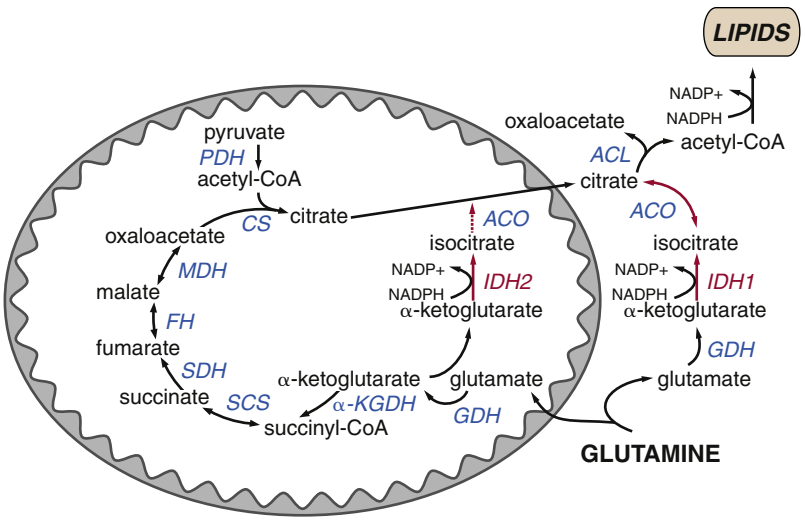

Figure 13-9 Reductive carboxylation supports lipid synthesis during hypoxia Citrate levels can be maintained even in cells with defective TCA cycles or during periods of hypoxia by the reductive metabolism of glutamine-derived α-ketoglutarate to citrate. Both mitochondrial and cytosolic isoforms of isocitrate dehydrogenase (IDH2 and IDH1, respectively) can function in reverse, reducing α-ketoglutarate to isocitrate and oxidizing NADPH to NADP+. Isocitrate is reversibly converted to citrate, which can be used to generate acetyl-CoA for lipid synthesis in the cytosol.

that metabolic transformation and oncogenic transformation would go hand in hand: As cancer cells acquire mutations that enable pathological proliferation, they must also acquire the means to support cell growth. Thus, many of the mutations that promote cancer growth also trigger metabolic reprogramming. This section discusses several common genetic oncogenic events that reprogram metabolism to support tumor growth.

Activation of the PI3K Pathway Promotes Metabolic Transformation

In normal cells, extracellular cues regulate the intracellular signaling pathways that tightly coordinate metabolism and proliferation. In many cells, this coordination is accomplished by the phosphatidylinositol-3-kinase (PI3K) pathway, a highly conserved signaling pathway that responds to a variety of extracellular cues. When growth factors bind to their cell surface receptors, receptor tyrosine kinases (RTKs) activate PI3K, which phosphorylates phosphatidylinositol lipids at the plasma membrane. These phosphorylated lipids recruit and activate downstream effectors of the PI3K pathway, triggering an intracellular signaling cascade that promotes cell growth, survival, and metabolism.

Constitutive activation of PI3K provides a growth stimulus and is therefore a major mechanism of tumorigenesis. In normal cells, PI3K activity is tightly guarded by a number of factors, ensuring that pathway activity is set at appropriate levels. RTK activity is strictly controlled by growth factor availability. In addition, negative feedback loops prevent prolonged pathway activation: The lipid phosphatase PTEN dephosphorylates phosphatidylinositol species to dampen PI3K signaling.

Cancers exhibit a variety of mutations to circumvent this regulation and gain cell-autonomous activation of the PI3K pathway.[36] Amplifications or mutations of growth factor receptors occur in a variety of cancers. Common examples are the amplification of the Her2/Neu receptor in breast cancer and epithelial growth factor receptor (EGFR) in lung cancer. Similarly, deletion, downregulation, or loss of function of PTEN increases cancer susceptibility and promotes tumor progression. Several tumor types display activating mutations in the catalytic PI3K subunit, PIK3CA; likewise, amplification of PIK3CA and the major PI3K effector, Akt, are common oncogenic events. All together, genetic activation of the PI3K pathway is one of the most prevalent classes of tumorigenic mutations.

Whereas PI3K signaling influences numerous cellular functions, the serine/threonine kinase Akt and its effector, mechanistic target of rapamycin (mTOR), are the PI3K effectors most commonly implicated in tumorigenesis. Akt coordinates cell growth and survival in a large part by rewiring metabolism to promote nutrient uptake and biosynthetic activities. Certainly, with regard to the regulation of cell metabolism, Akt activation is likely the most important consequence of PI3K pathway activation.

Akt induces many phenotypes consistent with the Warburg effect. Akt promotes the expression and membrane localization of glucose transporters, driving increased glucose uptake. Akt concurrently increases the expression of hexokinase, the enzyme that phosphorylates glucose so that it is retained in the cell and can undergo glycolysis. Akt regulates multiple steps of glycolysis through both gene expression and modulation of enzyme activity. Together, these activities result in a large increase in glycolytic flux in cells with active Akt. Similarly, both Akt and mTOR can trigger expression of lipogenic genes and lipid synthesis.[7,37] mTOR additionally promotes biosynthetic pathways by directly stimulating mRNA translation and ribosome biogenesis.[38] Thus, PI3K signaling is often sufficient to enhance the metabolic activities that support cell growth.

LKB1 and AMPK Are Metabolic Brakes That Circumvent Tumor Growth

While growth factor–stimulated signaling cascades promote cell growth under favorable conditions, cells have sophisticated nutrient sensing systems that serve to block growth when the internal energy supply is limiting. These regulators ensure that, during periods of intracellular nutrient depletion, metabolites are redirected from anabolic pathways and instead used to fuel catabolic pathways that will provide the energy required to survive the period of nutrient limitation. The AMP-activated protein kinase (AMPK) plays a major role coordinating cellular energy status with appropriate metabolic responses.

AMPK directly senses cellular energy levels in the form of the AMP/ATP ratio (Figure 13-10). Falling energy levels increase the cellular AMP/ATP ratio, priming AMPK for activation by the liver kinase B1 (LKB1). AMPK phosphorylates multiple targets with the cumulative effect of blocking anabolic reactions and stimulating energy-generating catabolic pathways. For example, AMPK phosphorylates and inhibits acetyl-CoA carboxylase (ACC), with the dual effect of blocking fatty acid synthesis and activating fatty acid oxidation. AMPK also directly inhibits cell growth, both by inducing a p53-dependent cell cycle arrest and by blocking mTOR activity at multiple levels (see Figure 13-10). Through these diverse activities, AMPK functions as a metabolic checkpoint, ensuring that cell growth is halted until bioenergetic conditions are favorable for growth.

This is particularly relevant in the tumor microenvironment, when varied nutrient delivery could occasionally activate such metabolic checkpoints and block growth. Suggestively, LKB1 is classified as a tumor suppressor. Inactivating mutations in LKB1 cause Peutz-Jeghers syndrome, a

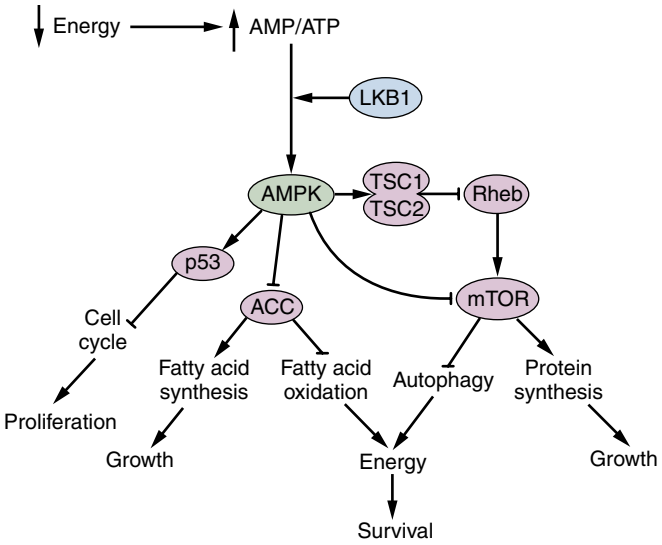

Figure 13-10 The LKB1/AMPK pathway coordinates the metabolic response to nutrient deprivation. A fall in cellular energy status, triggered by nutrient deprivation or other stressors, may increase the adenosine monophosphate (AMP):adenosine triphosphate (ATP) ratio. This activates the kinase KLB1 and its target, the AMP-activated protein kinase (AMPK). AMPK phosphorylates a number of targets to coordinately inhibit anabolic processes and activate catabolic, energy-generating pathways to restore cellular energy levels. In particular, AMPK triggers the phosphorylation and activation of p53, inducing cell cycle arrest; phosphorylation and inactivation of acetyl-CoA carboxylase (ACC), which suppresses fatty acid synthesis and promotes fatty acid oxidation, and direct and indirect inhibition of the mechanistic target of rapamycin (mTOR), thereby inhibiting protein synthesis and inducing autophagy. Suppression of growth and proliferation preserve existing energy stores, while fatty acid oxidation and autophagy generate ATP.

syndrome characterized by benign gastrointestinal and oral lesions and heightened susceptibility to a variety of cancers. Similarly, inactivating mutations in LKB1 are frequent in lung and ovarian carcinomas.[39] The pathogenic mechanisms of LKB1 loss of function are unclear, as LKB1 targets proteins involved in apoptosis, cell polarity, and cell cycle control in addition to activating AMPK. However, it is possible that failure to curtail cell growth in response to normal environmental cues contributes to the oncogenic potential of LKB1 inhibition. In line with this hypothesis, there is great interest in determining whether activating AMPK through agonists such as metformin could activate metabolic checkpoints to block tumor growth. Given the role of AMPK antagonizing many of the pro-growth functions of the PI3K pathway, such strategies may provide an effective way to harness our normal homeostatic mechanisms to slow cancer growth.

The Transcription Factor HIF1 Controls Glycolytic Metabolism

Conditions of low oxygen availability pose a threat to cell survival. Oxygen serves as the terminal electron acceptor of the electron transport chain; as a result, when oxygen is limiting, ATP production through oxidative phosphorylation can be compromised. Excess electrons leak out of the electron transport chain inappropriately, forming reactive oxygen species than can, in high doses, cause great cellular damage. Consequently, cells must rapidly sense and respond to conditions of low oxygen. The cellular response to low oxygen is coordinated by the hypoxia inducible factors (HIF1 and HIF2), transcription factors that are rapidly stabilized and activated during hypoxia. HIF1 and HIF2 promote survival in hypoxia through two mechanisms. First, they induce expression of angiogenic genes, such as vascular endothelial growth factor (VEGF), in order to increase the blood supply to reoxygenate the tissue. Second, they promote metabolic reprogramming in order to maintain ATP supplies while limiting damaging electron loss from the electron transport chain.[40]

Many of the activities of HIF1 and HIF2 would benefit tumor cell survival. As discussed earlier, tumors have frequent variations in oxygenation, often resulting in regions of hypoxia. Expression of HIF1 or HIF2 would help a tumor cell adapt and survive in a hypoxic microenvironment. In particular, HIF1 induces multiple metabolic changes that characterize cancer cells. HIF1 increases expression of glucose transporters and glycolytic enzymes, thereby elevating glucose consumption and glycolytic flux.

Many tumors display aberrant HIF1 expression. Most famously, von Hippel–Lindau disease, characterized by hemangioblastomas of the central nervous system, pheochromocytoma, and renal cell carcinomas, is caused by loss-of-function mutations of the von Hippel–Lindau (VHL) ubiquitin ligase that negatively regulates the stability of HIF1 and HIF2. Tumors exhibit high levels of HIF1, even under normoxia, and constitutively high levels of HIF1 targets. Elevated HIF1 is observed in several solid tumors outside of VHL disease, including breast, ovarian, colon, pancreas, and prostate.[41] In several cases, levels of HIF1 correlate with tumor aggressiveness and poor prognosis. Multiple mechanisms result in increased HIF1 expression: Variable oxygenation, ROS production, oncogene activation, and growth factor signaling (including PI3K and mTOR signaling) can all contribute to heightened HIF1 activity.

Although HIF1 increases glycolysis and lactate production, its effects on metabolism are not uniformly protumorigenic. First, hypoxia causes a decrease in protein synthesis rates—up to 50% of the rates in normal cells—and this decline in protein synthesis is mediated at least in part by repression of mTOR by HIF1.[42] Second, while HIF1 promotes glycolysis, it blocks the mitochondrial oxidation of glucose-derived pyruvate. HIF1 induces pyruvate dehydrogenase kinase (PDK), which inhibits PDH, the enzyme responsible for converting pyruvate to acetyl-CoA. HIF1 therefore reduces the amount of acetyl-CoA that is available for lipid synthesis, instead diverting pyruvate to lactate

for secretion.[43] Although HIF1 expression is sufficient to drive citrate production through reductive carboxylation of glutamine-derived α-ketoglutarate, it is not clear whether this citrate can fully compensate for reduced conversion of pyruvate to acetyl-CoA.[33] Thus, the effects of HIF1 on tumor metabolism are complex. During conditions of true hypoxia, HIF1 expression promotes metabolic adaptations that support tumor survival and increases angiogenesis to support tumor growth. However, during conditions of adequate oxygenation, persistent HIF1 expression would serve to reduce protein and lipid synthesis and hamper cell proliferation. These disparate effects of HIF1 on tumor growth could explain why HIF1 expression is associated with a tumor-suppressive function under certain circumstances.[44]

c-Myc Coordinates Cellular Proliferation and Metabolism

The Myc family of transcription factors (c-Myc, L-Myc, and N-Myc) both stimulates and represses transcription to regulate a vast array of cellular processes, including cell growth and cell cycle progression, and contributes to a variety of human tumors. Myc regulates the expression of an enormous number of genes and consequently can influence processes as diverse as differentiation, vasculogenesis, cell adhesion, cell growth, apoptosis, and DNA damage responses.[45] Although all of these outcomes could contribute significantly to the oncogenic effects of Myc expression, this section focuses on the potential role of Myc in coordinating cell metabolism to support cell proliferation.

Myc heterodimerizes with its binding partner Max to regulate expression of a large number of genes. In particular, c-Myc promotes expression of several cyclins and CDK4 while repressing the cyclin-dependent kinase inhibitors p21 and p27, thus promoting entry into S phase.[45] At the same time, Myc directly reprograms metabolism by increasing expression of genes involved in glycolysis, glutamine metabolism, and mitochondrial biogenesis.[46] c-Myc also targets a number of genes involved in nucleotide biosynthesis, ensuring that cells have the raw material to successfully complete S phase.[47] An extensive survey of Myc targets in a variety of cell lines revealed that genes involved in ribosome biogenesis form a large component of the core Myc signature, further highlighting Myc's function in regulating biomass accumulation.[48] Together, these findings demonstrate that c-Myc functions to upregulate energy production and biosynthetic processes that are required for successful cell replication, thus directly coordinating proliferative metabolism and cell cycle progression.

Myc is a powerful oncogene whose activity is pathologically enhanced in many human cancers; indeed, *MYC* is one of the most highly amplified oncogenes across all types of human cancers.[49] In other cases, chromosomal translocations or increased transcription downstream of hyperactive Wnt signaling contribute to oncogenic activation of Myc.[50] Myc has many activities that could contribute to its ability to promote tumor establishment and maintenance. In some cases, the metabolic reprogramming driven by Myc expression provides critical support for tumor growth. Myc-overexpressing cells are extremely sensitive to nutrient depletion. In particular, cells with high levels of Myc are glutamine addicted, using glutamine as a critical source of TCA cycle metabolites to support rapid cell growth. Consequently, removal of glutamine from the extracellular medium triggers apoptosis in Myc-overexpressing cells. Likewise, blocking conversion of glutamine to α-ketoglutarate through inhibition of glutaminase can block cellular transformation and tumor growth.[51,52]

Mutations in Metabolic Enzymes Can Influence Tumorigenesis

Although the bulk of cancer-associated metabolic rearrangements are directed by signaling events, cellular signaling pathways are not unidirectional. Metabolites themselves can serve as intracellular cues to regulate signaling proteins and influence gene expression. Activation of AMPK by AMP/ATP and mTOR by amino acid levels are common examples of how metabolites can inform signaling pathways. As with canonical signaling pathways, dysregulated activation of these metabolic signaling pathways can influence cancer susceptibility and tumor growth. Mutations in three TCA-cycle enzymes provide major examples of how inappropriate metabolite accumulation can trigger oncogenic signaling events.

Loss-of-function mutations in two consecutive enzymes of the TCA cycle, succinate dehydrogenase (SDH) and fumarate hydratase (FH), predispose patients to tumor formation. In both cases, the genes behave as classic tumor suppressors, in which mutation in one allele causes a dominant risk of tumor formation, followed by loss of function of the second, wild-type allele, in the tumor itself. SDH has four subunits and an assembly factor, and mutation in any of these five genes predisposes individuals to a variety of paragangliomas and pheochromocytomas, and in some cases, renal cell carcinomas or gastrointestinal stromal tumors.[53] In all cases, the pathogenic mechanisms linking SDH deficiency to tumor formation are attributed to elevated succinate levels, triggering a pseudohypoxic cellular state. In normoxia, HIF1 activity is repressed by the action of a family of prolyl hydroxylases (PHDs) that target the labile subunit of HIF1 (HIF1α) for ubiquitination and degradation by the proteasome. PHDs use oxygen, α-ketoglutarate, and ferrous iron to hydroxylate HIF1α, releasing carbon dioxide, succinate, and ferric iron. Consequently, accumulation of succinate blocks PHD activity, resulting in

aberrant stabilization of HIF1α.[54] Enhanced HIF1 activity is likely an important mechanism driving SDH-deficient tumor growth, as the clinical presentations of patients with dominant SDH mutations are similar to several hypoxia syndromes.[53]

Fumarate, likewise, is a potent inhibitor of the PHDs.[55,56] However, FH defects are associated with a predisposition to hereditary leiomyomatosis and renal cell carcinoma.[57] Although elevated HIF1 may contribute to the pathogenic mechanism of FH mutations, several additional consequences of elevated intracellular fumarate provide alternative avenues through which FH mutations may increase cancer susceptibility. First, fumarate can directly modify specific cysteine residues in Kelch-like ECH-associated protein 1 (KEAP1), thereby blocking its ability to suppress the Nrf2-mediated antioxidant response pathway.[58] Enhanced antioxidant defenses may, in some contexts, help guard cancer cell survival in the face of high proliferation-induced ROS production. Other studies have demonstrated that FH deficiency triggers a shift toward glycolytic metabolism, accompanied by reduced AMPK activity, lower intracellular iron, and elevated HIF1.[59] Regardless of the mechanism of tumorigenesis, both SDH- and FH-deficient tumors have the striking phenotype of interrupted TCA cycle function. Elevated aerobic glycolysis can increase glucose consumption and alleviate the bioenergetic constraints. In some cases, mitochondria may be able to funnel accumulated metabolites into alternate metabolic pathways, enabling partial mitochondrial NADH generation.[60] Similarly, glutamine-dependent reductive carboxylation can maintain citrate pools in cells with defective oxidative phosphorylation.[35] Given the critical role of the TCA cycle in supporting anaplerotic reactions, it will be important for future studies to clarify how cells with impaired TCA cycle activities can proliferate at pathological rates.

More recently, the discovery of mutations in the cytosolic and mitochondrial forms of isocitrate dehydrogenase (IDH) has provided the strongest evidence that altered metabolism can drive tumorigenesis. Somatic mutations at a defined number of residues on IDH occur at a high frequency in a variety of malignancies, most notably glioblastoma and acute myeloid leukemia. Oncogenic mutations in IDH confer a neomorphic activity: Rather than oxidizing isocitrate to α-ketoglutarate, mutant IDH isoforms reduce α-ketoglutarate, forming 2-hydroxyglutarate (2-HG).[61,62] A series of studies demonstrated that 2-HG, by virtue of its structural similarity to α-ketoglutarate, can act as an inhibitor of multiple α-ketoglutarate–dependent dioxygenases. In particular, 2-HG can inhibit the TET family of enzymes that convert 5-methylcytosine to 5-hydroxymethylcytosine, an intermediate step in the process of DNA demethylation.[63-65] Likewise, 2-HG can inhibit various histone demethylases in vitro, and mutant IDH expression correlates with increased H3K9 histone methylation in vivo.[65-67] In both cases, hypermethylation profiles (of DNA and/or histones) contribute to the silencing of differentiation-related genes, promoting the accumulation of cells arrested in the course of their differentiation, capable of self-renewal and prone to tumorigenesis.[68]

Together, these studies underscore the complex interplay between cellular signaling networks and metabolic pathways. In all cases, oncogenic activity is attributed to altered levels of particular metabolites (fumarate, succinate, or 2-HG), indicating that cells are highly responsive to alterations in metabolic enzymes and highlighting the possibility that metabolites themselves can function as potent signaling molecules.

Clinical Implications of Metabolic Transformation

The ultimate goal of cancer research is to improve cancer detection and treatment. Elucidating the differences between cancer and normal cells will provide a means to identify and attack cancer cells specifically. In this regard, the distinctive metabolic phenotype of cancer cells may provide a key therapeutic window to distinguish pathological proliferation.

The propensity of tumors to take up high levels of glucose is already extensively exploited in the clinic. Positron emission tomography (PET) enables in vivo visualization of radioactive tracers such as [^{18}F]fluorodeoxyglucose (FDG), a glucose analog that can be taken up by cells and phosphorylated by hexokinase but not further metabolized. Cellular accumulation of FDG therefore provides a reliable readout of the glycolytic activity of a cell, and whole-body scanning by PET can reveal regions of abnormally high glucose uptake and retention. Because cancer cells often take up high levels of glucose, FDG-PET provides a robust tool for detecting a variety of tumors, including breast, colorectal, lung, brain, and lymphoma. FDG-PET can also be used to monitor tumor growth and metastases. Importantly, FDG-PET provides a rapid readout of tumor response to therapy. Most therapies that effectively impair tumor growth or survival trigger a rapid decrease in FDG-PET signal, a change that can be observed within a few days after therapy initiation.[69,70] Because cancer cells often have aberrant nutrient uptake, future studies may reveal other radioactive metabolic tracers with tumor-specific uptake.

Tumor dependence on glycolysis provides additional therapeutic avenues. Promising preclinical data exist for the inhibition of multiple steps of glucose uptake and catabolism through glycolysis. One large caveat in the targeting of metabolic enzymes is that cancer cells often have a metabolic

profile very similar to rapidly proliferating normal cells. Consequently, blocking enzymes that promote proliferative metabolism may have adverse effects on multiple cell types in vivo, including the rapidly proliferating cells in the intestinal epithelium and bone marrow. Nevertheless, it may be possible to safely target glucose metabolism in patients. As discussed earlier, the rate of entry of pyruvate into the TCA cycle is determined by pyruvate dehydrogenase, which is inhibited by the PDKs. Dichloroacetate (DCA) inhibits the PDKs, thus increasing pyruvate flux into the TCA cycle and reducing lactate production. Although the therapeutic benefit of increasing glucose oxidation is not yet demonstrated in tumors in vivo, DCA is well tolerated in patients, suggesting that it may be possible to target aberrant glucose metabolism in cancer patients.[71]

The therapeutic potential of many of the pathways discussed in this chapter are targets of ongoing studies. In animal studies, inhibitors of several steps of glycolysis (phosphofructokinase,[72] lactate dehydrogenase[23,73]), glutamine anaplerosis (glutaminase,[51] glutamate dehydrogenase[74]), and fatty acid synthesis (ATP citrate lyase,[29] fatty acid synthase[75,76]) can inhibit tumor growth. These data suggest that carefully targeted administration of agents that block key nodes of proliferative metabolism may hold therapeutic promise.

Suggestively, some of the oldest and most effective cancer treatments target aspects of cell metabolism. For example, antifolates interfere with folate metabolism and thus disrupt nucleotide biosynthesis and other reactions that require one-carbon units, such as protein methylation. 5-Fluorouracil, a nucleoside analog, inhibits thymidylate synthase and blocks DNA synthesis. These antimetabolites are still effective therapies today, reinforcing the critical role of altered metabolism in the support of tumor growth. Further research into the specific metabolic abnormalities of cancer cells, and how these perturbations foster tumor growth, may uncover pharmacologic targets that will be effective and well tolerated.

Apoptosis, Necrosis, and Autophagy

In the simple arithmetic of life, a tissue grows if cells divide more frequently than they die, whereas one in which cell death is more frequent than cell division shrinks. This arithmetic, trivial as it seems, is at the heart of the understanding of cancer and the efforts to effectively treat it. However, the mechanisms that control this relationship are far from trivial.

One theory of cancer, in fact, suggests that an evolutionary "hard-wiring" of the machineries of tissue expansion and cell death is fundamental to tumor suppression. This concept, called *antagonistic pleiotropy* (Figure 14-1),[1] states that *any* molecular event in a multicellular organism that directs a cell to divide also instructs it to die, and that the latter will occur unless additional signals (either exogenous or endogenous) promote cell survival.

It is critical to note that this idea is fundamentally different from the prevalent (and incorrect) notion that "cancer cells are resistant to cell death," which as we will see is not only inaccurate, but patently untrue. Antagonistic pleiotropy only demands that the *specific* cell death pathways engaged by signals promoting clonal expansion be sufficiently muted that the rate of division exceeds the rate of cell death. Other pathways of cell death not only remain available, but may be sensitized in the process, providing us with the opportunity to shift the balance by therapies.

The Ways Cells Die

There are different ways in which cells die, and these are grouped on the basis of the morphologies of the dying cells (Figure 14-2)[2] and more recently by the mechanisms of cell death as we understand them.[3] By general agreement, there are three modalities of cell death: apoptosis (type I), autophagic cell death (type II), and necrosis (type III). Within each of these modes there are additional varieties of morphologies and/or pathways that engage death.

Apoptosis is characterized by condensed chromatin, membrane blebbing, and cell shrinkage, and the cell often breaks into smaller, membrane-bound bodies (see Figure 14-2). The DNA within chromatin is cleaved by the action of a nuclease that cuts the DNA between nucleosomes, producing the degraded DNA hallmark of apoptosis. Before the loss of plasma membrane integrity, the lipids of the membrane "scramble," resulting in the appearance of phospholipids on the surface, which are normally preferentially associated with the inner leaflet. All of these events are due to the action of caspase proteases that are activated during apoptosis. Usually, apoptotic cells are effectively cleared by phagocytosis ("cell eating") by macrophages and other cell types, before the contents of the dying cell can be released. This involves the recognition of a phospholipid, phosphatidylserine, which appears on the outer leaflet as a consequence of the scrambling event just noted. As a result, apoptotic cell death does not usually engage an inflammatory response and is sometimes described as being immunologically "silent."

Necrosis, in contrast, involves swelling of the cell and organelles. As plasma membrane integrity is disrupted and the contents of the cell spill out, some components act as signals to other cells that damage has occurred (see Figure 14-2). These signals, called *damage-associated molecular patterns* (DAMPs), can trigger inflammatory responses.

The third mode of cell death, autophagic cell death, is problematic. It is characterized by the formation of large vacuoles (often enlarged lysosomes) and the activation of autophagy (see Figure 14-2). As with necrosis, caspases are not activated. However, there is considerable disagreement regarding the role of autophagy in the cell death itself. In most cases, disruption of the autophagy machinery accelerates the cell death, and therefore this is viewed as "cell death accompanied by autophagy."[2] There are examples in *Drosophila*, however, in which the autophagic machinery is fundamentally involved in the cell death process itself,[4] although it is unclear to what extent such bona fide autophagic cell death occurs in mammals.

In thinking about the different modes of cell death, a useful distinction can be made between cell death that is "passive," meaning that the cell is killed, and that which is "active," that is, the cell participates in its own demise. In the first case, cell death can only be prevented by removing or blocking the toxic insult, or by repairing damage more quickly than it occurs. In cases of active cell death, this quietus may also be blocked if the cellular pathways involved are inhibited or disrupted.

It is important to note, however, that just because a cell death process is active, this does not mean that it represents a specialized cell death mechanism that was evolutionarily selected as a physiological pathway of cell death. Much as a running but not a motionless train can be destroyed by derailing, a cellular activity can be "sabotaged" to inflict lethal damage on the cell. In contrast, there are specialized cell death pathways that are indeed mechanisms of physiological cell death, and thus can be regarded as cellular "suicide."

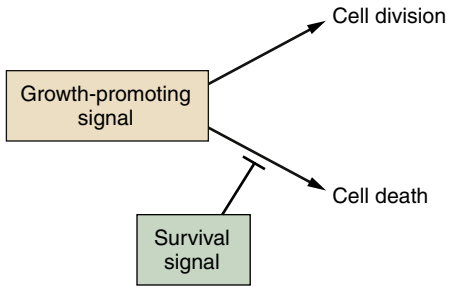

Figure 14-1 Antagonistic pleiotropy This concept states that signals that engage the cell cycle also engage cell death, and tissues therefore expand only if cell death is blocked. Note that this does not mean that the cell cycle, or any component of its machinery, is responsible for cell death. Survival signals can either be cell intrinsic or extrinsic and need only be specific for the death mechanism engaged by the original growth-promoting signal. The term *antagonistic pleiotropy* is borrowed from a theory of aging of the same name, which on the surface is very different from the concept of tumor suppression as used here. There are, however, interesting parallels. In the aging theory, genes that are beneficial early in the life of an animal will be selected, even if their activities are detrimental later in life. The reader might wish to consider how this concept may apply to aging and cancer and how these ideas relate to the use of the term here.

Figure 14-3 illustrates these distinctions, although in many cases we can only speculate as to whether a process is sabotage versus suicide.[5]

From the perspective of cancer biology, however, the distinction is particularly useful. When cell death is engaged as a mechanism of tumor suppression, it may be regarded as suicide, whereas the effects of therapeutic intervention may manifest either by recruiting such a suicide pathway or by effectively sabotaging a process in the cancer cell to result in its death.

The best example of active cell suicide is apoptosis, although there may be others (as we note in Figure 14-3 and in the following discussion). In contrast, the lethal overproduction of reactive oxygen species (ROS) by disruption of the mitochondrial electron transport chain, the engagement of membrane NADH oxidases, or the loss of ROS scavenging mechanisms may be regarded as cellular sabotage (see Figure 14-3, and other examples discussed later).

This distinction blurs when we consider the evolution of cell death. Any mechanism of cellular sabotage could well be selected to become a process of cellular suicide, and indeed, many scenarios for the evolution of apoptosis begin with this premise. At this point, it may be best to remind the

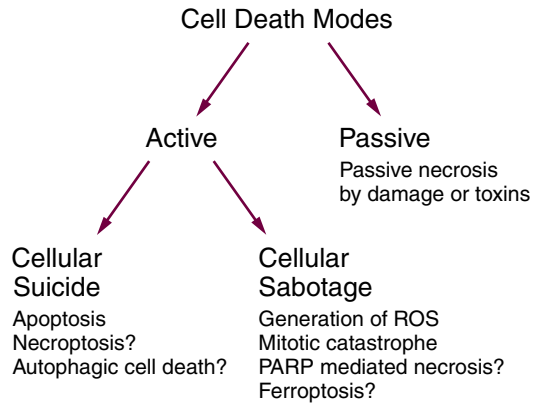

Figure 14-3 Active and passive cell death See text for explanation. *PARP*, polyADP-ribose polymerase; *ROS*, reactive oxygen species.

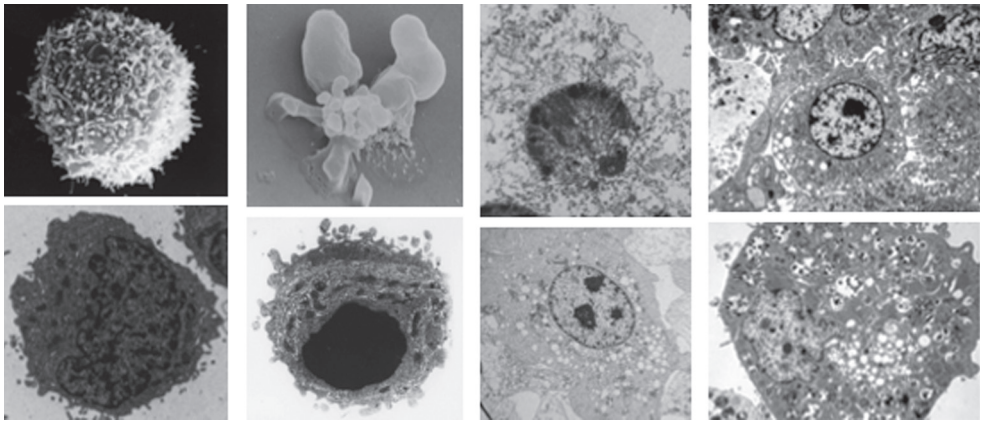

Figure 14-2 Types of cell death Electron micrographs of cell death showing features of each. See text for explanation. *NOTE: All figures except as noted are from DRG. reader that these distinctions are, like many classifications, merely a starting point for understanding the intricacies of the processes. Nevertheless, it might be interesting to think about why, of all the possible cell suicide mechanisms that *might* have evolved, apoptosis has emerged as the predominant form of active cell death in the animal kingdom.

Apoptosis

Caspase Activation

Apoptosis is orchestrated by the actions of caspases, which are cysteine proteases (that is, they have a cysteine at the active sites). There are at least 17 caspases that have been described in mammals, and we understand the functions of only a few of them. The process of apoptosis occurs through the activation of a subset of these, called the *executioner caspases* (caspase-3, caspase-6, and caspase-7 in mammals), and once activated, these cut up to a thousand different cellular substrates in the cell to precipitate the changes associated with this form of cell death. The "cuts" are at specific sites in the substrates and occur at aspartate residues. This is the origin of "caspase," a *c*ysteine protease with *Asp-ase* activity.

The executioner caspases are present in cells in an inactive, dimeric form, which becomes activated when cut at specific aspartate residues, resulting in a conformational change that forms the active enzyme. The active enzyme now cuts its substrates, some of which are responsible for the changes associated with apoptosis.[6]

In general, this activating cleavage is mediated by other caspases, called *initiator caspases*. Unlike the executioner caspases, the inactive forms of the initiator caspases present in cells are monomeric and contain large prodomains that include sites for protein-protein interaction. Adapter molecules, which form "caspase activation platforms," bind to the prodomains of initiator caspases, forcing them into contact, and the latter then fold into active enzymes. These can then process the executioner caspases, thereby activating them to cleave their substrates and precipitate apoptosis.

The formation of caspase activation platforms and the caspases they activate define the apoptotic pathways. Here we consider in detail only two major pathways of apoptosis, the mitochondrial pathway and the death receptor pathway. It should be noted, however, that there are others, reviewed elsewhere.[7] One of these involves the formation of caspase activation platforms for the engagement and activation of caspase-1, which is critically involved in inflammatory responses by processing specific cytokines and promoting their release. The activation of caspase-1 can also kill cells by a process resembling apoptosis (often called *pyroptosis*). The activation of caspase-1 occurs in response to many infectious agents and has been implicated in promoting forms of cancer that are associated with inflammatory conditions. Caspases can directly signal apoptosis or can use mitochondria as an intermediate, and additional point of regulation, in signaling of apoptosis.

The Mitochondrial Pathway of Apoptosis

Starting in the 1980s, the intracellular molecules that controlled the morphology referred to as apoptosis began to be identified.[8,9] Cell death had previously been thought of as a passive event (as noted earlier): a universally negative occurrence that cells were constructed to avoid at all costs. Careful observations in human pathological samples as well as in model systems revealed that instead, cell death in multicellular organisms was often a carefully controlled event with stereotypical morphologic and temporal patterns. Moreover, when it was observed that altering the function of certain genes could alter the commitment, phenotype, and progression to cell death, it became clear that cells contained within them genetic programs to perform a function of choosing death as a cell fate, and then committing cell suicide. Although several different forms of programmed cell death have been identified, the first to be characterized was apoptosis.

The mitochondrial (sometimes called *intrinsic*) pathway of apoptosis responds to a diverse group of initiating events, including treatment with a wide variety of cytotoxic drugs, growth factor withdrawal, and oncogene activation. The mitochondrial pathway of apoptosis get its name because of the centrality of this organelle in coordinating both cell fate decision making as well as execution. Key features of apoptosis via the mitochondrial pathway include mitochondrial outer membrane permeabilization (MOMP), followed by release to the cytosol of molecules that facilitate execution of the death program, including cytochrome c, SMAC, and Omi. Cytochrome c is essential to the formation of one of the caspase activation platforms, the apoptosome, which is formed when cytochrome c activates APAF-1 to oligomerize, and the latter then binds and activates caspase-9.[10] Although caspases may perform normal physiological functions, they are best known for cleavage of proteins during apoptosis important for cell integrity, including cytoskeletal proteins and PARP-1. Among the caspase-dependent phenomena commonly observed in association with apoptosis are extracellular exposure of the phosphatidylserine that is usually found only on the inner leaflet of the plasma membrane (which results in recognition by Annexin V) and internucleosomal cleavage of chromosomal DNA (which results in laddering of DNA on electrophoresis and nuclear condensation). In vivo in a multicellular organism, an important

consequence of these changes is recognition and clearance of the apoptotic cell by phagocytic cells. It may well be that commitment to cell death is already made at the point of MOMP, whereas many of the downstream morphologies we associate with apoptosis might be most important mainly in facilitating the clearance of apoptotic cells, minimizing inflammation, and optimizing cannibalization of their macromolecules.[11-13]

The BCL-2 Protein Family

The B cell leukemia/lymphoma 2 (BCL-2) family of proteins controls commitment to apoptotic cell death via the mitochondrial pathway.[9] The discovery and characterization of this important family is intimately linked to cancer, as BCL-2 was initially cloned from the t(14;18) chromosomal translocation that is present in nearly all cases of follicular lymphoma.[14-16] The translocation places the *bcl-2* gene on chromosome 18 under the control of regulatory elements of immunoglobulin genes, yielding overexpression of the BCL-2 protein in cells of the B-lineage.

The key step in apoptosis commitment that is controlled by the BCL-2 family is MOMP.[17-19] In simplest terms, there are pro- and anti-apoptotic members of the BCL-2 family. When the pro-apoptotic proteins overwhelm the anti-apoptotic ones, MOMP occurs, and the cell is irreversibly committed to apoptosis. The details of this commitment involve complicated interactions among the BCL-2 family proteins that number greater than a dozen. BAX and BAK are obligate pro-apoptotic "effectors," proteins that homo-oligomerize to form the pores that cause MOMP.[20] In order to form the oligomers required to cause MOMP, BAX and BAK must be activated.[21,22] Proteins of the pro-apoptotic "activator" BH3-only protein subfamily, which include BIM, BID, and perhaps PUMA, can directly interact with BAX and BAK to cause an allosteric change that functionally corresponds to activation. There may also be other ways that BAX and BAK are activated, perhaps even independent of interaction with other proteins.[23]

Anti-apoptotic BCL-2 family proteins include BCL-2, BCL-XL, BCL-w, MCL-1, and BFL-1 (A1). These proteins inhibit apoptosis by binding and sequestering activator proteins or monomeric "activator" BAX or BAK proteins before they can oligomerize.[24,25] Another subfamily, the pro-apoptotic "sensitizer" BH3-only proteins, lack the ability to directly activate BAX and BAK with high efficiency, but promote apoptosis by competitively inhibiting the ability of anti-apoptotic proteins to bind activators, BAX, or BAK (Figure 14-4).[21]

BH3-only proteins get their name from their possession of the BCL-2 homology 3 (BH3) region, but of no other BCL-2 homology region.[26] The BH3 domain is essential for the pro-death activity of all of the pro-apoptotic BCL-2 family proteins. It is a roughly 20 amino acid amphipathic α-helix that binds into a hydrophobic BH3 binding cleft present in all of the anti-apoptotic proteins. There is a selective pattern of interaction of BH3-only proteins with anti-apoptotic proteins.[24,27-29] For instance, the BAD BH3 domain interacts selectively with BCL-2, BCL-XL, and BCL-w, whereas the NOXA BH3 peptide interacts selectively with MCL-1. Small-molecule BH3 domain mimetics that compete for these interactions, effectively inhibiting anti-apoptotic protein function, are being tested in cancer clinical trials (see later discussion).[30]

Mitochondrial Priming and Chemotherapy Response

The concept has emerged from many studies, especially in murine models of cancer, that apoptosis serves as a natural barrier to carcinogenesis.[31,32] In several murine models, defects in apoptosis facilitate carcinogenesis, supporting this concept.[33-35] Many of the changes that commonly occur in oncogenesis, including genomic instability and oncogene activation, contribute to pro-apoptotic signaling, which may well result in deletion of nascent malignant clones. Malignant clones that do survive must therefore have selected for mechanisms of evading apoptotic death provoked by this pro-apoptotic signaling by some combination of fostering anti-apoptotic signaling and attenuating pro-apoptotic signaling.

However, as it is commonly used, the oft-made assertion that resistance to apoptosis is a fundamental property of all cancer begs the question, "Compared to what?" It is difficult to find experimental or clinical evidence that cancers generally are more resistant to apoptosis than the normal nonmalignant cells in the human body. The fact that cancer cells have successfully buffered prior pro-apoptotic signaling does not necessarily mean that they are well prepared to evade subsequent pro-apoptotic signaling.

In fact, many conventional chemotherapies used in the clinic kill cells via apoptosis. The specific mechanisms may vary widely. Taxanes may increase levels of BIM, alter subcellular localization of BH3-only proteins, and decrease levels of MCL-1.[36-38] Cytotoxic agents can induce a decrease in MCL-1 levels, though whether this is a necessary and sufficient step for commitment to apoptosis in these cases is less clear.[39] DNA-damaging agents, by activating p53, can activate transcription of pro-apoptotic PUMA, NOXA, and BAX (see also Chapters 3 and 15).[40-43] In addition, p53 may promote apoptosis via direct interaction with BCL-2 family proteins.[44,45] Space does not permit detailing all of the relationships that have been discovered between conventional

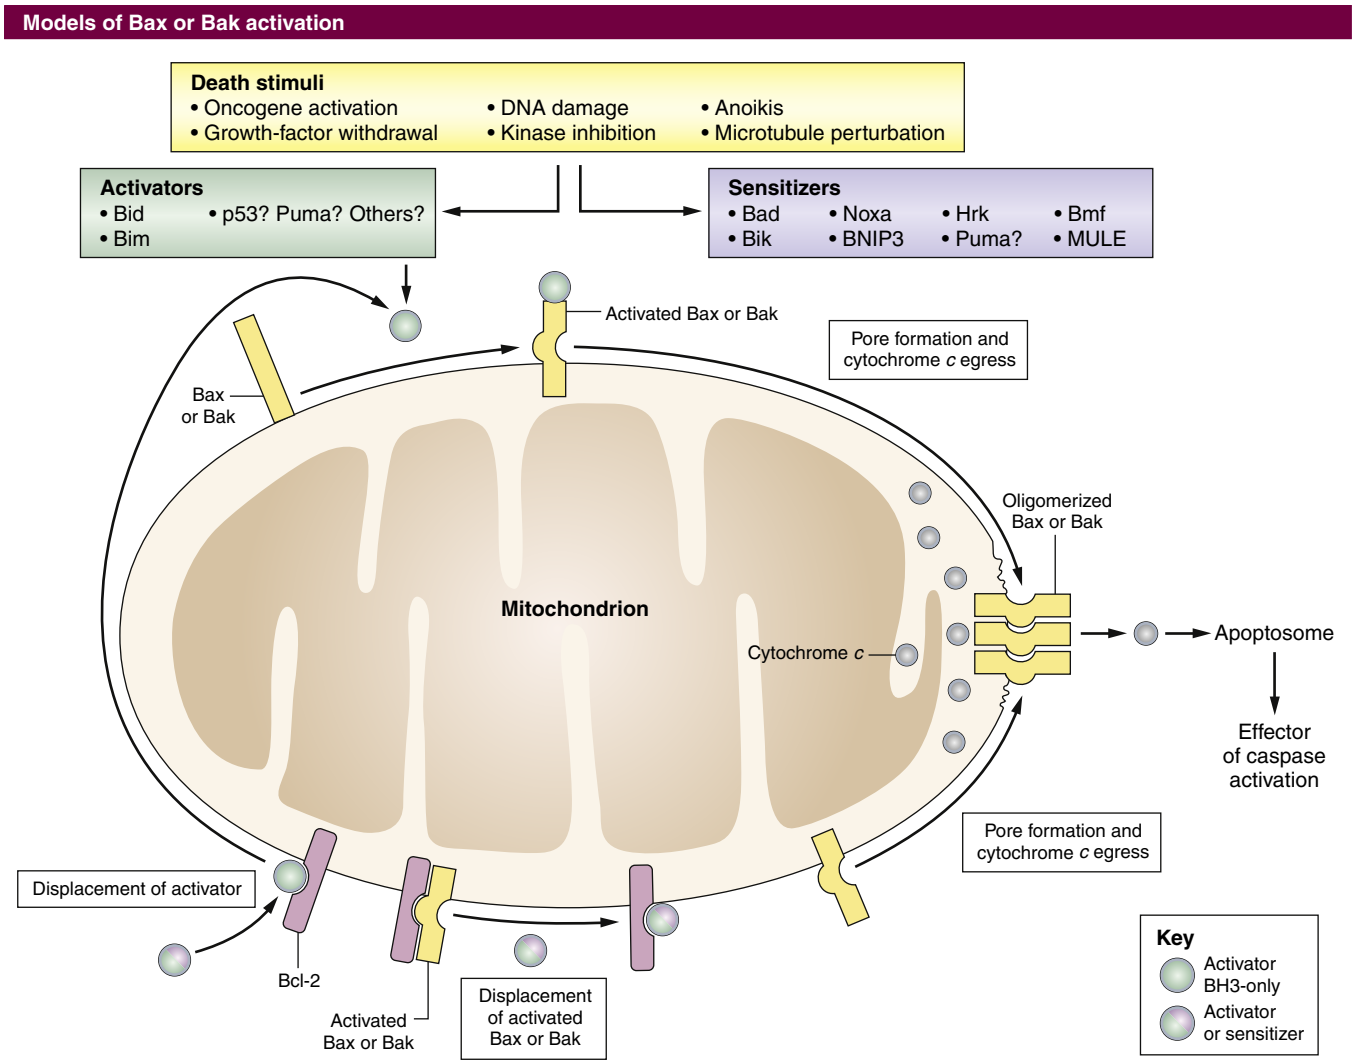

Figure 14-4 Control of MOMP by the BCL-2 family of proteins MOMP occurs following homo-oligomerization of activated BAX and/or BAK into a pore *(right)*, permitting release of proteins such as cytochrome c that facilitate caspase activation. BAX or BAK pore formation can be caused by the displacement of monomeric BAX or BAK that is already activated from anti-apoptotic proteins. This displacement can be effected by BH3-only proteins or BH3 mimetics *(bottom)*. Alternatively, in response to a variety of stimuli, an increase in activator proteins such as BIM or BID can activate BAX or BAK, which can then homo-oligomerize *(top)*. Sensitizer BH3 proteins or mimetics can also displace activators from anti-apoptotic proteins to effect BAX or BAK activation *(left)*.

chemotherapy agents and the BCL-2 family. Although there are sometimes attempts to identify the key BCL-2 family dictating response to a particular agent, it is likely that following most chemotherapies, more than one BCL-2 family protein takes part in determining the cell fate decision.

The ability of chemotherapy to selectively kill cancer cells makes it likely that in many cancer cells the apoptotic pathway is not only intact, but even more sensitive to pro-apoptotic signaling than in normal cells. This hypothesis has been directly tested using a mitochondrial assay called *BH3 profiling*, an assay that systematically compares mitochondrial response to a standardized panel of synthetic BH3 domain peptides.[46,47] These studies have shown that chemosensitive cancer cells are indeed more sensitive to pro-apoptotic signals than normal cells, suggesting mitochondrial apoptotic priming as an important determinant of the therapeutic index in vivo and in vitro. Normal hematopoietic cells are the most primed of normal tissues, consistent with their perennial role as the site of dose-limiting toxicity for most cytotoxic regimens. Measuring pretreatment mitochondrial priming may even be useful as a predictive biomarker, because it correlates well with clinical response.[46,47]

From a perspective of protein biochemistry, cells that are highly primed have little anti-apoptotic reserve to buffer subsequent pro-apoptotic signaling. Very often, a highly primed cell will express abundant anti-apoptotic BCL-2 family proteins, but these will already be occupied by pro-apoptotic activators such as BIM.[24,48,49] In these cases, the cells are dependent on the continuous function of the anti-apoptotic protein(s) for survival. Inhibition of one or more of

these can result in MOMP and apoptosis in highly primed cells (Figure 14-5).

It is worth considering the distinction between expression of an anti-apoptotic protein, and dependence on that anti-apoptotic protein. If one enforces BCL-2 overexpression via transfection of a plasmid vector in a healthy cell line already well established in culture, one will not necessarily obtain a BCL-2–dependent cell line, because there is likely no dependence on the additional BCL-2. The cell line was doing fine without it before transfection, and inhibition of BCL-2 would just restore the status quo ante. In oncogenesis, however, increased expression of BCL-2 is selected for, not extrinsically induced. This implies that the increased BCL-2 that was selected for is required for the continuous buffering of pro-apoptotic signals. In biochemical terms, that means that BCL-2 is largely already in complex with pro-apoptotic BCL-2 family members such as BIM or BAX. In the instance of the transfected cell line, however, BCL-2 is mainly empty and ready to buffer subsequent pro-apoptotic signaling. In the case where BCL-2 expression has been positively selected in the face of extant pro-apoptotic signaling, the BCL-2 is mainly full. Rather than providing anti-apoptotic reserve, the BCL-2 in the latter case is actually storing pro-apoptotic proteins at the mitochondrion, priming it for sensitivity to apoptosis.[24] The cancer cell just discussed is thus dependent on continuous BCL-2 function for survival. In other cancer cells, similar to the transfected cell line, BCL-2 expression may be incidental, rather than selected for, and the BCL-2 not required tonically. Protein and transcript levels of multiple BCL-2 family members, as well as functional assays such as BH3 profiling, have been used to identify cells that are dependent on BCL-2 and hence likely to be sensitive to antagonists of BCL-2 (see later discussion).[48,50,51]

Targeted Therapies and Apoptosis

In the past decade, modern "targeted" therapies have occupied the lion's share of attention in preclinical development, with several achieving approval for clinical use in cancer. Most of these agents also kill by inducing signaling via the mitochondrial apoptotic pathway. However, in this case, selective killing of cancer cells depends less on differences in pretreatment mitochondrial priming and more on selective dependencies of cancer cells. For instance, imatinib, the first small-molecule kinase inhibitor to be approved for use in cancer, inhibits activity of the Abl kinase, an activity that is enhanced by the BCR/ABL fusion protein created by the t(9;22) chromosomal translocation present in chronic myelogenous leukemia (CML). The selective killing of malignant CML cells over normal cells depends on the selective dependence of CML cells on activity of the BCR/ABL kinase.[52] Another family of tyrosine kinase inhibitors, those directed against epidermal growth factor receptor (EGFR), are selectively effective in lung cancers with activating mutations in EGFR.[53-55]

A general property of kinase inhibitors in cancer, whether tyrosine kinase or serine/threonine kinase inhibitors, is their utilization of the mitochondrial apoptotic pathway to kill cancer cells. Interestingly, although doubtless other BCL-2 family members also contribute, BIM, a pro-apoptotic activator BH3-only protein, is regulated by many different kinase inhibitors. In turn, lethality of kinase inhibition depends on the upregulation of BIM. BIM upregulation is required for killing by imatinib whether in CML or in gastrointestinal stromal tumors (GIST) where the constitutively active c-KIT kinase is the relevant target.[56,57] Similar observations have been made for inhibitors of EGFR, MEK, ALK, and b-RAF.[37,58-61] A fascinating human genetic study found that a germline polymorphism of BIM that removes the BH3 domain that is required for pro-apoptotic function is common in an Asian population.[62] Intriguingly, this polymorphism conferred inferior clinical response to inhibitors of both BCR-ABL in CML and of EGFR in non–small-cell lung cancer, apparently confirming its importance in cancer cell–fate decision making in clinical use of kinase inhibitors.

Proteasome inhibitors such as bortezomib have become a mainstay of multiple myeloma therapy and have found application in other diseases such as mantle-cell lymphoma. These also apparently kill via the mitochondrial apoptotic pathway. In this case, the most often cited mechanism of response is the pro-apoptotic BH3-only family protein NOXA, which can selectively bind and inactivate MCL-1, an anti-apoptotic protein also in the BCL-2 family.[63] Of course, proteasome inhibitors alter the levels of thousands of proteins, so that there may be several proteins that are affected that are important for cell-fate decision after proteasome inhibitors.

Directly Targeting the BCL-2 Family in Cancer Treatment

Given the centrality of the BCL-2 family of proteins in determining cell fate in cancer, considerable effort has been expended on inhibition of anti-apoptotic BCL-2 family proteins to induce cancer cell death.[30]

These efforts are in their infancy, and important questions need to be resolved. For example, should the agent have a narrow or broad spectrum of inhibition of anti-apoptotic BCL-2 family proteins? Broad-spectrum agents will likely be more toxic to more kinds of cancers; however, there is the possibility of a narrowed therapeutic index that could limit clinical utility. Will these agents be best used as single agents

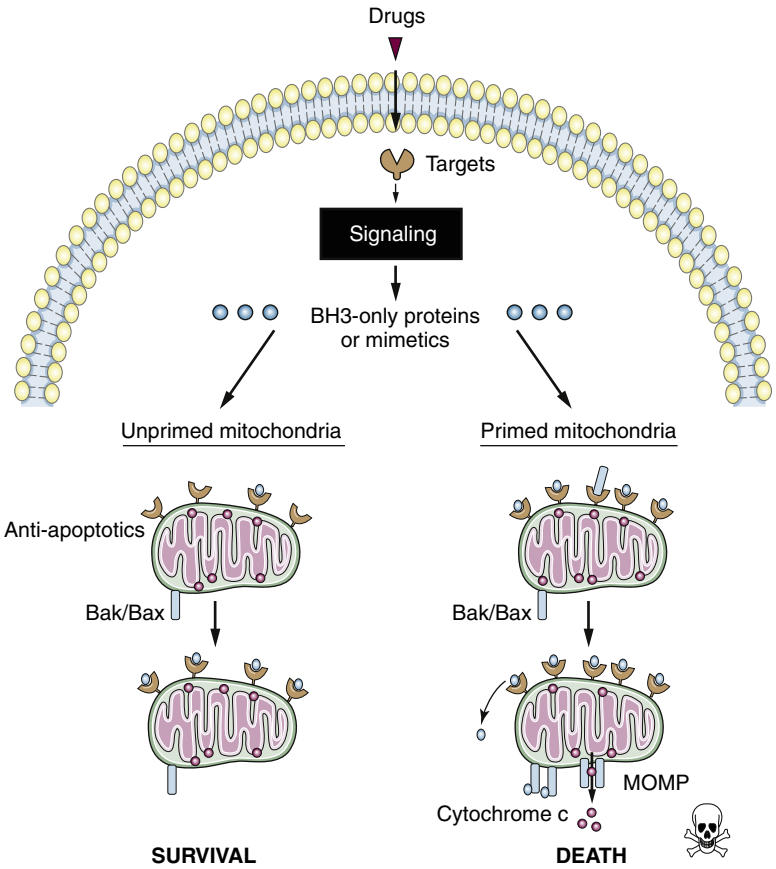

Figure 14-5 Primed versus unprimed mitochondria Functionally, primed mitochondria can be defined as those that are most sensitive to BH_3 peptides. Unprimed mitochondria *(left)* have a relative excess of "empty" anti-apoptotic proteins, affording anti-apoptotic reserve that can buffer subsequent death signaling. Primed mitochondria *(right)* may have abundant anti-apoptotic proteins, but these are relatively "full," occupied by pro-apoptotic proteins. Primed mitochondria have little anti-apoptotic reserve and are relatively sensitive to subsequent death signaling.

or in combination with others? Although some diseases may demonstrate clinical sensitivity to single agents, it may well be that combination with the powerful, albeit less selective, pro-death signaling induced by conventional cytotoxic agents will be necessary to provide the significant benefit in long-term clinical outcomes that is so badly needed in many cancers. In addition, combinations with targeted agents such as kinase inhibitors have proved promising in vitro.

The Death Receptor Pathway of Apoptosis

The death receptors are a subset of cell surface receptors that are members of the tumor necrosis factor (TNF) receptor (TNFR) superfamily. These receptors can be activated by ligands, which are themselves a subset of the TNF superfamily. The death receptors include one of the receptors for TNF, TNFR1, the TRAIL receptors, and CD95 (also called Fas or APO1).

When a death receptor is engaged by its ligand, this can result in apoptosis. In this death receptor pathway of apoptosis, the initiator caspase is caspase-8, and its activation platform involves the adapter protein, FADD, which binds to the prodomain of the caspase, allowing it to form its active dimer.

The simplest form of this process is seen in the ligation of CD95 (this may apply to the TRAIL receptors as well). Ligation of CD95 causes the exposure of a protein interaction region in the intracellular part of the receptor, which rapidly binds to FADD. Several receptors and the associated FADD form the caspase activation platform, and caspase-8 is recruited to FADD for its activation. The proteolytic activity of the bound caspase-8 now cuts the caspase, removing the prodomain and releasing the now-stabilized dimer (Figure 14-6, *A*).

In the case of TNFR1, the process is much more complex. Binding of ligand to TNFR1 induces exposure of the intracellular region of the receptor, but this does not bind FADD. Instead, another adapter, called TRADD, is bound, as well as a number of other signaling proteins, some of which modify the associated proteins with ubiquitin. Among these is RIPK1, a protein kinase, discussed further later. Also among these are proteins involved in the activation of a transcription factor, nuclear factor-κB (NFκB). The initial complex (complex I) is then released from the receptor, and its subsequent signaling outcome depends on additional protein interactions. Among these is a protein called c-$FLIP_L$ (also called CFLAR).

c-$FLIP_L$ closely resembles caspase-8 but lacks a catalytic cysteine. When complex I is released, TRADD binds to FADD in the cytosol, and this recruits caspase-8. However,

if c-FLIP$_L$ is present, the complex that forms (complex IIa) contains heterodimers of caspase-8 and c-FLIP$_L$, and this does not promote apoptosis (discussed later). However, if the activity of NFκB is blocked or disrupted, or if the expression of c-FLIP$_L$ is otherwise blocked, complex IIa activates caspase-8 (see Figure 14-6, *B*). Another complex that forms in cells exposed to TNF involves the kinase RIPK1 (complex IIb). Like TRADD, RIPK1 can bind to FADD and form a caspase-activation platform. Again, if c-FLIP$_L$ is present, caspase-8–c-FLIP$_L$ heterodimers form, and apoptosis does not proceed. However, if c-FLIP$_L$ is absent, this can also result in caspase-8 activation (see Figure 14-6, *C*).

The formation of the RIPK1-FADD complex is not restricted to the death receptor pathway. It can form as a consequence of DNA damage, although the precise signaling mechanisms are not fully elucidated.[64] Another way in which this forms is as a result of ligation of some Toll-like receptors (TLRs), molecules that recognize components of infectious organisms, such as bacteria. Some TLRs recruit a signaling molecule, called TRIF, and this can engage RIPK1 to form a complex with FADD.[65] As with the other cases, the subsequent activation of caspase-8 to promote apoptosis depends on the presence of c-FLIP$_L$. Efforts to therapeutically activate death receptor pathways for cancer therapy are in development.[66]

Mitochondrial Pathway Activation by Caspase-8

When we discussed caspase activation, we noted that initiator caspases, such as caspase-8, can cleave and thereby activate executioner caspases to promote apoptosis. However, in most cell types, the activated executioner caspases are bound by an inhibitor, X-linked inhibitor of apoptosis protein (XIAP), which then ubiquitinates the caspase and promotes its degradation. This prevents apoptosis from proceeding. However, caspase-8 has another substrate in the cell that indirectly overcomes this inhibition. This protein is BID, one of the BH3-only proteins discussed in the last section. When caspase-8 cleaves BID, this BH3-only protein translocates to the mitochondria to promote MOMP.

Although MOMP and the release of cytochrome c can then lead to activation of caspase-9, as we have noted previously, this event is not necessary in this case. Instead, the release of other proteins, such as Smac and Omi, is required, as these bind to and neutralize XIAP. As a result, the executioner caspases cleaved by caspase-8 can now precipitate apoptosis in the cell. This is illustrated in Figure 14-6, *D*. This explains the otherwise apparently paradoxical observation that anti-apoptotic Bcl-2 proteins can often inhibit apoptosis engaged by the death receptor pathway.

Necrosis

Passive and Active Necrosis

Necrosis (type III cell death) is distinct from apoptosis and autophagic cell death in terms of both morphology and mechanisms. Cells that die by necrosis generally have diffuse nuclei and a loss of organellar structures, as entry of water into the cell causes swelling and often rupture of membrane compartments.

Understanding necrosis is important in cancer biology for several reasons. Most importantly, cancers that contain high levels of necrosis often have a poor prognosis. This may be because such cancers grow so quickly that they outstrip their blood supply. Another important aspect of necrosis is that it is inflammatory: That is, the contents of the dying cells release mediators (DAMPs, see earlier discussion) that trigger inflammatory responses. Inflammation itself damages tissues and can cause cycles of repair and proliferation involving growth factors that can promote oncogenesis and tumor expansion. In many adult cancers, inflammation may be a major component of the process that promotes tumorigenesis.

As we noted earlier, it is useful to distinguish between cell death that is passive versus active, and this applies to necrosis. Passive necrosis occurs when cells are irreparably damaged by external forces, or when processes that are essential for sustaining cellular homeostasis are blocked or disrupted. This can occur as a consequence of mechanical stress or toxic chemicals or as a result of specialized pore-forming peptides or proteins (e.g., some venoms and bacterial toxins, complement, perforin). Because such processes are intuitively fairly obvious, our focus here is on forms of necrosis that are active, that is, depend on cellular processes and events that, if inhibited, preserve the survival of the cell. For the most part, these all correspond to forms of cellular "sabotage," although as we will see, there is one form of necrosis that might be "suicide."

Necrosis as an Adjunct to Other Cell Death Modalities

Before embarking on a survey of the mechanisms of active necrosis, we must note that there are processes that can confuse the distinctions between necrosis and other forms of cell death. These are secondary necrosis and caspase-independent cell death, both related to apoptosis, and many forms of autophagic cell death.

As we mentioned, when a cell dies by apoptosis, it is rapidly engulfed by other cells and removed from the system before any loss of plasma membrane integrity. However, if such engulfment does not occur, the dying cells will take on some features of necrosis as plasma membrane integrity is

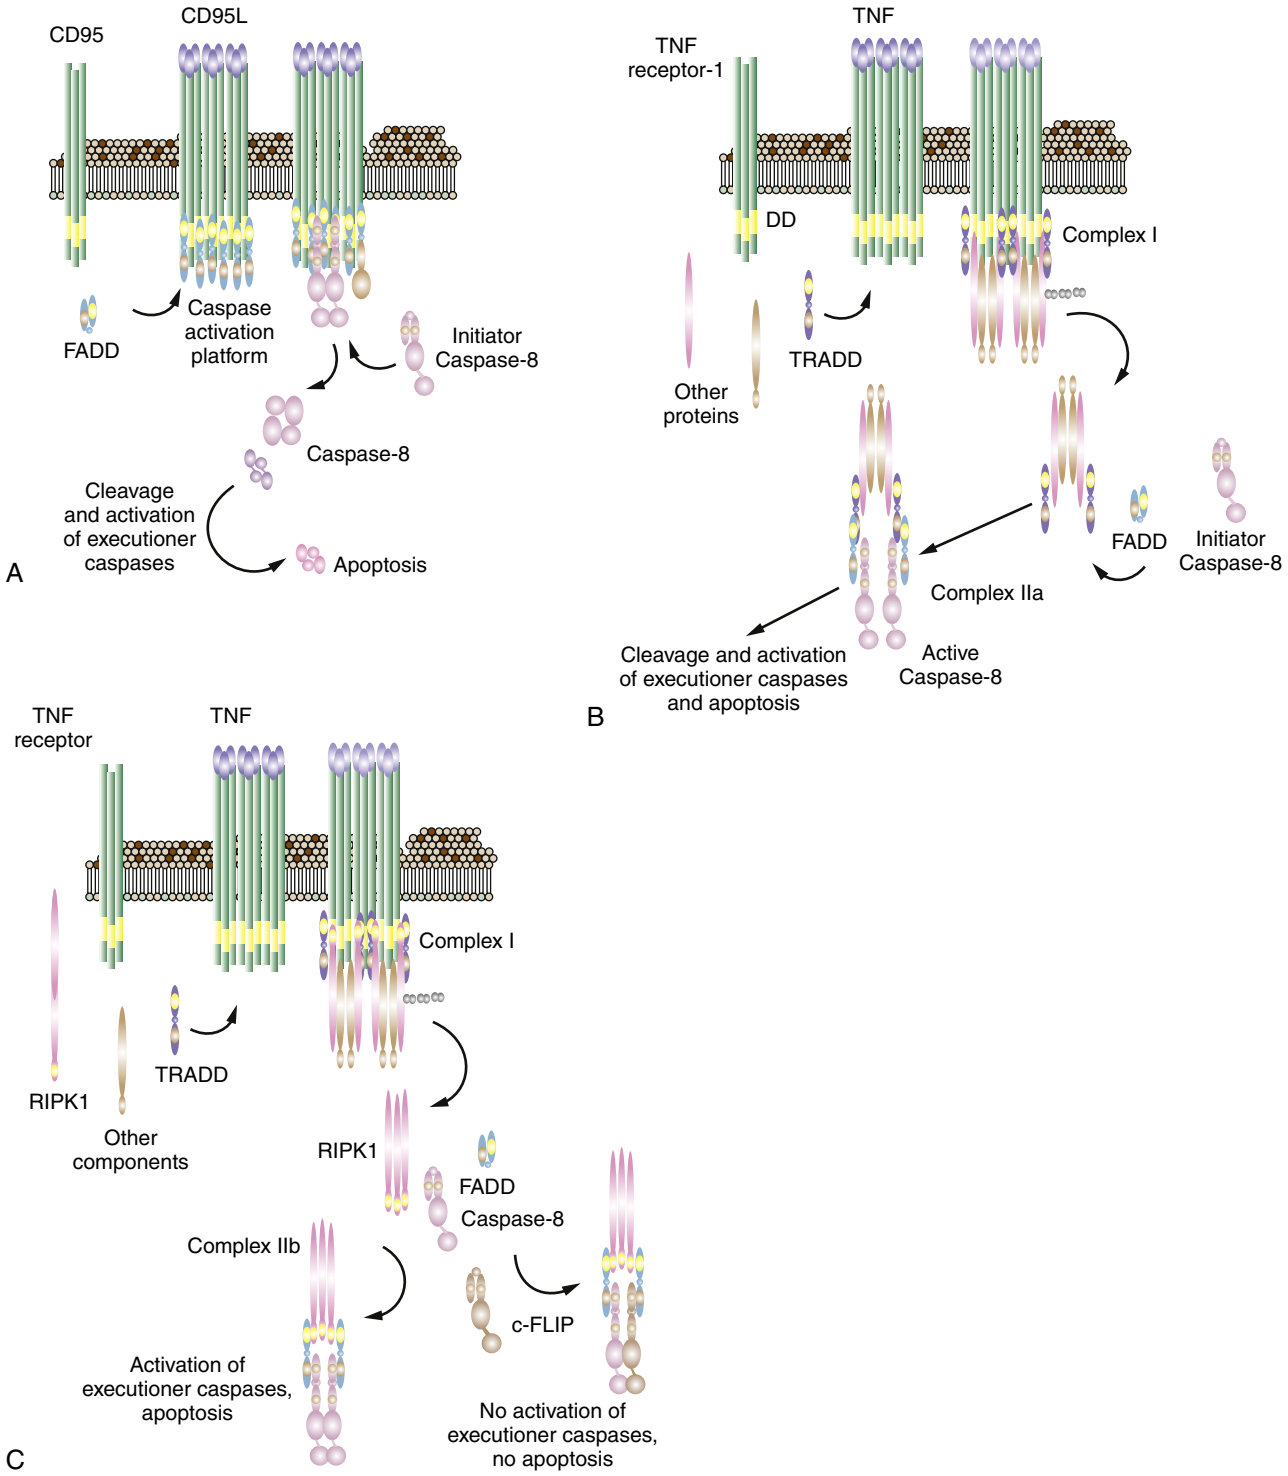

Figure 14-6 Signaling of cell death by death receptors Induction of cell death by **(A)** CD95; **(B)** TNF through complex IIa; **(C)** TNF through complex IIb; and **(D)** death receptor signaling through mitochondria. The often-used "Fas" to designate CD95 stands for "FS-7 associated surface" antigen, recognized by an antibody capable of inducing apoptosis, originally discovered by S. Yonehara. Because "FAS" designates fatty acid synthase, an unrelated protein, the term has been replaced by CD95. Unfortunately, however, the old nomenclature persists and may cause confusion.

Continued

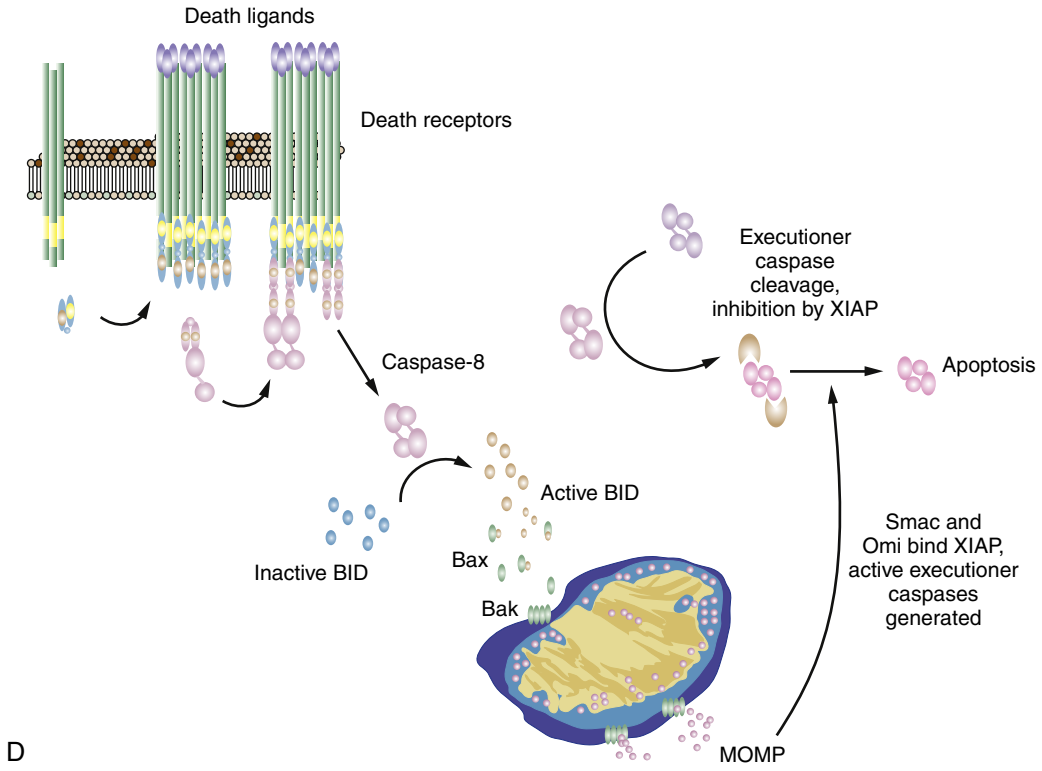

Figure 14-6, Cont'd

lost. This is called *secondary necrosis* and can often be distinguished from other forms of necrosis by some features of apoptosis, such as chromatin condensation. Whether or not secondary necrosis is inflammatory, and thus may contribute to some disease states, remains controversial, but there is accumulating evidence that defects in the engulfment and clearance of apoptotic cells can cause pathology arising from the effects of secondary necrosis.

A second form of necrosis that is related to apoptosis is *caspase-independent cell death* (CICD).[67] This occurs when a cell undergoes MOMP in the mitochondrial pathway of apoptosis, but caspase activation is blocked or disrupted. Although several mechanisms have been suggested for why CICD occurs, an emerging consensus suggests that this is mainly due to energetic consequences of the "mitochondrial catastrophe" produced by MOMP.[68] Notably, regulatory events that control MOMP, such as expression of anti-apoptotic BCL-2 proteins, effectively block CICD and thus distinguish this form of necrosis. Although cells that undergo MOMP but do not engage caspases often die by CICD, cells can survive this event,[69,70] and it is possible that such survival contributes to cancer and/or chemotherapeutic resistance in some cases.

As mentioned earlier, passive necrosis occurs when essential cellular processes are disrupted, but repair mechanisms can insulate a cell from such insults. One major repair mechanism is autophagy (discussed in much more detail later), and therefore a cell that dies as a consequence of such damage may show extensive evidence of autophagy. As a result, we may categorize cells dying in this way as so-called autophagic (type II) cell death. In such cases, however, inhibition or disruption of autophagy will render the cell more susceptible to necrosis, and therefore it may be more appropriate to regard this process as one of necrosis.

Ischemia and Necrosis

Probably the most common cause of necrosis in cancer is as a result of ischemic injury, the loss of blood supply to the tumor. There are two major ways ischemia causes necrosis; the first is via the deprivation of oxygen and nutrients. This occurs in tumors as regions of the mass are deprived of blood supply and can be regarded as passive necrosis. A second, more complex way occurs when blood supply is restricted and then regained, a condition referred to as *ischemia/reperfusion injury*. Paradoxically, reperfusion of a deprived tissue often results in massive necrosis, and this is a major clinical problem.

Ischemia/reperfusion injury is a complex process we can regard as a form of cell sabotage and thus active cell death, although it is not fully understood. There are three components of ischemia/reperfusion injury that are generally agreed on: a rise in intracellular calcium, the production of reactive oxygen species, and disruption of the mitochondria.

On reperfusion, potassium channels in the plasma membrane open, releasing potassium from the cytosol, and this in turn causes the opening of plasma membrane calcium channels and a rise in intracellular calcium (Ca^{2+}). The increase in Ca^{2+} has several effects. First, it can activate the protease calpain, which can inflict proteolytic damage to the cell. Pharmacologic inhibitors of calpain have some protective effects in ischemia/reperfusion injury. Second, Ca^{2+} activates NADPH-oxidases, causing the production of ROS, which can also damage the cell by targeting lipids and DNA. Damage to the DNA elicits activation of polyADP-ribose polymerase (PARP), and extensive activation of PARP can deplete stores of NADH, accelerating death. Scavenging ROS or inhibition of PARP can also produce some protection against this form of injury.

Both Ca^{2+} and ROS may precipitate necrosis in large part by affecting the mitochondria through a process called the *mitochondrial permeability transition*. The inner mitochondrial membrane is critical for mitochondrial function, as the control of the distribution of protons and other ions across this membrane drives ATP production and other activities of the organelle. High levels of Ca^{2+} and/or ROS cause the opening of a "pore" in the membrane that dissipates these critical gradients, and the matrix swells, ultimately destroying the organelle. The components of the permeability transition pore are largely unknown, with one exception: a protein of the mitochondrial matrix, cyclophilin D, has a major role in the process. Animals lacking cyclophilin D display no developmental abnormalities, but are resistant to ischemia/reperfusion injury. Whatever the function of the mitochondrial permeability transition might be, it may be safe to conclude that necrosis induced by ischemia/reperfusion that engages this mechanism represents a form of cellular sabotage. Whether this process can be used to promote cancer cell death therapeutically is not known.

Necroptosis Is a Form of Active Necrosis

In the discussion of the death receptor pathway of apoptosis, a kinase, RIPK1, was introduced, which participates in one of the TNFR complexes and can also function in complexes induced by other means (DNA damage, TLR-TRIF signaling). RIPK1 can also promote a form of necrosis, called *necroptosis* (to distinguish it from other forms, such as those discussed earlier).

Necroptosis involves the activation of another kinase, RIPK3, which binds to RIPK1 but can also be engaged by other proteins (a putative sensor of viral DNA, called DAI-1, activates RIPK3 and causes necroptosis independently of RIPK1). The activation of RIPK3 rapidly induces cell death with the features of necrosis.

How cell death occurs on activation of RIPK3 is largely unknown and is an area of intense research. One other player in the process is another protein, MLKL, which may itself be a kinase or may act as an adapter to bring specific substrates to RIPK3. Although a number of effector mechanisms have been proposed, including mitochondrial ROS and other mediators, at this point we simply do not know how this form of necrosis occurs.

As discussed in the consideration of death receptor signaling, RIPK1 can recruit the adapter, FADD, into a caspase activation platform that engages caspase-8 and the caspase-like molecule, c-$FLIP_L$. Although the caspase-8–c-$FLIP_L$ heterodimer is an enzymatically active protease, it does not promote apoptosis (for reasons that we still do not understand). However, it has now become clear that this activity serves an important function in cells: It blocks the activation of RIPK3 (Figure 14-7).

Ligation of TNFR1, or other ways in which RIPK1 is engaged and activated, generally does not cause necroptosis, unless the formation of the FADD–caspase-8–c-$FLIP_L$ complex is blocked or disrupted.[71,72] Mice in which the genes for FADD or caspase-8 are deleted die early in embryogenesis, but development is fully rescued by ablation of RIPK3. The effect of ablating c-FLIP is the same, but its rescue is more complex: In this case death occurs only if both RIPK3 and FADD are deleted, most likely because activity of FADD to activate caspase-8 promotes death in cells lacking c-FLIP.

How, exactly, the caspase-8–c-$FLIP_L$ heterodimer blocks necroptosis is not fully known. One simple possibility is that it cuts RIPK1 (and perhaps RIPK3), rendering it inactive. However, other possibilities exist, either upstream of RIPK1 or downstream of RIPK3. For example, an enzyme, CYLD, that removes ubiquitin from RIPK1 (required for its necroptotic function) is targeted by caspase-8[73] and therefore may also play a role in the protective function of caspase-8–c-$FLIP_L$.

Why is the system "built" this way? One possibility is that many viruses have evolved mechanisms to inhibit the activation of caspase-8 as a way to avoid immune attack, and therefore, linking RIPK3-induced necroptosis to the pathway ensures that cells infected by such viruses still die. Another, similar argument relates to c-$FLIP_L$, which is rapidly turned over in cells: When intracellular parasites (including viruses) disrupt the translation of cellular proteins, levels of c-$FLIP_L$ decline, thereby sensitizing the cell to necroptosis. The destruction of the cell not only limits the replication of the parasite, but also engages the inflammatory response elicited by the necrotic cells.

Because necroptosis appears to be a bona fide form of cellular suicide, it is possible that this cell death process can function in tumor suppression. As more is learned about this phenomenon, cancers may be found in which oncogenesis is offset by engagement of necroptosis. Alternatively, there may

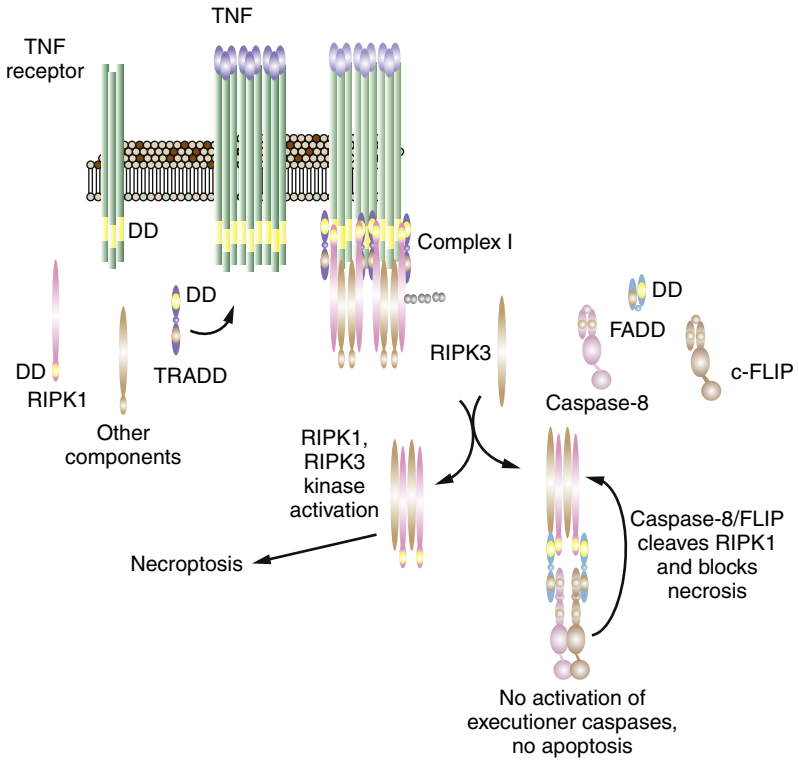

Figure 14-7 The necroptosis pathway See text for explanation.

be ways to exploit the process for tumor cell destruction in some forms of cancers.

Necroptosis, RIP Kinases, and Cancer Therapy

One area of cancer therapy involves a class of compounds called *Smac mimetics*, as they were originally designed to mimic the effects of the IAP antagonists (such as Smac) released upon MOMP. In fact, we now know that these agents work through targeting the cellular IAP molecules, c-IAP1 and c-IAP2.

The c-IAP molecules are E3 ligases that have, among their targets, the kinases RIPK1 and RIPK3. In healthy cells, the c-IAPs restrict the accumulation of these kinases and therefore prevent their activation. When cells are exposed to the Smac mimetics, the kinases accumulate, but if c-FLIP$_L$ is present, the action of FADD-caspase-8–c-FLIP$_L$ prevents death. However, if c-FLIP$_L$ is absent, the cells will die by caspase-8–mediated apoptosis or via necroptosis.

Autophagy

Autophagy, or cellular self-eating, is a process cells use to collect intracellular proteins, cytoplasm and organelles, and deliver them to lysosomes where they are degraded and recycled.[74] There are multiple forms of autophagy that use different routes to deliver cargo to lysosomes for degradation.[74] We focus here on macroautophagy (autophagy hereafter), where double membrane vesicles called *autophagosomes* capture cargo and then fuse with lysosomes. Autophagy has a dual role in cancer: It can be tumor suppressive by preserving cellular and tissue health and can be tumor promoting by supporting mitochondrial metabolism and survival in stress. We discuss the contexts in which autophagy influences cancer development, progression, and response to therapy.

Autophagy was discovered more than 50 years ago and was found to be activated by starvation in yeast, which enabled identification and characterization of many of what would become known as the approximately 30 autophagy-related (*atg*) genes.[75,76] This helped establish the framework for autophagy regulation, autophagosome formation, and the capture, delivery, and degradation of cargo in lysosomes. Discovery of orthologs of *atg* genes in other model organisms and in humans broadened our understanding of the role of autophagy in health and in disease.

There are two major functions of autophagy. The first is to eliminate damaged or superfluous proteins and organelles, commonly referred to as the protein and organelle quality control function of autophagy. The second is to degrade

and recycle intracellular components to sustain metabolism and homeostasis in the absence of external nutrients, commonly referred to as the catabolic function of autophagy. Autophagy occurs at a low basal level in normal cells and tissues and is dramatically upregulated by stress and starvation, which is critical for cellular and mammalian survival and homeostasis.[77] Variations of autophagy can also remodel tissues in development or capture and degrade intracellular pathogens and contribute to host defense.[74] Autophagy has been paradoxically referred to as type II programmed cell death, where instead autophagy is predominantly a survival mechanism. The long-ago observations of autophagosomes in dying cells that led to this designation are instead likely a result of cells attempting to save themselves by activating autophagy.[78]

Protein and Organelle Quality Control

A common feature of cells and tissues with defective autophagy is the accumulation of aggregated proteins and dysfunctional mitochondria and other organelles, which can be toxic.[79,80] Autophagy is specifically critical to purge bad mitochondria on a regular basis; otherwise cells fill up with these defective organelles. Cells can degrade individual soluble proteins via the ubiquitin-proteasome pathway; however, autophagy is the only mechanism cells have for large-scale bulk degradation and for degrading large structures such as protein aggregates and entire organelles. Autophagy is thereby a nonredundant process critical for cellular physiology. Tissues from mice deficient for essential autophagy (*atg*) genes accumulate autophagy substrates including lipids, aggregated proteins, and abnormal organelles, particularly mitochondria. Autophagy deficiency causes neurodegeneration,[81,82] liver damage and inflammation,[83-86] muscle cell deterioration,[87] degeneration of pancreatic islets,[88,89] and impairment of lymphocyte homeostasis.[90] Liver and brain appear to require autophagy more than other tissues.

Cell Catabolism

A common function of autophagy that is conserved from yeast to mammals is to provide survival in starvation through intracellular recycling.[91-94] This is dramatically demonstrated by the observation that mice deficient for the essential autophagy gene *atg5* are born but fail to survive the neonatal starvation period, and their tissues display signs of energy impairment.[92] In the absence of external nutrients, catabolic recycling of proteins and organelles by autophagy is essential to sustain mammalian metabolism and survival.

Quality Control and Catabolism Overlap

Mitochondria are the nexus of functional overlap between the quality control and catabolic functions of autophagy. On the one hand, the quality control activity of autophagy is required to preserve the functioning pool of mitochondria to sustain their metabolic activity and cell survival. On the other hand, the catabolic activity of autophagy supplies substrates to mitochondria for them to metabolize. Thus, a major role for autophagy is in the regulation of mitochondrial metabolism, which affects cellular energy status, oxidative stress, signaling, and anabolism.

Dual and Context-Specific Role for Autophagy in Cancer

Both the quality control and catabolic functions of autophagy promote cell, tissue, and organismal homeostasis and survival, and in most circumstances this suppresses or delays cell death mechanisms of apoptosis and necrosis by promoting cellular health.[95,96] Autophagy has a dual and context-specific role in cancer.[97,98] By preserving cell and tissue health in some circumstances, autophagy can be tumor suppressive. Autophagy, however, can enable survival of cancer cells (and normal cells) in stress and in response to activation of some oncogenic pathways, and in this context autophagy can be tumor promoting.

Process of Autophagy

The central functions of autophagy have at their core the ability to identify and capture cargo and deliver it to the lysosomal compartment where it is degraded.[74] The breakdown products of intracellular proteins and organelles are then released from lysosomes into the cytoplasm, where they can be reutilized.[93] These amino acids, nucleosides, sugars, and fatty acids are used either as substrates to drive metabolic pathways or as building blocks for generation of new biomass. Regulators of autophagy ensure that the right cargo is degraded at the right time in the right cells.

In normal conditions, autophagy functions at low basal levels to ensure the occasional, selective, and necessary turnover of proteins and organelles due to aging and normal wear and tear. Damaged proteins and organelles display the "eat me" signal, the addition of polyubiquitin chains to proteins, which are recognized by autophagy receptors that recruit autophagosomes. In response to stress and starvation, autophagy is robustly induced. This ensures the elimination of damaged proteins and organelles that are induced by stressful conditions and also provides an alternate source

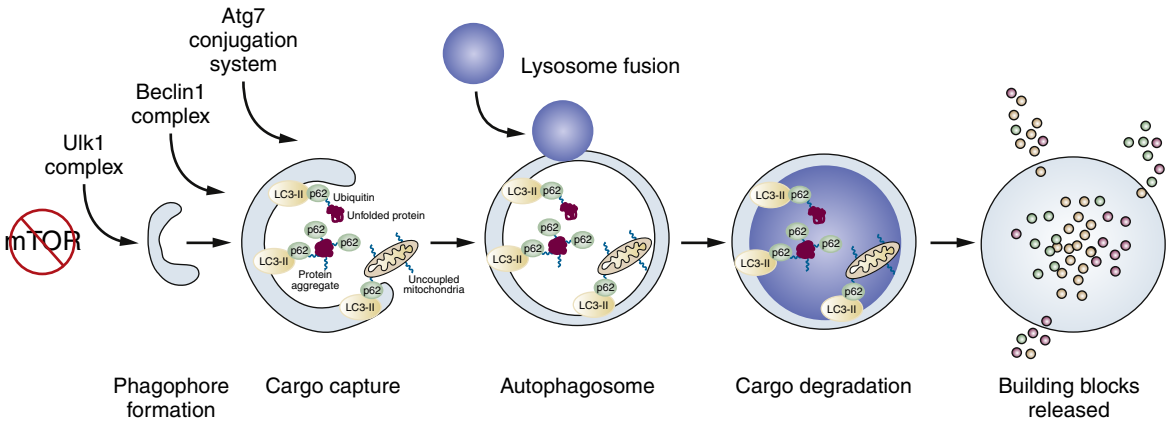

Figure 14-8 Process of autophagy See text for explanation.

of bulk metabolic substrates through intracellular recycling when external nutrient sources are limiting.

There are many growth regulatory and stress pathways that control the switch from basal to induced autophagy. Many of these pathways converge on the major nutrient-sensing and cell growth–promoting mammalian target of rapamycin (mTOR). Nutrients activate mTOR, which shuts off initiation of autophagosome formation by directly phosphorylating components of the *atg1*/unc-51–like kinase 1 (ULK1) complex (see Figure 14-8).[99] Starvation suppresses mTOR activity, de-repressing autophagy and providing a direct link between nutrient availability, cell growth, and catabolism (Figure 14-8). Simply put, cells have no need to eat themselves when there is plenty of food, and regulation of autophagy by mTOR integrates that important relationship.

mTOR is not the only way to regulate autophagy. For instance, cells regulate autophagy induction by monitoring their energy status. AMP-activated protein kinase (AMPK) is activated by interaction with AMP that accumulates when cells are energy deprived. In turn, AMPK potently activates autophagy by directly phosphorylating and activating the ULK1 complex to initiate autophagosome formation.[100,101] Stress also activates autophagy. For instance, low oxygen induces hypoxia-inducible transcription factors that turn on the expression of *atg* genes to stimulate autophagy.[102] Ammonia, a waste product of amino acid and nucleic acid metabolism, induces autophagy, linking autophagy to metabolic stress.[103,104] Activation of cancer pathways such as those controlled by oncogenic Ras,[105,106] p53 loss,[107] and activation of NFκB[108] activate autophagy, and the functional consequences are under active investigation.

The ULK1 complex activates autophagy by associating with membranes, often those of the endoplasmic reticulum, and recruiting the class III phosphatidylinositol (PtdIns) 3-kinase Vps34, Beclin1/Atg6 complex, and Atg9-containing vesicles. PtdIns production recruits double FYVE-containing protein 1 (DFCP1), which initiates autophagosome formation. Two ubiquitin-like conjugation systems governed by Atg7 form the Atg12-5-16L1 complex and process LC3/Atg8 to the cleaved, lipidated, and mature autophagosome-associated form LC3-II. The Atg5-12-16L1 complex and LC3-II function to elongate and close the autophagosome membrane. Autophagy receptors such as p62 bind cargo by interacting with their ubiquitin modifications and bind autophagosomes by interacting with LC3-II, thereby capturing the cargo in the forming autophagosome (see Figure 14-8). Autophagy can cause nonselective bulk degradation or can be highly selective, as is the case for mitophagy, which specifically targets depolarized mitochondria to the autophagy pathway for degradation.[80]

Autophagy-Mediated Tumor Suppression

The protein and organelle quality control function of autophagy plays an important role in maintaining tissue health that suppresses cancer. There are sweeping deleterious consequences to this failure to take out the "cellular garbage" that can ultimately render some tissues tumor prone. The mechanism of tumor suppression by autophagy is linked to degradation of oncogenic proteins, suppression of cell death, inflammation and chronic tissue damage, and ultimately to prevention of mutations and genetic instability (Figure 14-9).[97]

The essential autophagy gene *beclin1* was identified as a potential tumor suppressor gene when it was found to be monoallelically lost in a small cohort of human breast, ovarian, and prostate cancers and when its overexpression reduced the tumorigenicity of human cancer cell lines.[109,110] Knockout of *beclin1* in mice causes embryonic lethality; however, mice heterozygous for *beclin1* are prone to hepatocellular carcinoma, lung tumors, lymphomas, and mammary hyperplasia.[111,112] This suggested that *beclin1* is a haploinsufficient tumor suppressor. However, because it also functions in vesicle trafficking, it is not clear if this is due to its essential role in autophagy.

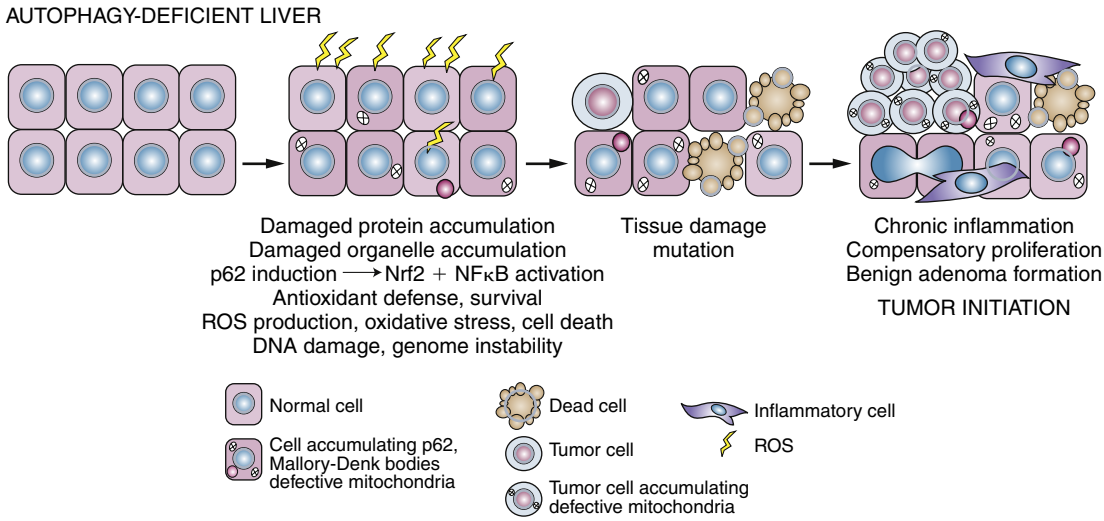

Figure 14-9 Tumor suppression by autophagy See text for explanation.

Mosaic knockout of the essential autophagy gene *atg5* in approximately 30% of cells throughout the mouse causes benign hepatoma (liver tumor) development without progression to hepatocellular carcinoma, and with no tumors in other tissues.[86] This suggests that autophagy deficiency promotes the initiation of cancer specifically in the liver, but because the neoplasms remain benign, autophagy may be required for progression to more aggressive cancers. It also suggests that tissues other than liver are less susceptible to tumor promotion caused by autophagy deficiency. Perhaps loss of other non–autophagy-related functions of *beclin1* are involved, or alternatively, partial autophagy deficiency due to allelic loss of *beclin1* may promote tumor initiation.

How autophagy defects promote cancer initiation in the liver is gradually emerging. Deficiency in *atg5* or *atg7* or allelic loss of *beclin1* in the liver causes fatty liver disease, and accumulation of abnormal mitochondria, the autophagy substrate p62, and p62- and ubiquitin-modified protein aggregates.[84-86] These p62 aggregates are also known as *Mallory-Denk bodies*, which are a hallmark of human liver disease and hepatocellular carcinoma. How these multiple aspects of autophagy deficiency may predispose to liver tumor promotion is then the question.

It is clear that degradation of the autophagy substrate p62 contributes to tumor suppression in the liver. p62 is a signaling adaptor protein that regulates cancer-promoting pathways, for instance, that of Nrf2 and NFκB.[113] This raised the possibility that deregulated levels of p62 resulting from impaired autophagy could promote the activation of pro-oncogenic pathways. p62 binds Keap1, the negative regulator of Nrf2, resulting in Nrf2 activation and upregulation of transcription of antioxidant defense genes that promote survival to oxidative stress.[83,114] Loss of autophagy and the resulting p62 accumulation activates Nrf2. Concurrent deficiency in *atg7* and *p62* prevents liver tumor initiation and enforced p62 accumulation in autophagy-deficient cancer cell lines accelerates tumorigenesis.[84-86,115] These findings demonstrate that p62 accumulation that results from autophagy defects promotes tumor initiation in the liver and can accelerate tumor progression.

p62 also interacts with TRAF6 and promotes NFκB activation. Autophagy defects and aberrant p62 accumulation and altered NFκB regulation may also contribute to the development of liver tumors.[85] Accumulation of p62 in aggregates blocks NFκB activation in hepatocytes, promoting cell death and triggering chronic inflammation that is known to cause liver cancer.[85,116] Suppression of inflammation may be another important tumor suppression mechanism mediated by autophagy independent of Nrf2 inhibition. In support of this concept, partial loss of *atg16L1*, which has been linked to the cancer-prone inflammatory condition Crohn disease, or deficiency in *atg5*, promotes Paneth cell dysfunction and inflammation of intestinal epithelium.[117]

Cancer development and progression can be facilitated by upregulation of Nrf2 and inflammation but ultimately requires acquisition of genetic changes. Autophagy defects activate the DNA damage response, suggesting that chronic tissue damage and ROS production can potentially generate cancer-causing genome mutations.[86,118-120] Indeed, autophagy-deficient tumor cells display an increased mutation rate, chromosome copy number variations, and genome instability compared to autophagy-functional tumor cells.[118,120] Thus, suppression of genetic instability by autophagy is likely the ultimate mechanism by which tumor suppression occurs. These and other findings have collectively suggested that autophagy stimulation may be beneficial for cancer prevention and the mechanism behind the health benefits of caloric restriction, fasting, and exercise that promote autophagy.[97]

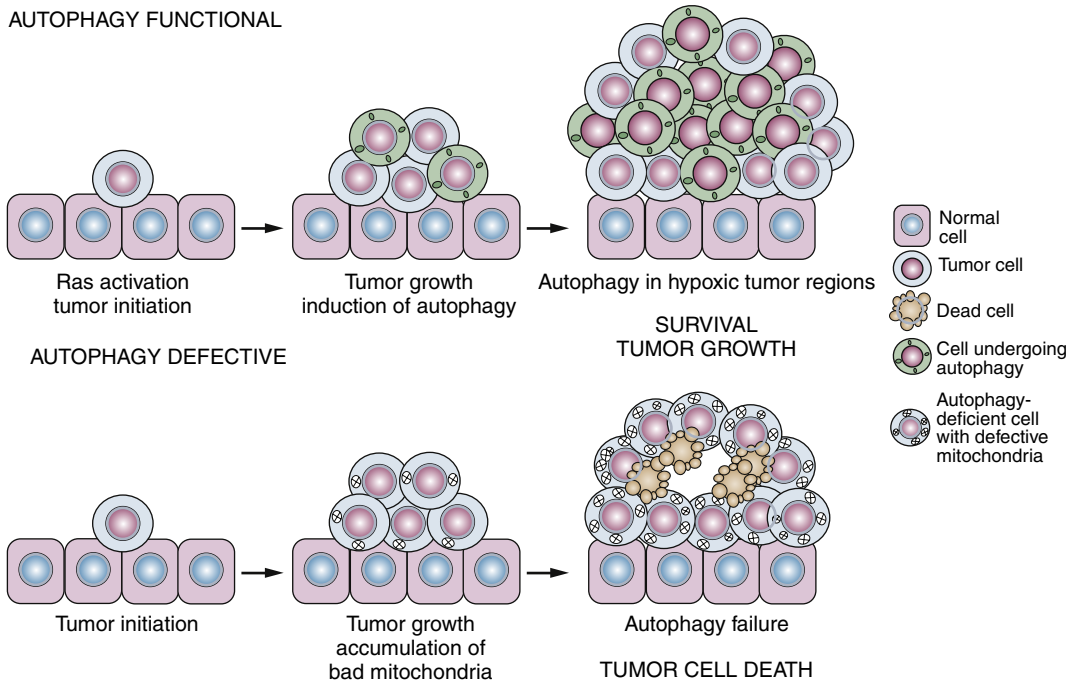

Figure 14-10 Tumor promotion by autophagy See text for explanation.

Tumor Promotion by Autophagy

Normal cells, tissues, and mammals require autophagy to sustain metabolism in starvation. Tumor cells also require autophagy for survival, but because tumor cells often reside in a metabolically stressed environment, their requirement for autophagy is often increased compared to normal cells. For instance, autophagy is upregulated in, and required for survival of, tumor cells that reside in hypoxic tumor regions, typically in the tumor center.[96,118,120] This is why tumor cells deficient for autophagy have a pronounced survival disadvantage in response to metabolic stress in vitro and form hollow tumors in comparison to autophagy-proficient tumor cells (Figure 14-10). Stressed, autophagy-deficient tumor cells die by necrosis or apoptosis, indicating that metabolic insufficiency is incompatible with survival and is independent of a specific cell death mechanism.

Activation of oncogenic pathways rewires metabolism to promote cell growth and elevate metabolic demand.[121] This suggests that tumor cells may have an intrinsic requirement for elevated autophagy to help meet this increased metabolic demand. Indeed, high basal autophagy is a common characteristic of human and mouse cancer cell lines bearing activated oncogenic *H-ras* or *K-ras* oncogenes.[105,106,122] These include human pancreatic cancer cell lines and tumors that have a high prevalence of activating *K-ras* mutations.[106] Moreover, introduction of activated Ras that confers tumorigenicity is sufficient to cause high basal autophagy.[105] Whether other oncogenic events also upregulate basal autophagy is not known; however, high levels of autophagosomes correlating with aggressive disease have been reported in some human tumors.[123]

High basal autophagy in Ras-driven cancers is required for survival in stress and for tumorigenesis. For instance, mouse cancer cell lines with activated Ras are highly tumorigenic, whereas those deficient for *atg* genes are defective for tumor growth.[105] Stable knockdown of essential autophagy genes in human cancer cell lines also compromises growth and survival in vitro and impairs tumor growth in vivo.[105,106] Human pancreatic cancer cell line xenographs were also highly sensitive to autophagy inhibition with hydroxychloroquine (HCQ),[106] which interferes with lysosome function and blocks the degradation of autophagy cargo delivered to the lysosomal compartment for degradation.[124] These findings suggest that cancer cells can be addicted to autophagy to survive stress and sustain tumor growth. This has stimulated interest in inhibiting autophagy in established tumors to improve cancer therapy.

Analysis of cancer cells and tumors with and without autophagy is beginning to reveal the possible mechanism of autophagy addiction. In contrast to tumor cell lines with functional autophagy, those that are autophagy deficient accumulate defective mitochondria.[105,106] The mitochondria from autophagy-deficient tumor cells are morphologically abnormal and display aberrant ROS production, reduced respiration, and depletion of key tricarboxylic acid (TCA) cycle metabolites in starvation.[105,106] Thus, tumor cells need autophagy to maintain the functional pool of mitochondria required for efficient tumor growth. Although tumors

upregulate glycolytic metabolism, they still require mitochondria for anabolic purposes such as citrate production for lipid and new membrane synthesis and to produce signaling levels of ROS essential for tumor growth.[125,126]

Role of Autophagy in Cancer Therapy

The survival-promoting function of autophagy in stressed tumor cells and the autophagy addiction of Ras-driven cancers support the concept that autophagy inhibition may be a useful approach to enhance cancer therapy.[97,98,127] Moreover, most anticancer therapeutics induce autophagy, either indirectly because they are cytotoxic, or directly because they block pathways that inhibit autophagy, such as those upstream of mTOR, and even mTOR itself.[128] This has suggested that therapeutic autophagy induction may be a resistance mechanism and that combination with autophagy inhibition may enhance efficacy.[97,98,127] Clinical trials are under way to test this hypothesis using HCQ, more potent analogs of HCQ are being assessed,[129] and new autophagy inhibitors targeting different points in the autophagy pathway are in development. Combining autophagy inhibition with nutritional stress[130] or targeted metabolic inhibitors is also promising.

15 Cellular Senescence

The term *senescence* was coined more than 50 years ago to describe the loss of replicative capacity of normal human diploid cells in culture.[1] At that time, senescence was proposed to generally reflect the process of cellular aging.[2,3] Early studies also noted differences between the propensity of normal and malignant cells to senesce, with malignant cells being frequently "immortalized" or capable of unlimited subcultivation in vitro. These observations were some of the first conceptual links between the bypass of replicative senescence and tumorigenesis.

Cellular senescence is now appreciated to be much more than a passive cell-autonomous antiproliferative program reflecting the normal aging process. In fact, senescence is a key cellular program that can be induced and plays an important role in permanently restricting the propagation of damaged and defective cells. Hence, senescence responses can be induced prematurely in actively dividing cells both in vitro and in vivo through the application of endogenous and exogenous stimuli that are associated with proliferative stress and/or evoke DNA damage. Such stimuli include the aberrant expression and/or activation of oncogenes, direct DNA damage caused by exposure to ionizing radiation, reactive oxygen species, and chemotherapeutic drugs. Consequently, the integrity of the senescence program can have an active impact on cellular stress responses, cancer development and treatment outcome.

Although the process of cellular senescence is not a precise cellular counterpart of normal organismal aging, genes important for the execution of senescence have been linked to longevity, and it is clear that senescent cells accumulate in tissues with age. Interestingly, beyond the cell-autonomous control of the cell cycle arrest program, senescent cells actively secrete molecules that influence the behavior of neighboring cells, resulting in the paracrine induction of senescence, tissue remodeling, and recruitment of immune cells. Thus senescent cells may contribute to the etiology of age-related disease by restricting the proliferation of neighboring stem-cell populations needed for ongoing tissue rejuvenation, and through its secretory program modulate tissue remodeling and inflammation.

Still, the most exciting recent developments in the senescence field relate to the biology of cancer, with ramifications for understanding of the tumorigenic process, therapy responses, and new approaches to treat the disease. This chapter outlines the molecular basis of senescence and highlights the importance of this permanent cytostatic program as a protective mechanism against the propagation of damaged/defective cells. We discuss the physiological roles of senescence in vivo, focusing on its contributions as a barrier to cellular transformation.

Biochemical and Morphological Characteristics of Senescent Cells

To date, most studies describing the senescence phenotype have been performed in fibroblasts, although at least some senescence characteristics occur in epithelial and hematopoietic tissues as well. Despite induction of replicative and premature senescence by diverse stimuli, the biochemical and morphological characteristics of senescent cells are similar (Figure 15-1). In vitro, senescent cells can be identified on the basis of their large flattened morphology, a lack of DNA replication (detected by the reduced incorporation of 5-bromodeoxyuridine or ^{3}H-thymidine), increased expression of proteins associated with cell cycle arrest and tumor suppression (such as the tumor suppressor p53 and cyclin-dependent kinase inhibitors [CDKi] $p16^{INK4A}$, $p21^{CIP1/WAF1}$, and $p15^{INK4B}$), and the presence of senescence-associated β-galactosidase activity, which is attributed to the high lysosomal content of senescent cells. Senescent cells undergo marked changes in chromatin structure, as characterized by the presence of densely staining senescence-associated heterochromatic foci (SAHF), and also display altered histone modification profiles. Finally, senescent cells secrete a diverse array of proinflammatory and extracellular matrix

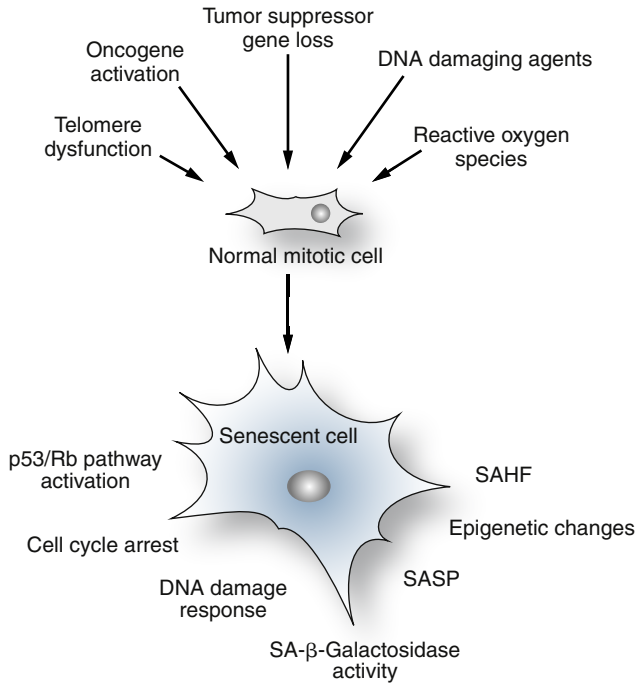

Figure 15-1 Senescence stimuli and biological characteristics Senescence is induced by diverse endogenous and exogenous stresses that promote strong pro-proliferative signaling and DNA damage responses. Senescent cells undergo a permanent proliferative arrest and are identified by the combined presence of multiple biochemical and morphological characteristics. In vitro senescent cells display an enlarged and flattened morphology, have elevated senescence-associated β-galactosidase activity, and express markers consistent with RB and p53 tumor suppressor pathway activation, cell cycle arrest, and DNA damage response signaling. Senescent cells also undergo marked changes in chromatin organization (the formation of senescence-associated heterochromatic foci—SAHF), undergo epigenetic changes, and secrete a diverse collection of soluble and insoluble factors (the senescence-associated secretory phenotype—SASP).

remodeling factors, collectively referred to as the *senescence-associated secretory phenotype* (SASP).

The challenges associated with studying senescence in vivo have been a roadblock in the advancement of the senescence field. In contrast to apoptosis, another program that restricts proliferation and tumorigenesis, the morphological changes associated with senescence are difficult to visualize in whole tissues, and there are no simple assays (analogous to assessing DNA fragmentation or caspase activation during apoptosis) for definitively identifying senescent cells histologically. Thus senescent cells are predominantly identified in vivo by the presence of a collection of biochemical marks. Unfortunately, many "senescence markers" are not unique to the program; for example, upregulation of certain CDKi also occurs in quiescent cells. Moreover, the combination of biochemical marks expressed by given senescent cells can be cell-type and stimulus dependent. Despite these limitations, cells with combinations of senescent markers have been observed in aged, damaged and fibrotic tissues, in premalignant lesions, and in malignant tumors following chemotherapy, suggesting key processes in which the program might participate.

Replicative Senescence and the Hayflick Limit

Studies by Hayflick and colleagues[1-3] demonstrated that most normal human diploid cells could not be subcultured beyond about 50 passages in vitro—the so-called Hayflick limit. On reaching this limit, cells remained irreversibly arrested with a senescent morphology, even when presented with growth factors in an optimal proliferative environment. Although later reports demonstrated that the cellular lifespan of clones within a bulk population is more variable than originally proposed,[3] the original concept that normal cells invariably stop dividing in culture, even in optimal growth conditions, holds true.

Over the ensuing decades, the Hayflick limit was shown to occur as a consequence of accumulated telomere erosion and dysfunction.[4] Telomeres are complex structures consisting of repetitive DNA sequences ($[TTAGGG]_n$ in vertebrates) and specialized proteins that form protective caps on the ends of linear chromosomes to prevent their recognition as a DNA break.[5] The "directional" nature of DNA replication prevents the replication of the extreme ends of telomeres (the "end replication problem"); thus telomeric DNA shortens with every cell division.[5] With repeated divisions, telomeres can become critically short and fail to form the protective cap, resulting in activation of DNA damage signaling and the onset of replicative senescence[6-8] and thereby preventing cellular immortalization. Even when senescence is prevented through a variety of genetic perturbations in the program, ongoing telomere dysfunction creates a state of chromosomal instability called *crisis* that limits proliferation.[9]

In order for cancer cells to bypass senescence and become immortal, they must acquire an ability to regulate telomere length and/or integrity. The addition of telomeric DNA repeats can be catalyzed by the enzyme telomerase.[10] On rare occasions cells can aberrantly upregulate the expression of telomerase (or elongate telomeres through alternative pathways), enabling bypass of replicative senescence and crisis. This effectively facilitates the unlimited propagation of cells with chromosomal fusions and genomic instability, a critical step preceding cellular transformation.[9] Indeed, expression of telomerase alone is sufficient to delay or completely abrogate the onset of replicative senescence in certain cell types, which provides definitive evidence linking telomere shortening to the onset of senescence.[11]

Most normal cells do not express telomerase and are therefore susceptible to replicative senescence. However, telomerase is expressed by normal cells that are dependent on long-term proliferative potential for their biological function, such as germ, stem, and progenitor cells.[9] Although the expression of telomerase alone is insufficient to transform human cells,[12] telomerase activity is often associated with human cell immortalization and is upregulated in many cancer cells.[13] Moreover, expression of telomerase is a key factor in an oncogene "cocktail" capable of fully transforming normal human fibroblasts.[14] Hence, strategies to target telomerase for cancer control have received much attention.

Senescence and Viral Oncoproteins

The study of oncoproteins encoded by DNA tumor viruses has been instrumental in enabling the study of senescence and its contribution to cellular immortalization and transformation. Specifically, the expression of oncoproteins such as SV40 large T antigen, human papillomavirus (HPV) E6 and E7 proteins, and adenoviral E1A proteins can bypass cellular senescence under appropriate conditions. Moreover, such oncoproteins can collaborate with constitutively activated Ras proteins to transform normal cells,[15-19] implying indirectly that senescence provides a barrier to malignant transformation, at least in vitro. Furthermore, sustained expression of these viral oncoproteins is required to maintain the immortalized/transformed state. For example, knockdown of HPV E6/E7 proteins is sufficient to induce senescence in HeLa and cervical cancer cell lines.[20-23] It is now appreciated that these viral oncoproteins disable the retinoblastoma (RB) and p53 proteins, which are key tumor suppressors and central regulators of the senescence program (see later discussion). Collectively these studies helped reveal that the senescence program is genetically controlled and, indeed, might play a role in limiting cancer.

Premature Senescence

Senescence is more than merely a cell division clock that regulates the proliferative lifespan of normal cells. "Premature" senescence is an active cytostatic program that is triggered in response to proliferative or genotoxic stress, such as the expression of strong oncogenes, tumor suppressor loss, exposure to DNA damage, and reactivation of tumor suppressor pathways. Unlike replicative senescence, premature senescence can be induced irrespective of the replicative "age" of cells, is independent of telomere attrition, and cannot be overridden by restoration of telomerase activity.[24]

The first example of *oncogene-induced senescence* was described in 1997, where forced expression of an oncogenic allele of Ras induced a senescence response in primary human and rodent cells that was accompanied by the induction of p53 and $p16^{INK4A}$.[25] Inactivation of p53 or $p16^{INK4A}$ was sufficient to enable the proliferation of Ras-expressing rodent cells, and co-expression of adenoviral protein E1A and Ras was sufficient to enable senescence bypass in human cells. Of note, this study implied that oncogene-induced senescence acted as an important barrier to uncontrolled proliferation during multistep tumorigenesis and also provided a biological mechanism for the observed cooperation between Ras and immortalizing oncogenes (such as viral oncoproteins) alluded to earlier.

The Ras proteins are master regulators of pathways that cooperate to drive cell proliferation, growth, and survival. Dissection of Ras signaling through the use of engineered Ras mutants and activated forms of downstream signaling components identified the Raf/MEK/MAPK cascade as the major arm of Ras signaling that triggered senescence.[26,27] Hence, activation of the very same pathways that promote cellular transformation can also drive senescence when tumor suppressor genes are intact, thus implying that senescence can serve as an antiproliferative response to aberrant mitogenic cues.

Oncogene-induced senescence is not the only form of premature senescence that has been described. In fact, many forms of cellular damage, including exposure to ionizing radiation, cytotoxic drugs, and oxidative stress, can induce a cytostatic program that is phenotypically indistinguishable from senescence. Gene expression profiling studies support the notion that these senescence programs are related and demonstrate a strong similarity to the canonical replicative senescence program triggered by telomere erosion. Cellular senescence thus appears to represent a common response to cellular stress.

Interestingly, virtually all of the known stimuli that induce senescence—including telomere malfunction and hyperproliferation—can activate a DNA damage response (DDR), suggesting that some aspects of DDR signaling are crucial triggers of senescence. Accordingly, abrogation of DNA damage signaling through mutation/deletion of key regulators such as ATM, NBS1, CHK2, and ATR suppresses senescence, largely due to a failure to activate the p53 pathway.[7,28] Furthermore, DDR signaling can trigger generation of the SASP[29] and the global chromatin changes that are observed in senescent cells.[30]

Generally, it appears that a substantial damage "threshold" must be reached before replicative or premature senescence responses can be triggered. For example, cells with minor DNA damage may arrest only transiently, providing an opportunity for the repair of genetic lesions. However,

when DNA damage is extensive, cells may opt to undergo cell death or enter senescence. This notion of dose dependence holds true for oncogene-induced senescence, which is partly governed by the induction of negative feedback mechanisms that control mitogenic signaling.[31] High levels of Ras causing hyperreplication, extreme mitogenic stress, negative feedback signaling, and a strong DDR are required for Ras-induced senescence, whereas mutation of Ras without overexpression instead promotes proliferation and cellular transformation.[32,33]

Senescence in Vivo

Traditionally, oncologists have relied on cytotoxic chemotherapy regimens for the treatment of patients with diverse tumor types. Because many of these agents cause widespread DNA damage, it is perhaps not surprising that senescence can be induced in tumor cells following treatment with chemotherapy. Early demonstrations of therapy-induced senescence in vivo employed a transgenic mouse model of lymphoma, where lymphomas engineered to be unable to apoptose underwent senescence in response to the chemotherapeutic agent cyclophosphamide, and the animals harboring these lymphomas showed prolonged survival. By contrast, mice harboring lymphomas in which senescence was also disabled responded much more poorly to chemotherapy and displayed a very poor prognosis.[34] Senescence markers are also detectable in patient tumor biopsies following neoadjuvant chemotherapy,[35,36] suggesting that therapy-induced-senescence is not just a phenomenon restricted to preclinical tumor models but an important determinant of therapeutic outcomes in patients.

Senescent cells have been identified in a variety of premalignant lesions, including lung adenomas, pancreatic intraductal neoplasias, chemically induced skin papillomas,[37] lymphocytes,[38] pituitary hyperplasia,[39] prostatic intraepithelial neoplasia,[40,41] and serrated colon hyperplasia.[42] A compelling example highlighting the potential importance of this program involves the occurrence of senescent melanocytes in benign melanocytic nevi (moles).[43] Most nevi harbor Ras pathway mutations, yet are capable of remaining in a growth-arrested state for decades.[44,45] In these nevi, melanocytes express hallmarks of senescent cells, including upregulation of $p16^{INK4A}$ and senescence-associated β-galactosidase activity.[43] Nevi are effectively poised for malignant progression following bypass of senescence (e.g., via deletion or silencing of $p16^{INK4A}$); thus, in the context of melanoma, oncogene-induced senescence genuinely protects premalignant cells from tumor progression. The fact that Ras pathway mutations and INK4a loss commonly occur in human melanomas provides genetic support for the program as a barrier to cancer.[46]

As occurs after activation of oncogenic Ras, senescence can also be triggered in vivo following the loss of tumor suppressor genes. For example, prostate-specific deletion of PTEN, a phosphatase responsible for suppressing mitogenic signals, evokes a senescence response that is dependent on p53 and opposes the development of late-stage invasive prostate tumors.[40] Irrespective of the proposed stimulus, the studies just mentioned strongly noted the conspicuous absence of senescent cells in malignant tumors, consistent with the notion that senescence acts as a barrier to tumorigenesis that must be disabled before tumors can progress. Ongoing studies of senescence continue to identify key regulators of the program that are also capable of influencing the tumorigenic process in animal models and human tumors.

Convergence of Senescence Stimuli on Two Major Pathways

The senescence-associated cell cycle arrest typically involves interplay between the RB and p53 tumor suppressor pathways (Figure 15-2), which are two of the most frequently disabled pathways in human cancer. Indeed, mutations compromising some aspect of each pathway may be a prerequisite for the formation of an advanced cancer. Crosstalk between RB and p53 occurs at multiple levels in their respective signaling hierarchies; thus the pathways actively modulate and reinforce each other to promote the senescence response. Accordingly, most human cells require defects in both pathways to efficiently bypass senescence. By contrast, inactivation of either p53 or RB is sufficient to bypass senescence in mouse embryo fibroblasts, though whether this reflects species differences in pathway wiring or merely variation between cell types is unclear.

$p16^{INK4A}$/RB Pathway

RB is a member of a multigene family that also includes the structurally and functionally related proteins p107 and p130.[47] The tumor-suppressive capacity of RB predominantly arises in part from its ability to repress the E2F family of transcription factors and thereby regulate G_1-S phase cell cycle transition. It is now appreciated that RB also controls many aspects of tumor biology, including apoptosis, differentiation, and the maintenance of chromosomal stability.[47]

RB is frequently inactivated in diverse types of human cancer, and experiments with genetically modified mice have revealed a causal role for RB loss in tumor initiation and progression in a variety of different tissue types.[47] Hints that RB might be a senescence regulator came from studies that identified associations between RB and viral oncoproteins

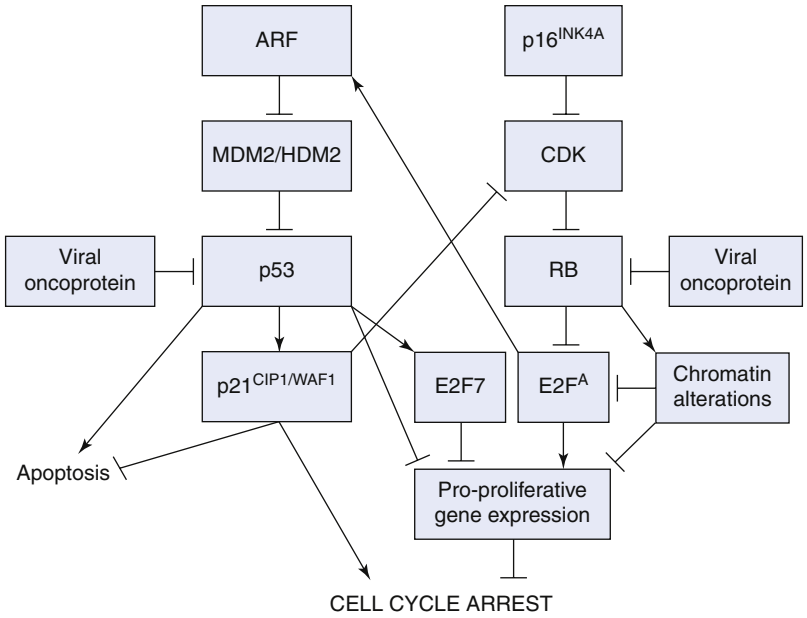

Figure 15-2 The RB and p53 tumor suppressor pathways cooperatively control the senescence cell cycle arrest In normal cells, p53 is maintained at low steady-state levels through activity of the E3 ligase MDM2 (HDM2 in humans). Hyperproliferative stresses, such as oncogene expression, can drive the induction of ARF, which sequesters MDM2, resulting in the stabilization of p53. Following DNA damage response signaling, p53 becomes hyperphosphorylated and stabilized, thus enabling its activity as a DNA-binding transcription factor. p53 transcriptionally upregulates the cyclin-dependent kinase (CDK) inhibitor $p21^{CIP1/WAF1}$, which promotes cell cycle arrest by inhibiting cyclin/cdk2 complexes, and thereby activating RB. RB is expressed in proliferating and noncycling cells, and its activity is primarily regulated at the posttranslational level.[47] As dividing cells approach the G_1/S boundary of the cell cycle, RB is phosphorylated by cyclin D/CDK4 and cyclin E/cdk2 complexes, causing the release of activator E2F factors ($E2F^A$) from RB and transcriptional activation of E2F target genes required for DNA synthesis. During senescence, elevation of CDK inhibitors including $p16^{INK4A}$ and $p21^{CIP1/WAF1}$ ultimately promotes hypophosphorylation of RB, inhibition of E2F-responsive gene expression, and arrest of cells at the G_1/S checkpoint. Multiple opportunities exist for crosstalk between the pathways, including the p53-mediated induction of $p21^{CIP1/WAF1}$ and E2F7 (a repressor E2F family member), which operate at different levels in the signaling hierarchy to reinforce RB pathway activity. In addition, deregulation of $E2F^A$ activity leads to upregulation of ARF, thus activating p53 signaling to initiate a secondary proliferative block.[48] Viral oncoproteins disable both p53 and RB to bypass senescence and facilitate cell immortalization. Some components of the pathways are tumor suppressors in their own right. *CDKN2A* (encoding $p16^{INK4A}$) is frequently mutated and/or lost in a variety of human tumors, and there is extensive evidence for gene silencing through methylation of the $p16^{INK4A}$ promoter in tumors.[49] $p16^{INK4A}$-null mouse embryonic fibroblasts (MEFs) possess normal growth characteristics and can senesce in response to oncogenic Ras but have increased immortalization rates in comparison with wild-type MEFs, and $p16^{INK4A}$-null mice are predisposed to tumorigenesis.[50] Consistent with ARF acting as a major regulator of p53 during oncogene-induced senescence, fibroblasts isolated from ARF-deficient embryos do not senesce and are transformed by oncogenic Ras alone.[51] ARF-deficient mice are also tumor prone.[51]

with immortalizing activity. Nevertheless, a clear-cut interpretation of these observations was confounded by the fact that these oncoproteins bind all three RB family members.[52] Moreover, RB, p107, and p130 have partly redundant functions and can often compensate for each other if one member is inactivated.[53-55] Studies using conditional knockouts[56] and RNA interference[57,58] have since revealed a unique role for RB during senescence, such that specific depletion of RB (without affecting p130 or p107) can cooperate with p53 loss to bypass senescence. The fact that RB, and not p107 and p130, is a frequently mutated tumor suppressor gene suggests that control of senescence contributes to its tumor-suppressive role.

In human cells, RB inhibits senescence by binding to E2F factors and preventing the expression of a series of E2F-responsive genes linked to DNA replication.[58] RB achieves this by inhibiting E2F proteins capable of otherwise activating growth-promoting genes and/or by recruiting chromatin-modifying factors to E2F-responsive promoters that repress gene transcription.[59] During senescence, RB also inhibits E2F-induced gene expression by incorporating E2F target genes into dense heterochromatic regions known as *SAHF*.[57] Each SAHF is thought to consist of a single condensed chromosome, enriched in histone modifications and proteins that are typically associated with transcriptionally silent heterochromatin, and largely devoid of sites of active transcription.[57,60] Consistent with these observations, proteomic analyses of the histone content of senescent cells indicate that they generally harbor modifications linked with gene repression, and certain enzymes (e.g., Jarid histone demethylases) associated with gene repression are required for the repression of some E2F target genes during senescence.[61]

The RB-directed changes just described appear to buffer E2F target genes from activation by normal mitogenic cues, thereby contributing to the stable cell cycle arrest that is a hallmark of senescence. Accordingly, disruption of RB prevents SAHF formation and gene silencing in cells given a senescence stimulus.[57] However, inactivation of RB alone is insufficient to bypass senescence in many cell types. This

is largely due to compensatory activation of the p53 pathway, which modulates an independent set of antiproliferative genes and also reinforces RB signaling to provide a secondary proliferative block.

ARF/p53/p21$^{CIP1/WAF1}$ Pathway

The ARF/p53/p21$^{CIP1/WAF1}$ tumor suppressor pathway is a major regulator of cellular responses to oncogenic stress and DNA damage, resulting in the induction of cell cycle arrest, apoptosis, and senescence, depending on the stimulus. Cells isolated from p53-deficient mice are largely resistant to stimuli that would promote growth arrest or apoptosis under normal culture conditions,[62] and p53-deficient mouse embryo fibroblasts bypass the senescence response that usually occurs following extensive DNA damage or forced expression of oncogenic Ras.[25] Not only is loss of p53 required for bypass of senescence; restoration of p53 in Ras-transformed cells causes the induction of senescence and the subsequent regression of established tumors, demonstrating that continual suppression of p53 is required for tumor maintenance.[63-65] Beyond their biological significance, these data suggest that p53-reactivation "therapies" may hold promise for the treatment of established tumors by promoting a senescence response.

p53 primarily exerts its antitumor effects by acting as a DNA-binding transcription factor that directly regulates the expression of many genes involved in apoptosis and cell cycle arrest. The effect of p53 during senescence is due, in part, to the direct transcriptional upregulation of the cyclin/cdk2 inhibitor p21$^{CIP1/WAF1}$. By inhibiting cyclin/cdk2, p21$^{CIP1/WAF1}$ promotes activation of the p16^{INK4A}/RB pathway and subsequent cell cycle arrest, thus serving as an important point of crosstalk between the two central pathways of the senescence program. In support of this hypothesis, cosuppression of p21$^{CIP1/WAF1}$ and RB pathway components (RB or p16^{INK4A}) by RNA interference inhibits senescence in human fibroblasts, highlighting p21$^{CIP1/WAF1}$ as a critical component of the p53 pathway.[58]

Deletion of p21$^{CIP1/WAF1}$ alone is not sufficient to bypass senescence in mouse embryo fibroblasts,[66] suggesting that additional p53 targets contribute to the senescence response. Such targets include the p53-responsive gene PML, which is induced by oncogenic Ras and promotes senescence by localizing RB/E2F proteins into PML bodies, thereby repressing E2F transcriptional activity.[67-69]

Another recently described point of crosstalk between the p53 and RB pathways involves the p53 transcriptional target E2F7 (an atypical E2F family member), which represses a subset of E2F target genes required for mitotic progression.[70,71] As seen for p21$^{CIP1/WAF1}$, co-inhibition of E2F7 and RB is sufficient to circumvent Ras-mediated senescence and enable transformation of mouse embryo fibroblasts.[70] Collectively, these studies highlight the interplay between the p53 and RB pathways that govern institution of the senescence proliferative block and thereby the suppression of tumorigenesis. The extent to which the control of senescence contributes to the tumor-suppressive function in human cancer remains to be determined, but the co-occurrence of Ras, p53, and RB mutations in human tumors suggests that disruption of senescence may be required for cells to tolerate high levels of oncogenic signaling and become fully malignant.

The Senescence-Associated Secretory Phenotype

Previously, we have focused largely on the cell-intrinsic mechanisms that govern senescence responses and tumorigenesis—these mechanistically explain much of the biology underlying the cell cycle arrest associated with the Hayflick limit. Senescent cells also secrete a multitude of factors, predominantly proinflammatory cytokines, chemokines, growth factors, and extracellular matrix remodeling factors, that have collectively been referred to as the senescence-associated secretory phenotype (SASP—Figure 15-3). Initially, SASP factors were used as biomarkers to confirm the presence of senescent cells. Now, emerging evidence indicates that the SASP acts in an autocrine and paracrine manner to influence the senescence program and profoundly alter the behavior of neighboring cells. This secretory program may contribute to the natural role of senescence in aged or damaged tissues.

The contribution of the SASP toward the biology of senescence and tissues is complex and can promote and suppress tumorigenesis depending on the context. Perhaps the greatest consequence of the SASP in vivo, in terms of tumor suppression, chemotherapy-induced senescence, and disease resolution, is enhanced immune surveillance and subsequent clearance of senescent cells. In such scenarios, the secretion of proinflammatory cytokines and chemokines by senescent cells attracts innate and adaptive immune cells (including natural killer cells, macrophages, and T cells) to the site of senescence and cell/tissue damage. The immune cells subsequently kill and clear the senescent cells, restoring tissue homeostasis.[63,72]

Senescent cells also upregulate the expression of cell surface receptors, ligands, and intracellular signaling components that facilitate recognition of senescent cells and aid their elimination by immune cells.[72,73] Indeed, immune surveillance of senescent cells has been positively linked to regression of established tumors,[63] the prevention of tumor

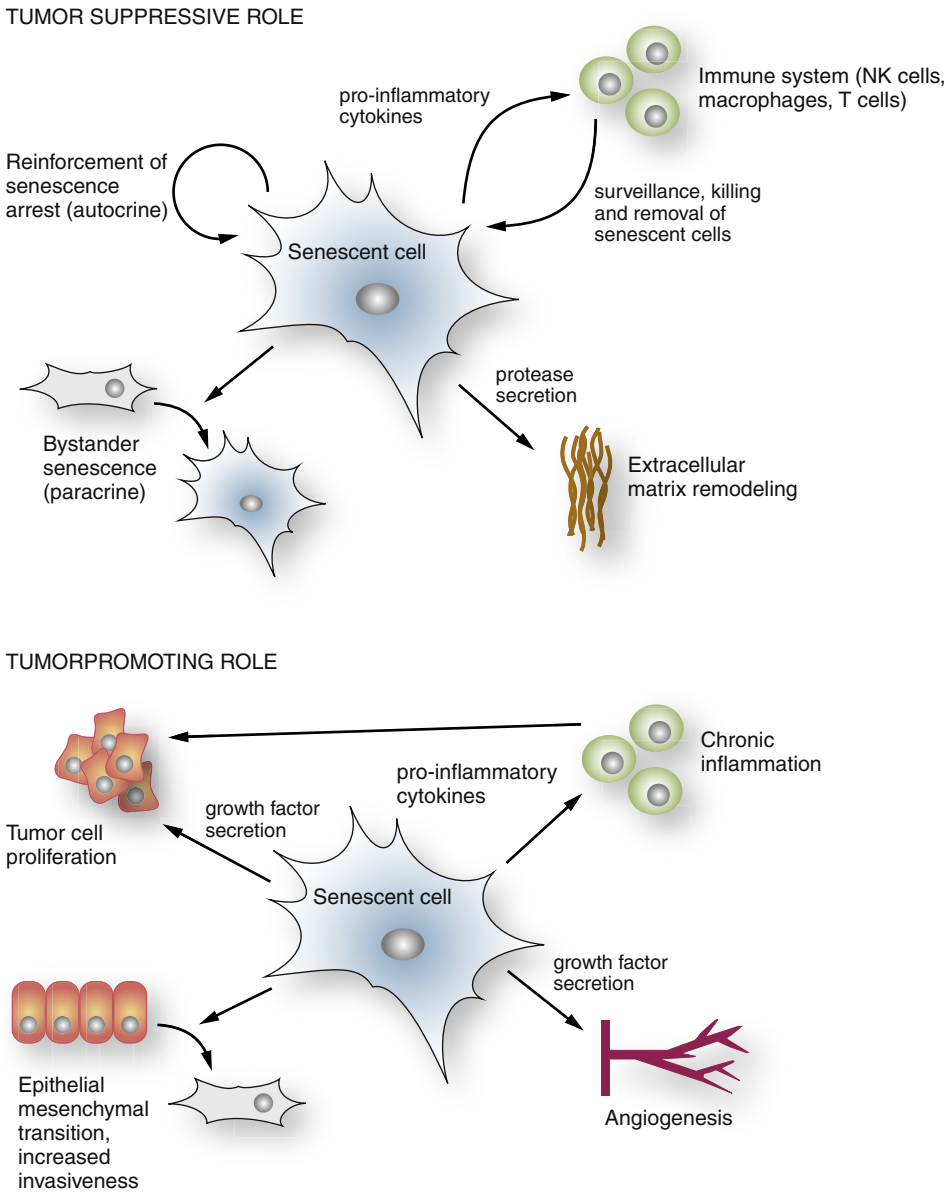

Figure 15-3 Tumor suppressive and tumor-promoting activities of the SASP Senescent cells secrete a range of factors that profoundly affect the tissue microenvironment. In the context of tumor suppression, wound healing, and disease resolution, factors secreted by senescent cells attract components of the innate and adaptive immune system, which recognize, kill, and clear the senescent cells. This results in removal of damaged/stressed cells and restoration of tissue integrity. Senescent cells secrete molecules that actively reinforce the senescence arrest and can induce secondary "bystander" senescence in neighboring cells. The secretion of proteases enables remodeling of the extracellular matrix, which facilitates resolution of tissue disease (such as fibrosis) and thereby promotes wound healing. The consequence of the SASP is context dependent. Senescent cells secrete proinflammatory cytokines and growth factors known to enhance cell proliferation and transformation. Pro-angiogenic factors from senescent cells can promote tissue vascularization, while additional factors drive epithelial-to-mesenchymal transitions and increased invasiveness of premalignant cells.

development,[74] and the improved survival of animals following treatment with chemotherapy.[75] Of course, some senescent cells—for example, those occurring in benign melanocytic nevi—remain in tissues for reasons that are yet to be elucidated.

Perhaps counterintuitively, SASP factors previously appreciated for their protumorigenic activity contribute to tumor-suppressive aspects of the senescence response. For example, the proinflammatory cytokines interleukin-6 (IL6) and interleukin-8 (IL8) reinforce the senescence growth arrest, presumably by continuing to drive pro-proliferative and DDR signaling within the senescent cells.[76,77] The nuclear factor-κB (NFκB) family of transcription factors (master regulators of immune signaling traditionally regarded for their protumorigenic activity) is responsible for transcription of a substantial part of the SASP signature, including the expression of IL6 and IL8.[75,76,78,79]

Gene expression profiling indicates that NFκB controls the expression of more SASP genes during senescence than either p53 or RB, cementing its role as a key regulator of the senescence program.[75] During therapy-induced senescence, canonical NFκB activity was required both for the induction of senescence in tumor cells and for tumor regression following administration of chemotherapy, implying that the NFκB-driven SASP contributes to the senescent cell-intrinsic and -extrinsic aspects of the program and that NFκB can have remarkable antitumor activity.[75,78] These observations also suggest an important role for the SASP in facilitating chemotherapy responses, a possibility that is consistent with clinical data.[78]

Secreted factors are capable of influencing their microenvironment for as long as they persist. It is therefore possible that promitogenic SASP factors can promote the hyperproliferation and subsequent "bystander" or "secondary" senescence of normal and/or premalignant neighboring cells. In agreement, secondary senescence can be conferred on incubating normal growing cells in "conditioned" media from senescent cells.[80]

Alternatively, SASP factors might simultaneously drive the proliferation/invasiveness of neighboring malignant cells in which the senescence response is defective. For example, factors such as growth-related oncogene (GRO)-α and VEGF can facilitate the proliferation and transformation of premalignant cells[81] or promote tumor vascularization,[82] respectively. SASP factors can also promote invasiveness of premalignant cells.[79,83-85] Hence, in some circumstances, the continued presence of senescent cells (and thus production of SASP factors) in aged, damaged, and premalignant tissues may exacerbate the decline of tissue integrity and/or promote tumor development or relapse.[79,86,87] The precise contexts in which SASP factors are pro- or antitumorigenic remain to be determined.

Senescence and Noncancer Disease States

Because senescence limited the replicative capacity of cells in vitro, Hayflick and colleagues proposed that replicative senescence might generally reflect the process of aging at the cellular level.[2,3] Although there is perhaps little evidence to demonstrate that organismal aging occurs as a direct consequence of cellular aging, senescent cells accumulate in aging tissues at sites of age-related diseases, such as in atherosclerotic plaques, skin ulcers, and arthritic joints,[88,89] and expression of senescence markers such as $p16^{INK4A}$ increases in aging tissues.[90-92]

Consistent with an active contribution of senescent cells to aging, elimination of $p16^{INK4A}$-expressing cells from mouse tissues delays aging-related phenotypes such as sarcopenia, cataracts, and loss of adipose tissue.[93] Moreover, the late-life removal of $p16^{INK4A}$-expressing cells was sufficient to attenuate the progression of already established age-related disorders, suggesting that senescent cells contribute to the initiation and maintenance of the aging phenotype.[93] Although the etiology of the senescent cells in aging tissues is often unclear, at least some cases have been attributed to telomere dysfunction,[91,92] and experimental manipulations to produce telomere dysfunction can reproduce aging phenotypes.

Senescent cells may contribute to organismal aging in a number of ways. For example, because senescent cells are irreversibly arrested, they may be incapable of effectively repopulating aged/damaged tissue and thus promote tissue decline. At the same time, senescent cells remain metabolically active and have a SASP that may also influence the behavior of neighboring cells and promote tissue dysfunction.[94] They may also promote chronic inflammation, which is associated with diverse age-related diseases including cancer.[95] Conversely, senescence can positively facilitate wound-healing responses and promote the resolution of disease states, which may produce positive effects on tissue function. For example, in a murine model of chemical-induced liver fibrosis, the senescence program limited the extent of fibrosis by halting the proliferation of fibrogenic (activated stellate) cells, reducing extracellular matrix production, and promoting immune clearance of the senescent cells, suggesting a positive role in this wound-healing response. Other studies imply that senescence restricts fibrosis in cutaneous wound healing.[96] In both models, the SASP played a prominent role in the elimination of senescent cells and tissue restoration.

Emerging evidence thus suggests that the impact of senescence on tissue function may be influenced by acute versus chronic induction. Hence, senescence can facilitate tissue homeostasis following acute damage through a two-pronged mechanism, resulting in the proliferative arrest and changes to the microenvironment that lead to the elimination of damaged cells and the remodeling of the surrounding tissue to restore tissue structure and function. However, persistent cellular damage would continue to produce excessive presenescent or senescent cells that might contribute to tissue degeneration, the onset of age-related disease, or tumor formation.

Conclusions and Perspectives

The true physiological role for senescence appears to be the prevention of the propagation of damaged cells, where autonomous aspects control the proliferative arrest and the SASP reinforces arrest and further directs the immune system to promote their elimination. In a speculative model, the original evolutionary purpose of senescence might be to help coordinate wound-healing responses, and these actions may be co-opted, directly or indirectly, for tumor suppression. Ironically, when persistent, some of these activities may be protumorigenic and contribute to age-related pathologies.

Mechanistically, the program involves active interplay among at least three major transcription factors (Rb, p53, and NFκB) whose activities are known to play an important roles in cancer. Because senescence can be influenced by extracellular factors and molecules, for which drugs and inhibitors

are available, the possibilities for therapeutic modulation of the program in various settings exist. Such therapies could, in principle, harness the cell-autonomous aspects of the program to promote arrest or, alternatively, aid the immune recognition and clearance of senescent cells. Imperative for the success of such treatments is a thorough understanding of the molecules that govern senescence. Gaining new insight into senescence markers and biological aspects of the program in normal and pathological states is therefore of key importance for current and future biomedical research.

The Role of the Microenvironment in Tumor Initiation, Progression, and Metastasis

The discovery in the 1970s of proto-oncogenes, genes that become oncogenic ("cancer causing") either through genetic modifications or increased expression, and tumor suppressor genes, those that if expressed at the right levels would suppress progression to malignancy, spurred a revolution. Given the excitement and the implication of these discoveries, it may not be surprising that most cancer researchers never looked back. Thus much of the work of the early cancer research pioneers such as Paget, Rous, Warburg, and Berenblum (see later discussion) that drew attention to other aspects of cancer became unpopular and were considered beside the point.

The subsequent decades brought technologies that enabled automated sequencing of DNA, which eventually made the dream of sequencing whole organismal and tumor genomes a reality. The hope was that pinpointing aberrations in genetic sequence would allow one to understand the origins of cancer.[1] Dealing with the mutations by fixing the genes through gene therapy or neutralizing the gene products would thus provide a viable cure. However, the picture that emerges 40 years later is much more complex.[2] For breast cancer, we know now that the frequency of somatic mutations exceeds 1 per 1 million DNA base pairs.[3] We also know that a single tumor may have hundreds of mutations,[3] that some mutations *(TP53, PIK3CA, GATA3)* are more prevalent than others,[4] but that even these are not present in the majority of patients.[4] Given this enormous complexity, where would we start?

This approach has also taught us a lot about what the genome may not be able to tell us. For instance, autopsy studies have revealed that the fraction of individuals harboring neoplastic lesions within their breast or prostate is 27- to 142-fold higher than the actual incidence rates of breast and prostate cancer.[7,8] If the initial mutation was sufficient to cause cancer, why do the great majority of these neoplasms fail to progress to frank carcinomas? Another aspect of tumor progression that cannot be explained solely by genomic aberrations is why tumors metastasize when they do. The prevailing hypothesis had been that metastases reflect the pinnacle of tumor evolution: tumor cells would have to acquire a set of mutations in order to disseminate from the primary tumor to another tissue.[9] Now, it is clear that tumor cells disseminate very early during tumor progression despite few genetic abnormalities[10-12] and that these tumors may emerge even faster than the primary tumor itself (this is referred to as *cancer of unknown primary*). So, if metastatic outgrowth does not require additional mutations from the primary tumor, what drives the metastatic program? Other questions along these lines are outlined elsewhere.[13]

The need to answer such questions has spawned a newfound appreciation that the complexity that governs tumor phenotype cannot be explained only at the genetic level. As a result, the focus has slowly begun to shift to the study of the tumor's microenvironment. Whereas this appreciation may be newfound, the concept of the microenvironment's importance is not (see Figure 16-1 for a timeline).[14-17]

Half of the secret of the cell is outside the cell: a historical perspective on the role of the microenvironment

In 1889, Stephen Paget published results of an autopsy study he conducted on 735 breast cancer patients. His study revealed that these patients tended to have metastases within four tissues: lung, liver, uterus, and bone. Empowered by these observations, as well as those of peers such as Langenbeck and Fuchs, Paget formulated his now-famous "seed and soil" hypothesis: "Every single cancer cell must be regarded as an organism, alive and capable of development. When a plant goes to seed, its seeds are carried in all directions; but they can only live and grow if they fall on congenial soil."[18] Perhaps this is where an appreciation for

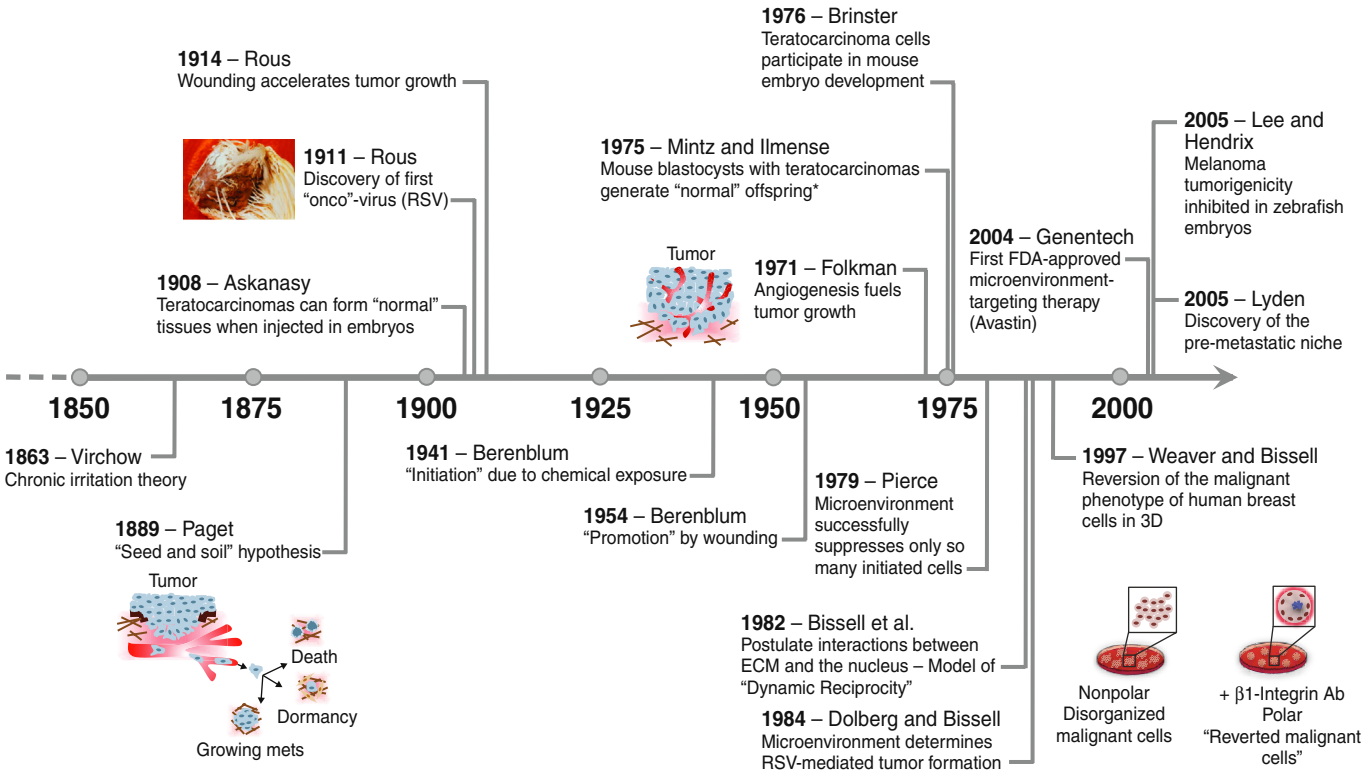

Figure 16-1 A historical perspective on the role of the microenvironment in cancer A timeline detailing landmark discoveries that showed the dominance of microenvironment over genotype. If space had permitted, a number of other important experiments could have been included, such as Emerman and Pitelka's demonstration that normal mammary epithelial cells on floating collagen gels recapitulate their in vivo phenotype,[14] Folkman's demonstration that cell shape regulates DNA synthesis,[15] and experiments demonstrating that reconstituted 3D BM gels act as a "blotter" to distinguish the normal from the malignant phenotype.[16,17]

the microenvironment began. Remarkably, the enduring interpretation of Paget's hypothesis is that certain soils are favorable for tumor growth. This has indeed dominated the landscape of metastasis research and is the subject of the following subsection (Promoting Microenvironments). Inherent in Paget's message, however, was that certain soils are inhospitable to a tumor's seed. In the same article, Paget remarks on a colleague's interpretation that instead of a predisposition to receive a seed, certain organs exhibit "diminished resistance."[18] Thus the second subsection (Suppressive Microenvironments) deals with this idea.

Promoting Microenvironments

What makes a given microenvironment favorable for the growth of a tumor cell is a topic that is germane to all tumors, disseminated or not. For instance, the probability of harboring an occult (i.e., hidden) neoplasm increases with age to nearly 100% in an organ like the thyroid gland, yet only 0.1% of the population is ever diagnosed with thyroid cancer.[19] What allows the emergence of tumors in some, but not others, is a question that has been pursued since the turn of the 20th century. Peyton Rous and others concluded that a transplanted tumor would not take unless there was a stromal reaction and immediate vascularization of the implant.[20] These properties are common to both inflammation and wounding, and each has long been suspected of creating a tumor-promoting microenvironment. As early as 1863, Virchow noted that chronic irritation and prior injury could precondition tissue for tumor formation.[21] Rous was among the first to show this conclusively by demonstrating that wounding the peritoneal cavities of mice inoculated with tumor cells accelerated the growth of tumors within their visceral organs.[22]

Further evidence for the tumor-promoting power of the wounding microenvironment came from the vast literature on chemical carcinogens. An extensive body of work established that chemicals within coal tar such as benzo[*a*]pyrene derivatives, despite being known mutagens, were not sufficient to cause skin cancer on their own. Despite "initiation" due to chemical exposure, normal skin guards against progression unless the carcinogen dose is so excessive that it damages the tissue in addition to causing mutagenesis.[23,24] This second step, called *promotion*, is required and is generally caused by wounding or by other toxic agents, many of which are associated with aberrant tissue repair and fibrosis.[25-27] The discovery of the first "onco"-virus, referred to as *Rous sarcoma virus* (RSV),[28] later provided some of the most conclusive evidence that wounding promotes tumor

formation. In discovering RSV, Rous took the filtrate of a chicken tumor and noted that this cell-free filtrate would induce sarcomas in recipient chickens,[28] thus proving Koch's postulate. Decades later, when experimenting with RSV, Bissell and colleagues noted that the injected virus circulated throughout the bird, but tumors tended to arise only at the injection site.[29] Was the wound created by the injection needle the key factor? Nicking the contralateral wing of infected chickens caused tumors to arise also at the sites of abrasions.[29] This phenomenon was mediated by transforming growth factor (TGF)-β1, which was expressed at the site of injection shortly after wounding and shown to induce tumors on its own even in the absence of wounding.[30]

Of course, processes such as wounding and fibrosis are inextricably linked with the formation of new vasculature (e.g., through angiogenesis), but it was not until Judah Folkman's work in the early 1970s that a causal relationship between tumor growth and angiogenesis was established. Tumor fragments or tumor cells grafted onto the rabbit cornea were observed to induce sprouting from existing vasculature as they grew.[31] Physically preventing microvasculature from reaching the implant resulted in a latent mass where tumor cell proliferation was countered by apoptosis. Folkman's work demonstrated, for the first time, a nontumor cell—the endothelial cell—that was critical to the growth of a tumor. His work also started a new field focused on "anti-angiogenesis" based on Folkman's hypothesis: "Solid tumors can grow to visibility only if they can vascularize themselves. Therefore, the mechanism by which tumor implants stimulate neovascularization must be well understood before therapy based upon interference with angiogenesis can be devised."[32] The angiogenesis inhibitor bevacizumab (Avastin) would become the first therapy explicitly targeting the microenvironment approved by the United States FDA (2004) (see Chapter 17 for more information).

Suppressive Microenvironments

The studies just described established key roles for the microenvironment in promoting tumor growth, which is the primary focus of this chapter. However, it is worth mentioning that much of the milestone research in demonstrating the importance of the microenvironment did so by showing that context could override tumorigenicity—that is, tumor cells could be tricked into thinking they are normal if provided the right cues. The observation that the embryo comprises such a suppressive microenvironment is one that was first made more than 100 years ago, when Askanazy showed that ovarian teratomas could form "normal" tissues composed of the correct embryonic germinal layers when injected into embryos.[33] Decades later, a series of studies from different laboratories provided further evidence that the embryonic microenvironment could induce tumors to function normally in development. Mintz and Illmensee reported to have injected embryonic teratoma core cells from mice with a steel coat genotype into blastocysts from C57-b/b mice (which have black coats). The blastocysts gave rise to functionally "normal" offspring.[34] Their next paper[35] reported that the mice born from the initial experiments produced an offspring that was completely normal and had a mosaic (i.e., striped) coat, implying that the teratocarcinoma could pass through the germline. Although it is true that this work has not been confirmed in other laboratories, there are some dramatic variations on the theme. For instance, Brinster injected two to four teratocarcinoma cells from agouti brown mice into 4-day-old blastocysts of Swiss albino mice. One of the 60 injected mice retained the teratocarcinoma cells (based on the presence of brown hair patches on the white mouse) and proceeded to develop normally as well.[36] Pierce later essentially quantified the balance of power between the embryonic microenvironment and the malignant cell by demonstrating that the embryonic microenvironment could suppress the malignant phenotype of one to a few implanted tumor cells, but that this ability diminished as the number of injected tumor cells increased.[37] Perhaps this offers a hint that our bodies are able to successfully suppress only so many initiated cells, and that this power diminishes with age.

The suppressive effect of the embryonic microenvironment was demonstrated in species other than mice as well. Using RSV, Dolberg and Bissell showed conclusively that cells within injected chick embryos expressed the virus, but early embryos failed to form tumors.[38] Maintaining embryonic architecture was key, however, as dissociating the embryos and placing the $PP60^{src}$-marked cells (using *LacZ*) in culture resulted in rapid transformation of the blue-labeled cells.[39] Hendrix and colleagues more recently reported similar findings for aggressive melanoma cells injected into zebrafish embryos.[40] The lasting impact of these studies is that tissue architecture is dominant even to a powerful oncogene in embryos. These studies also offered the clue that the malignant genotype could be overridden if somehow provided with suppressive cues from the microenvironment.

Taking advantage of this insight required an assay that would allow normal and malignant cells to recapitulate their in vivo phenotypes in culture. This was achieved by Petersen, Bissell, and colleagues culturing cells in a three-dimensional (3D) reconstituted basement membrane (BM) gel. In 3D but not 2D conditions, primary mammary epithelial cells or nonmalignant cell lines formed growth-arrested, polarized acini resembling terminal ductal lobular units of the breast, whereas malignant cells formed disorganized masses that continued to grow.[16,17] By examining the expression profiles of integrins—heterodimeric receptors on the cellular surface that transduce signals from the extracellular matrix (ECM) through traditional and nontraditional pathways

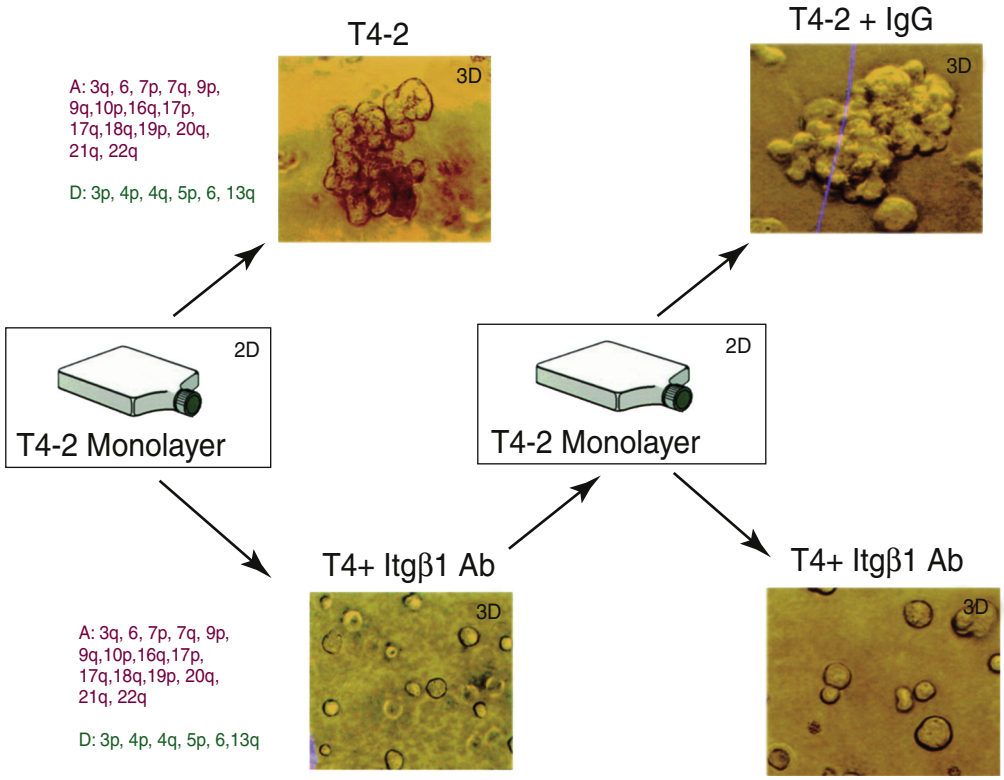

Figure 16-2 Serial passaging from 3D to 2D cultures (and back) demonstrates phenotypic reversion as opposed to selection Phase contrast micrographs of T4-2 cells grown in the presence of mock antibody (IgG) or anti–β1-integrin function blocking antibody (Itgb1 Ab) within 3D reconstituted basement membrane gels. Despite two rounds of treatment, reverted cells were able to resume their original tumorigenic phenotypes after being passaged and recultured in the absence of antibody. Note that despite displaying a nonmalignant phenotype, reverted tumor cells retain an aberrant genome (genomic amplifications [*A*] shown in *red*, deletions [*D*] shown in *green*). *(Figure adapted from Weaver VM, Petersen OW, Wang F, et al. Reversion of the malignant phenotype of human breast cells in three-dimensional culture and in vivo by integrin blocking antibodies.* J Cell Biol. *1997;137:231-245.)*

to alter gene expression—Weaver, Bissell, and colleagues noted aberrant overexpression of integrins and a number of other receptors such as EGFR on malignant cells.[41] Suspecting that these receptors were key nodes that integrated signals from the microenvironment to direct cell behavior, the authors began to restore levels of aberrant receptors to normal levels, starting by applying inhibitory antibodies targeting integrin β1 in malignant cells cultured in 3D gels. The result was a dramatic "phenotypic reversion" of malignant breast epithelial cells to structures that looked and behaved like their normal counterparts.[41] To show that this treatment was not somehow selecting for a nonmalignant subpopulation of cells, Weaver and colleagues dissociated tumor cell clusters from 3D gels, replated them onto plastic, and then passaged them back into 3D gels in the absence of blocking antibody. Tumor cells once again formed malignant clusters (Figure 16-2).[41] This strategy led to the discovery of a host of signaling molecules that act in concert to regulate/integrate epithelial phenotype. Many of these molecules effect interactions between cells and their microenvironments, including ECM molecules,[42] growth/ECM receptors,[43,44] and matrix metalloproteinases (MMPs) that digest ECM components.[45] Remarkably, targeting only one of these aberrantly expressed molecules restores the levels of all the others back to normal, demonstrating the potential of normalizing aberrant microenvironmental signaling to redirect entire signaling webs and impair manifestation of the malignant genotype.[13,46] It is critical to re-emphasize that these pathways integrate only in 3D; even something as seemingly well-understood as glucose metabolism ties into these noncanonical pathways and regulates malignancy only when interrogated in context.[47]

The Tumor Organ

The historical studies detailed above demonstrate that a tumor is a product of aberrant genomes interacting with an enabling microenvironment. This concept is easier to appreciate if one considers the tumor as a dysfunctional organ.[48] On a basic level, an organ has the following properties:

1. Organs are multicellular and are composed of multiple tissue layers. Functional tissue layers consist of epithelia, which are tubelike structures that carry fluid, and epithelia are separated from surrounding stroma by a specialized ECM called the basement membrane (BM).

2. Organs are governed by properties that emerge as a result of the interactions between the cells, ECM molecules, and soluble factors composing the organ, and the sum of these interactions is greater than any one of the individual parts.
3. Organs have unique signatures of functional differentiation; for instance, the mammary gland produces milk, the pancreas produces insulin, and bone marrow is responsible for maintaining homeostasis of the hematopoietic and lymphatic systems.

Although tumors lack proper function, they do have the first two of these traits in common with organs. The focus of this section is on the second of these traits: the properties that emerge as a result of a tumor's interactions with its microenvironment. There are two ways to illustrate this concept. The first would be to consider the parallels between a developing organ and a developing tumor. The scope of this discussion would extend well beyond this chapter, however, because just as each organ develops differently, tumors of these organs develop distinctly as well. Instead, a more general way to illustrate the concept of the tumor organ is to consider what happens when an organ is injured—it attempts to heal. The wounding microenvironment shares a great deal in common with the tumor microenvironment (illustrated in Figure 16-3), the difference being that wounds eventually stop healing, whereas a tumor's microenvironment persists. This is why tumors have been called "wounds that do not heal."[49]

The Wounding Microenvironment

With a wound, the goal is to restore function of injured tissue, which means that damaged epithelia must be resealed. Compromised blood vessels leak plasma and platelets into the wound site (or simply hemorrhage blood because of more serious injury).[48,50] Tissue procoagulants such as tissue factor initiate a cascade resulting in a clot, rich in the ECM molecules fibrin and fibronectin, which entraps platelets and blood cells. Platelets are a rich initial source of clotting factors, mitogens, and chemoattracting cues that lure cells into the wound site. Inflammatory cells are among these cells, releasing extracellular proteinases such as MMPs and cysteine cathepsins that cleave the provisional ECM to facilitate migration. Fibroblasts follow and become activated by TGF-β and fibronectin splice variants within the clot to become myofibroblasts—muscle-like cells with an enhanced ability to exert contractile force.[51,52] These cells are charged with cinching the wound, and in doing so deposit copious amounts of ECM, consisting primarily of type I collagen (Col-1), to scaffold the tissue in its contracted state.[50] Endothelial cells are stimulated to invade from nearby microvasculature by angiogenic factors (e.g., VEGF, FGF-2) secreted by platelets, immune cells, and fibroblasts, and also released from the provisional ECM by MMPs (e.g., MMP-9), to rapidly vascularize and feed the new tissue.[53] Meanwhile, this complex cascade of events reduces adhesiveness of adjacent epithelial cells, which undergo an epithelial-mesenchymal transition (EMT) in order to migrate to reseal the epithelium. The cells will later revert back to their normal state by redepositing BM, reengaging each other through cell-cell junctions, growth arresting, and functionally differentiating.[48]

Thus, the wounding microenvironment is populated by circulating cell types such as immune cells and platelets, and resident tissue cells such as fibroblasts and endothelial cells. These cellular constituents engage in a dynamic and reciprocal chorus via secreted factors and ECM molecules to activate nearby epithelial cells to close the wound via proliferation and migration. The biggest difference between a tumor and the healing wound is what happens next. In the proper wounding context, not only does the epithelium differentiate, but activated cell types do not persist, the provisional ECM is remodeled, and secretion of stimulatory growth factors and cytokines is dampened. There is still much to be learned about what comprises this "homeostatic switch"—that is, the cues that tell a tissue to stop remodeling, presumably because it is now fully functional. For instance, what exactly happens to all of the activated myofibroblasts is not known. They may deactivate, transdifferentiate, or undergo apoptosis (this fails to occur in individuals with chronic wounding disorders, and it should not surprise the reader that these individuals are also more susceptible to cancer[54]). The stimuli that cause myofibroblasts to undergo any of these programs are also unknown. Perhaps uncovering these cues will offer insight as to how the tumor microenvironment itself can be phenotypically reverted so that it does not persist.

The Tumor Microenvironment

Whether a tumor creates its own microenvironment or the aberrant microenvironment causes a tumor is a conundrum of tumor biology. There is evidence for both. Regardless, what manifests is a dynamic interplay between a tumor and its surroundings that ultimately results in loss of organ structure and architecture. Loss of architecture is a hallmark of cancer that reflects behaviors such as deregulated growth, enhanced survival, new blood vessel formation, stromal activation, and inappropriate migratory and invasive behavior of cells.[55] The microenvironment becomes a runaway train, and activation is heightened as entropy (loss of cell and tissue architecture) increases. As the reader goes through the remainder of this chapter, keep the following questions in mind: at what stage of progression do tumor cells or cells in

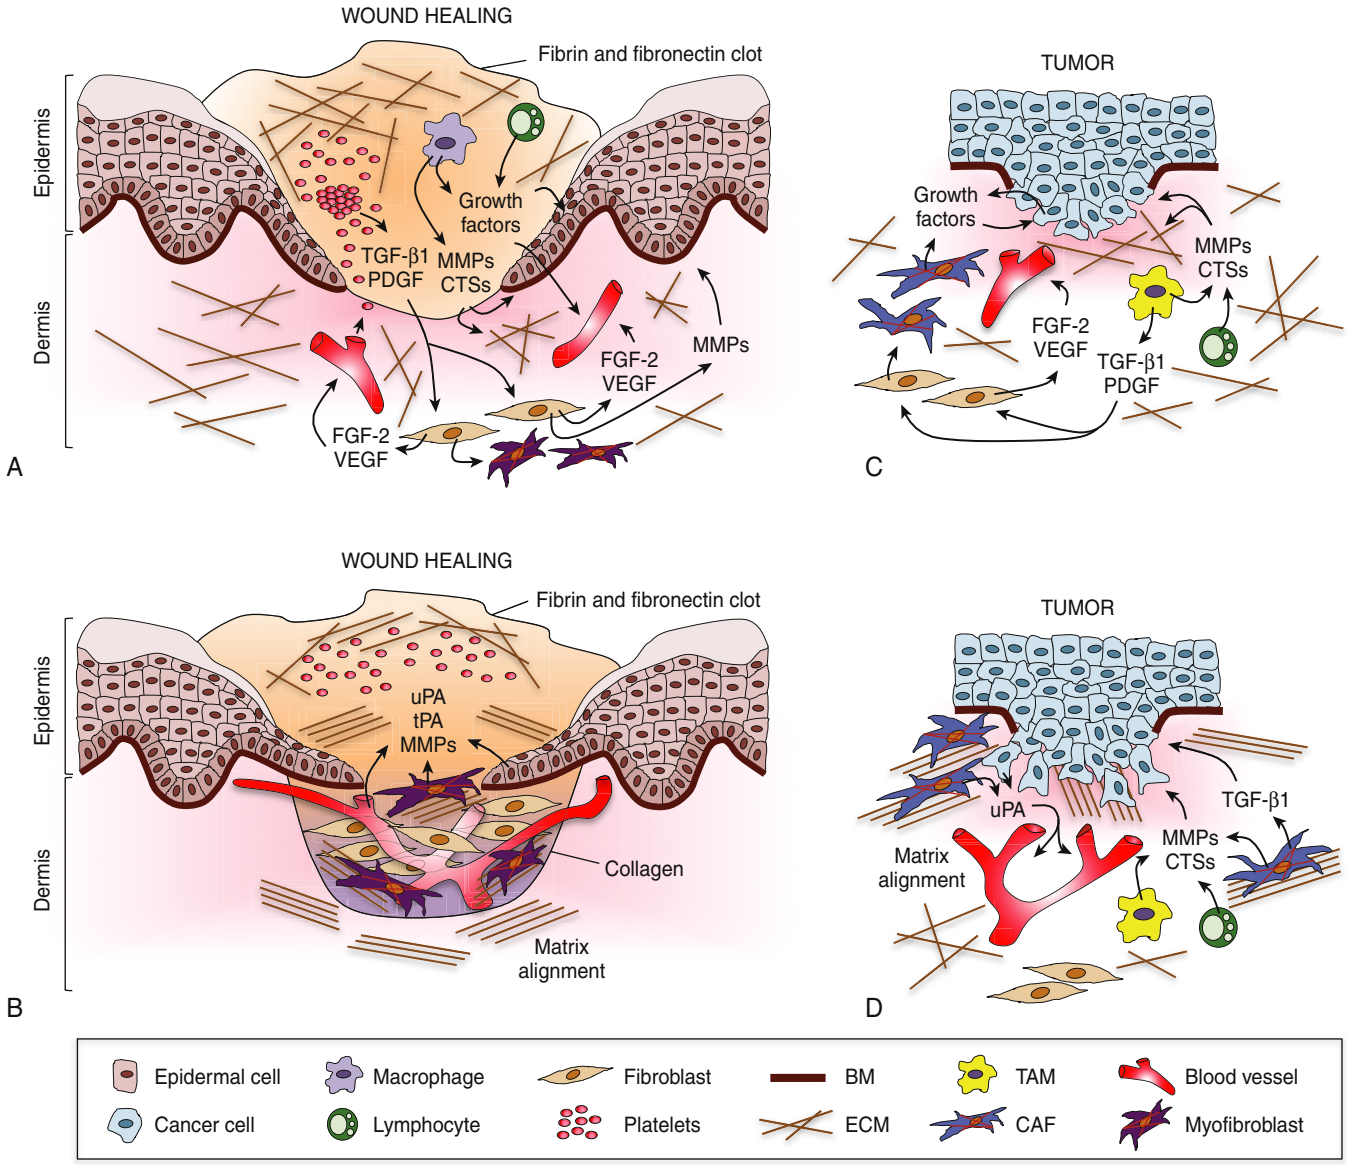

Figure 16-3 Tumors: "Wounds that do not heal" **(A)** Immediately after injury, damaged blood vessels leak plasma and platelets, which form a hemostatic plug and release vasoactive mediators to increase vascular permeability and enable the influx of serum fibrinogen to generate a fibrin and fibronectin-rich clot. Platelets produce chemotactic factors such as TGF-β and PDGF, which lure inflammatory cells and fibroblasts into the wound site. These cells produce extracellular proteases, including matrix metalloproteinases (MMPs) and cathepsins (CTSs), which remodel extracellular matrix (ECM) to facilitate cell migration. Recruited cells also secrete a number of growth factors, such as FGF-2, which promote the development of new blood vessels. Many of the fibroblasts take on a myofibroblast phenotype to facilitate wound contraction. **(B)** In order for the wound to close, myofibroblasts deposit and align abundant amounts of ECM, mainly Col-1. The intricate reaction to wounding reduces epithelial adhesiveness and increases epithelial cell mobility to re-form an intact sheet of tissue over the wound. Production of MMPs, uroplasminogen activator (uPA), and tissue plasminogen activator (tPA) facilitates the re-epithelialization. Blood vessels can then enter the fibrin- and fibronectin-rich clot to rapidly vascularize and feed the new tissue. The lateral migration of the epidermal cells is followed by a reversion to their normal state by redepositing basement membrane (BM), reengaging intercellular adhesions, growth arresting, and functionally differentiating. **(C)** Similarly, the tumor microenvironment is populated by immune cells, fibroblasts, and endothelial cells, and tumor cells produce many of the same growth factors that activate the adjacent stromal tissues in wounding in order to create a reactive stroma. **(D)** Tumor cells, cancer-associated fibroblasts (CAFs), and tumor-associated macrophages (TAMs) increase production of MMPs and uPA at the invasive tumor front to stimulate angiogenesis and proliferation. CAFs exert also contractile forces to generate tracks within the ECM through which epithelial cells subsequently invade in a collective fashion.

the vicinity of tumors begin to secrete and deposit factors that cause aberrant growth and invasion? At what stage of progression do epithelial cells (transformed or not) respond? Once a tumor disseminates, what type of microenvironment is necessary for it to grow? And finally, once a reactive stroma has formed, can it be reversed?

Initiation

Perhaps the most convincing demonstration of the microenvironment's influence is that its disruption causes not just aberrant growth but also de novo genetic lesions and full-blown malignancy (Figure 16-4, *A*). This has been shown in mouse models in which ECM remodeling enzymes

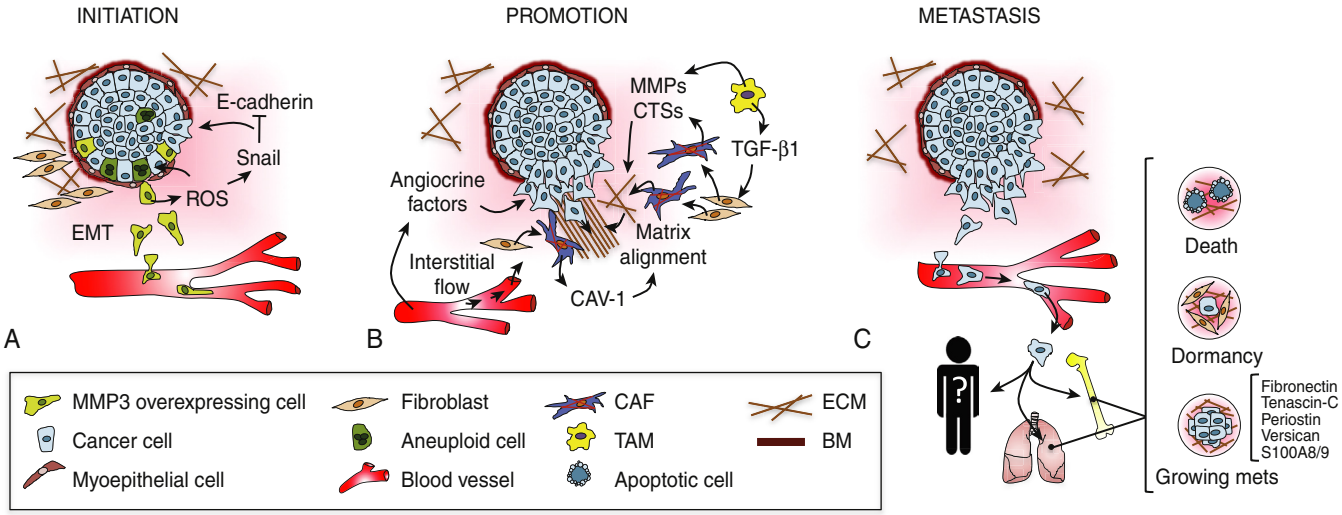

Figure 16-4 The microenvironment is a dominant force in tumor initiation, promotion, and metastasis **(A)** Forcing the expression of a single extracellular matrix (ECM) remodeling enzyme, MMP3, in mammary epithelial cells *in the absence of any additional mutations* initiates genetic lesions and full-blown malignancy. Activation of MMP3 leads to epithelial-to-mesenchymal transitions (EMT), as well as genomic instability through the formation of reactive oxygen species (ROS). In addition, ROS stimulate the expression of Snail, which negatively regulates E-cadherin, loosening cell-cell adhesion and facilitating invasion. **(B)** The microenvironment unleashes initiated epithelium. An increase in the interstitial flow combined with TGF-β1 released by the tumor and by TAMs induces dermal fibroblasts to differentiate into CAFs. These cells secrete several growth factors and cytokines that enhance the proliferation of nearby tumor cells. In addition, CAFs and TAMs produce proteases such as MMPs and cysteine cathepsins (CTSs) to remodel and align the ECM, thus creating tracks through which epithelial cells subsequently invade in a collective fashion. **(C)** The microenvironment is also a potent enhancer of distant metastatic spread. Invasive cancer cells enter local microvasculature and travel through hematogenous and/or lymphatic routes to distant organ sites. Formation of a metastatic niche, characterized by elevated expression of ECM molecules such as fibronectin, tenascin-C, or periostin, may be required in order for disseminated tumor cells to colonize distant tissue.

MMP-3 and MMP-14 are overexpressed in the murine mammary gland.[56,57] Both of these proteases are expressed normally during mammary epithelial morphogenesis and function in part to execute the branching program.[58,59] However, sustained ectopic expression of MMP-3 in luminal epithelial cells (via a MMP-3 transgene driven by a milk protein promoter [WAP], which is primarily active in the murine mammary gland[59]), led to a dramatic upregulation in murine MMP-3 expression in the mammary stroma. This was sufficient to cause the formation of a *reactive stroma* characterized by increased blood vessel density, accumulation of collagen, and expression of ECM molecules typically observed only during development or wounding (e.g., tenascin-C).[60] By 6 months, these mice exhibited substantially more epithelial hyperplasia than their wild-type counterparts, and a small percentage of these mice eventually formed full-blown carcinomas[56] (Figure 16-5, *A*). MMP-3 does not only act on the stroma; epithelial cells are affected directly as well. Exogenous MMP-3 causes oxidative DNA damage through the production of reactive oxygen species (ROS), causing genomic instability and aneuploidy in epithelial cells[61] (see Figure 16-5, *B*). Additionally, ROS stimulate expression of Snail, which negatively regulates E-Cadherin, causing loss of cell-cell adhesion and EMT.[61] In sum, forcing the overexpression of a single ECM remodeling enzyme—without addition of an oncogene or knockdown of a tumor suppressor gene in the mammary gland—results in the manifestation of all of the putative hallmarks of cancer.[55]

More sophisticated transgenic models allow tissue-specific recombination events to facilitate genetic deletion in specific tissue compartments.[62] This strategy has been utilized to demonstrate that introducing a genetic aberration to fibroblasts is sufficient to cause cancer in adjacent epithelium. For instance, driving TGF-β receptor type II (TGF-βRII) deletion by the fibroblast-specific protein 1 (FSP1) promoter (which is expressed ubiquitously by fibroblasts) renders fibroblasts unresponsive to TGF-β signaling and results in a three- to fourfold increase in hepatocyte growth factor (HGF) secretion in the prostate and forestomach of these mice.[63] The ultimate consequence is the induction of proliferative, intraepithelial neoplasms within the prostates of young mice, and of invasive squamous cell carcinomas in the forestomachs of these mice. Similarly, engineering human fibroblasts to overexpress either HGF or TGF-β is sufficient to induce tumorigenic growths from ostensibly normal co-implanted human epithelial tissue.[64]

Fibroblasts also play key roles during tissue development by producing ECM and other molecules that induce growth, branching, and tissue-specific gene expression of resident epithelia. Ostensibly, if fibroblasts were engineered to re-express developmental markers in the mature gland, they have the potential to severely affect epithelial homeostasis. This was tested by co-implanting urogenital sinus

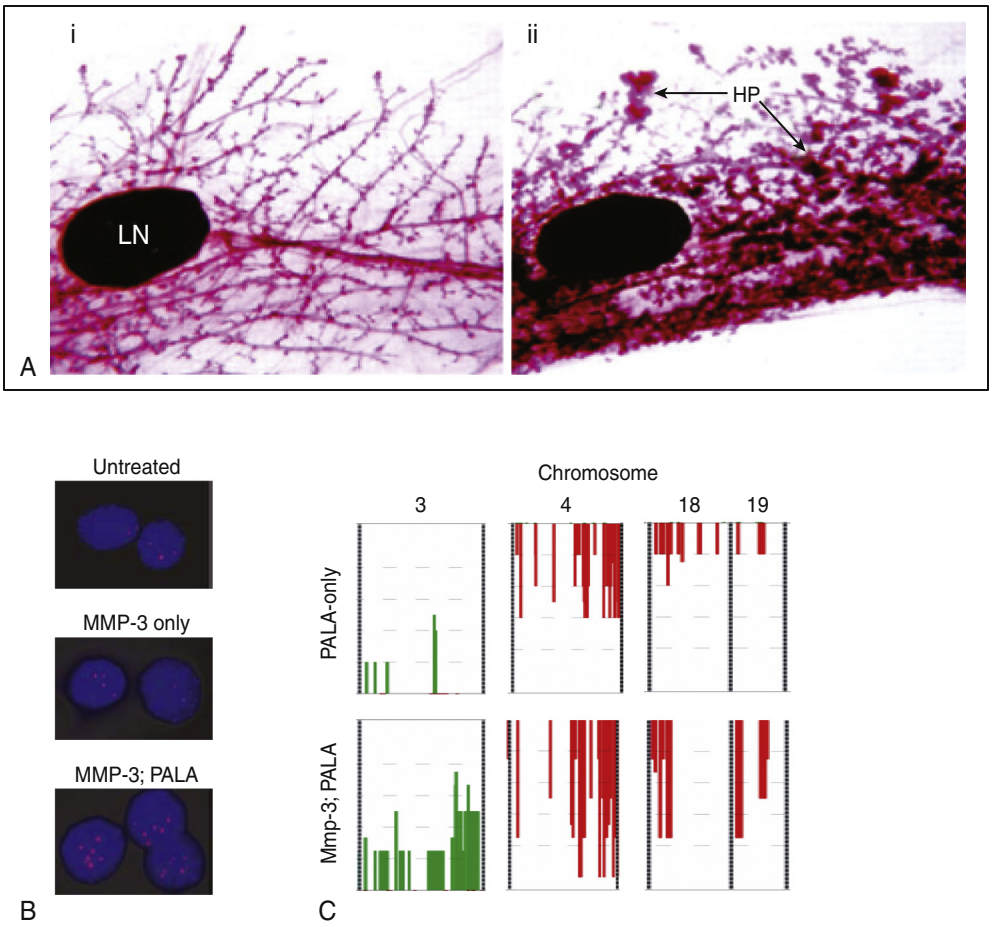

Figure 16-5 Forced overexpression of MMP-3 in the murine mammary gland results in tumor formation in part by causing genomic instability in mammary epithelial cells **(A)** As opposed to nontransgenic control mice (**A** i), WAP-*Mmp3* mice (**A** ii) exhibit multifocal hyperplasia (HP) by 16 months of age. Mmp-3 functions to induce tumorigenesis via reciprocal overexpression of Mmp-3 in the mammary stroma to induce a reactive stroma *(not shown)*, and by acting directly on mammary epithelial cells to induce reactive oxygen species, which cause genomic instability. This is shown by **(B)** amplification of the *CAD* locus *(red)*, which confers resistance to *N*-(phosphonacetyl)-L-aspartate (PALA) treatment, in Mmp-3 treated mammary epithelial cells and by **(C)** comparative genomic hybridization analysis (*green*, amplifications; *red*, deletions) of Mmp-3–treated cells (vs. control [PALA]-treated cells).[56,61] *LN*, lymph node.

mesenchymal cells overexpressing the global epigenetic regulator Hmga2, which is expressed primarily during embryonic development, in a sustained fashion. When implanted with adult prostate cells, Hmga2-overexpressing mesenchyme fostered formation of frank carcinomas primarily by acting on the basal stem cell population of prostate epithelia.[65]

These studies demonstrate that inducing aberrations within the stromal compartment is sufficient, in and of itself, to induce genomic instability, sustained growth, and the transition to an invasive phenotype by uninitiated and untransformed epithelia. Once the epithelium has been initiated, the activated microenvironment also plays a key role in accelerating the progression of transformed epithelium into frank carcinomas.[66,67]

Progression

The previously described wounding studies in RSV-injected chickens[25,30] were among the first to show conclusively that the wounding microenvironment is sufficient to push transformed cells (in this case, those expressing the Src oncogene) to form tumors. More recent works have pinpointed precise roles for specific cell types, growth factors, cytokines, ECM molecules, and associated physicochemical properties in creating a biochemical and mechanical signaling milieu that unleashes initiated/transformed epithelium (see Figure 16-4, *B*).

Before delving into all of the ways that the microenvironment conspires to promote loss of architecture, growth, and invasion, it is important to note that we likely harbor initiated cells throughout our body, which accumulate over the course of our lives as a result of diet, radiation, and so forth.[13,19] Yet on a per-cell level, progression to malignancy is actually an extremely rare event. The reason is that normal tissue architecture supersedes an aberrant genome, as detailed earlier. For epithelial tissues, the BM is the principal biochemical and physical scaffold that must be compromised for in situ disease to become invasive. This specialized, layered ECM

typically consists of at least one member of the laminin family (e.g., both laminin-111 and -332 for mammary epithelium), type IV collagen, nidogens, and heparin sulfate proteoglycans, among others, and signals in a tissue-specific fashion to confer architecture[68] and function to the epithelium.[69,70] Depriving normal cells of BM can have dramatic consequences. Not only does adhesion to BM protect epithelial cells from apoptosis,[71] it confers proper tissue polarity to epithelium. For instance, luminal epithelial cells from the mammary gland "reverse polarize" when removed from BM and cultured in Col-1 (which is found mainly in the stroma)—that is, they express apical proteins basally, and vice versa.[72] Addition of myoepithelial cells, which lie basal to the luminal epithelium and secrete laminin-111 in vivo, restores proper polarity to luminal epithelial cells.[72] Laminin-111 is critical also to tissue-specific gene expression within the mammary gland,[17,73-76] and its organized presence is quite important for preventing carcinoma progression. Co-implantation of myoepithelial cells with a cell line that forms ductal carcinoma in situ–like lesions in vivo restrains progression of these cells even in the presence of CAFs or fibroblasts taken from a chronically inflamed microenvironment.[77] Myoepithelial cells derived from cancer patients, which fail to express laminin-111,[72] cannot confer proper polarity to luminal epithelial cells in culture and fail to prevent fibroblast-mediated invasion of in situ lesions.[77] This establishes a vicious cycle, as loss of epithelial polarity results in upregulated expression of MMP-9, which degrades remaining BM and effects further loss of tissue architecture.[45] Thus, loss of laminins, or inability to produce them, results in loss of tissue architecture, accelerated degradation of preexisting laminin-111, and, if additional necessary signals are present, progression to malignancy. Taken together, these data demonstrate how disruption of tumor-suppressive components within tissues renders cells sensitive to the coercive elements of the tumor microenvironment.

Carcinoma-Associated Fibroblasts and the Factors They Produce Promote Tumor Progression

CAFs account for up to 80% of the fibroblast population in a tumor.[78] They arise from fibroblasts resident to the tissue, as well as vascular smooth muscle cells, pericytes,[79] mesenchymal stem cells,[80] and even epithelial[81] and endothelial cells (via mesenchymal transitions[82]). CAFs phenotypically resemble myofibroblasts—they express fibroblast activation protein, incorporate alpha smooth muscle actin within their actin stress fibers, and deposit copious amounts of fibronectin, including the extra domain (ED)-A–containing splice variant.[49,83] CAF phenotype is stimulated initially, at least in part, by tumor-derived TGF-β1,[84] and the diffusible nature of this stimulation is reflected by the graded pattern of fibroblast activation observed in tumors.[85] Fibroblasts closest to the tumor exhibit the highest level of activation.[79,81,85]

The demonstration that activated stroma associated with tumors actually promotes tumor progression has been known in the literature for decades. An example of increased tumor growth was demonstrated clearly when CAFs isolated from prostate tumors were recombined with SV40-transformed prostate epithelial cells and induced formation of masses more than 10-fold larger than those formed by recombinants composed of normal human prostate fibroblasts and initiated epithelial cells.[86] CAFs from other tissues effect similar outcomes; there is evidence that CAFs play a role in accelerating tumor progression in breast,[87] ovarian,[88] pancreatic,[89] and liver[90] cancers and others. Sustained secretion of growth factors and cytokines such as TGF-β, HGF, SDF-1, and IL-1β by CAFs enhance proliferation and invasion of nearby tumor cells, promote angiogenesis (including recruitment of circulating endothelial progenitor cells), and stimulate a tumor-promoting inflammatory response.[84,87,91,92] However, it should be cautioned that fibroblasts from different organs are not the same, since fibroblasts exhibit substantial heterogeneity between organs.[93] Hence, the mechanisms by which CAFs from a given tissue promote tumor progression are likely to differ as well. Case in point, analysis of CAFs from skin, cervical, mammary, and pancreatic tumors revealed that each have unique expression signatures of a pro-inflammatory gene set.[91]

What is clear from these experiments, which in general require the isolation and expansion of CAFs, is that the CAF phenotype persists in culture despite the absence of a tumor. What is unclear, however, is why. Interestingly, CAFs rarely exhibit somatic genetic alterations[94]; however, on a population level, they do have reduced expression of the well-known tumor suppressors p53 and PTEN. Deletion of PTEN in mammary fibroblasts is sufficient, all on its own, to steer these cells toward a desmoplastic, pro-inflammatory, pro-angiogenic phenotype that drastically accelerates tumor growth in mice.[95] Therefore, epigenetic changes, perhaps caused by sustained overstimulation by TGF-β and SDF-1,[92] or effected even by direct transfer of genetic material from the tumor itself,[96] may drive altered expression profiles in local fibroblasts that are sufficient to induce and sustain the CAF phenotype. Because CAFs persist in culture without the tumor (although the tissue culture plastic milieu is analogous to wounding), the likelihood is that they persist also in vivo once the tumor has been removed. What role residual CAFs play in tumor recurrence has yet to be defined.

CAF-Mediated ECM Remodeling Promotes Loss of Tissue Architecture and Tumor Invasion

In addition to soluble factor–mediated effects, CAFs influence tumor progression by remodeling the ECM in three

distinct but nonexclusive fashions. Destructive remodeling refers to proteolytic breakdown of ECM. Using organotypic skin reconstructs, Gaggioli and colleagues demonstrated that CAFs use a combination of MMP- and force-mediated remodeling of ECM to promote invasion of squamous cell carcinoma (SCC) cells. The authors reached this conclusion after first observing that SCC cells required a physical association with CAFs in order to invade subjacent ECM. Remarkably, preconditioning the underlying ECM with CAFs was still sufficient to induce SCC cell invasion. But how? CAFs secrete MMPs and exert contractile forces to generate tracks within the ECM through which epithelial cells subsequently invade in a collective fashion.[97] Once these tracks are generated, it is quite possible that trailing cells no longer require the proteolytic function of MMP molecules to invade the ECM.[58,98-100] Thus, depending on the amount and type of ECM remodeling that has taken place, inhibiting the proteolytic function of MMPs (which was hailed as a promising strategy for targeting the microenvironment, but has failed to live up to that promise[101]) may prove inadequate to prevent the invasion of tumor cells.

Activated fibroblasts are the principal mediator of desmoplasia or excessive ECM deposition. Tumors exhibit up to 10-fold increases in collagen concentration over physiologic conditions,[102] corresponding to a 24-fold increase in tissue stiffness in a tissue such as the mammary gland.[103] Elevating stiffness out of the physiological range is sufficient to alter the function of normal mammary epithelial cells by altering cell shape,[14] increasing intracellular elasticity, inhibiting tissue-specific gene expression,[104] and causing disorganization of nonmalignant epithelia.[103] Once epithelia are initiated by any means, pathological ECM stiffness drives integrin clustering, focal adhesion formation, ERK activation, and ROCK-mediated contractility, ultimately resulting in disrupted tissue architecture and an invasive phenotype.[103,105,106] Blocking integrin clustering or Rho signaling in 3D culture is sufficient to restore proper epithelial architecture; inhibiting collagen crosslinking in MMTV-Neu mice through lysyl oxidase (LOX) blockade slows tumor progression.[103,105]

Cell-intrinsic and cell-extrinsic forces also have a significant effect on ECM alignment, which in turn profoundly influences tumor invasion. "Tumor-associated collagen signatures" were first described by Provenzano and Keely[107] and refer to three possible alignments of fibrillar collagen observed at the tumor-stroma interface: random, perpendicular/belt-like, or radially aligned. The last is observed at invasive tumor fronts, and patients with radially aligned collagen at the tumor-stroma interface have significantly diminished disease-free and overall survival.[109-110] One potential mediator of collagen alignment is the tumor itself, particularly in instances where stiffening of the stroma enhances contractility of tumor cells.[105,111] Physical stimulus from the microenvironment also triggers ECM alignment by fibroblasts. Hydrostatic pressure drives water out of capillaries into the interstitial (tissue) space to be collected, in part, by lymphatic vessels present within the tissue. This interstitial flow can increase by an order of magnitude in a tumor.[112] When subjected to pathological flow rates, dermal fibroblasts differentiate into myofibroblasts and align themselves and their surrounding ECM perpendicular to the direction of flow.[113] Strain from the aligned ECM may potentiate TGF-β1 activation by allowing fibroblasts to physically pull apart the molecule from its ECM-bound latent complex,[114] creating a feed-forward loop to sustain the activated phenotype. The aligned ECM, in conjunction with factors secreted by activated fibroblasts, can then direct tumor invasion.

Recently, a molecular mediator of CAF-mediated ECM alignment was uncovered. This molecule, known as Caveolin-1 (Cav-1), is a scaffolding protein essential to the structure of caveolae, or "little caves," in cellular plasma membranes.[114] Cav-1 assists with focal adhesion maturation[115] and promotes force-dependent remodeling of surrounding ECM[116] by embryonic fibroblasts. Although loss of Cav-1 in patient stroma is associated with increased primary tumor size,[117,118] Cav-1–mediated ECM remodeling by fibroblasts enhances invasion and distant metastatic spread. In coculture assays consisting of breast tumor cells and embryonic fibroblasts, Cav-1 expression within the fibroblast compartment potentiates directional alignment of Col-1 and fibronectin-rich ECM to facilitate tumor cell invasion.[116] *Cav-1*–null fibroblasts are unable to align ECM in culture and fail to promote distant metastasis of co-implanted breast cancer cells in vivo.[116] These findings open the door for therapies that target both CAF-derived soluble factors that promote tumor growth, and molecules such as Cav-1 that promote CAF-mediated disruption of tissue architecture to facilitate tumor invasion. However, although CAFs are representative of how nontumor cells function in the tumor microenvironment, they are only part of the story. It is important to realize that other cell types can also be induced to aid tumor cell survival, growth, and invasion.

Other Cell Types Contribute to the Tumor Microenvironment

Our bodies consist of more than 300 different cell types, a subset of which constantly engage each other in any given organ to direct development and maintain homeostasis. One would expect that few, if any, of the cells in an organ act as silent bystanders during tumor initiation, formation, and progression. Thus, although we describe known roles for immune cells and endothelial cells later, the reader should not infer that any cell types not mentioned are uninvolved. Instead, the reader should consider these unknown interactions as potential avenues of exploration and an opportunity to define new connections that shape the tumor microenvironment.

Because the immune system is known to protect the host, it was expected that immune cells would be protected against cancer. However, it is now clear that a subset of immune cells in fact promote tumor progression. No immune cell type embodies this paradigm shift better than the macrophage, which was long pigeonholed as a phagocytic cell tasked with rejecting a tumor until its trophic functions in development and disease became clear.[119,120] Macrophages have been classified based on their mode of activation: classically activated/M1 macrophages respond to interferon-γ by releasing pro-inflammatory cytokines and are involved in T helper 1 cell–mediated resolution of acute infection, whereas alternatively activated/M2 macrophages respond to cytokines from T helper 2 cells and are involved in wounding and fibrosis.[119] To some, this classification is overly restrictive and ignores the phenotypic diversity displayed by macrophages, given that they also maintain bone homeostasis,[121] promote ductal branching or involution of the mammary gland,[122,123] function in various steps of the angiogenic cascade,[119] and guide neural networking.[124] These diverse functions are executed in a tissue- and context-specific fashion by a number of discrete macrophage subtypes, which aid these developmental processes by remodeling collagen and secreting a host of pro-angiogenic, pro-inflammatory, and matrix-degrading factors (reviewed in Ref. 125).

Tumor-associated macrophages (TAMs) are M2-like in function, and their presence correlates with increased vascular density and poor clinical outcome for a number of human cancers, including breast, lung, and ovarian cancer.[119] A principal mediator of macrophage recruitment to the tumor microenvironment is colony stimulating factor (CSF)-1. Once there, CD4-positive ($CD4^+$) and $CD8^+$ T cells steer recruited macrophages toward an M2-like phenotype via IL-4. Diminishing CSF-1 levels[126] or neutralizing IL-4[127] have similar effects on mammary tumor progression. Whereas neither of these manipulations inhibits tumor growth, tumor progression is slowed, and mice have significantly fewer metastases.[126,127] TAMs promote progression and metastasis through ECM remodeling and by secreting many of the same trophic factors released by M2-like macrophages during development, such as extracellular proteases that degrade BM, disrupt epithelial architecture, and enable invasion[126,128]; angiogenic factors that promote new blood vessel formation[129,130]; and epidermal growth factor (EGF) as part of a chemotactic EGF-CSF1 paracrine loop that mediates co-invasion of tumor cells and macrophages.[127,131]

It is important to note that immune cell distributions are tissue-specific beyond macrophage subsets and involve a host of other leukocytes in normal organs and during tumor progression.[132] Thus, in order to design therapies that effectively target tumor-associated inflammation, it is likely as important to understand how leukocyte populations shift during tumor progression as it is to understand how different leukocytes change phenotypic characteristics.

Blood vessels are generally regarded as conduits for oxygen, nutrients, and hematopoietic cells and thus as passive participants in the tumor microenvironment.[133] However, this is not the case. Endothelial cells are active participants in the dynamic interactions that occur between cells in any tissue. This was established first in development: endothelial cells secrete soluble factors that stimulate liver growth and tissue-specific gene expression from the pancreas in developing embryos.[134,135] More recently, endothelial cell–derived "angiocrine factors" have been shown to comprise niches that maintain stem cells in both brain[136,137] and bone marrow.[138-140] Increasing evidence suggests also that NOTCH ligands and specific BM molecules expressed in the brain perivasculature mediate the survival of glioma-initiating cells and disseminated tumor cells in the brain.[141-144]

Significant tumor-promoting roles have also been defined for other immune cells,[145] as well as endothelial progenitor cells,[146] mesenchymal stem cells,[80,147] neurons,[148] and adipocytes.[149] We direct the reader to the references listed to learn more about the contributions that these cell types make to the tumor microenvironment.

Metastasis

The study of the microenvironment's role in metastasis returns us to the beginning of the chapter and harks back to Paget's observation regarding the spread of breast cancer that was the basis of his "seed and soil" hypothesis.[18] The mechanistic underpinnings of this hypothesis are perhaps the hottest topic in metastasis research today.[150] Whereas it has been postulated that tumor cells actively "home" to a given organ site, there is also evidence that tumor cells spread indiscriminately.[151] In this latter case, certain secondary tissue microenvironments, or "soils," must be particularly hospitable for growth of disseminated tumor cells (DTCs). This could happen in three ways: (1) tumor cells preferentially remodel target organ sites *before* they get there (i.e., they form a premetastatic niche); (2) tumor cells bring their own microenvironment with them; or (3) surviving DTCs are dependent on formation of a niche that favors their growth after arriving to the secondary site. The dynamics of metastatic relapse displayed by cancer patients suggest that all three of these mechanisms are plausible,[152] and experimental data from spontaneous and experimental metastasis assays in mice offer some insight. We discuss these three possibilities in more detail next.

The concept of the premetastatic niche refers to the priming of distant organs by tumor-derived factors. This was demonstrated first in immune-competent mice inoculated subcutaneously with either B16 melanoma or Lewis lung carcinoma cells. In these mice, $VEGFR1^+$ bone marrow–derived

progenitor cells (BMDCs) are recruited to future sites of metastasis before even the first tumor cells arrive.[153] On arriving at target organs, BMDCs secrete the chemokine SDF-1 to recruit tumor cells,[154] upregulate fibronectin expression in these tissues to promote engraftment and growth of the recruited tumor cells, and activate MMP-9 to destroy BM, disorganize epithelial tissues, and liberate VEGF from the ECM.[45,155] In addition to promoting angiogenesis within the tissue, VEGF functions to enhance permeability of the microvasculature and to recruit $VEGFR2^+$ BMDCs that contribute to new blood vessel formation. The ultimate result is more rapid activation of the angiogenic switch and hence accelerated metastatic outgrowth.[153] Subsequent studies have pinpointed induction of MMP-2, S100A8, and S100A9 at secondary sites as other principal constituents of the premetastatic niche.[156,157]

Tumor-derived agents that induce formation of the premetastatic niche continue to be uncovered. In a study by Kaplan and colleagues, media conditioned by B16 melanoma cells, which metastasize to the lung, liver, testis, spleen, and kidney, primed Lewis lung carcinoma cells, which metastasize only to the lung and liver, to metastasize to a wider array of organs.[153] What is it in the tumor-conditioned medium that causes this effect? Whereas tumor-derived factors such as VEGF-A, VEGF-C, and LOX have been implicated in modulating distant microenvironments,[156,158,159] secretion of soluble factors, which ostensibly circulate systemically and thus have the potential to modulate any organ site, does not account for the organ specificity of premetastatic niche formation.

A breakthrough study revealed that tumors can execute tissue-specific remodeling of distant microenvironments through *exosomes*, small (30 to 100 nm) cell membrane–derived microvesicles packed with a selected number of molecules. Cargo carried by exosomes includes cytokines, growth factors, ECM proteins, mRNA, microRNAs, and even phosphorylated signaling proteins.[160] The exciting discovery that exosomes can be transferred from cell to cell would indicate that tumor-derived exosomes can activate or deactivate a number of signaling pathways in recipient cells to effect tissue remodeling from near or far.[160]

Specific exosome cargos evolve with tumor progression. For instance, a number of proteins are upregulated in exosomes from metastatic melanoma (compared to nonmetastatic disease), including the oncoprotein MET.[161] Preconditioning mice with exosomes from highly metastatic melanoma cells causes subsequently injected poorly metastatic melanoma cells to home to a greater number of organs and rapidly form lethal metastases.[161] How? Melanoma exosomes home to target organs (possibly influenced by expression of specific integrins on their surface) and induce vascular permeability to promote entry of circulating tumor cells. In addition, exosomes are taken up by BMDCs, resulting in a MET-directed education toward a pro-vasculogenic phenotype. Pro-vasculogenic BMDCs promote metastatic outgrowth of disseminated cells on arriving to target organs.[161] Accordingly, exosomes derived from metastatic tumor cells can prime distant organ sites for tumor cell extravasation, adhesion, and growth. Thus inhibiting exosome production, engraftment, or specific exosome contents could prove effective in blocking or disrupting formation of the pre-metastatic niche.

Whereas tumor cells and tumor-derived exosomes have been observed in the blood, only recently has the possibility been raised that stromal cells from the tumor microenvironment may also wind up in the body's circulation. Is it possible that tumor cells could be bringing their own soil to distant organs? A small-scale study revealed that nonepithelial, nonlymphocytic, fibroblast-like cells were present in the blood of more than 50% of patients with metastatic disease, but absent in all participants with localized cancer.[162] Experiments in mice have shown the potential significance of circulating fibroblasts, as tumor cells in heterotypic tumor-fibroblast fragments exhibit enhanced survival and enhanced efficiency of metastatic outgrowth on reaching target organs.[163,164]

Aside from preconditioning metastatic sites before their arrival or bringing activated stromal cells with them as they metastasize, tumor cells are also able to disrupt homeostasis in target organs and induce stromal cells to deposit factors that create a favorable *metastatic niche*[165] (see Figure 16-4, *C*). Metastatic tumor cell lines can be enriched for lung, bone, and brain tropism by serial passaging through mice, and these cells reveal distinct gene expression signatures that enable more efficient metastasis to these target organs.[166-168] The products of a number of these genes mediate interactions between the tumor and its microenvironment. Follow-up studies have defined a number of ECM molecules and extracellular factors such as tenascin-C,[169] periostin,[170] versican,[171] col-1,[172] interleukin-6,[173] and tissue factor[174] that make up the metastatic niche. From these studies, two themes emerge: (1) it is not necessary for both the tumor and the stromal cells to express these factors—either will do, and induction could be reciprocal; and (2) these molecules are also commonly expressed during development or wounding in a temporally regulated fashion. As a result, the metastatic niche comprises a familiar, hospitable milieu that supports DTC survival and growth.

The Frontiers of the Microenvironment

There are a number of conclusions that can be made from the newly appreciated field of the microenvironment. One is that the microenvironment can have both positive and negative influences on aberrant cells. The second is that the normal microenvironment may indeed protect against tumor

progression (for review, see Ref. 13). In addition, two of the most crucial directions in this research are understanding how the microenvironment contributes to chemotherapeutic resistance, and how therapeutic regimens could be devised that simultaneously target tumor cells and their surrounding microenvironment.

The Tumor Microenvironment Promotes Drug Resistance

A popular theory about how tumors become chemoresistant is that a given chemotherapeutic kills all of the susceptible cells. The fraction that survives then clonally expands, and the genetic alterations that rendered these cells resistant largely remain, resulting in a tumor that may no longer respond to that given therapy.[175] However, it is increasingly appreciated that the microenvironment also significantly affects treatment response.

One way it does so is by influencing the delivery and distribution of administered drugs. Blood vessels in tumors are highly heterogeneous in terms of blood flow and permeability.[176,177] Thus, depending on its molecular weight, a drug may be able to enter one portion of a tumor, but never reach another.[176] Even if it exits the vasculature, drug transport through the bulk of the tumor is greatly influenced by the density of cells and the ECM molecules. Cell density affects the effective concentration of drug taken up by tumor cells, whereas ECM molecules restrict the effective diffusion of a drug via binding interactions and/or by physically restricting mobility through the proteinaceous mesh.[69,176,178] Thus, one may conclude that pretargeting fibrosis and desmoplasia is a promising approach to improve the distribution and efficacy of subsequently delivered chemotherapeutics. Indeed, initial attempts at this approach by pretreating tumors with ECM-degrading or antifibrotic agents before administering chemotherapeutics appear quite promising.[179,180]

Aside from directly affecting delivery of drugs, it is apparent also that privileged niches within the microenvironment protect tumor cells from the damaging effects of therapeutics. One such niche is the BM. It has long been established that β1 integrin–mediated binding of BM suppresses apoptosis of normal mammary epithelial cells.[71,181] Binding of a principal constituent of BM—laminin-111—via integrin-β1 has also been shown to mediate resistance of small-cell lung carcinoma to cytotoxic agents.[182] BM also directs formation of polarized acini that render mammary epithelial cells resistant to a host of cytotoxic drugs and death receptor ligands independent of growth status. This laminin-induced resistance to apoptosis is transmitted via integrin $\alpha_6\beta_4$ through formation of mature hemidesmosomes to direct cytoskeletal organization and polarity.[183]

Adhesion to other ECM molecules also plays a role in therapeutic resistance. For instance, engagement of the fibronectin ED-A splice variant via integrin $\alpha_5\beta_1$ diminishes the radioresponse of breast cancer cells,[184] and association with type VI collagen renders ovarian cancer cells resistant to cisplatin.[185] These molecules as well as others are likely to act by hyperactivating integrin-mediated survival pathways (e.g., integrin→focal adhesion kinase→Akt),[186] thus providing tumor cells with a survival advantage.

It is also important to consider the effects of chemotherapeutics on nontumor cells, and how their response alters the tumor microenvironment. For instance, normal epithelial cells and stromal fibroblasts respond to the chemotherapeutic mitoxantrone by shifting toward a senescence-associated secretory phenotype. This phenotype is characterized by secretion of a host of molecules associated with angiogenesis, immune cell recruitment, and EMT.[187] Hence, a possible by-product of treatment is that the reactive stroma secretes factors that stimulate nearby tumor cells to grow, invade, and spread. This applies not just to resident tissue cells, but to recruited myeloid cells as well.[188-190]

Because tumor cells are able to successfully seek refuge in a variety of protective niches, single therapies are highly unlikely to retain their efficacy over the long-term. An attractive solution is to devise therapeutic regimens that target the tumor and its microenvironment simultaneously or in stepwise fashion to deprive the tumor of the interactions that sustain it in the face of chemotherapy.

Targeting the Tumor Microenvironment

In this chapter, we have provided a number of examples of how reciprocal interactions between cells and their microenvironment function to initiate tumors, force progression, facilitate metastatic outgrowth, and compose a privileged niche that confers therapeutic resistance. A logical extension of these findings is that inhibiting critical interactions between tumor cells and their microenvironmental constituents could slow tumor progression and render these cells more susceptible to treatment. The growing literature on the importance of microenvironment that now spans more than a century offers a blueprint as to how this can be accomplished, including:

1. Targeting reactive elements of the tumor microenvironment. This notion has spurred a number of studies aimed at testing new therapies (and revisiting others) that target angiogenesis, fibrosis, inflammation, desmoplasia, and other aspects of the tumor microenvironment. A brief summary of these drugs is presented in Table 16-1 (for a detailed list, see Ref. 13).

Table 16-1 A Sampling of Drugs Developed to Target the Tumor Microenvironment

Common Name (Trade Name)	Company	Drug Information
Bevacizumab (Avastin)	Genentech/Roche	In 2004, bevacizumab became the first FDA-approved angiogenesis inhibitor. It is a humanized monoclonal antibody with specific affinity for VEGF-A, thus inhibiting the signaling between the tumor and endothelial cells in the microenvironment.[191]
Sunitinib, SU11248 (Sutent)	Pfizer	Sunitinib garnered FDA approval in 2006. A small-molecule receptor tyrosine kinase inhibitor, it inhibits signaling through PDGFRα, PDGFRβ, VEGFR1, VEGFR2, VEGFR3, KIT, FLT3, CSF-1R, and RET to disrupt angiogenesis, macrophage recruitment, lymphangiogenesis, and tumor cell growth.
Endostatin (Endostar)	Simcere	Endostatin is a 20-kDa peptide fragment derived from the extracellular matrix protein collagen XVIII.[192] Endostatin has a potent effect on endothelial cell proliferation and angiogenesis. It is currently used therapeutically (and in clinical studies) only in China under the trade name Endostar.
Sorafenib, BAY 43-9006 (Nexavar)	Bayer	Approved by the FDA in 2005, sorafenib is a small-molecule kinase inhibitor that inhibits many intracellular and extracellular kinases. Most affected are Raf kinase, VEGF receptor, and PDGFRs, thus resulting in reduced tumor growth and angiogenesis.[193]
MK-2461	Merck	MK-2461 is a small-molecule inhibitor of c-MET kinase, the receptor of the stromal-derived hepatocyte growth factor (HGF). c-MET activation stimulates proliferation and invasion of tumor cells and also stimulates angiogenesis.[194]
Zoledronate (Zometa)	Novartis	Zoledronate belongs to the bisphosphonate class of drugs. It inhibits bone resorption by osteoclasts. Also inhibited is the differentiation of myeloid cells; TAMs are also affected.[195,196]
Denosumab (Xgeva)	Amgen	Approved by the FDA in 2010, denosumab is a human antibody that binds to human receptor activator of nuclear factor kappa-B ligand (RANKL). RANKL regulates osteoclastogenesis and is involved in pathways regulating osteoclastogenesis and tumor cell metastasis to bone, as well as endothelial cell proliferation and apoptosis.[197,198]
Anastrozole (Armidex)	Novartis	Anastrozole is a third-generation inhibitor of aromatase, a cytochrome p450 complex present in the stromal fibroblasts and adipocytes. Aromatase catalyzes the conversion of androgens to estrogens; the inhibitors are approved for the treatment of breast cancer in postmenopausal women.
AMD070	Genzyme	Currently in clinical trials, AMD070 belongs to a class of drugs that inhibit CXCR4. CXCR4 is specific for stromal-derived factor 1 (SDF-1/CXCL12) ligand, which is predominantly expressed by fibroblasts and pericytes.
DX2400	Dyax	In development, DX2400 is a new-generation MMP inhibitor, a human monoclonal antibody specific for MMP14. Previous broad-spectrum MMP inhibitors were generally plagued by a lack of efficacy. However, since the end of the previous trials, much has been learned about MMPs, notably the need for specificity. Some are regarded as being protective, and others not. Thus, newer inhibitors are being designed with specificity in mind.[199]
MK0822	Merck	MK0822 is an inhibitor of cathepsin K, a secreted protease involved in bone resorption. Similar to bisphosphonates, inhibitors of cathepsin K proteases may protect against bone loss induced by metastatic tumor cells.[200] Cathepsin inhibitors may be useful also in blocking cathepsin-mediated protumor effects of TAMs.[201]
TGF-β2 AP12009 (Trabedersen)	Antisense Pharma	Trabedersen is an antisense oligodeoxynucleotide with specificity toward TGFβ2. It is currently in phase I, II, and III clinical trials and is being developed for the treatment of tumors that exhibit high levels of TGFβ2 (pancreatic carcinoma, melanoma, and gliomas). Reductions in TGFβ2 in the tumor are likely to be profound, affecting both tumor and stromal cells (tumor cell growth, angiogenesis, and immune response).
AVE1642	Immunogen/Sanofi Aventis	AVE1642, a humanized monoclonal antibody, is a specific antagonist of the insulin-like growth factor 1 receptor (IGF-1R). IGF-1 derived from bone-marrow stroma promotes survival and growth of multiple myeloma cells. IGF-1R signaling also contributes to angiogenesis via its influence on HIF1α/VEGF expression.[202]
BGJ398	Novartis	Currently in clinical trials, BGJ398 is a small-molecule inhibitor of fibroblast growth factor receptors (FGFR). The ligands of this receptor, FGFs, are expressed by the activated fibroblasts of tumor stroma and have a protumorigenic effect.
Bortezomib, PS-341 (Velcade)	Millennium Pharmaceuticals	Bortezomib is a novel inhibitor of the 26S proteasome complex and is indicated for the treatment of relapsed multiple myeloma and mantle-cell lymphoma. In addition to direct inhibition of the tumor cells, bortezomib interferes with MM tumor and bone marrow stromal cell interactions, inhibiting cytokine signaling and angiogenesis.[203]
PEGPH20	Halozyme	PEGPH20 is a covalently modified form of hyaluronidase, which catalyzes the degradation of the extracellular matrix component hyaluronan. In preclinical animal models, PEGPH20 led to dramatic reductions of the tumor interstitial fluid pressure, subsequently enhancing the delivery of co-administered drugs.[179] PEGPH20 is currently in Phase II clinical trials for patients with stage IV pancreatic cancer.[204]

2. Inhibiting signals that impart chemotherapeutic resistance, e.g., β1-integrin–mediated signaling, prior to or coincident with administration of chemotherapeutics or radiation.
3. Reverting the tumor microenvironment. A more complete understanding about the signals that end the development of tissues, or those that deactivate wounding stroma, could lead to therapies based on these same cues that neutralize tumor stroma.

In the end, it is important to remember that the tumor and its microenvironment do not function in a vacuum. They are constantly engaged in dynamic and reciprocal interactions, and it is the balance of signaling among all of these components that is key to homeostasis. Disrupting this balance without correction can result in tumor initiation and accelerated progression. Remember also that there is likely no uniform way to restore the balance of signaling in a tumor. Just as tumor types are different, tumor microenvironments differ from tumor to tumor and from patient to patient. Accordingly, one should investigate multiple therapeutic avenues and remain open to how these can be applied in concert, as this is likely to provide the best means to manage tumors and improve patient outcome.

17 Tumor Angiogenesis

Solid tumors require a vascular system to grow beyond about 2 mm in diameter, a size at which diffusion of oxygen and nutrients is limiting. The establishment of a tumor vasculature through the process of *angiogenesis* overcomes these limitations, while also providing a conduit through which cancer cells can metastasize. The close association between tumor growth and increased vascularity was described in the 19th century by several researchers,[1] including the pathologist Rudolf Virchow, who also first proposed a link between chronic inflammation and cancer.[2] An important experimental advance in angiogenic research came in the 1920s, when transparent chambers were first used to observe the growth of vessels into tumors in animals in real time.[1] In a seminal study published in 1950, Algire and colleagues[3] used transparent chambers to follow vessel recruitment to a variety of normal and malignant tissues transplanted into mice. Their studies provided some of the first observations that transplanted tumor tissue, in contrast to normal tissue, induced the development of an extensive vascular bed; moreover, this angiogenic response preceded rapid tumor growth. The authors succinctly stated the now-axiomatic idea that "the rapid growth of tumor explants is dependent on the development of a rich vascular supply."[3] Judah Folkman's proposal in 1971 that tumor growth might be inhibited, or even reversed, by blocking tumor angiogenesis[4] sparked a remarkable flurry of activity in basic and clinical research. A milestone in angiogenic cancer therapy was passed in 2003, when the U.S. Food and Drug Administration (FDA) approved the anti-angiogenic monoclonal antibody Avastin (bevacizumab) as a first-line treatment for metastatic colorectal cancer.

This chapter provides a general overview of tumor angiogenesis, highlighting specific molecular pathways that regulate this process, and discusses the ongoing development and clinical evaluation of anti-angiogenic therapies. It is organized into sections that describe (1) the development of vascular structures in normal and malignant tissues, (2) the signaling pathways that regulate their formation, and (3) the therapeutic strategies that underlie ongoing drug development, as well as the current results of clinical trials using anti-angiogenic therapies. Finally, we discuss some of the remaining questions and challenges that are likely to drive angiogenic research in the coming years.

Vascular Development

Normal Vascular Development

Development of the vascular system is one of the first events in embryonic organogenesis. Mesoderm-derived *vascular endothelial cells (ECs)* generate lumen-containing tubular structures that form the basic functional unit of blood vessels. Initially, vascular networks form independently in the yolk sac and the embryo, and then connect to generate a closed circulatory system. In a process known as *vasculogenesis*, endothelial cell progenitors (*angioblasts*) and their derivative ECs aggregate de novo in the yolk sac to form a primitive vascular network or plexus of approximately uniform dimensions (Figure 17-1). Subsequent *angiogenesis* occurs through vessel *sprouting*, in which ECs from existing vessels respond to angiogenic signals by degrading their basement membrane, loosening their association with support cells, altering their morphology, and proliferating. These ECs migrate in response to chemotactic signals and coalesce to form new vessels that connect to the existing vasculature. The coordinated recruitment of supporting mural cells, including *pericytes* and *smooth muscle cells*, results in vessel maturation. In a parallel mechanism termed *intussusception*, columns of endothelial cells create a barrier in the lumen of a preexisting vessel, thus partitioning it into multiple independent vessels[5,6] (Figure 17-2). This complex series of events produces a closed, highly arborized system of larger and smaller vessels including arteries, veins, and capillaries.

In contrast to the yolk sac, angioblasts in the embryo migrate along specific pathways and aggregate directly to form the dorsal aorta and posterior cardinal vein, without

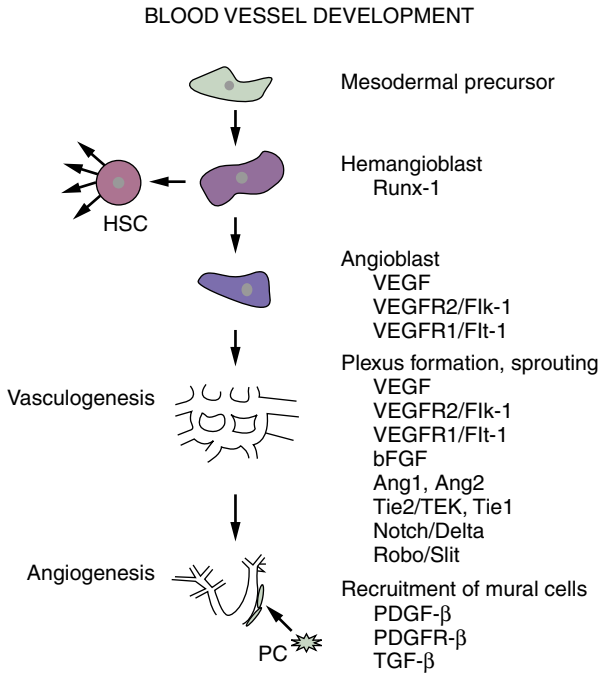

Figure 17-1 Major events in vascular development Some of the critical signaling molecules and receptors are shown corresponding to the cells or processes in which they are known to play a role. Vascular progenitors are derived from vascular endothelial growth receptor-2 (VEGFR2/Flk-1)-positive cells in the lateral plate mesoderm. Hemogenic endothelial cells give rise to hematopoietic stem cells (HSCs) and vascular endothelial precursors (angioblasts). In the yolk sac, angioblasts align to generate a primary capillary plexus (vasculogenesis). Vessels in this plexus grow primarily by sprouting, which involves endothelial cell proliferation and migration (angiogenesis), and eventually connect to vessels in the embryo to form a closed vascular system. Vasculogenesis and angiogenesis are both highly dependent on VEGF, angiopoietins, and their receptors, along with many other signaling molecules (see figure and text). Maturation of the vascular system requires remodeling of the vascular network into large and small vessels, along with the recruitment of supporting mural cells (pericytes and smooth-muscle cells). *Ang*, Angiopoietin; *Notch/Delta4*, Notch receptor/Delta4 ligand; *PC*, pericyte; *PDGF-β*, platelet-derived growth factor β; *PDGFR-β*, PDGF receptor β; *Robo/Slit*, roundabout receptor/slit ligand; *TGF-β*, transforming growth factor-β; *Tie2/Tek* and *Tie1*, Tie family of endothelial receptor tyrosine kinases. *(Adapted from Risau W. Mechanisms of angiogenesis.* Nature. *1997;386:671-674).*

passing through an intermediate plexus phase.[7] These vessels undergo subsequent remodeling and ultimately connect to the extra-embryonic yolk sac vessels to form a mature vascular system. Interestingly, vascular development is also intimately associated with the development of hematopoietic cell lineages, as *hematopoietic stem cells* (HSCs) have been shown to arise from the *hemogenic endothelium*, which comprises Runx-1 expressing ECs restricted to the ventral portion of the developing dorsal aorta (see Figure 17-1).[8]

The vessels of the parallel *lymphatic* system collect and return interstitial fluids, particulates, and extravasated cells to the venous circulation. Lymphatic vessels differ from blood vessels in that lymphatic capillaries have internal membranous valves that prevent fluid backflow, and they are generally not surrounded by support cells.[9] Lymphatic ECs are derived from primitive veins and express and respond to a different spectrum of receptors and signaling molecules than ECs in blood vessels (Ref. 9, and see later discussion). The ability of cancer cells to invade lymphatics and collect in lymph nodes, complex organs involved in local immune surveillance, is an important indicator of tumor metastasis. It is likely that the lymphatic vessels at the periphery of a solid tumor are most directly involved in metastasis, as interstitial pressure within the tumor often leads to vessel collapse.[5,9] Recent evidence supports the idea that lymphatic ECs may secrete chemokines that attract tumor cells and may therefore participate more actively in metastasis than was previously recognized.[10]

In adult humans and mice, there is little regular angiogenic activity, with the notable exception of the female reproductive system. Localized angiogenesis is, however, an important aspect of normal wound healing, and *inflammatory cells* including macrophages, neutrophils, and mast cells, as well as activated resident fibroblasts, are an important source of angiogenic modulators during wound repair. Recently, it was shown that macrophages directly bind angiogenic ECs and promote the formation of anastomoses between them.[11] On remodeling and fusion with the surrounding vasculature, these new vessels restore normal blood supply to the wounded area. These infiltrating stromal cells also represent an important component of many solid tumors, where they can produce angiogenic factors as part of what may be considered an aberrant wound healing response, leading to the idea that tumors represent "wounds that never heal."[12] Genetic experiments using multiple murine cancer models have established that tumor-associated macrophages play a critical role in driving tumor angiogenesis and metastasis.[12]

Rapid growth of any tissue (embryos, neoplasias, adipose tissue, regenerating liver, etc.) invariably requires a supply of oxygen, nutrients, and hormones and is typically accompanied by active angiogenesis. Consequently, angiogenesis can be seen as a genetically programmed, dynamic process that can be activated locally in response to stimulatory signals. The fact that most blood vessels in the adult body are quiescent has been proposed as an advantage of anti-angiogenic strategies, which typically target actively dividing ECs, as these drugs may be less generally toxic to quiescent ECs lining established vessels.

Tumor Vasculature

The blood vessels found in solid tumors are notable for being highly disorganized compared to those of normal organs and are characterized by tortuous and misshapen vessels that sometimes terminate in open-ended blood lakes[5,13] (Figure 17-3). These aberrant vessels are thought to result from dysregulated angiogenic signaling in the tumor bed, as a result

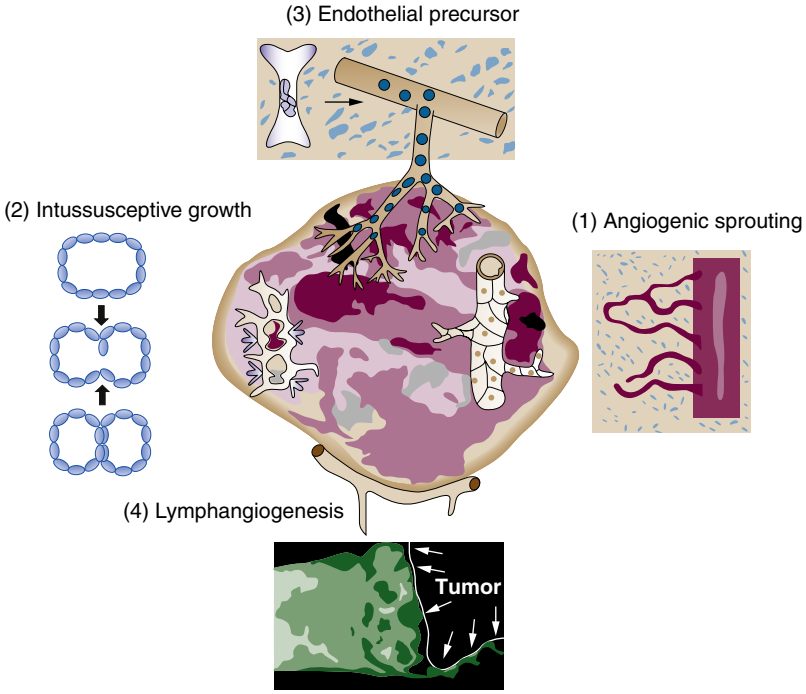

Figure 17-2 Cellular mechanisms of tumor angiogenesis Tumor vessels grow by multiple mechanisms, some of which are formally similar to those observed in normal vascular development: (1) budding of endothelial sprouts and formation of bridges (angiogenesis) and (2) insertion of interstitial tissue columns into the lumen of preexisting vessels (intussusception). In contrast to normal vascular development, the signaling events controlling these events are often highly disordered, resulting in chaotic vascular organization, uneven blood flow, and localized hypoxia. In addition, endothelial cell precursors home to tumors from the bone marrow or peripheral blood (3) where they can contribute, either directly or indirectly, to the endothelial lining of tumor vessels. Lymphatic vessels (4) around tumors drain interstitial fluid and also provide a gateway for metastasizing tumor cells. *(Reproduced from Carmeliet P, Jain RK. Angiogenesis in cancer and other diseases.* Nature. *2000;407:249-257).*

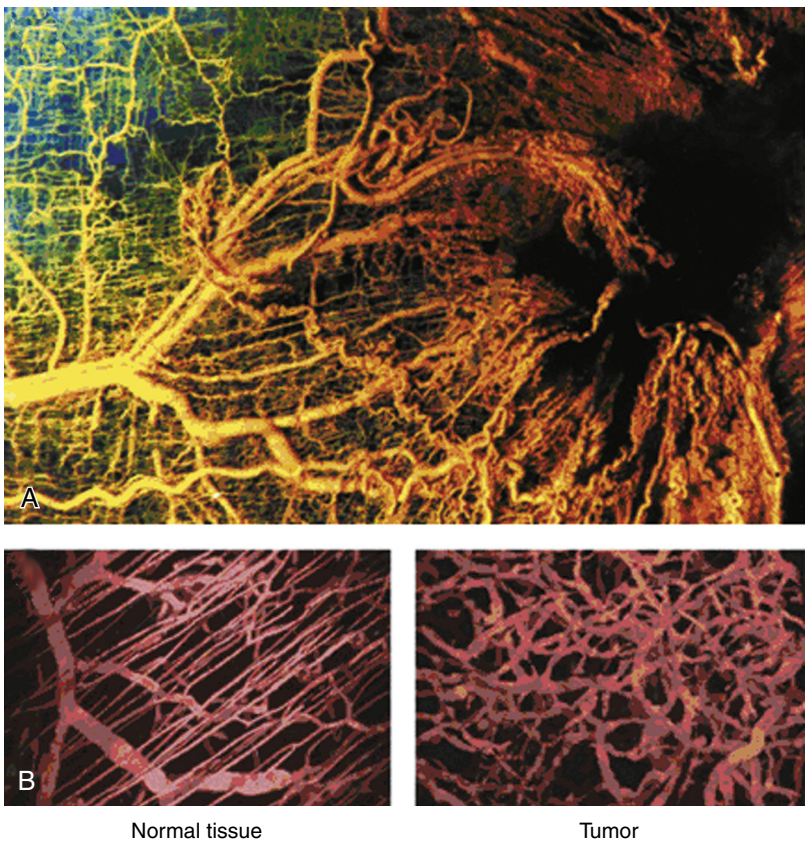

Figure 17-3 The highly disorganized nature of tumor vasculature can be visualized by generating a polymer cast before fixation **(A)** or using intravital imaging techniques that reveal functional vessels in live tissues **(B)**. As opposed to the clearly ordered arrangement of vessels in normal tissue, the chaotic nature of tumor vessels reflects the disrupted balance of pro- and anti-angiogenic factors generated by tumor and stromal cells. *(Reproduced from Weinberg RA.* The Biology of Cancer. *New York, NY: Garland Science; 2007:562).*

of oncogene activation and tumor suppressor loss. Microscopic analysis of tumor vessels reveals disrupted junctions between tumor ECs and reduced or inconsistent coverage by pericytes, which helps explain the increased permeability characteristic of tumor vessels.[14] The origin of some tumor ECs is also controversial: In addition to ECs recruited through sprouting of preexisting vessels, growing evidence supports a role of circulating endothelial progenitor cells (EPCs) that either differentiate into endothelial-like cells or promote expansion of bona fide ECs (see Figure 17-2). The precise cellular origins and complexity of these cells remain controversial, and the degree to which murine EPCs actually contribute directly to the lining of new tumor vessels varies considerably, depending on the model used, genetic background, and other factors.[15,16] In addition, bone marrow–derived myeloid cells contribute to tumor angiogenesis; these cells have been reported to express a variety of cell surface markers, including those common to endothelial cells (Tie-2) and myeloid cells (CD11b, Gr-1), and may function by providing paracrine angiogenic signals.[17,18] It is interesting to note that genetic ablation of bone marrow–derived Tie-2 expressing monocytes (TEMs), in particular, has profound effects on tumor angiogenesis in mice (see Refs. 19 and 20, and references therein).

Tumors often display sluggish, uneven, and highly variable patterns of blood flow,[13] as well as direct arteriole-venule shunts.[21] Tumor vessels also differ from normal vasculature in being exposed to an acidic microenvironment characterized by oxygen and nutrient deprivation. In rapidly growing tumors, aberrant angiogenic regulation and high interstitial pressure can produce regions of localized anoxia and/or ischemia. This typically results in pockets of necrosis surrounded by a penumbra of hypoxic but living cells. Severely hypoxic conditions are thought to protect tumor cells from radiation therapy, which depends on the generation of reactive oxygen intermediates to kill tumor cells. Moreover, hypoxic regions in tumors appear to select for highly malignant cancer cells.[22] In particular, hypoxia directly promotes angiogenic signaling in tumors, as discussed in more detail later.[23]

The degree to which tumors generate vascular beds is often expressed as *microvessel*, or *mean vessel*, *density (MVD)*, which can vary widely within a given tumor and between tumors of similar or different tissues. MVD is traditionally determined by staining tumor sections with antibodies raised against proteins expressed on ECs, including CD31 (PECAM), CD34, and von Willebrand factor. Clinical studies have demonstrated that MVD is a useful prognostic indicator for a wide array of cancers, including breast, prostate, non–small-cell lung, gastrointestinal, and even hematological tumors.[24] It is important to note, however, that not all tumor vessels are functional and that MVD may greatly exceed the basic metabolic requirements of a growing tumor. The striking functional heterogeneity of vessels within a tumor, and the ability of many cancer cells to withstand severe hypoxia, glucose deprivation, and tissue acidity, makes it difficult to assess the effects of angiogenesis-based therapies based solely on MVD.[24]

Critical Signaling Factors—Targets for Therapy

Over the past 15 years, work from many laboratories has demonstrated that vascular development in normal tissues is under elaborate genetic and molecular control. Many of the signaling molecules that regulate normal developmental angiogenesis have also been shown to drive angiogenesis in cancer and other pathophysiological conditions, although their expression and function in tumors are often highly uncoordinated. A growing list of molecules has been shown to regulate different aspects of developmental and pathological angiogenesis. Primary among these is the family of vascular endothelial growth factors (*VEGF*s) that, along with their receptors, regulate endothelial cell proliferation, survival, and function. The vascular-specific *angiopoietins* and their receptor tyrosine kinases also play important roles in angiogenic remodeling. In addition, vascular development is regulated by signaling pathways familiar from other developmental processes, including fibroblast growth factors (in particular, basic or *bFGF*), transforming growth factor beta *(TGF-β)*, *Notch* and its ligand Delta-like ligand 4 *(Dll4)*, and platelet-derived growth factor *(PDGF)*. In addition, a number of molecules originally implicated in controlling axon guidance, including the *semaphorins*, *netrins*, and *Robo/slit*, have been shown to contribute to vascular development.[7,25] Finally, the Notch pathway, along with the *EphB4/ephrinB2* signaling system, has been shown to control specification of arteries and veins (see Refs. 7 and 25, and references therein). Our understanding of the mechanisms by which these genes and pathways regulate angiogenesis is based largely on genetic "knockout" experiments in mice, often confirmed by in vitro cell-based assays or in experimental tumors. How this complex array of signaling pathways is coordinated to regulate angiogenic events in normal organogenesis and disease is a focus of intensive research. The discovery of endogenous angiogenic inhibitors, including *thrombospondin-1*, *endostatin*, *tumstatin*, and others, provided strong support for the idea that angiogenesis regulated by the balance between pro- and anti-angiogenic factors.[26] In this section, we discuss the molecular biology and function of a small subset of pro-angiogenic and anti-angiogenic factors that show particular promise as targets for cancer therapies.

Pro-angiogenic Factors

VEGF

Vascular endothelial growth factor (also known as *VEGF-A*) is among the most potent angiogenic factors described and stimulates EC proliferation, survival, chemotaxis, and vessel permeability. VEGF belongs to a family of structurally related growth factors that includes placental growth factor (PlGF), VEGF-B, VEGF-C, and VEGF-D. VEGF is a homodimeric glycoprotein of 45 kDa and is expressed in four different molecular-weight forms—VEGF-121, VEGF-165, VEGF-189, and VEGF-206—produced by differential mRNA splicing. VEGF-121 is diffusible, whereas the other forms bind to heparin and heparin proteoglycans in the extracellular matrix (ECM) and on cell surfaces. These bound forms are released through the action of proteases, including plasmin and matrix metalloproteases (MMPs), which are produced by tumor cells and/or by activated stromal cells. Interestingly, VEGF was first identified as vascular permeability factor (VPF) based on its ability to increase the leakage of fluid and plasma proteins from blood vessels (see Refs. 1, 5, 14, and 27 for details). These leaked proteins provide an ECM for migrating ECs, and their release into interstitial spaces represents an early step in angiogenesis. The central importance of VEGF in regulating angiogenesis became clear through genetic targeting experiments in mice. Loss of only one *Vegf* allele resulted in lethality at embryonic day 9.5 (E9.5), characterized by a reduction in ECs and abnormal vessel morphology.[28,29] Embryos lacking both *Vegf* alleles died even earlier (E8.5) and displayed a complete absence of the dorsal aorta and other vascular structures.

VEGF mediates its effects by binding its cognate receptor tyrosine kinases, VEGFR1 (also called Flt-1) and VEGFR-2 (also called Flk-1 or KDR). Binding of VEGF to VEGFR-2/Flk-1 triggers receptor autophosphorylation and robustly activates several downstream signaling pathways (including phosphoinositide 3-kinase [PI3K], Src, and protein kinase C [PKC]), leading to rapid and profound effects on EC proliferation, survival, migration and gene expression.[7,30] Genetic ablation of Flk-1 in mice caused embryonic lethality at E8.5 that correlated with a loss of normal vascular structures and hematopoietic cells, consistent with the bipotential fate of *hemogenic endothelial* cells.[8,31] Subsequent studies have confirmed the importance of VEGF and VEGFR-2/Flk-1 in hematopoietic development (Ref. 7 and references therein). Although VEGFR-1/Flt-1 also binds VEGF, its major angiogenic function may be to modulate the amount of VEGF available to bind to VEGFR-2/Flk-1.[14] Deletion of the gene encoding murine VEGFR-1/Flt-1 resulted in embryonic lethality; however, this lethality was rescued by transgenic expression of a truncated VEGFR-1/Flt-1 protein that lacked its cytoplasmic signaling domain. Although these results argue strongly that VEGFR-1/Flt-1 acts as a nonsignaling sink for free VEGF, subsequent studies indicate that it can, in fact, modulate pathophysiological angiogenesis, possibly by intermolecular phosphorylation of VEGFR-2/Flk-1.[9] Neuropilins 1 and 2 can also act as a sink for VEGF and appear to function, at least in part, by presenting VEGF to VEGFR-2/Flk-1 or by modulating its effective free concentration.[32]

The central role of VEGF signaling in tumor angiogenesis has been clearly demonstrated in a wide variety of experimental models, including VEGF overexpression in tumor or host cells, treatment with recombinant VEGF, increased VEGF expression in response to oncogene activation, or inhibition by antisense VEGF oligonucleotides or anti-VEGF antibodies.[1,25] Furthermore, many oncoproteins (including KRAS, HER2, FOS, and TRKB), tumor suppressor proteins (including pVHL and p53), and growth factors (including PDGF, bFGF, and TGF-β) regulate angiogenesis, partly by inducing the expression of VEGF either directly or indirectly.[25]

The *von Hippel–Lindau* (pVHL) tumor suppressor is a particularly interesting case in point. Patients with VHL disease, a hereditary cancer syndrome, develop a variety of tumor types including highly vascularized renal clear cell carcinomas, cerebral hemangioblastomas, and retinal hemangiomas. The pVHL protein functions as an E3 ubiquitin ligase that targets the *hypoxia inducible factor (HIF)* subunits HIF-1α and HIF-2α for oxygen-dependent degradation via the 26S proteasome.[33] HIF-1α and HIF-2α play a predominant role in hypoxic responses,[34] and their activity is controlled in a similar oxygen-dependent fashion. Both proteins regulate the expression of target genes that mediate adaptive responses to hypoxic stress, including those encoding VEGF and many other angiogenic factors[23,35] (see Figures 17-3 and 17-4). When pVHL expression or function is lost, cells can no longer degrade the HIF-α subunits under conditions of abundant oxygen, leading to constitutive expression of VEGF and other HIF target genes, thereby promoting tumor angiogenesis (Figure 17-5). Both HIF-α subunits are often overexpressed in cancer cells as a consequence of oncogene activation, tumor suppressor loss, or tumor hypoxia. The close spatial overlap between HIF-α protein accumulation and VEGF expression in hypoxic tumor cells is a further indication that HIF-dependent VEGF expression is an important aspect of tumor angiogenesis (see Figure 17-3).

Both HIF-1α and HIF-2α bind to the *Vegf* gene promoter and can activate VEGF expression independently; hence, deletion of either subunit has relatively subtle effects on embryonic VEGF expression, despite the fact that both mutations are embryonically lethal.[23,36-38] Targeted deletion of the common binding partner (HIF-1β or ARNT), however, resulted in early embryonic lethality with substantial

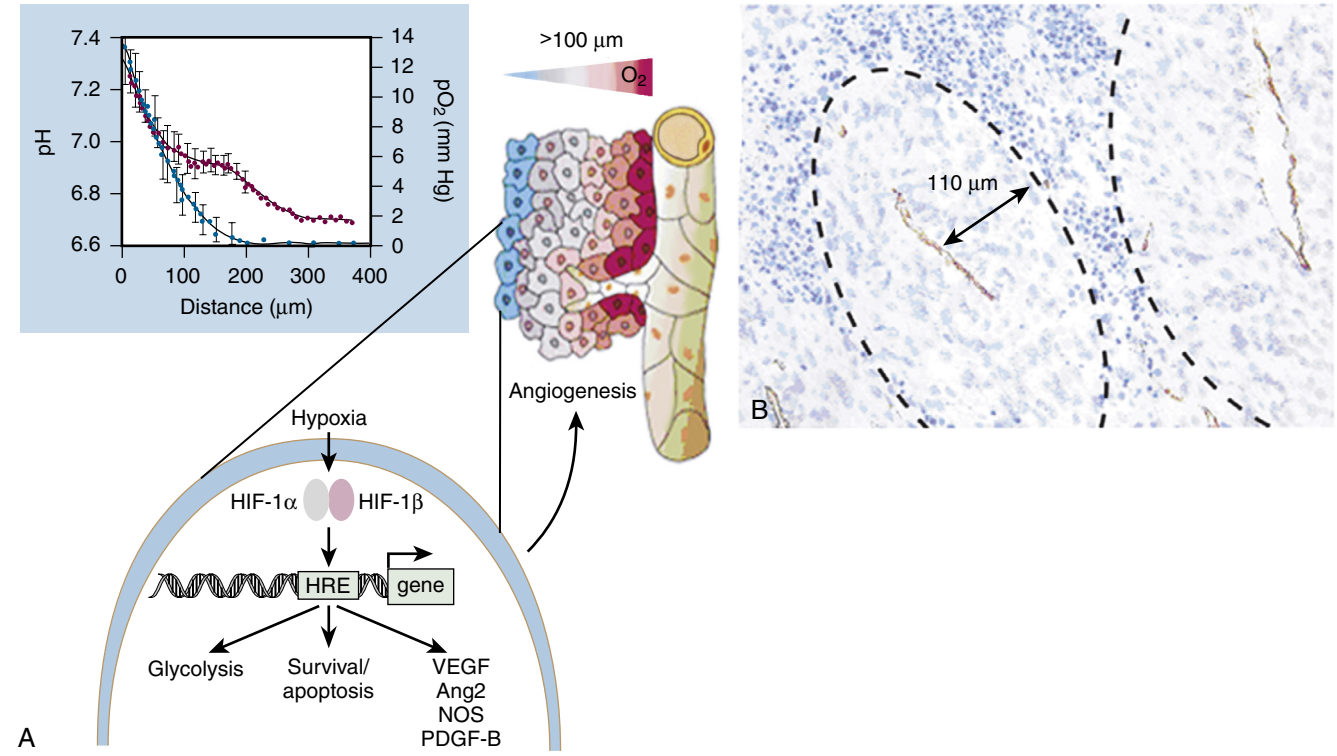

Figure 17-4 **(A)** Because of the irregular pattern and organization of the tumor vasculature, some cells in tumors are located more than 100 m (the diffusion limit for oxygen) away from blood vessels and become hypoxic (red-to-blue gradient indicates progressive hypoxia). Tumor cells survive fluctuations in oxygen tensions, in part because clones are selected in hypoxic tumors that switch to a pro-angiogenic phenotype. HIFs increase transcription of several angiogenic genes (for example, genes encoding VEGF, PDGF-BB, and nitric oxide synthase [NOS]). HIFs also affect cellular survival/apoptosis pathways. *Inset:* Relationship between the distance of tumor cells from nearby vessels and their degree of hypoxia (*blue* symbols) and acidosis (*red* symbols). *(Reproduced from Carmeliet P, Jain RK. Angiogenesis in cancer and other diseases.* Nature. *2000;407:249-257).* **(B)** Section of rat prostatic carcinoma in which vessels were identified by CD31 immunostaining. loss of VEGF expression[39] associated with fundamental defects in angiogenesis.[40] The close link between the HIFs and VEGF expression in tumors has prompted the design of specific HIF inhibitors, partly to limit expression of VEGF and other hypoxically induced angiogenic factors in cancer and other diseases.[41,42]

Each of the several VEGF homologs in mammals (VEGF-B, VEGF-C, VEGF-D, and PlGF) has distinct influences on angiogenesis and binds to one or more of the family of VEGF receptors. VEGF-C and VEGF-D regulate lymphangiogenesis through their effects on VEGFR-3/Flt-3, which is expressed on lymphatic ECs.[9] PlGF binds to both VEGFR-1/Flt-1 and the neuropilins, displacing VEGF and thereby making it available for binding to VEGFR-2.[32] Some data, however, suggest that heterodimers of PlGF and VEGF may be more potent in some contexts than the more typical VEGF homodimer.[14] Much work remains to be done to tease apart the unique and overlapping functions of the various VEGF homologs and their receptors.

bFGF

Basic FGF (bFGF or FGF2) is one of more than 20 known fibroblast growth factors that mediate a large number of developmental and homeostatic functions in different tissues. bFGF was identified biochemically in a search for angiogenic molecules released by tumor cells. When added to tissues exogenously or overexpressed in transplanted tumor cells, bFGF has potent angiogenic properties.[43] Like VEGF, bFGF binds to extracellular heparan sulfate proteoglycans and activates cognate receptor tyrosine kinases. Interestingly, loss-of-function studies have failed to reveal an inherent role of bFGF in embryonic angiogenesis, although this may be due to functional complementation by other FGF family members. As many of the angiogenic properties of bFGF appear to require VEGF function, however, one important role of bFGF in tumor angiogenesis may be to induce VEGF expression.[43] The situation is almost certainly more complex, because VEGF and bFGF act synergistically in some contexts but clearly have independent effects on ECs in others. The emerging picture suggests that bFGF and many other angiogenic factors act as general growth and survival factors for ECs partly by regulating VEGF expression, whereas VEGF itself may preferentially stimulate many of the cellular processes that lead to new vessel formation.

Angiopoietins/Tie Receptors

In addition to VEGF and FGF receptors, ECs express the Tie1 and Tie2/Tek receptor tyrosine kinases. Genetic ablation of either Tie1 or Tie2 in mice produced embryos in which vasculogenesis was intact, but subsequent angiogenic remodeling was inhibited. Soluble forms of these receptors were used to identify endogenous ligands, called *angiopoietins* (Ang1-4) (reviewed in Ref. 44). Deletion of Ang1 produced a phenotype similar to loss of Tie2, supporting a role for Ang1 as an important activator of Tie2 signaling. Interestingly, Ang2 also binds to Tie2 with high affinity but does not stimulate Tie2 tyrosine phosphorylation or downstream signaling. Transgenic overexpression of Ang2 produced a phenotype similar to that associated with loss of Ang1 or Tie2, suggesting that Ang2 may be a naturally occurring inhibitor of Ang1 signaling. The role of Ang2 became clearer when it was found to be induced in concert with VEGF at sites of vascular remodeling. Several studies have suggested a model in which Ang2 interferes with the stabilizing effects of Ang1 (such as increased pericyte and smooth muscle recruitment), thereby allowing VEGF to stimulate EC division and migration more efficiently. The roles of Ang3 and Ang4 are less clear, and a cognate ligand for Tie1 has not yet been identified,[44] although Tie1 may act primarily as a repressor of Tie2 signaling.[45]

PDGF

Maturation and maintenance of the vascular system require the establishment of a close functional relationship between ECs and pericytes (PCs). ECs undergoing active division and morphogenesis express PDGF-B, and PCs express the corresponding receptor PDGFRβ. Genetic ablation of either ligand or receptor in mice disrupts PC recruitment, resulting in leaky, malformed blood vessels and increased EC apoptosis.[46] Bergers and colleagues identified a population of c-Kit+, Sca-1+ bone marrow–derived progenitor cells that are recruited to perivascular sites in tumors, where they differentiate into PCs and stabilize the tumor vessels in a PDGFRβ-dependent manner.[47] Overexpression of PDGF promoted recruitment of PCs and tumor vessel stabilization, whereas inhibition of PDGF signaling reduced PC recruitment with a concomitant increase in EC apoptosis.[25] Consequently, a combination of therapies that target both tumor ECs and PCs may prove to be a particularly effective approach.[25,48]

Anti-angiogenic Factors

In his landmark 1971 paper, Judah Folkman not only proposed that tumor growth depends on angiogenesis, but also suggested that endogenous angiogenic inhibitors could be identified and used therapeutically.[4] Intensive efforts over the subsequent three decades have led to the identification of more than 30 endogenous inhibitors whose application can block angiogenesis in a variety of assays and genetic models.[49,50] These naturally occurring compounds include proteolytic cleavage products of extracellular matrix proteins (thrombospondin, endostatin, tumstatin), the protease

plasminogen (angiostatin), and clotting factors (cleaved antithrombin III and prothrombin kringle-2), as well as immune modulators such as interferons and interleukins.[49] The specific function of each of these compounds in tumor angiogenesis, and their possible utility as therapies for cancer treatment, continues to be an area of active investigation.

Thrombospondin 1 (TSP-1)

Initially identified as an extracellular glycoprotein with cell-adhesive properties, TSP-1 binds to integrin and nonintegrin cellular receptors, cytokines, growth factors, and extracellular proteases. TSP-1 is thought to act as a molecular scaffold that facilitates interactions between proteins that regulate cell morphology, signaling, and adhesion, possibly by promoting receptor clustering.[51] In 1990, Bouck, Polverini, and colleagues described the strong anti-angiogenic activity of a TSP-1 proteolytic fragment.[52] Targeted deletion of TSP-1 in mice increased tumor angiogenesis and growth, and subsequent reports confirm the inability of TSP-1 mutant mice to mount a normal angiogenic response in other assays.[53] The *Tsp-1* gene has been shown to be a direct target of the p53 tumor suppressor, and TSP-1 expression has been inversely correlated with the progression of carcinomas and melanoma in humans.[49] The molecular mechanisms by which TSP-1 blocks angiogenesis are likely to be complex, but may include integrin inhibition, interference with VEGF and bFGF signaling, and/or induced expression of the pro-apoptotic FasL protein on ECs.[49] The identification of the gene encoding TSP-1 as a direct p53 target suggests yet another mechanism whereby p53 inactivation can promote tumor progression.

Endostatin and Tumstatin

Both endostatin and tumstatin are proteolytic cleavage fragments derived from collagen molecules. Endostatin was initially purified from a murine hemangioendothelioma cell line and identified as a 20-kDa carboxy-terminal fragment of type XVIII collagen. Recombinant endostatin has multiple anti-angiogenic properties, including the ability to interfere with VEGF and bFGF signaling, inhibit EC motility, and induce EC cell cycle arrest and apoptosis.[49] Endostatin appears to mediate these pleiotropic effects by binding EC integrins, including α5β1, αVβ3, and αVβ1. Tumstatin consists of a 28-kDa fragment of the α3 chain of type IV collagen, promotes EC apoptosis, and suppresses the growth of various human tumor cells in xenograft experiments. Similar to endostatin, tumstatin binds to integrins and thereby inhibits activation of downstream signaling pathways.[49,50] Despite their similarities, endostatin and tumstatin peptides share little sequence identity and can clearly mediate independent functions: For example, endostatin inhibits EC migration with little effect on VEGF-induced proliferation, whereas tumstatin inhibits EC proliferation without significantly affecting migration.

It is interesting to note that many endogenous angiogenesis inhibitors are generated by proteolytic degradation of ECM proteins, or from proteins involved in blood clotting, and that many bind directly to integrin receptors. Growing evidence supports the notion that these compounds play an important role in fine-tuning the angiogenic response that accompanies thrombosis and tissue repair.[54] The production of these endogenous angiogenesis inhibitors may also help explain tumor dormancy, as first proposed by Folkman in 1971. Control of local angiogenic activity in a tumor is thought to be determined by the balance of pro-angiogenic factors (VEGF, angiopoietin 1, bFGF, etc.) and angiogenesis inhibitors (TSP-1, endostatin, tumstatin, etc.). Consequently, it may take months or years to generate the proper genetic and physiological conditions necessary to tip the balance to favor active blood vessel development and tumor growth—an event called the *angiogenic switch*.[55]

Multiple lines of evidence from preclinical models, as well as patient data, support the role of an angiogenic switch in regulating tumor growth. For example, several murine genetic models have shown that tumors generated by transgenic expression of oncogenes initially remain small, with tumor cell proliferation largely offset by apoptosis. After a period of relative stasis, the tumors begin to show evidence of increased vascularity, after which they grow rapidly.[55] The synthesis of angiogenesis inhibitors by a primary tumor may also keep distant metastases from progressing, as removal of a large primary tumor often correlates with the rapid outgrowth of previously unidentified metastatic tumors in patients.[4,50] It has also been suggested that bone marrow–derived EPCs may play an important role in controlling this event and may regulate a critical step in the progression of micrometastases into macrometastases.[16] Collectively, a growing body of data suggests that manipulating the angiogenic switch can control tumor growth; this has prompted the development of clinically relevant angiogenesis inhibitors as cancer therapies.

Targeting Tumor Angiogenesis in Patients

Over the past 15 years, a large number of clinical trials have been conducted to test the efficacy of anti-angiogenic compounds in cancer therapy. Early results, however, were mixed: For example, early trials of endostatin and other compounds that showed promise in preclinical models yielded disappointing results in the clinic,[56,57] although exceptions included a trial showing positive effects of angiostatin in

treating non–small-cell lung cancer when combined with cytotoxic chemotherapy.[58] Some possible reasons for the apparent discrepancies between dramatic results in preclinical models and actual patient responses are discussed next. Despite this somewhat rocky beginning, a number of targeted therapies have shown clinical benefit and have attained approval from the U.S. FDA and the EMA (European Medicines Agency) for treating cancer. In particular, the prominent role of VEGF in tumor angiogenesis made it an obvious therapeutic target, and multiple drugs have been developed that either sequester free VEGF (reducing its effective concentration) or block VEGFR-dependent signaling. The large number of preclinical and clinical studies on drugs directed against VEGF signaling provides an instructive paradigm for the potential successes and shortcomings of other anti-angiogenic strategies to treat cancer.

VEGF-Based Therapies

In 1993, Ferrara and colleagues reported that a murine anti-human VEGF monoclonal antibody could inhibit the growth of different human tumor cell lines in immunocompromised mice, although the antibody had no effect on tumor cell proliferation in vitro.[59] Subsequent analysis revealed that the antibody blocked angiogenic activity in these xenografts, and this led to the development of a humanized version of the antibody, called *bevacizumab* or *Avastin*, for human clinical trials. In 2003, results from two clinical trials of bevacizumab function generated tremendous excitement in the field. In one phase III trial, patients with advanced metastatic colorectal cancer were treated with bevacizumab in conjunction with cytotoxic chemotherapy[60] and displayed an average increase in *overall survival (OS)* of approximately 4 months (from 16 to 20). Although this response seems modest, it was the first indication that specific targeting of VEGF in highly metastatic human cancer could have a survival benefit. In a separate phase II trial, patients with metastatic renal cancer showed a significant, dose-dependent increase in *progression-free survival (PFS)* when treated with bevacizumab compared to placebo.[61] Interestingly, an Fab fragment of bevacizumab (marketed as Lucentis) has shown great success in treating patients with the angiogenic, or "wet," form of age-related macular degeneration.[62]

Since garnering FDA approval as a first-line treatment (along with standard chemotherapy) for metastatic colorectal cancer in 2003, bevacizumab has been subjected to more than 400 different clinical trials in a broad array of cancer types. The FDA approved bevacizumab for treating advanced non-squamous non–small-cell lung cancer (NSCLC) in 2006, metastatic breast cancer in 2008, and metastatic renal cancer and recurrent gliobastoma multiforme in 2009. In each case, increases in PFS were observed, although improved OS was reported in only some cases (e.g., NSCLC patients had increased OS by 2 to 4 months[63]). In 2011, the FDA withdrew its approval for bevacizumab in treating metastatic breast cancer, citing the absence of an OS benefit, and the UK also rejected bevacizumab for this purpose in 2012.

What explains the relatively short-lived responses observed in the clinic, given that bevacizumab clearly increases PFS in multiple cancers, and diverse preclinical models have shown that this activity correlates with predicted reductions in MVD and perfusion? Compensatory signaling through alternative pro-angiogenic pathways (e.g., bFGF) is likely a major factor in acquired resistance to bevacizumab and disease progression, as observed for other selectively targeted therapies. It has also been proposed that decreased perfusion increases tumor hypoxia, which then promotes tumor cell invasion and metastasis promoted in part by HIF activation. Recently, two groups reported increased tumor cell invasiveness and metastasis in independent murine cancer models when mice were treated with a variety of different anti-VEGF therapies.[64,65] Although these results suggest that anti-angiogenics may ultimately drive hypoxic tumor progression, they remain controversial.[35] It is also possible that recruitment of pro-angiogenic EPCs and bone marrow–derived myeloid cells to tumors could help tumors overcome anti-VEGF therapy.[66] In a similar vein, the demonstration that elevated tumor hypoxia can select for the emergence of more malignant tumor cell clones is potentially worrisome.

The relatively short-term improvements attained with bevacizumab and other anti-VEGF therapies may reflect the aggressive and advanced nature of the tumors treated in most clinical trials and suggests that effects on earlier stage tumors might be more dramatic. Surprisingly, a recent randomized phase III trial on patients with stage II and III colon cancer demonstrated no benefit when bevacizumab was added to the standard FOLFOX chemotherapy regimen.[67,68] These data suggest that bevacizumab (and possibly other anti-angiogenic compounds) may not prove helpful in treating early-stage disease, although this needs to be tested directly in multiple tumor types.

Although substantial evidence from preclinical models indicates that bevacizumab blocks tumor angiogenesis, Jain and colleagues have proposed an alternative model in which bevacizumab (and other anti-angiogenic therapies) may actually "normalize" highly aberrant tumor vasculature by restoring the local balance of pro- and anti-angiogenic signaling.[69] Vessel normalization would therefore be predicted to improve overall perfusion and consequent delivery of chemotherapeutic compounds. This model is consistent with the observation that anti-angiogenic therapies are generally not effective as single agents but function best when combined with standard-of-care chemotherapy. If true, it also raises the

specter that anti-angiogenic therapy could paradoxically provide a tumor with a more functional vasculature, ultimately promoting its growth. Recently, however, Van der Velt and colleagues measured perfusion and delivery of radiolabeled chemotherapeutic agents to tumors in NSCLC patients directly and found no evidence that bevacizumab promoted vessel normalization in this setting.[70] In contrast, bevacizumab treatment rapidly decreased tumor perfusion and infiltration of ^{11}C-docetaxel, effects that were maintained for several days posttreatment. Although a preliminary study with only 10 patients, these data argue strongly for similar direct measurement of perfusion and drug delivery in distinct tumor types, as vessel normalization could still be an important phenomenon in other settings.

We have thus far focused primarily on bevacizumab, as it is the most well-studied anti-VEGF therapy in clinical use to date, but there are many other VEGF-related drugs currently in clinical trials. These include small-molecule kinase inhibitors such as *sorafenib* (Bayer-43-0009, Nexavar), originally designed as a Raf kinase inhibitor. Sorafenib also binds and inhibits VEGFR-2/Flk-1, VEGFR-3/Flt-3, and PDGFRβ and was approved by the FDA for treating renal cancer in 2006 and hepatocellular carcinoma in 2007. Another small-molecule kinase inhibitor, *sunitinib* (Sugen11248), that inhibits all three VEGF receptors, c-Kit, and PDGFRβ was approved for treating renal cancer and imatinib-resistant gastrointestinal stromal tumors (GISTs) in 2006. Given the broad substrate specificity of both drugs, however, the degree to which their anti-angiogenic activity underlies clinical effectiveness is not entirely clear. In addition, multiple VEGF-related therapies developed over the past decade, including small-molecule kinase inhibitors and monoclonal antibodies, are in clinical trials for cancer treatment. Similar drugs targeted toward distinct angiogenic signaling pathways are also under development as cancer therapies and will be the focus of additional preclinical and clinical investigation in the coming years.

Metronomic Therapy

Traditional chemotherapy regimens are based on treating patients with drugs at the *MTD* (maximum tolerated dose), typically followed by a break period to allow recovery from the toxic and myelosuppressive effects of the chemotherapeutic agent. MTD chemotherapy typically causes a significant decrease in the number of circulating hematopoietic cells, including neutrophils and other myeloid cells, as well as EPCs. These drops can be quite precipitous and are usually followed by a rapid "rebound" period in which circulating progenitors are mobilized from the bone marrow, a response observed both in mice and in humans. One potentially unfortunate consequence of this response is the increase in EPCs, which, along with recruitment of bone marrow–derived myeloid cells, such as TEMs, could contribute directly or indirectly to tumor angiogenesis (Ref. 71 and references therein). The breaks in MTD regimens may therefore allow repair or expansion of the tumor vasculature and reduce cytotoxic benefit. Although the precise nature and function of EPCs and their differentiated progeny cells remain controversial, there is evidence that VEGF and other angiogenic factors stimulate their release from the bone marrow.[17] Therefore, the addition of anti-angiogenic drugs to standard chemotherapeutic treatments may suppress the ability of tumors to recruit EPCs and their progeny during the drug-free break periods between MTD treatments.

The reduction in drug-free breaks appears to have an additional inhibitory effect on tumor angiogenesis. In 2000, the effects on tumor growth in mice were greater when an MTD regimen was changed to one in which animals were treated with low doses of the same drug but at more frequent intervals.[72] Surprisingly, tumor growth was inhibited or reversed, despite the fact that (in some cases) the tumor cells were themselves resistant to the same cytotoxic drug. These results suggest that the chemotherapy was not only targeting the tumor cells but also inhibiting normal cells such as ECs or recruitment of EPCs. Subsequent work showed that regular, low-dose chemotherapy (also termed *metronomic* dosing) induced the expression of the angiogenic inhibitor TSP-1 in mice, and that genetic deletion of TSP-1 promoted tumor growth and angiogenesis in this model.[53] In fact, one might predict that normal ECs, which are neither transformed nor genetically unstable, would be more sensitive to the cytotoxic effects of chemotherapeutics than tumor cells. By treating patients with a sustained, low dose of the drug and avoiding the breaks inherent to MTD regimens, it is possible that EC recruitment to the tumor vasculature could be more uniformly suppressed, thereby limiting tumor growth.

Remaining Challenges

The clear success of anti-angiogenic therapies, tempered by the relatively short gains in OS, suggests that oncologists will have a new and growing arsenal of weapons to complement standard chemo- and radiation-based therapies in the future. As always, caution is necessary, as preclinical data have only rarely predicted the outcome of treatments in patients. One reason for this discrepancy is that many preclinical studies have continued to rely on xenograft models, in which a large number of highly malignant tumor cells are introduced subcutaneously into recipient mice. Although a quick and

reproducible approach, it is perhaps not surprising that events that are rate limiting for xenograft growth may have little to do with those controlling human cancer progression. Some anti-angiogenic compounds, such as endostatin, profoundly limited or regressed tumor growth in xenografts but failed to show any significant benefit in early clinical trials.[56,57] The development of genetically altered strains of mice that more closely mimic the development and histology of human cancers[73] may offer more predictive preclinical models for anti-angiogenic therapy.

It is increasingly clear that anti-angiogenic therapies are likely to be most effective when combined with other treatments, for the reasons elaborated earlier. Currently, however, it is essentially impossible to predict which specific combinations of drugs, and which specific delivery strategies, are likely to be effective in inhibiting angiogenesis for a given tumor type or in a given patient.[74] The largely encouraging clinical trial results argue for additional research to determine precisely how tumor and stromal cells respond to specific targeted anti-angiogenic therapies, as well as metronomic therapy. Equally important, protocols need to be developed to integrate anti-angiogenic approaches effectively with standard MTD chemotherapy and radiation therapy. Finally, tumors can develop resistance to specific angiogenesis inhibitors, either by altering the expression of multiple pro- and anti-angiogenic factors or by modulating the tumor stroma. A great deal more research will be necessary to establish even the most general guidelines, but the potential benefits of treating cancer patients with angiogenesis inhibitors are considerable. It is likely that our current understanding of tumor angiogenesis, and our ability to manipulate it clinically, will have once again altered greatly by the next edition of this book.

18 Invasion and Metastasis

In the written history of medicine, neoplasms have been diagnosed for nearly 4000 years. Almost from the beginning, medical practitioners recognized that the most life-threatening attribute of neoplastic cells is the ability to disseminate and colonize distant tissues. When tumors are diagnosed and have not spread beyond the tissue of origin, cure rates for most cancers approach 100%. However, when tumor cells have established colonies elsewhere, cancer is often incurable.

The process of converting a normal cell into a life-threatening metastatic cancer cell is referred to as tumor progression (Figure 18-1). As discussed in previous chapters, medicine has evolved toward a recognition that neoplasia is a cellular disease, and further advanced to understand the molecular underpinnings of the early stages of progression resulting in cancer development. It is now recognized that metastases represent a subset of cells that have left the primary tumor, which are behaviorally distinct from the cells remaining at the site of tumor origin, and the molecular mechanisms underlying the phenotypic differences that characterize a metastatic cell are being elucidated.

Generation of a Metastatic Cell

Metastasis is defined as the dissemination of neoplastic cells to discontiguous nearby or distant secondary sites where they proliferate to form a mass. But how did tumor cells acquire the ability to metastasize? The answer to this question requires examination of the mechanisms underlying how tumors arose and progressed toward increasingly aggressive behavior.

By the time a neoplasm is diagnosed, it comprises at least 10^9 cells. Yet, even cursory examination of a tumor histologically reveals that the cells are pleiomorphic. Furthermore, if one isolates single cell clones from a tumor, they vary dramatically in terms of biological behavior.

Tumor heterogeneity exists for virtually every phenotype measured.[1,2] There are three types of heterogeneity within a tumor: positional, temporal, and genetic. Positional heterogeneity is determined by the accessibility of a cell to external stimuli (e.g., oxygen [O_2] levels). For example, radiation sensitivity is proportional to oxygenation; therefore, two identical cells would exhibit differences in radioresponse depending on distance from a capillary. Temporal heterogeneity is relevant with regard to changes in cells due to cyclical signals. Cells in the G_0/G_1 phase of the cell cycle would be less sensitive than cells in the S phase to drugs targeting DNA replication. Genetic heterogeneity is the result of inherent properties of tumor cells themselves. Isolation of single-cell clones confirms that there are inherent differences between subpopulations comprising a single tumor mass.

The heterogeneity of tumors raises an important question regarding tumor origin: Are tumors of unicellular or multicellular origin? Tumors express maternal or paternal isoenzymes, but rarely both, strongly suggesting that they arose from a single cell. Analysis of karyotypes reveals that virtually all cells within a tumor share a common abnormal chromosomal change (e.g., all CML cells have t[9;22]). Additional karyotypic abnormalities may be superimposed on the shared ones. If tumors are monoclonal, how, then, does heterogeneity arise?

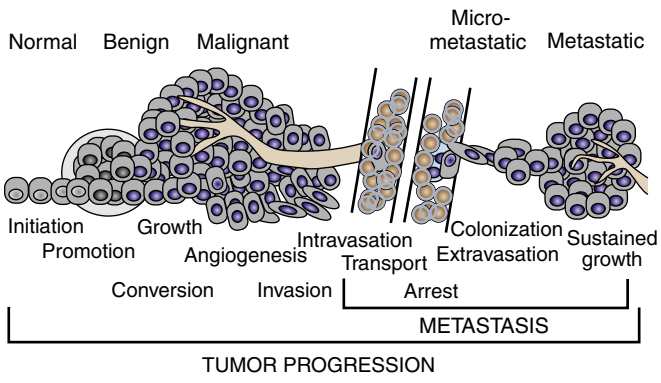

Figure 18-1 Tumor progression

The generation of heterogeneity requires divergence of single transformed cells into multiple phenotypically distinct progeny. The process appears to be fundamental to tumor progression, but it also occurs in normal physiology. For example, pluripotent hematopoietic stem cells can generate cells along multiple lineages, and a single fertilized egg yields a multicellular organism with organs and tissues. Although stem cell theory accommodates diversification, the molecular mechanisms underlying differentiation and diversification of both normal and cancer cells are still being elucidated (see Chapter 10). The journey of a metastatic cell is described in the next sections.

Tumor Invasion

Tumor invasion, the capacity for tumor cells to disrupt the basement membrane and penetrate underlying stroma, is the distinguishing feature of malignancy. Invasion requires major changes in cell morphology and phenotype, in particular for epithelial cells that represent the precursors to over 90% of human cancers. Normal epithelial cells form polarized sheets maintained by tight junctions, adherens junctions that organize the actin (microfilament) and tubulin (microtubule) cytoskeleton, and desmosomes attached to keratin-containing intermediate filaments. They are anchored to the basement membrane by hemidesmosomes and their associated intermediate filaments and integrin contacts that organize actin. Invasion requires alterations in cell-cell and cell-matrix adhesion, coordinated with matrix degradation and cellular motility (Figure 18-2).[5] The structural and regulatory proteins that control cell adhesion and migration are key downstream targets of oncogene and tumor suppressor-controlled signaling pathways, providing insights into how oncogenic transformation results in progression to an invasive phenotype. An interesting observation has been that many of the molecules implicated in tumor invasion also affect other processes involved in tumor progression, including cell survival, growth, apoptosis, and angiogenesis, highlighting the intricacy of the network of interrelated pathways that controls cellular behavior.[6]

Adhesion

Invasion of epithelial cell–derived carcinomas often involves dramatic changes in cell shape. Conversion from an epithelial morphology to a nonpolarized, motile, spindle-shaped cell resembling a fibroblast is referred to as the *epithelial-mesenchymal transition* (EMT).[7] EMT is characterized by the loss of epithelial-specific E-cadherin from the adherens junctions and a switch from the expression of keratins as the major intermediate filament to the mesenchymal intermediate-filament vimentin. EMT is not cancer specific; it is a normal process that occurs during embryonic development and wound healing. EMT is influenced by the tumor microenvironment and is observed primarily at the edge of the tumor in contact with tumor stroma. Soluble factors, in particular transforming growth factor-β and hepatocyte growth factor/scatter factor, are regulators of EMT. Tumor cells may reverse the process and undergo a mesenchymal-epithelial transition (MET) in the absence of EMT-inducing signals. The transient nature of EMT helps explain why metastatic cells can morphologically resemble cells in the primary tumor despite the fact that they by necessity have accomplished all the steps of the metastatic cascade.

Epithelial cell-cell interactions are mediated primarily by cadherins, transmembrane glycoproteins that form calcium-dependent homotypic complexes. The epithelial-specific cadherin, E-cadherin, functions as a tumor suppressor and a metastasis suppressor.[8] Loss of E-cadherin correlates with increased invasion and metastatic potential in most tumor types. Reexpression of E-cadherin in experimental models can block invasion, suggesting that E-cadherin loss is indeed causative. Loss of E-cadherin in cancer occurs through several mechanisms, including transcriptional repression and proteolytic degradation. The zinc finger transcriptional repressors Snail and Slug, in particular, have been implicated in regulating EMT by virtue of their ability to repress E-cadherin transcription. Cadherins are regulated by catenins (α-, β-, γ-, and p120 catenins), cytoplasmic proteins that functionally link the cadherin complex to the actin cytoskeleton. β-Catenin is a cell adhesion protein and a transcription factor. In addition to its role in adherens junctions, it participates in canonical Wnt signaling, a signaling

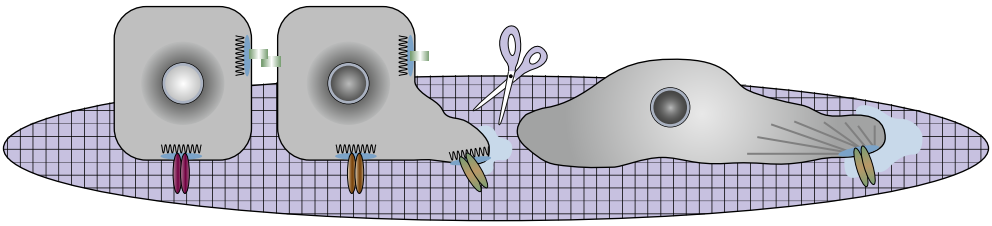

Figure 18-2 The steps of tumor invasion Tumor invasion involves the loss of cell-cell adhesions (cadherins represented by *green bars*), alterations in cell-matrix adhesion (integrins represented by *ovals*), proteolysis of the extracellular matrix (*blue matrix*, degradation demonstrated by clearing of matrix mediated by proteinases represented by scissors), and motility involving alterations in the actin cytoskeleton (*intracellular black* and *gray lines*).

pathway important in development and cancer. E-cadherin levels and function are also disrupted by loss of p120 catenin, which occurs in many tumor types and may also contribute to tumor metastasis.

Loss of function of cell-cell adhesion molecules other than E-cadherin is associated with the ability of tumor cells to invade and metastasize. Neural cell adhesion molecule (NCAM), a member of the immunoglobulin-like cell adhesion molecule Ig-CAM family, is downregulated in several tumor types, and NCAM loss results in an increased ability of tumor cells to disseminate.[8] Other Ig-CAMs, such as DCC (deleted in colorectal carcinoma), CEACAM1 (carcinoembryonic antigen CAM1), and Mel-CAM (melanoma-CAM), also demonstrate reduced expression in specific cancer types. However, not all cell-cell adhesion molecules can be viewed as potential invasion suppressors. N-cadherin promotes motility in some cell types, and Ig-CAMs such as L1, CEA (carcinoembryonic antigen), and ALCAM (activated leukocyte CAM) are often overexpressed in advanced cancers and have functions associated with cancer progression. This complexity may be explained by signaling functions for these molecules, either direct or indirect, that are distinct from their role in cell-cell adhesion. The interrelatedness of tumor growth and tumor invasion, and limitations of experimental model systems, often does not allow a distinction between growth effects that influence the appearance of an invasive phenotype and an effect on cellular invasion per se.

The extracellular matrix (ECM) provides a scaffold for the organization of cells and spatial cues that dictate cell behavior.[9] The ECM is composed of proteins, primarily triple-helical collagens, glycoproteins such as laminins and fibronectin, and proteoglycans. The basement membrane is an organized ECM that separates polarized epithelial, endothelial, and muscle cells from the underlying tissue. Interstitial matrix provides the structure characteristic of connective tissues. The molecular composition of the ECM varies between tissues and organs and provides contextual information to cellular constituents. In addition, the ECM serves as a repository for secreted regulatory proteins and growth factors. Finally, ECM proteins themselves can be active signaling molecules, activities that frequently are only revealed after proteolysis reveals cryptic sites. Thus, the interaction of cells with ECM molecules determines their capacity for survival, growth, differentiation, and migration.

Cells adhere to ECM via integrins, a family of transmembrane glycoproteins assembled as specific combinations of 18 α and 8 β subunits.[5] Integrins bind to distinct but overlapping subsets of ECM components. During tumor progression, cancer cells tend to undergo a switch in their integrin expression pattern, downregulating the integrins that mediate adhesion and maintain a quiescent, differentiated state, and expressing integrins that promotes survival, migration, and proliferation.[10] Although there is a cell-type dependency on integrin function, in general integrins $\alpha_2\beta_1$ and $\alpha_3\beta_1$ are viewed as suppressors of tumor progression, whereas $\alpha_v\beta_3$, $\alpha\beta_6$, and $\alpha_6\beta_4$ promote cellular proliferation and migration. Integrins mediate both "outside-in" and "inside-out" signaling, so that changes in cellular adhesion can alter cellular phenotype, and changes in intracellular signaling pathways can modulate cellular adhesion. A well-described and important mechanism whereby integrin-ECM interactions modulate cell function is by cooperative signaling with different growth factor receptors. Many of the cellular responses induced by activation of tyrosine kinase growth factor receptors are dependent on the cells being able to adhere to an ECM substrate in an integrin-dependent fashion. Signaling in response to ECM ligation usually activates focal adhesion kinase (FAK) and nonreceptor tyrosine kinases of the *src* family.

Matrix Degradation

Disruption of basement membrane is a hallmark of malignancy. Degradative enzymes produced by the tumor cells, and by resident and infiltrating cells as a response to the tumor, contribute to matrix degradation and facilitate tumor cell invasion. Proteolytic enzymes of many classes have been implicated in tumor cell invasion, including the serine proteinases plasmin, plasminogen activator, seprase, hepsin, several kallikreins, the cysteine proteinase cathepsin-B, the aspartyl proteinase cathepsin-D, and metal-dependent proteinases of the matrix metalloproteinase (MMP) and a disintegrin and metalloproteinase (ADAM) families. Other matrix-degrading enzymes such as heparanase, which cleaves heparin sulfate proteoglycans, and hyaluronidase cleavage of its substrate hyaluronic acid have also been causally associated with tumor progression and invasion.

Liotta and colleagues observed that metastatic potential correlates with the degradation of type IV basement membrane collagen and focused attention on the metal-dependent gelatinases.[11] These enzymes are now recognized as MMP2 and MMP9, and many of the 23 members of the MMP family of matrix-degrading metalloproteinases have been associated with tumor progression. Elevated MMP levels correlate with invasion, metastasis, and poor prognosis in many cancer types, and animal models provide evidence for a causal role for MMP activity in cancer progression.[12] The plasminogen activator/plasmin system has also been causally implicated in cancer invasion,[13] and urokinase plasminogen activator (uPA) and plasminogen activator inhibitor-1

(PAI-1) are validated prognostic and predictive markers for breast cancer.[14]

The regulation of matrix proteolysis is complex and can involve the concerted action of multiple proteinases and proteinase classes from both tumor cells and adjacent resident and infiltrating cells (Figure 18-3). The conversion of pro-MMP2 to active MMP2 requires membrane-type MT1-MMP (MMP14), a transmembrane MMP that is activated intracellularly by the proprotein convertase family member, furin. There is evidence for a cascade of cathepsin-D–cathepsin-B–uPA–plasmin–MMP activation that results in activated enzymes capable of degrading all components of the ECM. Proteolysis is also regulated by the production of specific endogenous protease inhibitors, including the tissue inhibitors of metalloproteinases (TIMPs), serine proteinase inhibitors (serpins), and cysteine protease inhibitors (cystatins). These inhibitory activities are produced and secreted by tumor or stromal cell types, and some proteinase inhibitors are stored in high concentrations in the ECM. Proteinase activity cascades can function via proteolytic degradation of some of these proteinase inhibitors in addition to activation of other proteinases.

The original view that proteolytic enzymes function predominantly to remove physical ECM barriers has been expanded with the realization that proteolysis is a key regulator of multiple steps of tumor progression. For example, MMP substrates in the matrix or on the cell surface that modulate cellular growth, differentiation, apoptosis, angiogenesis, chemotaxis, and migration have been identified.[12] The abundant evidence for a role for MMPs in tumor progression led to the design and testing of synthetic MMP inhibitors for cancer therapy.[15] These inhibitors proved to be ineffective in clinical trials, results that have been explained by problems with inhibitor or clinical trial design and a lack of understanding of the broad range of MMP activities resulting in both cancer-promoting and cancer-inhibitory effects.

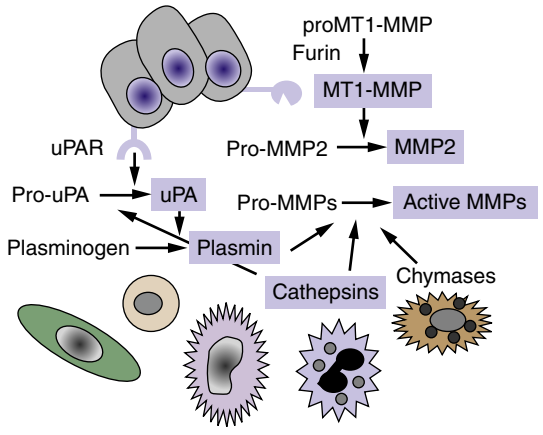

Figure 18-3 Proteolytic cascades Extracellular proteinases are made by tumor cells as well as by stromal fibroblasts and inflammatory cells. Proteolytic cascades result in the conversion of proenzymes to their active form. Enzymes in blue boxes are capable of degrading components of the extracellular matrix (ECM). In many cases, proteolytic cascades are localized to the surface of tumor cells. The urinary plasminogen activator receptor (uPAR) is expressed by many tumor cells and initiates and localizes the conversion of pro-urokinase plasminogen activator (pro-uPA) to its active form, which then converts the serum protein plasminogen into the active serine proteinase, plasmin. The membrane type 1-matrix metalloproteinase (MT1-MMP) is a transmembrane protein that is activated intracellularly by the proprotein convertase furin. MT1-MMP converts pro-MMP2 to its active form, MMP-2. Enzymes of many classes convert pro-MMPs to their active form.

Motility

Cellular locomotion occurs as the result of coordinated polymerization and depolymerization of the actin cytoskeleton to extend a pseudopod at the leading edge of the cell, followed by contraction associated with disassembly of cell-matrix adhesive contacts at the trailing edge.[16] Lamellipodial protrusions at the leading edge are nucleated by a branched actin network involving the Arp2/3 complex and its regulators, the WASp (Wiskott-Aldrich syndrome protein) family, cortactin, and the GTPase Rac. Actin contractility is regulated by myosin light-chain kinase and upstream small GTPases, in particular Rho and its effector Rho-kinase (ROCK). Single cells migrate with a spindle-shaped morphology, referred to as *mesenchymal migration*, or with the less adhesive ellipsoid shape used by leukocytes and *Dictyostelium* termed *amoeboid migration* (Figure 18-4). Collective migration can occur when the cells retain cell-cell junctions and clusters of cells move in single file through a tissue.

Tumor cells can secrete factors that stimulate motility in an autocrine fashion. Tumor cell–produced lysophospholipase D (autotaxin) stimulates motility, as does lysophosphatidic acid (LPA), which can be produced by lysophospholipase D

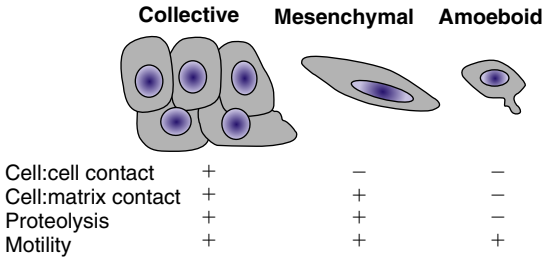

Figure 18-4 Types of cellular invasion Cells can move through matrix barriers as collectives, in which multiple cells remain attached and move together, or as single cells with mesenchymal or amoeboid characteristics. Epithelial-derived tumor cells undergoing collective migration retain cell-cell adhesions, whereas those undergoing mesenchymal or amoeboid movement have reduced or absent cadherin-mediated adhesions. Mesenchymal motility requires proteolysis and integrin-mediated cell-matrix adhesion. In the absence of proteolysis and extracellular matrix (ECM) adhesions, tumor cells can move through ECM using amoeboid movement, similar to that displayed by infiltrating leukocytes. Amoeboid movement is characterized by elevated actin cytoskeleton activity mediated by the small GTPase Rho and its regulator Rho-kinase.

activity on lysophosphatidylcholine. Hepatocyte growth factor/scatter factor (HGF/SF) interacts with its receptor, *c-met*, to induce chemokinetic activity of epithelial cells, resulting in an invasive phenotype. Directional motility is a chemotactic or haptotactic effect in response to a gradient of soluble or localized factors, respectively. Chemotaxis is often the result of growth factors such as IGF, and chemokines of the CCR and CXC family. Haptotaxis is characterized as a response to gradients of ECM components such as laminin-5 and fibronectin and can be modulated positively or negatively by proteolysis.

Coordination of Cancer Invasion

The coordination of cell-cell and cell-matrix adhesion, matrix degradation, and cytoskeletal activity is required for cellular invasion. The type of cell migration (i.e., collective, mesenchymal, or amoeboid) is influenced by the relative levels of adhesion mediated by cadherins and integrins, proteolytic activity, and actin contractility. Modulation of any of these factors can convert one type of motility into another.[16]

Invadopodia is the name that has been given to structures identified in invading cells that represent the physical convergence of the adhesive, proteolytic, and motility components of invasion (Figure 18-5).[4] Invadopodia are actin-rich organelles that protrude from the plasma membrane and contact and locally degrade the ECM. Invadopodia contain adhesion molecules, including several β1 integrins and CD44, the serine proteinases seprase and dipeptidyl dipeptidase IV, and several MMP and ADAM metalloproteinases. Inside the plasma membrane, invadopodia contain actin and actin assembly molecules and multiple signaling molecules including focal adhesion kinase (FAK), *src*-associated proteins such as p130Cas and Tks5/FISH (tyrosine kinase substrate 5/five SH3 domains), and the small GTPases cdc42, Arf1, and Arf6. Thus, invadopodia are implicated as key cellular structures that are used to coordinate and regulate the various components of the process of cancer invasion.

The Metastatic Cascade

Although invasion is required for metastasis, the ability to invade is not sufficient for metastasis (see Figure 18-1). Some tumors are highly aggressive, forming secondary lesions with high frequency (e.g., small-cell carcinoma of the lung,

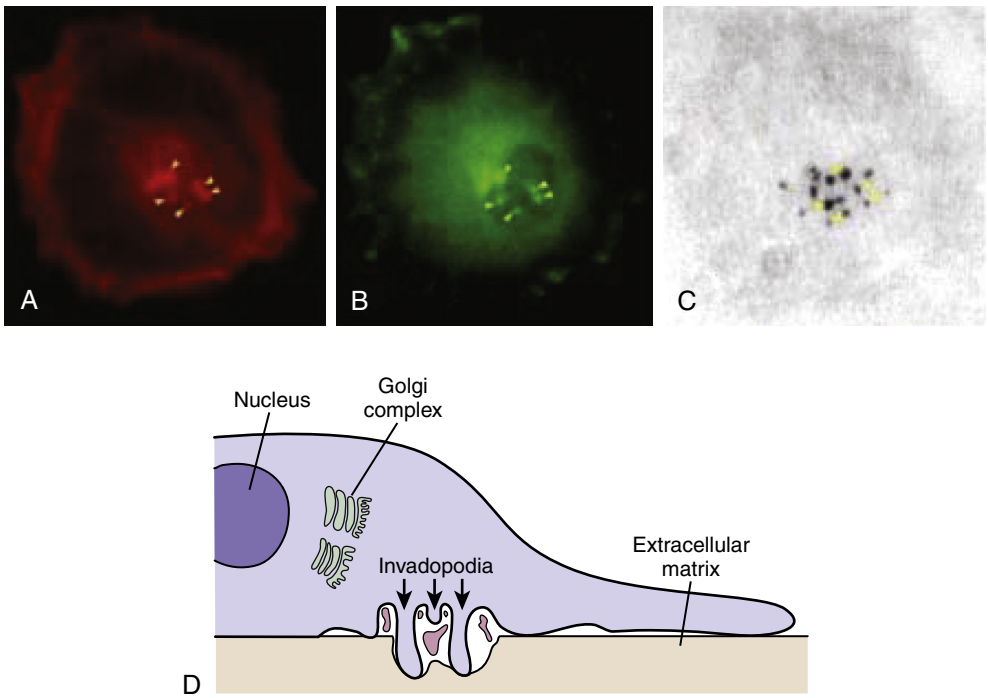

Figure 18-5 Invadopodia Confocal laser image showing triple immunofluorescence labeling of A375MM melanoma cells plated on tetramethylrhodamine isothiocyanate (TRITCJ)-conjugated gelatin. **(A)** Invadopodial structures marked by actin-binding phalloidin-Alexa 546. **(B)** Invadopodial structures marked by Alexa 633-conjugated anti-phosphotyrosine antibodies. **(C)** Degradation areas on the underlying Alexa 488-conjugated gelatin. Image shows colocalization between actin, phosphotyrosine, and patches of degraded extracellular matrix, fulfilling the criteria for the definition of invadopodia. **(D)** Schematic diagram of the invadopodial complex based on correlative light-electron microscopy reconstructions. Spatial relationships with the nucleus and the Golgi complex are shown. Invadopodial protrusions originate from profound invaginations of the ventral surface of the plasma membrane; within the area delimited by the large invagination, large fragments of gelatin can often be seen. *From Ayala I, Baldassarre M, Caldieri G, et al. Invadopodia: a guided tour.* Eur J Cell Biol. *2006;85:159-164, with permission.*

melanoma, pancreatic carcinoma), whereas others are rarely metastatic despite being locally invasive (e.g., basal cell carcinomas of the skin, glioblastoma multiforme). Fidler and colleagues have proposed an analogy regarding metastasis that is highly illustrative. Metastatic cells are likened to athletes participating in the decathlon. Each cell must be capable of completing every step of the metastatic cascade. If a cell cannot complete any step, it cannot go on to subsequent steps and cannot form a metastasis.

Metastasis is primarily thought of as developing via dissemination in the bloodstream, although other routes of spread occur. Carcinoma cells tend to escape and spread initially to draining lymph nodes, becoming trapped and proliferating. The thoracic duct links the lymphatic system to the bloodstream, connecting lymphatic to hematogenous spread. Metastases can also develop by spreading across body cavities. For example, ovarian carcinoma cells most frequently establish secondary tumors by dissemination in the peritoneum while rarely forming metastases via hematogenous spread. Other routes of spread also exist but are far less common (e.g., dissemination of melanoma cells along the space between endothelium and basement membrane or perineural spread in pancreatic and prostatic carcinomas). Thus, the route of dissemination is not inherent to a definition of metastasis.

Intravasation

How tumor cells enter the bloodstream is not clearly understood. The growth of a tumor exerts a hydrostatic pressure, and studies imply that tumor-cell invasive cords follow lines of least resistance. Angiogenesis is likely to be a prerequisite for metastasis, but this has not been formally proven (see Chapter 17). Tumor cell entry into intact blood vessels is an active process that requires serine and metalloproteinase activity in an experimental model of intravasation.[17] Tumor blood vessels, however, are highly abnormal, with fewer pericytes and increased permeability compared with normal vessels, and presumably provide an easier route for direct entry into the bloodstream.[18] Lymphatic vessels are also abnormal, but their role in intravasation is unknown. Regardless of the route, tumor cells enter the circulation in great numbers: Estimates are 3 to 4 million cells/day/g of tumor.[19] The number of tumor cells in the peripheral blood, however, does not necessarily predict whether the patient will develop metastases.[20] In contrast, the detection of disseminated tumor cells in lymph nodes and bone marrow does correlate with metastatic relapse, suggesting that, at least in breast cancer, the properties that allow the cells to find their way to these tissues and survive are the same properties that permit distant metastases.

Transport

Once tumor cells enter a circulatory compartment, they can move actively by motility mechanisms or passively, carried or pushed along with fluid flow. Injection of radiolabeled cells directly into circulation reveals that a substantial proportion is lost during the transport phase of the metastatic cascade. Many tumor cells are eliminated by natural killer (NK) cells or monocytes before arrival in a secondary site. Tumor cells that escape immune recognition are frequently killed by exposure to hemostatic shear forces.[21] Bioassays in the lungs, liver, heart, and muscle have been performed following intravenous injection of tumor cells. It is noted that by the time it takes to remove the tissues for assay (2 to 3 minutes), most cells are dead due to mechanical trauma.[21] The average tumor cell diameter ranges from 20 to 30 μm but must navigate through vessels significantly smaller (e.g., 6- to 7-μm capillaries). Even if tumor cells have the ability to deform and squeeze through the passages, they are subjected to significant hydrostatic pressures. Depending on the tumor type and biophysical parameters such as membrane fluidity, cellular elasticity, and cytoskeletal organization, the cells will remain intact or be broken by shear. Deformability is also affected by the pressures found within various tissues. In contrast to the shear forces usually encountered in the vasculature, blood flow in bone sinusoids is sluggish (about 30-fold less than in capillaries and postcapillary venules), and diameter is not a concern.[22]

During transport, the behavior of tumor cells is often determined by their presence as single cells or as emboli. Embolization can be homotypic (tumor cell–tumor cell) or heterotypic (tumor cell–leukocyte, tumor cell–platelet, tumor cell–fibrin). The association of tumor cells with blood cells can be the result of altered cell surface glycosylation and expression of sialyl Lewis X/A on the tumor cell that permits interaction with a class of vascular adhesion molecules found on normal leukocytes and endothelium, the selectins. Alterations in the adherence of tumor cells to endothelium via E-selectin, platelets via P-selectin, and leukocytes via L-selectin alter the metastatic potential in animal models.[23] Embolus size can also contribute to protection of the tumor cells from biophysical forces or immune attack. In essence, encapsulation of tumor cells helps to protect them. As a result of the consequence of embolus formation, heparin, an inhibitor of selectin/glycan interactions, has been considered as an antimetastatic agent.

Visualization of tumor cells in the circulation during transport indicates that the cells roll rather than float in a manner analogous to leukocytes. Nonetheless, during this time, tumor cells are weakly adherent and subject to anoikis, a specialized type of apoptosis in which cells that are

anchorage dependent are induced to die.[24] In general, metastatic cells are more resistant to anoikis than nonmetastatic cells and are frequently referred to as being anchorage independent. This is somewhat misleading, because some tumor cells will induce apoptosis even if firmly attached to a substrate if that substrate is not the preferred one for the type of cell. It is possible, then, that circulating tumor cells receive sufficient signals from the ECM, other cells, and/or serum proteins to limit their susceptibility to anoikis.

Arrest

It is important to discriminate between the physical trapping and arrest of circulating cells in the microvasculature and selective adhesion to the walls of the microvasculature. Both processes have been observed, and the relative importance of these mechanisms in specific organs is debated.

There are three types of endothelial structures found in higher vertebrates: continuous, discontinuous, and fenestrated. Most endothelial cells form tight junctions with their neighbors and have a continuous, unbroken basement membrane beneath them. However, in certain organs, such as liver and spleen, the endothelial cells and the basement membrane have gaps, or discontinuities, in their structure. In the kidney, a fenestrated endothelium, there are gaps between endothelial cells, but a membrane-like structure connects them and the entire structure overlaps in a continuous basement membrane. The structure of these endothelial/basement membrane barriers contributes to the normal function of the tissues and forms different barriers through which tumor cells must pass.

Adhesion of circulating tumor cells to organ microvessel endothelial cells represents one of the more important steps in metastasis, especially organ-specific metastasis. In general, higher rates of tumor cell–endothelial adhesion correlate well with metastatic potential. In vivo and in vitro kinetic studies indicate that initial attachment of cancer cells occurs preferentially at endothelial cell junctions.[25] Frequently, tumor cells adhere at sites where inflammation is taking place and is most likely related to alterations in cell surface components of endothelial cells at these sites. Tumor cells use many of the same mechanisms to attach to and traverse endothelium as inflammatory cells, including glycan/selectin interactions.

Once tumor cells bind to the endothelium, they induce the endothelial cells to retract and eventually overlap the tumor cell. During this time, there is no loss of electrical resistance, suggesting that tight junction integrity is maintained. Tumor cells then adhere to subendothelial basement membrane components, and a higher rate of tumor cell adhesion to subendothelial basement membrane correlates with metastatic potential. In the case of HT1080 fibrosarcoma cells, the attachment of circulating tumor cells to the lung vasculature is mediated by tumor $\alpha_3\beta_1$ integrin ligation to laminin-5 in the basement membrane.[26] Patches of exposed basement membrane were found to be preexisting using intravital microscopy techniques in isolated, perfused lungs.

Arrested tumor cells can undergo rapid apoptosis. It is envisioned that in some cases this is the result of the lack of suitable survival signals and the initiation of anoikis. In addition, the attachment of tumor cells to endothelium can release nitric oxide (NO) produced by endothelial nitric oxide synthase.[27] NO can induce apoptosis of tumor cells, indicating an active process that contributes to tumor cell loss and metastatic inefficiency.

Extravasation

Extravasation is the process of tumor cells invading from the interior of a vessel into the organ parenchyma. Extravasation was viewed as a rate-limiting step for metastasis formation, but intravital microscopy studies have indicated that extravasation can be a remarkably efficient process, at least in some situations. For example, 87% of B16F1 murine melanoma cells that were injected through the mesenteric vein into the liver were arrested in the liver 90 minutes after injection, and 83% of the injected cells were found in the liver parenchyma by 3 days, indicating that more than 95% of the arrested cells extravasated.[28] The molecular mechanisms underlying extravasation are viewed as being identical to those involved in invasion, and in vitro assays for extravasation reveal a contribution of cellular adhesion molecules, proteinases, and motility factors.

There is controversy as to whether extravasation is required for the formation of metastases. In the case of some pulmonary metastases, there is evidence that tumor cells can attach to the lung endothelium, survive, and grow intravascularly.[29] Extravasation occurs in this model only when the intravascular foci outgrow the vessel.

Colonization

Colonization, the formation of clusters of tumor cells at ectopic sites, represents a highly inefficient step in the metastatic cascade. In the model of B16F1 cells injected into the liver vasculature, only 2% of the injected cells formed micrometastases, and only 0.02% formed lesions that persisted,

grew progressively, and threatened the life of the animal.[28] The formation of micrometastatic lesions requires that the tumor cell must first survive and then grow in the foreign environment. In some tumor types (i.e., breast and melanoma), metastases can arise decades after the treatment of the primary tumor, indicating that tumor cells can survive in a state of dormancy for long periods. Tumor cells can persist as solitary cells, or they can grow to a size of several hundred cells in which the rate of growth is balanced by the rate of apoptosis. Conversion to a clinically detectable metastatic lesion requires the subsequent initiation of angiogenesis (see Chapter 17). The growth of the cells is dependent on factors, primarily soluble growth factors, present at the site of colonization. Although it is natural to focus on factors that promote the growth of tumor cells in selective sites, there is ample experimental evidence showing that some tissues are hostile to tumor cells.

A tumor cell's ability to establish a metastatic lesion is very much dependent on the microenvironment (see Chapter 16). A prime example of this effect is the role of the "vicious cycle" in the propensity for breast carcinoma to metastasize to bone (Figure 18-6).[30] The mammary carcinoma cells produce parathyroid hormone–related peptide (PTHrP), which during pregnancy would function to release calcium from bone stores. Using the same molecular pathways, tumor cell-produced PTHrP acts on its receptors on osteoblasts to release the tumor necrosis factor-α (TNF-α) family member, receptor activator of nuclear factor-κB ligand (RANKL). RANKL interacts with its receptor RANK on osteoclasts and activates them to degrade mineralized bone.

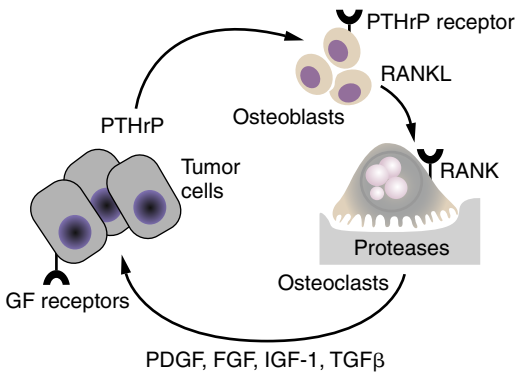

Figure 18-6 The vicious cycle of host-tumor interactions in breast cancer metastasis to bone Breast cancer cells produce parathyroid hormone–related protein (PTHrP), which stimulates bone osteoblasts to express the tumor necrosis factor-α (TNF-α) family member receptor activator of nuclear factor-κB ligand (RANKL). RANKL interacts with its receptor RANK on osteoclast precursors to differentiate into active osteoclasts, resulting in the release of proteases and bone degradation. Growth factors such as platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), insulin-like growth factor (IGF-1), and transforming growth factor-β (TGF-β), which are stored in the bone matrix, are released and stimulate the growth of receptor-containing tumor cells. An increase in tumor cells results in an increase in PTHrP release, leading to a vicious cycle of tumor cell growth and bone degradation.

The bone matrix contains an abundance of growth factors, including PDGF, FGFs, IGF-1, and TGF-β/bone morphogenetic protein family members, which are released during the osteolytic process. It is the release of these growth factors that stimulates the breast cancer cells to grow and to continue to secrete PTHrP and fuel the "vicious cycle." The colonization of breast cancer cells in the bone is thus facilitated by specific characteristics of the bone microenvironment that promote the growth of breast cancer cells.

Organ Selectivity of Metastasis

There is a clear tendency for primary tumors to form metastatic lesions in specific organ sites (Table 18-1). Common regional metastatic involvements can often be attributed to anatomic or mechanical considerations (e.g., efferent venous circulation or lymphatic drainage) and explained by arrest of tumor cells in the first capillary bed or lymph node encountered.[31] Because most tumor cells enter the vasculature in small veins or capillaries, the most common site of metastasis is lung and liver. However, distant metastasis patterns are typically more site specific. In 1889, Paget analyzed postmortem data of women who died of breast cancer and noticed a higher frequency of metastasis to skeleton than would be expected based solely on cardiac output to each organ.[32] He concluded that the pattern of organ distribution of metastases was not simply a matter of chance and suggested that metastases develop only when the "seed" (tumor cells with metastatic ability) and the "soil" (organs or tissues providing growth advantages to seeds) are compatible. Importantly, the mechanical theory and the "seed and soil" hypothesis are not mutually exclusive, and both contribute to metastatic dissemination.

Experimental data supporting the seed and soil hypothesis include preferential invasion and growth of B16 melanoma metastases in specific organs.[33] In addition, palliative treatment of women with advanced ovarian carcinoma has provided an opportunity to test this theory in humans. These patients often have a large ascites burden, but seldom present with disease outside the peritoneal cavity. Tarin and colleagues treated patients with potentially lethal malignant ascites by introducing a tube that drains the peritoneal ascites into the vena cava.[34] In doing so, tumor cells in the ascites were given direct entry into the circulation. Despite continuous entry of billions of viable tumor cells into the circulation, metastases to the lung (i.e., the first capillary bed encountered) were rare. This single clinical observation highlights the inefficiency of the metastatic process and, more important, demonstrates that merely seeding cells in different tissues is not adequate to develop metastases.

Table 18-1 Common Sites of Metastasis

Primary Tumor Site	Most Common Sites of Metastases
Breast	Axillary RLN, contralateral breast via lymphatics, lung, pleura, liver, bone, brain, adrenal, spleen, ovary
Colon	RLN, liver, lung, direct extension into urinary bladder or stomach
Kidney	Lung, liver, bone
Lung	RLN, pleura, diaphragm by direct extension, liver, bone, brain, kidney, adrenal, thyroid, spleen
Ovary	Peritoneum, RLN, lung, liver
Pancreas	Liver, stomach by direct extension, colon, peritoneum
Prostate	Bones of spine and pelvis, RLN
Stomach	RLN, liver, lung, bone
Testis	RLN, lung, liver
Urinary bladder	Direct extension into rectum, colon, prostate, ureter, vagina, bone, RLN, lung, peritoneum, pleura, liver, brain
Uterine endometrium	RLN, lung, liver, ovary

RLN, Regional lymph nodes.

The mechanisms responsible for organ selectivity in tissues can be attributed to the arrest and the colonization steps of the metastatic cascade in particular. Tumor cells adhere more selectively to organ-derived microvascular endothelial cells than to large-vessel endothelial cells, and variants of the B16 melanoma previously selected for metastases to brain, lung, ovary, or liver adhere at a more rapid rate to brain, lung, ovary, or liver endothelial cells, respectively.[35] Using phage-display technology, endothelial cells in different tissues have been demonstrated to express unique markers, and tumor cells recognize the molecular "addresses" to adhere to in a selective manner.[35] Tumor cells are also able to recognize subendothelial basement membrane differences. In vitro studies demonstrate the selective growth of tumor cells in organ-derived soluble growth factors or cells.[36] In vivo, breast tumor cells that express the chemokine receptor CXCR4 preferentially metastasized to tissues that expressed the ligand SDF1/CXCL12.[37] There is a concept that tumor cells colonize in a premetastatic niche initiated in target organs by tumor cell–generated soluble factors that induce the expression of fibronectin by resident fibroblast-like cells.[38] Bone marrow–derived cells that express the vascular endothelial cell growth factor receptor 1 and the integrin $\alpha_4\beta_1$ selectively adhere to these regions, produce the proteinase MMP9 and the chemokine SDF1/CXCL12, and provide a permissive niche for colonization by tumor cells.

Although the data strongly support the notion that there are soluble factors produced in different tissues to which tumor cells can respond, the process of homing has not been validated. Strictly speaking, homing would require directed movement throughout the transit of tumor cells as they leave the primary tumor. Rather, tumor cells distribute according to circulatory patterns initially but may "home" once they are more proximate. Many of the mechanisms used by lymphocytes to home to peripheral lymph nodes or sites of inflammation are apparently shared by tumor cells.

Some of the strongest evidence supporting organ selectivity of cancer cells comes from data showing selection of variants that colonize different tissues. The first selections were done by repetitive isolation of lung metastases from the B16 melanoma followed by reinjection and recolonization.[33] Similar approaches have been used for other tumors, most recently using a human breast carcinoma cell line with selection of metastases to bone, lung, and adrenal gland. Using these breast carcinoma cell lines coupled with a comparison by cDNA microarray has highlighted the requirement for coordinated expression of multiple genes for metastasis.[39] Transcriptomes were compared between parental and bone-selective variants, and over- and underexpressed genes were identified. Among the overexpressed genes in the bone metastasis signature were a matrix metalloproteinase, MMP1; the ECM component osteopontin; the cytokine interleukin-11; the chemokine receptor, CXCR4; and connective tissue–derived growth factor. Subpopulations within the parental population expressed one or more of the bone signature genes, but only a few expressed all of them. Transfection of individual cDNAs only modestly increased bone metastatic efficiency, whereas cotransfection of gene combinations into the parental cells resulted in populations as efficient at bone colonization as the bone-selective variants. Similar studies with a lung-selective variant revealed a lung metastasis signature that overlapped only minimally with the bone metastasis signature.[40] These data highlight that there are specific genes that control metastasis in an organ-specific fashion, and coordinated expression of multiple genes is required.

Metastatic Progression

The journey of a metastatic cancer cell involves several steps from the time it leaves the primary site to the moment it reaches a distant organ. So how long does this journey take to commence, and what is the path that these cells take? Are these metastatic cancer cells or "seeds" disseminated early or late in the life of an evolving primary tumor? These questions are important to understand, because they are linked to the functional consequences of genetic and epigenetic changes that are accrued by metastatic cancer cells when compared to their originating primary tumor. If metastatic progression

occurs early and takes place in parallel to the primary tumor, the genomic landscape of the primary tumor and metastasis can be predicted to be significantly different. On the other hand, if metastatic progression occurs late through clonal evolution within the primary tumor and the cancer cells that left the tumor early became dead ends, then one can expect the primary tumor and metastases to look genetically similar. These questions have direct clinical implications because several drugs that target the primary tumor fail to treat advanced metastatic disease in the clinic. If the metastases were indeed genetically distinct from the primary tumors, it could be envisioned that drugs that target oncogenic changes in the primary tumor would not work for metastases.

Deciphering both the similarities and distinctions between the primary tumor and the metastases may be important in devising strategies to successfully treat metastatic cancer. What is also necessary is gaining an understanding of the regional differences and heterogeneity within the tumor and metastases. A large part of the intratumoral heterogeneity and metastatic diversity is shaped by the distinct tumor microenvironment in which the cancer cells reside. Therefore it can be envisioned that microenvironment-linked selective pressures influence the genetic and epigenetic heterogeneity of tumors and determine the evolutionary trajectory of cancer cells during metastatic progression. Recognition and characterization of such genetic and phenotypic diversity is therefore key for designing rational therapeutic interventions.

The advent of major technological advances over the past decade in the field of sequencing and high-resolution analysis of disseminated cancer cells has made it possible to begin to address such complex biological questions. Deciphering metastatic progression and phylogeny of metastases is an emerging goal as sequencing data from different cancers accumulate, with several hypotheses and models being discussed and debated. Two hypotheses that tower over the rest in explaining the origin of metastatic cells are the linear progression and clonal evolution model on one hand and the parallel progression model on the other. The two models are not mutually exclusive and could be at play to different degrees, depending on the tumor type and its oncogenetic composition.

Linear Progression Model

Pioneering work by the group of Isaiah Fidler has shown that only a subset of preexisting cells within a heterogeneous primary tumor is competent to metastasize.[41] The linear progression paradigm has been the prevalent model to explain this observation. According to this model, cancer cells undergo multiple rounds of mutation and selection in the primary tumor, and only a small subset of these malignant clones acquire the genetic and epigenetic alterations necessary for metastasis.[42,43] A clinical correlation between tumor size and frequency of metastasis is in line with this model.[44] The model also suggests that larger tumors growing over time would have a higher likelihood of containing metastasis-competent clones within their heterogeneous population. The reduced probability of metastasis in cases where primary tumors of less than 2 cm in size are surgically resected in the clinic lends support to this model. New insights into genomic evolution during tumor progression came from Aparicio and colleagues, who sequenced a breast cancer metastasis and its corresponding primary tumor that was removed 9 years earlier.[45] Eleven of the 30 mutations detected in the metastatic lesion were present in the primary tumor. This study revealed that preexisting mutations in the primary tumor do get selected in the metastases, but there is also considerable genomic evolution that occurs during the metastatic process. Comparing the frequency of these somatic mutations in the primary tumors and metastases revealed two discernible trends. Five of the 11 shared mutations were prevalent in the primary tumor, whereas 6 were present in low frequencies. In contrast, all these mutations were prevalent in the metastases, indicating less heterogeneity than the primary tumors. These data are compatible with the clonal expansion model and suggest that a clone from the heterogeneous primary tumor is selected, expands, and generates the distant metastasis. More recently, analysis of tumor evolution using single-cell sequencing technology in two breast cancer cases, by Michael Wigler and colleagues, suggested that a single clonal expansion both formed the primary tumor and seeded the metastasis in the examined cases.[46] It remains to be seen how general these findings are as more matched primary tumors and their metastases in different cancers are sequenced.

In the context of metastasis, what is the time line of metastatic progression? The linear progression model would predict metastatic spread to be a late event in tumor progression, given the time required for the accumulation of sufficient genetic and epigenetic alterations within the primary tumor that permits metastasis. Also implicit in the assumptions from this model and discussed earlier, primary tumors and metastasis are expected to be genetically similar, and a majority of the mutations detected in metastasis should preexist in the primary tumor. Indeed, new insights from genomic sequencing of pancreatic cancer patients suggest that metastasis is a late event in the genetic evolution of pancreatic cancer.[47] Clonal populations that give rise to metastasis preexist within the primary tumor but are more genetically evolved than the original parental, nonmetastatic clone. Using mathematical modeling, Yachida and colleagues showed that a decade passes between the occurrence of an

initiating mutation and the birth of a parental, nonmetastatic cancer cell clone in a pancreatic tumor. Thereafter, at least 5 years pass before metastatic ability is gained in these clones and an average of 2 years elapses until the patient's death. In an analogous manner, colorectal cancer progression was calculated to be 17 years between the birth of an adenoma founder cell and advanced carcinoma; however, only a further 1.8 years pass until the evolution of a metastatic founder cell appears.[48] These studies provide several key insights into the time scale of evolution of metastases in the setting of pancreatic and colon cancer. They suggest that clones in certain advanced cancer already harbor most of the mutations needed for metastatic competence and it takes a relatively short time to develop into metastases. We have to keep in mind that the temporal course of acquisition of metastatic traits might vary greatly between different types of cancers. It is thought that in the case of estrogen receptor–positive breast cancer, there is usually a prolonged latency period, often up to a decade, from gaining infiltration potential and seeding until competence to colonize and outgrow in a distant organ is gained. However, in the case of lung cancer, there is a relatively short interval (often measured in months) between gaining infiltration ability and successful colonization.[49] Large-scale sequencing efforts are under way to reveal the genetic landscape of primary tumors and their metastases in other cancer types, and this could provide insights into the generality of these observations.

Parallel Progression Model

Although there is supportive evidence for the linear progression model, single-cell comparative genomic hybridization analysis of isolated disseminated tumor cells (DTCs) in the bone marrow and primary breast tumors provides an alternative explanation. Christoph Klein and colleagues observed that the genetic changes in the DTCs in the bone marrow did not resemble those in their corresponding primary breast tumor, which led to the conception of the "parallel progression model." According to this model, quasinormal cells disseminate relatively early in the course of tumor progression and evolve independently from the cells in the primary tumor.[50] As a result, genetic and epigenetic evolution occurs through multiple rounds of genetic diversification and clonal selection mostly at the distant organ site(s), which ultimately gives rise to overt metastasis. Parallel evolution thus predicts divergence for many mutations and genetic alterations for the selected cells at the distant sites.[51] Based on the mathematical modeling of tumor growth rates, the parallel progression model questions how large sizes of metastases can be explained by the linear model if they arise only at the advanced stages of tumor progression. Work emerging from several laboratories has shown that tumor cells can indeed disseminate early at the pre-invasive stages in breast cancer progression, both in human breast cancer patients and in experimental mammary tumor models.[52-54] Moreover, Podsypanina and colleagues[54] showed that even untransformed mouse mammary epithelial progenitor cells are able to extravasate and survive at the distant site for prolonged periods and start to grow again on oncogene induction. Collectively, these findings in breast cancer lend support to the parallel progression model and underscore the need for a deeper understanding of metastatic progression in different cancers.

Tumor Self-Seeding

Self-seeding is a recent paradigm that addresses the directionality of tumor seeding by experimental modeling and provides new insights into tumor progression.[55] The concept of self-seeding is not in conflict with either of the models discussed earlier but is complementary to both and provides deeper insights into how the disease can progress. According to this model, cancer dissemination is a bidirectional process in which cancer cells not only seed distant sites but some of these cells reenter the circulation and are attracted back to the original primary tumor.[55] Having egressed to distant organs and having gained increased metastatic abilities, many of these aggressive circulating tumor cells (CTCs) also return to their birthplace using the acquired metastatic abilities. In experimental tumor models, self-seeders are attracted back to the primary tumor by cytokines such as interleukins IL-6 and IL-8. Moreover, seeder cells express high levels of the proteolytic enzyme matrix metalloproteinase 1 (MMP1) and the actin crosslinking protein of invadopodia, Fascin-1, to aid in their infiltration back to the primary tumor. Once back in the primary tumors, self-seeders clonally expand, enriching the tumor population with aggressive clones. Self-seeders may also promote tumor growth using a number of genes, including the chemokine CXC motif ligand1 (CXCL-1) that recruits leukocytes to the tumor microenvironment. Therefore this model predicts that the process of tumor self-seeding can select for aggressive CTCs that can accelerate primary tumor growth and in the process also selects for aggressive subpopulations that are primed for metastasis. Local growth of the primary tumor can therefore be promoted by returning metastatic cells, which in turn can act as a reservoir for breeding aggressive clones through the process of "self-seeding."

In summary, the recent studies on linear progression, parallel progression, and DTC dynamics are clearly bellwethers that have provided new molecular insights into tumor progression. However, it has to be kept in mind that these

efforts represent only early steps of decoding metastatic evolution with several open questions. Though there has been a plethora of supportive evidence for the linear progression model over the past decades, the parallel progression model is intriguing and deserves careful consideration. It is becoming increasingly evident that quasinormal cancer cells can be detected early in circulation during the course of tumor progression, but whether these disseminated cells give rise to pathologically detectable, overt metastasis remains to be shown. None of the models of metastatic progression alone can explain all the phenomena in their entirety in all cancers.

Colonization and Interactions with the Tumor Microenvironment

One of the most challenging and rate-limiting steps of the metastasis cascade is the final step of colonization. On arrival in distant organs, cancer cells need not only to survive in a new and unfamiliar microenvironment but also to grow out into overt metastasis. A large proportion of cancer cells die soon after extravasation; among the few that survive, some remain singly and some in clusters known as *micrometastases*. A vast majority of these cells will stay in a dormant state and never form clinically detectable metastases. However, some of these cells may successfully withstand these unfavorable conditions, or *metastatic stress*, and are able to reinitiate tumor growth, resulting in macrometastases. It is not difficult to envision that the cancer cells that can give rise to metastatic lesions are one of the most aggressively selected populations and are often refractory to most standard therapies.

It is now well recognized that tumors grow in a complex environment composed of multiple cell types and supporting structures together known as the *tumor microenvironment*. Tumor cells interact with their neighbors in this microenvironment, composed of ECM, immune cells, and blood vessels, which influences metastatic success. Recent examples of interactions of metastatic cells with components of the tumor microenvironment are discussed next.

Extracellular Matrix

A major component of the metastasis niche or tumor microenvironment is the ECM, a network of proteins, proteoglycans, glycoproteins, and polysaccharides that constitutes the scaffold and milieu in which all cells sit and migrate. The diverse functions of ECM have been well characterized in primary tumors, where this molecular meshwork provides physical support and serves as a base for cell anchorage. The ECM is also critical in determining polarity and acts as a substrate for migration. Adding to its versatile role, the ECM also acts as a reservoir for bound factors that can be released as bioactive ligands. As a tumor grows with the disruption of tissue organization and remodeling, the mechanical state of the tumor in relation to force, tension, and stiffness of the matrix constantly changes and evolves. ECM remodeling is a highly dynamic process in which the biomechanical cues and ECM alterations influence cell growth, migration, and survival in various stages of tumor progression.[56] For example, lysyl oxidase (LOX) activity is upregulated in several cancers and is tightly linked to the biomechanical properties of the ECM. LOX acts as a crosslinking enzyme that increases ECM stiffness to promote tumor cell invasion and progression in breast cancer models.[57] LOX has been also shown to promote primary tumor growth and metastasis in colon cancer models.[58]

Several studies have shed light on new roles of ECM proteins in premetastatic and metastatic niches. ECM molecules have been shown to be important components of stem cell niches. Perturbation of ECM function by either loss of ECM contact or inhibition of ECM receptor integrins or other ECM binding components leads to reduction of stem cells.[56] Furthermore, ECM proteins can provide anchorage for stem cells that is essential for maintaining their stem-cell characteristics.[59] An interesting example is that of ECM proteins such as fibronectin and osteopontin, which can modulate recruitment of bone marrow–derived cells in the distant microenvironment before the arrival of tumor cells.[60, 61] Such interactions in the premetastatic niche can dictate the pattern and success of colonization of metastatic tumor cells.

The function of ECM proteins as niche components in metastasis is becoming increasingly appreciated. New studies suggest that the ECM provides essential support for metastasis-initiating cells. Recent reports elucidate how two ECM components, tenascin-C (TNC) and periostin, that coexist in the metastatic niche maintain the viability of metastasis-initiating cells. TNC and periostin bind to each other tightly to form scaffolding. TNC enhances metastatic colonization by promoting the survival and fitness of metastasis-initiating cells.[62] Interestingly, stem cell–like breast cancer cells express the ECM component TNC, which enhances their response to Wnt and Notch signaling pathways. TNC expression therefore can help metastasis-initiating cells to thrive in harsh microenvironments and promote metastatic outgrowth. In the lung parenchyma, TGFβ3 stimulates myofibroblast cells that produce the other ECM protein, periostin, which then binds to stromal Wnt factors.[63] Periostin thus concentrates Wnt ligands and presents them to cancer cells, which results in their enhanced ability for lung colonization. Moreover, the cancer cells that benefit from the periostin-Wnt axis are thought to be stem cell–like, metastasis-initiating cells.

Immune Cells

Myeloid cells are the most abundant nucleated hematopoietic cells in the body, consisting of several types of cells with diverse functions. Among myeloid cells, tumor-associated macrophages (TAMs) represent one of the most abundant immune infiltrates in a tumor, and their presence is clinically correlated with poor patient outcome.[64] TAMs belong to a subcategory of macrophages that is associated with immunosuppressive cytokines and pro-angiogenic factors.[65] Several tumor growth-promoting factors and paracrine interactions between cancer cells and macrophages have been characterized in the past few years. Pollard, Condeelis, and colleagues have elucidated how TAMs increase the invasiveness of breast cancer cells via the paracrine interaction between cancer cells and TAMs.[66] Cancer cells express colony-stimulating factor (CSF)1, a critical cytokine for macrophage maturation and activation. CSF1 is also a potent chemoattractant for TAMs that express the CSF1R receptor. TAMs, for their part, express epidermal growth factor that enhances the migration and invasiveness of breast cancer cells expressing the EGF receptor (EGFR). These studies showed how the density of TAMs influences the efficiency of the intravasation of tumor cells. An effector of the CSF1 signaling pathway is the transcription factor Ets2. Deletion of Ets2 in TAMs decreases tumor angiogenesis and lung metastasis in breast tumor models.[67] Yet another interesting interaction is between TAMs and breast cancer cells in the lung involving the cell adhesion molecule vascular cell adhesion molecule 1 (VCAM-1) that promotes cell survival of metastatic cells in the lung.[68] VCAM-1 expressed on breast cancer cells binds to α_4 integrin on TAMs. Thus engaged, VCAM1 activates the adaptor protein Ezrin, which enhances PI3K/Akt signaling in the cancer cells to suppress apoptosis.

Recent studies have shed new light on novel interactions between cells of the adaptive immune system and TAMs that promote metastatic progression. The cross talk between helper T cells and TAMs serves as an example. A large portion of the literature has been focused on T-cell responses in mediating anti-tumor immunity. T-cell activation pathways can be categorized into Th1, Th2, and Th17 responses based on the three different known subsets of helper T cells.[69] Th1 effector cells are characterized by producing γ-interferon, Th2 cells by IL-4 and IL-13 production, and Th17 by IL-17A production. With current advances in understanding the adaptive immune system, it is becoming clear that the presence of $CD8^+$ T cells with markers of Th1 response overall signify good prognosis in solid tumors. Recent studies have revealed that IL-4–expressing $CD4^+$ T cells promote lung metastasis in breast cancer models by affecting macrophage phenotype and effector functions. This prometastatic Th2 CD4 response is mediated by a subset of macrophages that are dependent on IL-4 and IL-13. Such macrophages (referred to as M2 macrophages) produce a number of cytokines, including TGF-β that suppresses antitumor immune responses and EGFR ligands that promote tumor growth. IL-4–producing T cells therefore are able to program macrophages toward a prometastatic phenotype that enhances both tumor invasion and metastasis. Another mechanism by which IL-4 regulates growth-promoting functions of TAM in metastasis is by inducing cathepsin protease activity.[70] Cathepsin proteases are a class of proteolytic enzymes that have been associated with increased motility of tumor cells through the matrix and vasculature. Studies in prostate cancer suggest that T cell and macrophage-derived factor RANKL promotes metastasis.[71] This effect is mediated through the activation of inhibitor of nuclear factor kappa-B kinase subunit alpha (IKK-α). Upon activation, IKK alpha represses a metastasis suppressor gene called *maspin*.[72]

Myeloid-derived suppressor cells, or MDSCs, have become the focus of intense study in cancer biology over the past few years in the context of tumor progression. MDSCs are a heterogeneous population of myeloid cells composed of immature myeloid cells and progenitor cells. These cells are usually not abundant under normal physiological conditions. In healthy individuals, immature myeloid cells differentiate into mature granulocytes or macrophages. However, in individuals with cancer, these bone marrow–derived cells have a partial block in differentiation that results in an expansion of the immature population. The ability of the MDSC population to suppress immune function has major implications for cancer progression. The MDSCs can be categorized into two distinct groups, granulocytic/polymorphonuclear MDSCs (G/PMN-MDSCs) and monocytic MDSCs (M-MDSCs), based on their phenotype.[73] Besides phenotypic differences, the two subsets of MDSCs also differ in the mechanisms they use to suppress immune functions. G-MDSCs use reactive oxygen species (ROS) for immunosuppression, whereas M-MDSCs use inducible nitric oxide synthase (iNOS) and arginase for suppressing immune functions.[74] G/PMN-MDSCs are immature neutrophils that express abnormally high ROS, myeloperoxidase, and lysosomal enzymes compared to differentiated neutrophils (PMN). G/PMN-MDSCs are also less phagocytic than neutrophils. MDSCs isolated from cancer patients with the phenotype $LIN^-HLA^-DR^-CD33^+CD11b^+$ share properties of granulocyte precursors or progranulocytes. The abundance of these cells correlates with poor prognosis and radiographic progression of disease in breast and colorectal cancers. In animal models, MDSCs are shown to infiltrate at the invasive front of tumors, where they contribute to metastasis through enhanced metalloproteinase activity.[75] MDSCs are also responsible for the refractoriness of anti-angiogenic VEGF

inhibitors at least in part by promoting tumor angiogenesis bypassing the VEGF requirement.[76] Recently, G/PMN-MDSCs have been shown to play a critical role in mediating both chemoresistance and metastasis in breast cancer through a network of paracrine signals between carcinoma, endothelial cells, and G/PMN-MDSCs.[77] M-MDSCs in metastatic sites express versican, an ECM proteoglycan that promote metastasis in animal models.[78]

Platelets are specialized blood cells that are produced from megakaryocytes in the bone marrow. Their main function in physiology is to prevent hemorrhage from injury. In the mid-19th century, Trousseau first documented that excessive clotting was related to occult cancer in the body, thus proposing a link between the hemostatic system and malignancy. Since then it has been well recognized that clinical signs of thrombosis or aberrant platelet activation and aggregation are often present in cancer patients with advanced metastatic disease.[79] High platelet counts are associated with poor prognosis in breast, lung, and pancreatic cancers. It has been also shown that depletion of platelets or inhibition of platelet aggregation indeed reduces experimental metastasis in animals.[80] Experimental insights from several laboratories suggest that several functions of platelets might be at play in promoting metastatic progression.[81] Early studies showed that platelets might be functioning in shielding tumor cells from the immune system, in particular from NK cell–mediated tumor lysis.[82] Interestingly, TGF-β released from platelets can also diminish NK function by affecting their granule mobilization and cytotoxicity. Recently Labelle and colleagues showed that platelets could actively signal to tumor cells in transit outside the primary microenvironment.[83] A transient contact between platelets and tumor cells can induce an EMT phenotype by synergistic action of both TGF-β/Smad and NFκB pathways that can increase the invasiveness and metastatic potential in tumor cells. Ablation of TGF-β in platelets or inhibition of NFκB in tumor cells significantly reduces lung metastasis. However, activation of neither the TGF-β/Smad nor the NFκB pathway alone in this context is sufficient to promote lung metastasis. What this study suggests is that tumor cells that have intravasated without losing their epithelial properties might become more mesenchymal and invasive on interactions with platelets in circulation. Although our understanding of platelet function advances, the pro-metastatic functions of platelets in cancer progression remain to be fully explored. It is interesting that platelets can release the neurotransmitter serotonin on activation and thus modulate vascular tone.[84] Future research is necessary to determine how platelets support metastatic growth by altering blood vessel permeability. Given the promising mechanistic studies on platelet function in metastasis, the clinical correlation of platelet activities and cancer, and the potential for antimetastatic therapy, it is imperative to understand platelet involvement in metastatic progression.

In summary, as advances in genomics usher us into an era of personalized diagnostics and treatment development, combinatorial targeting approaches of inhibiting both cancer cell intrinsic and microenvironment-linked pathways are much needed. A deeper understanding of the biology of metastases will be gained by comparing the genetic and phenotypic characteristics of the primary tumor and associated metastases in different cancers and by predicting the course of the development of metastases.

Challenges and Opportunities in Studying the Biology of Disseminated Cancer Cells

New insights into the process of metastasis are pointing to new clinical opportunities for prognosis and intervention and have paved the way for future research. Beyond this, it is becoming increasingly recognized that genetic variations in individual tumors fueled by gene amplification, specific mutations, and single-nucleotide polymorphisms greatly affect the relative efficacy of anticancer treatment. These observations stimulate the consideration of personalized medicine, where treatment would ultimately be determined by each tumor's unique molecular and genomic features. A critical question for oncologists is to define which cancer patients are at a higher risk of metastatic relapse so that treatments can be tailored to those patients most likely to benefit. Research is currently geared toward developing new technologies for detecting cancer cells in the blood (CTCs) and in various organs (DTCs) and to correlate the presence of these cells with the risk of metastatic relapse.

Advanced molecular, cytometric and immunological approaches have improved the ability to detect, monitor, and analyze single DTCs in the bone marrow and CTCs in the blood of cancer patients. Detecting these cells early could provide insights into the biology of metastatic spread and serve as a diagnostic resource for monitoring the efficacy of current cancer therapy. CTC numbers in several cancers have been shown to be prognostic of disease recurrence.[85] For example, CTC numbers before treatment and at the first follow-up visit after initiation of therapy were found to be independently associated with progression-free and overall survival in patients with metastatic breast cancer.[86] Clinical evidence also exists for the association between the presence of DTCs at the time of tumor resection and postoperative metastatic relapse.[87-89] Several new techniques based on cytometric/immunological and molecular approaches have been developed for the detection of CTCs/DTCs over the

past few years. For example, the commercially available CellSearch system (Johnson & Johnson, USA), which consists of an automated enrichment and immunostaining device, was approved by the FDA for the detection of CTCs in patients with breast, colon, and prostate cancer.[90] Other examples include EPISPOT (epithelial immunospot) for the detection of viable DTCs and CTCs and the microfluid platform called the *CTC chip* that captures CTCs from unfractionated blood under controlled laminar flow. Molecular polymerase chain reaction (PCR)-based techniques are also under development. In the future, analysis of CTCs and perhaps DTCs could also be helpful when estimating the efficacy of therapy. However, as is the case with developing new technologies, there are several hurdles to be overcome. At present, a major limitation is that CTCs can be detected in many more patients than ever experience relapse. Other hurdles include tumor heterogeneity, lack of expression of uniform surface markers, limit of detection, and repeated need for bone marrow sampling in cancer patients, to name only a few. Nonetheless, these efforts represent steps in the right direction that could provide critical tools for diagnosis and guiding personalized treatment of metastatic disease in the future.

Inflammation and Cancer

Introduction

Adult tissues contain a multitude of cell types that are spatially and functionally coordinated to regulate normal tissue homeostasis. When a tissue becomes injured, for example, from a skin wound, there is a surge of infiltrating cell types and inflammatory responses within the microenvironment that work in concert to heal the injury and restore tissue homeostasis. Interestingly, tumors share many features with injured tissue, as their microenvironment is characterized by various infiltrating immune cell types and chronic inflammation.[1] However, in cancer, the coordinated cell-cell interactions that are critical during normal tissue homeostasis are disrupted, as the tumor acquires the capacity to chronically circumvent normalizing cues from the microenvironment, and in turn, the microenvironment evolves to accommodate the growing tumor.[2] In this chapter, we discuss representative examples of the positive and negative roles that different types of immune cells can play in cancer, to underscore the importance of inflammation in regulating the initiation and progression of this disease. We review the multifaceted role of inflammation in cancer, with a focus on hematopoiesis, chronic injury and tumorigenesis, and the contributions of myeloid and lymphoid cell types to a growing tumor.

Hematopoiesis and the Immune System

Hematopoiesis is the process by which hematopoietic progenitor cells (HPCs) from the bone marrow constitute all mature cell types in the blood (Figure 19-1). As progenitor cells, HPCs have the capacity to either self-renew or differentiate into either myeloid or lymphoid lineages, to ensure that both immature and mature components of the blood system are not depleted.[3] The myeloid lineage of HPC differentiation gives rise to thrombocytes, erythrocytes, mast cells, granulocytes, and monocytes, which further differentiate into macrophages and myeloid dendritic cells. In contrast, the lymphoid lineage of HPC differentiation gives rise to lymphoblasts, which undergo lymphopoiesis to generate B cells, T cells, and natural killer (NK) cells.

There are two arms of the immune system that use cells generated through hematopoiesis to mediate immunogenic functions: the innate and adaptive arms. The innate immune system provides immediate chemical and cellular responses to foreign microorganisms that invade the body. Chemical defenses, including the complement system, consist of biochemical cascades that attack invading cells, via the exponential activation and release of proteases. Cellular defenses are largely mediated by NK and myeloid cell types, including macrophages, dendritic cells (DCs), mast cells, and granulocytes. These cells work together to phagocytose or ingest invading microorganisms, including bacteria and viruses, or to present antigens for recognition by cells of the adaptive immune system. Of note, the adaptive arm of the immune system is largely mediated by lymphoid cell types. Examples include T cells, which recognize antigens presented by major histocompatibility complex (MHC) molecules, and B cells, which recognize antigens in their native form. Whereas the innate immune system provides an immediate defense mechanism against foreign invaders, the adaptive immune system ensures that the body remembers how to protect itself against specific microorganisms in the future.

Chronic Inflammation and Tumor Incidence

The link between chronic inflammation and tumorigenesis was first proposed by Rudolf Virchow in 1863 after he made a seminal observation that linked the presence of infiltrating leukocytes with cancer.[4] Perhaps one of the most straightforward pieces of evidence that deregulated

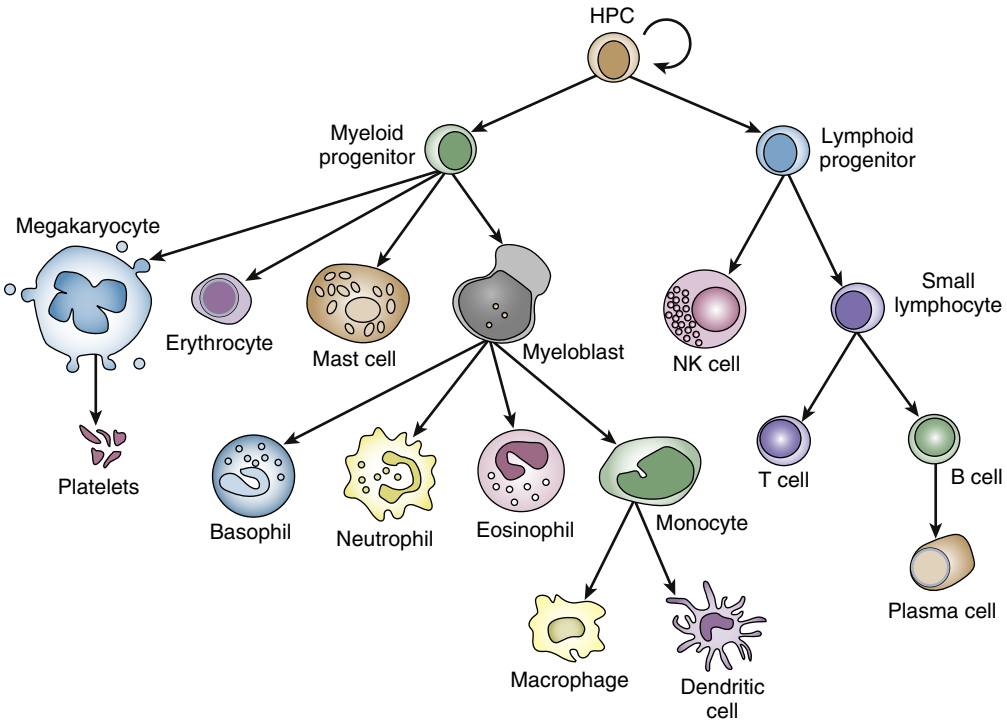

Figure 19-1 Hematopoiesis Hematopoietic progenitor cells (HPCs) can self-renew or differentiate into two multipotent progenitor cell types, myeloid and lymphoid progenitors, which further differentiate to give rise to all cells of the immune system. Myeloid cells differentiate into megakaryocytes, erythrocytes, mast cells, and myeloblasts, which further differentiate into macrophages and dendritic cells. Lymphoid cells give rise to natural killer (NK) cells, and small lymphocytes including T cells (including helper, cytotoxic, and regulatory T cells) and B cells. Together, these cell types work in concert to coordinate both innate and adaptive inflammatory responses.

Table 19-1 Inflammatory Conditions and Infectious Agents That Are Associated with Specific Types of Cancers

Condition/Infection	Associated Neoplasm(s)
Asbestos	Lung cancer
Bronchitis	Lung cancer
Gingivitis	Oral cancer
Inflammatory bowel disease	Colorectal cancer
Skin inflammation (UV)	Skin cancer
Hepatitis	Liver cancer
AIDS	Non-Hodgkin's lymphoma
Chronic pancreatitis	Pancreatic cancer

AIDS, Acquired immunodeficiency syndrome; *UV*, ultraviolet.

inflammation affects tumorigenesis is that tissues which experience chronic injury exhibit a high risk for subsequently developing tumors. Classic examples of tissue damage leading to chronic inflammation include the development of lung cancer arising from tobacco smoke, or skin cancer resulting from exposure to UV (ultraviolet) light (Table 19-1).[1] In both of these cases, the onset of tumorigenesis is supported by a repetitive inflammatory response, whereby immune cells accumulate and their tissue-repair functions become excessive and maladaptive, leading to the development of a pro-tumorigenic niche.[2,5] Recruited inflammatory cells support disease progression by providing critical growth factors and cytokines to sustain tumorigenesis.[5]

Another piece of evidence that deregulated inflammation contributes to tumorigenesis is the correlation between chronic viral infection and cancer initiation. In 1911, the discovery of a tumor virus in chickens by Peyton Rous, later termed the *Rous sarcoma virus* (RSV), was a pivotal discovery in molecular cancer biology that led to the discovery of *src*, the first oncogene.[6,7] Decades later, Bissell and colleagues demonstrated a clear connection between inflammation and tumorigenesis, when they showed that chickens systemically infected with RSV only developed tumors at the site of initial injection or a subsequent inflicted wound.[8,9] It is also known that people infected with hepatitis B or C virus are prone to developing cirrhosis of the liver, which increases the risk of hepatocellular carcinoma by 100-fold.[10] In fact, it has recently been estimated that approximately 2 million cancer cases worldwide, representing 16% of total cases, are caused by infectious agents every year.[11] For a list of infectious agents, inflammatory conditions, and associated cancers, refer to Table 19-1.[1]

Recent attempts to understand the connection between infection, inflammation, and cancer have led to the Human Microbiome Project, which was initiated by the National Institutes of Health (NIH) Roadmap for Medical Research.[12] The project was launched in an effort to gain insight into how microorganisms influence health and disease, given that the human body contains 10 times more microbial cells than human cells, and 100 times more microbial genes (i.e., the microbiome) than human genes.[13] Indeed, it is estimated that in humans, the distal gut contains up to 1000 species and 7000 strains of microbes. It is currently

Table 19-2 Stromal Cell Populations in the Tumor Microenvironment Are Defined by Various Cell Surface Markers and Have Distinct Functions During Tumorigenesis

Cell Type	Functions in the Tumor Microenvironment
Myeloid Lineage	
TAM	Classically activated M1 macrophages are pro-inflammatory and anti-tumorigenic and secrete T_H1 cytokines. Alternatively activated M2 macrophages are anti-inflammatory and pro-tumorigenic and secrete T_H2 cytokines. TAMs exhibit an M2 phenotype; their presence in tumors supports angiogenesis and invasive phenotypes.
TEM	TEMs are monocytes that express the angiopoietin receptor TIE-2. TEMs play a role during tumor angiogenesis through paracrine signaling with angiopoietin-expressing endothelial cells.
Neutrophil	N1 neutrophils are pro-inflammatory and anti-tumorigenic and secrete T_H1 cytokines. N2 neutrophils are anti-inflammatory and pro-tumorigenic and secrete T_H2 cytokines. TGFβ mediates the transition from an N1 to an N2 phenotype.
Mast cell	Mast cells are important in generating and maintaining innate and adaptive immune responses. Mast cells are recruited to tumors where they release factors that enhance proliferation of endothelial cells to promote tumor angiogenesis.
MDSC	MDSCs are elevated in circulation of patients with cancer. Their main function is to disrupt tumor immunosurveillance by interfering with T and NK cell function and promoting M2 macrophage polarization.
Lymphoid Lineage	
NK cell	NK cells are cytotoxic lymphocytes that can kill stressed cells in the absence of antigen presentation. NK cells can detect and kill tumor cells through "missing-self" activation (loss of healthy cell markers) or "stress-induced" activation (gain of stressed cell markers).
CD4+ T_H cell	CD4+ helper T (T_H) cells can be divided into T_H1 and T_H2 lineages. T_H1 cells secrete pro-inflammatory cytokines and are anti-tumorigenic. T_H2 cells secrete anti-inflammatory cytokines and are pro-tumorigenic. The ratio of T_H1:T_H2 cells in cancer correlates with tumor stage and grade.
T_{REG} cell	T_{REG} cells play divergent roles in cancer. They elicit pro-tumorigenic roles by suppressing immunosurveillance; yet their presence in tumors is positively correlated with overall survival in multiple cancer types. These divergent roles may be attributed to context-dependent functions or an inability to distinguish between subpopulations using conventional markers.
CD8+ T_C cell	CD8+ cytotoxic T (T_C) cells are effector cells of the adaptive immune system. They specifically recognize and destroy cancer cells through perforin and granzyme-mediated apoptosis.
B cell	B lymphocytes are important mediators of humoral immunity. In cancer, they play a pro-tumorigenic role by secreting pro-tumorigenic cytokines and altering T_H1:T_H2 ratios. Their importance in supporting tumor growth is evident in B-cell–deficient mice, which exhibit resistance to engraftment of syngeneic tumors.

known that microorganisms contribute to the development of diseases including cancer, despite often maintaining symbiotic relationships with the human body.[13-15] For example, it has been shown that stomach cancer can arise from chronic gastric inflammation caused by *Helicobacter pylori* infection. Inflammatory bowel disease, comprising ulcerative colitis and Crohn's disease, is also associated with recurrent bacterial infection and can predispose to colorectal cancer.[16,17] However, the specific mechanisms and intercellular interactions that disrupt microbial homeostasis, leading to inflammation-induced cancer, remain elusive and an area of active investigation.

Inflammation and the Metastatic Cascade

In each of the cases just described, the onset of tumorigenesis is supported by an unresolved inflammatory response that contributes to a pro-tumorigenic niche, characterized by a plethora of different stromal cell types, growth factors, and cytokines (Figure 19-2).[2,5] For example, studies in breast cancer have shown that the type of inflammatory response is an important predictor of tumor development. In particular, acute inflammation involving cytolytic $CD8^+$ T lymphocytes, $CD4^+$ T helper (T_H1) cells, or classically activated M1 macrophages is generally anti-tumorigenic, whereas chronic inflammation involving B lymphocytes, $CD4^+$ T helper (T_H2) cells, or alternatively activated M2 macrophages is frequently pro-tumorigenic (Table 19-2).[2,18,19] These findings demonstrate a complex relationship between tumor cells and their microenvironment and suggest that the development of a pro-tumorigenic niche is highly dependent on the type of immune response that ensues.

The metastatic cascade begins at the primary tumor site, when tumor cells recruit a vascular supply (angiogenesis), invade through the extracellular matrix (ECM), intravasate into the circulation, disseminate through the body, extravasate at secondary sites, and self-renew to sustain secondary tumor growth. Bone marrow–derived cells have diverse effects on each step of the metastatic cascade and

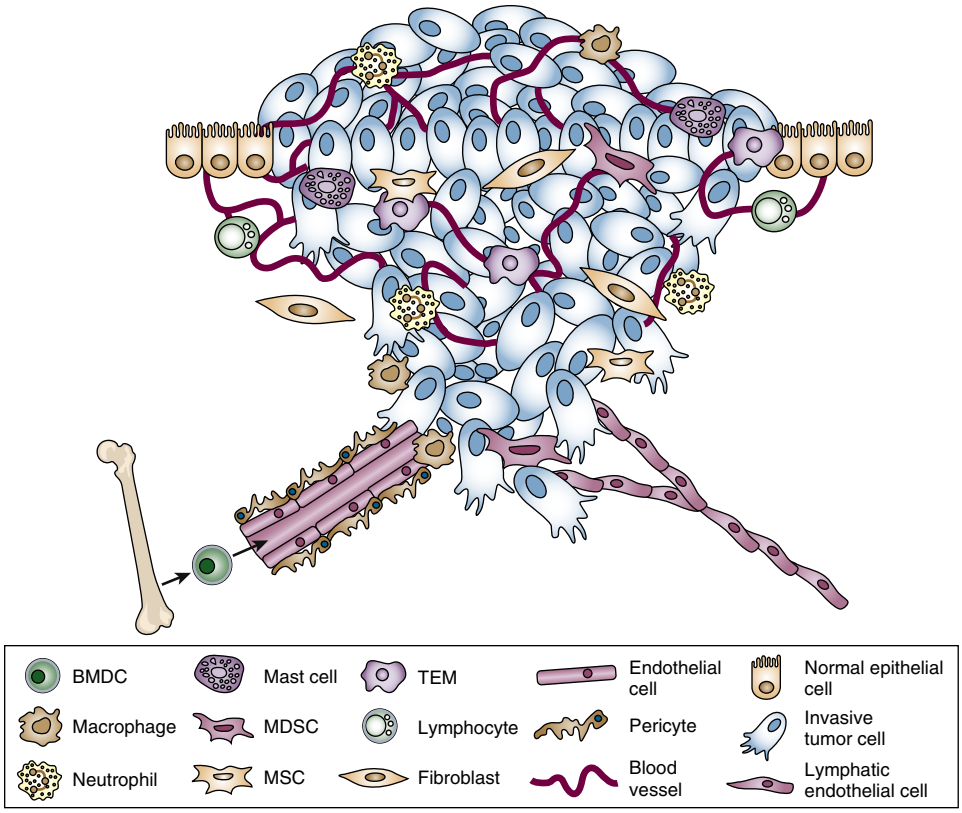

Figure 19-2 The primary tumor environment Cells within a tumor are supported by a complex and dynamic microenvironment composed of multiple infiltrating cell types, including endothelial cells (which line blood and lymphatic vessels), cancer-associated fibroblasts (CAFs), and a variety of bone marrow–derived cells (BMDCs). Infiltrating BMDCs mediate inflammatory responses during cancer progression and can have negative or positive consequences. Major BMDCs within the tumor niche include tumor-associated macrophages (TAMs), myeloid-derived suppressor cells (MDSCs), TIE2-expressing monocytes (TEMs), mesenchymal stem cells (MSCs), and various other cell types from lymphocyte and monocyte lineages. This tumor-associated cellular cocktail largely dictates the evolution of the surrounding environment and, ultimately, the outcome of disease. *(Image adapted from Joyce JA, Pollard JW. Microenvironmental regulation of metastasis.* Nat Rev Cancer. *2009;9: 239-252).*

render the microenvironment susceptible or resistant to tumorigenic growth.[2] For example, studies in breast cancer have shown that tumor-associated macrophages (TAMs) are critical for promoting angiogenesis and tumor cell invasion and helping cancer cells to cross blood vessel walls. Within the circulation, platelets can enhance the survival of tumor cells by protecting them from NK cell-mediated death and promoting their adhesion to the endothelium at the site of metastasis.[20] Furthermore, myeloid-derived suppressor cells play a role in suppressing immune surveillance of cancer cells, promoting tumor growth.[21] In an elegant study by Lyden and colleagues, hematopoietic progenitor cells (HPCs) positive for vascular endothelial growth factor receptor 1 (VEGFR1) and endothelial progenitor cells positive for VEGFR2 were both shown to be required for mediating neovascularization at sites of future metastasis: the premetastatic niche.[22] Another study reported that recruited $CD11c^+$ DC precursors were capable of assembling tumor-associated neovessels in a model of ovarian carcinoma.[23] As illustrated by these examples, the diverse effects of all these different immune cell types during multiple steps of the metastatic cascade underscore the complexity of tumor-microenvironment relationships in cancer. In the following section, various immune cell types and their roles during tumorigenesis and metastasis are reviewed.

Immune Cells in Cancer

Myeloid Lineage

Macrophages

In normal physiological contexts, macrophages defend against infection, clear debris, and remodel injured tissue to maintain homeostasis. In cancer, normal macrophage function is hijacked by tumor cells to support tumor progression. In fact, in 80% of epithelial cancers, it has been shown that high macrophage infiltration is associated with poor patient prognosis.[24] TAMs typically represent the major immune cell type infiltrating tumors, and in some cancers, such as gliomas and breast cancer, TAMs can constitute up to 30% of the total tumor mass. TAM progenitors are largely recruited from the bone marrow and, once in the tumor mass, represent a critical source of secreted growth factors, proteases, and cytokines that participate in paracrine signaling loops with tumor cells to support invasive phenotypes.[25,26] One important function of TAMs is that they help tumor cells enter blood vessels, a process called *intravasation*. Condeelis and colleagues have published seminal studies using sophisticated multiphoton intravital imaging techniques to observe intimate macrophage–tumor cell interactions during metastatic dissemination in

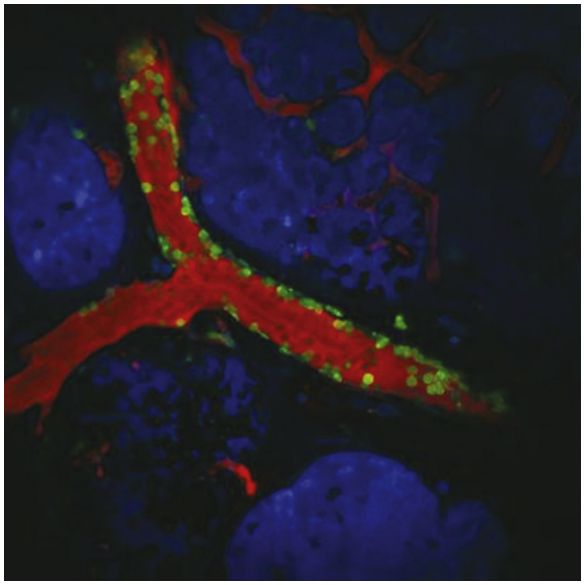

Figure 19-3 Live images of the tumor microenvironment of metastasis (TMEM) in a mouse breast carcinoma TMEM, the direct interaction of a macrophage, migratory tumor cell, and vascular endothelial cell, are sites of intravasation of tumor cells into the circulation. TMEM density correlates with increased risk of distant metastasis in breast cancer patients.[29,30] TMEM are detected in this live image, from a mouse model of breast cancer, as pairs of macrophages *(green)* and tumor cells *(blue)* attached to blood vessels *(red)*, as visualized with a custom-built high-resolution multiphoton microscope. *(Image courtesy of Drs. Allison Harney and John Condeelis. Microscope details obtained from Entenberg D, et al. Setup and use of a two-laser multiphoton microscope for multichannel intravital fluorescence imaging.* Nat Protoc. *2011;6:1500-1520).*

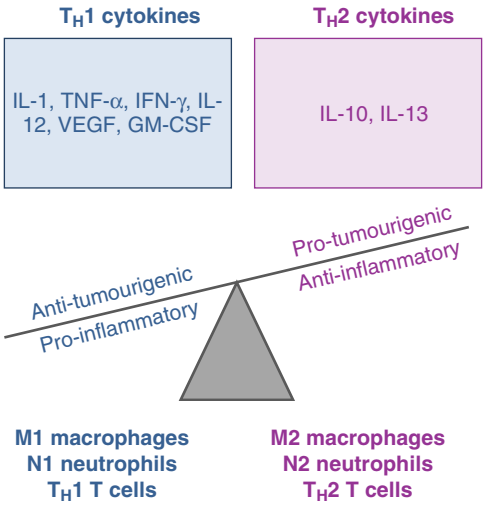

Figure 19-4 The balance of pro- and anti-inflammatory cytokines and cellular states govern cancer outcome Tumor and stromal cells produce a variety of cytokines and chemokines that either contribute to or disrupt the development of a pro-tumorigenic niche. These factors can also reprogram infiltrating immune cells to adopt a pro- or anti-inflammatory state. Generally, M1, N1, and T_H1 cell types produce and respond to T_H1 cytokines and exhibit anti-tumorigenic phenotypes, whereas M2, N2, and T_H2 cell types produce and respond to T_H2 cytokines and exhibit pro-tumorigenic phenotypes. It is likely that this inherent plasticity is important for these cells to reestablish normal homeostasis during inflammation; however, their ability to adapt to different types of microenvironments is hijacked in the tumor niche. *(Image adapted from Coussens LM, Werb Z. Inflammation and cancer.* Nature. *2002;420:860-867).*

live animals.[27] These studies have shown that macrophages are primarily localized in perivascular areas, where they help tumor cells intravasate into the circulation (Figure 19-3).[27-30]

One explanation for the divergent functions of macrophages during normal tissue homeostasis versus tumorigenesis lies in their polarization state. Macrophages are phenotypically plastic. They can alter their polarization status to rapidly accommodate for the needs of different physiological contexts. At the extremes of their phenotypic continuum, macrophages range from M1 to M2 polarization states.[31] "Classically activated" (M1-polarized) macrophages produce type I pro-inflammatory cytokines and participate in antigen presentation, and they play an anti-tumorigenic role in cancer.[2,32] On the other hand, "alternatively activated" (M2-polarized) macrophages produce type II cytokines and anti-inflammatory responses, and they play a pro-tumorigenic role in cancer (Figure 19-4).[2,32] Of note, M2-polarized TAMs have been shown to promote tumorigenesis by providing a major source of proteases and chemokines that support tumor invasion and therapeutic resistance in multiple cancer types.[33-36] For example, it has been shown that TAM-derived cathepsin proteases B and S promote breast cancer growth and metastasis by blunting chemotherapy-induced apoptosis.[34] Furthermore, tumor-secreted cytokines, such as interleukin-4 (IL-4), hijack macrophages in the tumor niche, activating them toward a pro-tumorigenic state.[33,37] Additional characterization of bidirectional interactions between tumor cells and TAMs will likely provide valuable information about how to manipulate the tumor niche in a therapeutic context.

TIE-2–Expressing Monocytes

TEMs are monocytes that express TIE-2, which is a tyrosine kinase receptor for the angiogenic growth factor Angiopoietin. In healthy individuals, TEMs are present at very low levels in the bloodstream and are rarely detected in normal tissue. In contrast, in cancer patients, TEMs are present in higher numbers in the bloodstream and infiltrate neoplastic tissue.[38] TEMs have been implicated in various aspects of tumorigenesis, but they are best known for their role in promoting tumor angiogenesis.[38,39] TEMs regulate angiogenesis by participating in a paracrine signaling loop with Angiopoietin-expressing endothelial cells. This signaling loop is thought to contribute to the inefficacy of anti-angiogenic therapies, such as VEGF-targeted agents. Studies have shown that interfering with the TIE-2/Angiopoietin signaling axis in spontaneous breast or pancreatic

neuroendocrine tumor models significantly inhibits tumor vascularization and blocks tumor growth.[40] These findings suggest that interfering with the TIE-2/Angiopoietin axis may have clinical benefits in reducing tumor vascularization; however, this has not yet been explored in humans.

Neutrophils

Neutrophil granulocytes are the most abundant circulating leukocyte population in humans and play an early role during inflammation by rapidly defending against microorganisms at the site of an infection. Likewise, neutrophils are recruited to tumor sites in response to cytokines and chemoattractants, and the neutrophil:lymphocyte ratio is used as a prognostic indicator of survival and therapeutic outcome in a variety of cancer types.[41-45] At the tumor site, neutrophils have quite diverse roles. For example, it has been shown that neutrophils stimulated with granulocyte colony-stimulating factor (G-CSF) enhance the capacity of circulating tumor cells to seed and grow in secondary sites such as lung.[46] Infiltrating neutrophils were implicated in driving the initial angiogenic switch in pancreatic islet cancers through their ability to activate matrix metalloproteinase (MMP)-9.[47] In contrast, in a recent report on breast cancer by Benezra and colleagues, primary tumor-entrained neutrophils were shown to colonize the premetastatic lung, where they prevented metastatic colonization of disseminated tumor cells via H_2O_2-mediated cell death.[48] In another study, in renal cell carcinoma, it was demonstrated that tumor-secreted chemokines induce recruitment of neutrophils to the premetastatic lung, where they establish a barrier that blunts metastatic colonization.[49] Interestingly, microarray expression analysis revealed that poorly metastatic tumor cells expressed higher levels of these neutrophil chemokines compared to highly metastatic tumor cells, providing a possible explanation for their metastatic inefficiency.[49]

In light of these divergent findings, the role of neutrophils during tumor progression remains unclear. However, similar to the different polarized states of macrophages, it has been shown that neutrophils can acquire N1 or N2 phenotypes, which have very different effects on cancer[50] (see Figure 19-4). The N1 phenotype is pro-inflammatory and elicits an anti-tumoral response by recruiting $CD8^+$ T cells and secreting pro-inflammatory T_H1 cytokines such as tumor necrosis factor-α (TNFα) or IL-12 (see Figure 19-4). In contrast, the N2 phenotype promotes tumorigenesis and plays a role in immune suppression mediated by transforming growth factor (TGF)-β. Indeed, studies have shown that blocking TGFβ signaling can revert pro-tumorigenic N2 neutrophils to an anti-tumorigenic N1 phenotype.[51] This inherent plasticity may explain why neutrophils have been reported to have both pro- and anti-tumorigenic effects in animal models and in patients.[50]

Interestingly, a common side effect of patients undergoing chemotherapy is neutropenia, which is characterized by a significant deficiency in the population of neutrophil white blood cells. This deficiency underlies the extreme risk of infection in cancer patients, as the body loses a major rapid defensive mechanism against invading microorganisms. Recombinant G-CSF protein is frequently used in combination with chemotherapy in cancer patients in order to stimulate the bone marrow to produce more neutrophils.[52] Despite the fact that neutropenia is dangerous for patients because of increased risk of infection, retrospective analyses have reported that neutropenia in response to chemotherapy is correlated with improved overall survival, suggesting that a depletion of systemic neutrophils may be important for optimizing the anti-tumoral effects of therapy.[52,53]

Mast Cells

Mast cells are also derived from myeloid progenitors and act as cellular barriers of infection. Mast cells contain histamine and are best known for their roles during allergic responses and autoimmune diseases. As mediators of inflammation, mast cells become activated in response to tissue injury and release their granules containing histamine, proteases, heparin, prostaglandins, and various cytokines into the microenvironment, where they induce proliferation of nearby endothelial cells. Of note, as tumors hijack inflammatory responses to tissue injury, it is not surprising that mast cells have also been implicated during tumor angiogenesis.[54,55] In patients, studies have shown that mast cells are abundant in the tumor microenvironment and that the degree of mast cell infiltration correlates with microvascular density and poor prognosis.[54,55] Moreover, in animal models of squamous-cell carcinoma and pancreatic islet cancer, oncogene activation was shown to rapidly recruit mast cells, which were essential for induction of angiogenesis via activation of different proteolytic cascades.[56,57]

Myeloid-Derived Suppressor Cells

Myeloid-derived suppressor cells (MDSCs) are immunosuppressive precursors of dendritic cells, macrophages, and granulocytes and play a role in maintaining normal tissue homeostasis in response to various systemic insults. MDSCs are elevated in the circulation in response to bacterial and parasitic infection[58-60] and are also elevated in the blood of tumor-bearing hosts. Mobilization of MDSCs into the bloodstream is mediated by cytokines that are secreted by tumor cells. For example, studies in breast cancer have shown that TGFβ signaling in tumor cells increases secretion of tumor-derived chemokine CXCL5, which acts as a chemoattractant for CXCR2-expressing MDSCs.[61] Interestingly, the accumulation of MDSCs is a common response to cancer therapy and is thought to contribute to lack of

therapeutic efficacy. For instance, MDSCs have been shown to accumulate in the blood of breast cancer patients receiving doxorubicin-cyclophosphamide chemotherapy and are present in highest numbers in stage IV patients with metastatic disease.[62]

Once MDSCs arrive at the tumor site, their main function is to disrupt major mechanisms of tumor immune surveillance, including antigen presentation and cell-mediated anti-tumor immunity.[21] They achieve immune suppression in multiple ways: First, they have been reported to directly inhibit proliferation and activation of $CD4^+$ T cells and $CD8^+$ T cells.[63,64] Several studies have demonstrated that the immunosuppressive effects of MDSCs on T cells are largely mediated by the production of nitric oxide, among other factors.[64-66] They are also associated with promoting M2-polarization of TAMs to yield a pro-tumorigenic phenotype, as described earlier.[67] MDSCs have also been shown to participate in a paracrine loop with TAMs, whereby MDSC-derived IL-10 (a type II cytokine) causes inhibition of macrophage-derived IL-12 (a type I cytokine), which feeds back to amplify the production of IL-10 from MDSCs.[68] Last, they are capable of impairing NK cell function. Specifically, MDSCs inhibit cytotoxicity of NK cells by reducing production of NK-derived interferon γ (IFNγ) in a TGF-β–dependent manner.[69,70] In light of these findings, it is not surprising that increased peripheral MDSC levels correlate with advanced disease.[62]

Lymphoid Lineage

NK Cells

Natural killer (NK) cells are cytotoxic lymphocytes that play an important role in both innate and adaptive immune responses. NK cells are unique compared to other lymphoid cell types in that they are capable of distinguishing between healthy cells and stressed cells (such as tumor cells) in the absence of antigen presentation.[71] Therefore, it is generally recognized that NK cells provide an anti-tumorigenic immune response. Indeed, reduced NK cell levels in patients with cancer have been shown to correlate with decreased overall survival.[72-74] One way that NK cells can recognize and kill cancer is through "missing-self" activation, whereby MHC class I molecules, which characterize healthy cells and inhibit NK cytotoxicity, are lost from tumor cells. Alternatively, NK cells can recognize cancer through "stress-induced activation," whereby stress-induced ligands are upregulated on tumor cells to activate receptors on adjacent NK cells.[71]

Despite the many anti-tumor roles that NK cells have, it has been recently shown that following surgical removal of tumors in cancer patients, NK cell cytotoxicity is significantly reduced, largely attributed to surgical tissue stress.[75] This effect is correlated with increased metastatic incidence in mouse models, demonstrating that the anti-tumorigenic functions of NK cells can be disrupted with standard-of-care treatment regimens. Therefore, therapies that opt to enhance NK populations following surgery may provide an opportunity for improving therapeutic efficacy at early stages of treatment.

$CD4^+$ Helper T Cells

$CD4^+$ helper T (T_H) cells play diverse roles in cancer. Like polarized macrophages, they can be subdivided into phenotypically divergent T_H1 and T_H2 lineages, directed by secretion of IL-12 and IL-4, respectively.[76] Specifically, T_H1 cells secrete pro-inflammatory cytokines, including IFN-γ, TNFα, IL-2, and IL-12 (see Figure 19-4) to induce antigen presentation on MHC molecules by antigen-presenting cells (APCs), and $CD8^+$ T cell cytotoxicity. They also exhibit direct cytotoxic functions by releasing granules that directly kill tumor cells in their microenvironment.[77] On the other hand, T_H2 cells play a role in humoral immunity. They secrete high levels of anti-inflammatory cytokines, such as IL4-6, IL-10, and IL-13 (see Figure 19-4), and elicit pro-tumorigenic effects through inhibition of $CD8^+$ T-cell cytotoxicity and immunosuppression to promote tumor growth.[77]

Despite the finding that T_H2 cells are generally associated with pro-tumorigenic functions, they may retain some inherent plasticity that allows them to provide beneficial anti-tumor effects. For instance, it has been shown that T_H2 cell infiltrates are positively correlated with disease-free survival in patients with Hodgkin's lymphoma.[78] In other types of cancers, the T_H cell balance seems to be more important for disease outcome. For example, in breast cancer, the ratio of T_H1 to T_H2 cells within the tumor microenvironment correlates with tumor stage and grade, suggesting that the balance of T_H cell types, rather than the degree of infiltration of any one T_H subset, may be useful for predicting prognosis in patients.[79]

Regulatory T Cells (T_{REGS})

Regulatory T cells, or T_{REG} cells, are a unique subtype of $CD4^+FoxP3^+$ T cells that play divergent roles during tumorigenesis. On the one hand, increased T_{REG} cell infiltrate has been correlated with reduced overall survival in various cancers such as breast cancer and hepatocellular carcinoma.[80,81] In these pro-tumorigenic roles, T_{REG} cells function by releasing immunosuppressive factors, such as TGF-β and T_H2 cytokines, which disrupt antigen presentation by APCs and impair the anti-tumorigenic effects of $CD8^+$ cytotoxic T cells and NK cells.[82,83] Furthermore, T_{REG} cells have been shown to impair M1-polarization of macrophages and support immunosuppressive myeloid cells.[84]

On the other hand, it has been shown that infiltration of T_{REG} cells is correlated with improved overall survival in cancers as diverse as colorectal cancer, bladder cancer, and head and neck cancer.[85-87] The mechanisms of these divergent roles remain elusive in the literature; it is not clear whether T_{REG} cells exhibit context-dependent functionality or whether they encompass multiple subpopulations of cell types, with distinct functions, that are not differentiated using conventional markers.[76]

$CD8^+$ Cytotoxic T Cells

Cytotoxic $CD8^+$ T (T_C) cells are lymphocytes that kill cells infected with viruses and also have the capacity to kill tumor cells. They express T-cell receptors (TCRs) on their surfaces, which recognize antigens presented on MHC molecules on APCs. In cancer, infiltration of T_C cells is associated with an anti-tumorigenic capacity across a wide range of cancer types, including melanoma, breast cancer, ovarian cancer, gliomas, and hepatocellular carcinoma, and is associated with prolonged overall survival in patients.[76,88,89] On activation, T_C cells release granules containing cytotoxic factors, for example, perforin and granzyme proteases, which induce apoptosis of infected cells.[83] It has been reported that T_C cells are abundant at the invasive edge of tumors, where they improve patient response to chemotherapy and prognosis.[88]

B Cells

B cells play an important role in humoral immunity and mediate both antibody production and activation of T cells through antigen presentation. They are most abundant at the tumor invasive edge and in adjacent tertiary lymphoid structures.[76] Although infiltration of B cells in tumors tends to be correlated with better disease outcome and prolonged survival in patients, it remains largely unclear whether B cells have positive or negative roles in disease progression based on confounding literature.[90] For instance, it has been reported that B cells elicit pro-tumorigenic effects by secreting tumorigenic cytokines, altering the ratio of T_H1:T_H2 cell infiltrates within tumors, and mediating immune cell recruitment.[91] In addition, studies in breast cancer have shown that B cells influence phenotypic transitions between T-cell states and mediate the conversion of $CD4^+$ T_H cells into T_{REG} cells to promote metastatic dissemination.[92] In contrast, other studies have demonstrated anti-tumorigenic effects of tumor-infiltrating B cells. For example, B cells can release cytotoxic factors to directly kill tumor cells, such as TNFα and the protease granzyme B, and can induce immune suppression through secretion of IL-10.[93] Taken together, these studies suggest that further classification of B-cell subpopulations may explain their diverse functions and may suggest novel therapeutic avenues for disease intervention.

Nonhematopoietic Stromal Cell Types in the Tumor Microenvironment

In addition to the inflammatory cells that constitute the primary tumor and metastatic microenvironment, additional accessory cells in the tumor stroma, such as cancer-associated fibroblasts (CAFs) and mesenchymal stem cells (MSCs), engage in a dynamic interplay between immune cells and tumor cells. In the following section, we discuss the role of CAFs and MSCs during tumor progression and how immune cells modulate their function.

Cancer-Associated Fibroblasts

Fibroblasts are a predominant cell type in connective tissue and are responsible for depositing ECM and basement membrane components, regulating differentiation events in associated epithelial cells, modulating immune responses, and mediating wound healing.[94,95] In the tumor microenvironment, fibroblasts are present in aberrantly high numbers and are generally regarded as genomically stable compared to tumor cells.[96] However, CAFs are quite different from normal fibroblasts; it has been reported that normal prostate epithelial cells resemble intraepithelial neoplasia in mice when co-injected with CAFs, but not when co-injected with normal fibroblasts.[97] Once CAFs accumulate in the tumor microenvironment, they are activated by growth factors and cytokines such as TGF-β, platelet-derived growth factor (PDGF), and various proteases.[95,98,99] Following activation, CAFs provide a major source of oncoproteins and growth factors that fuel the growing tumor and modulate immune function.[100,101] For example, CAFs are a significant source of hepatocyte growth factor (HGF) in the tumor microenvironment, which supports angiogenesis, acts as a chemotactic agent for monocytes, and interferes with normal function and maturation of B cells.[102-104]

Mesenchymal Stem Cells

Bone marrow–derived MSCs play an important role during tissue remodeling and repair. They are mobilized into the circulation in response to cytokines released by tissue injury and have a multipotent capacity to give rise to osteoblasts, adipocytes, and chondrocytes.[105] Given that tumorigenesis shares many similarities with the process of wound healing, tumors are likewise able to mobilize and recruit bone marrow–derived MSCs to support remodeling events.[106] Indeed, it has been shown that mobilization of MSCs into circulation is pronounced in patients with advanced breast

cancer and is associated with metastasis and chemoresistance.[107,108] Similar to the divergent roles that immune cells play in cancer, MSCs likewise have seemingly distinct functions. For example, it has been shown that glioma cells co-injected with MSCs into BALB/c-nu/nu mice exhibit a marked reduction of tumor vascularization compared to glioma cells injected with normal astrocytes.[109] In contrast, other studies have demonstrated a positive regulatory relationship between MSCs and tumor angiogenesis, whereby co-injection of MSCs and colon cancer cells into BALB/c-nu/nu mice induces a significant increase in tumor volume and microvascular density.[110] The differential effects of MSCs may be due to their capacity to modulate immune cells and thereby change the landscape and secretome of the tumor microenvironment.[105] Indeed, MSCs have been shown to alter both innate and adaptive arms of the immune system. For example, tumor-associated MSCs have been shown to suppress the pro-inflammatory function of dendritic cells, by blunting their ability to produce TNFα.[101] Furthermore, MSCs can interfere with NK activation and cytotoxicity.[111] Finally, MSCs have been shown to negatively regulate $CD8^+$ T_C cell–mediated cytotoxicity and have a capacity to switch pro-inflammatory T_H1 cells to adopt an anti-inflammatory phenotype.[101,112] Taken together, in addition to the complex relationship between tumor cells and immune cells, additional accessory cells in the tumor-associated stroma contribute to disease progression by influencing tumor-immune interactions.

Summary

Despite the classical role of the immune system in defending against infection and systemic insult, many studies have shown that immune cell functions in the tumor niche often correlate with disease progression. This correlation is largely attributed to the reprogramming effects of the tumor microenvironment, which contains a plethora of growth factors and cytokines that hijack immune cells to play oncogenic roles. Although many immune cells are receptive to tumor-secreted factors and can adopt pro-tumorigenic functions, these cells have also been reported to retain many defensive functions in the tumor microenvironment, speaking to the complexity of tumor–stroma interactions during disease. It is likely that the diverse outcomes of immune cell function are highly context dependent, involving a reprogramming decision that is based on a large variety of factors, including tissue type, tumor secretome, tumor landscape, oxygen availability, tissue pH, and ECM architecture.

The therapeutic implications of tumor microenvironment research are vast. For example, disrupting key tumor–stroma interactions that play known roles during disease progression may interfere with the tumor's ability to exploit immune cells in the microenvironment. Furthermore, attempts have been made to deplete specific immune-cell populations in the tumor environment; however, this type of an approach has been reported to lead to compensatory infiltration of alternative cell types that completely alter the tumor landscape in a way that is unpredictable and often unfavorable.[113,114] Of note, rather than depleting immune cell populations in tumors, it may be advantageous to develop therapies that opt to "re-educate" immune cells in the microenvironment, in order to take advantage of the valuable defense functions of these cell types. For instance, inducing anti-tumorigenic activation states in plastic immune-cell types, such as forcing classical activation of TAMs, may be a unique way to manipulate the tumor microenvironment in a way that re-establishes normal mechanisms of tissue homeostasis. Many of these therapies have been studied or are currently being explored in the laboratory; it will be interesting to observe the evolution of these novel approaches in patients in the future, with the ultimate goal of maximizing positive responses to therapy.

Cancer Systems Biology: The Future

Over the past decade, complementary and at times antithetic views of tumor initiation and progression have emerged, often based on the introduction of novel high-throughput technologies for the characterization of the cell's genetic and epigenetic landscape. On the one hand, the availability of a comprehensive map of the human genome has allowed the development of gene expression profiling techniques, mostly microarray based, to monitor the dynamic state of RNA transcripts in cancer cells. These efforts have revealed the existence of molecularly distinct subtypes of morphologically indistinguishable tumors, often associated with differential outcome,[1] progression,[2] and chemosensitivity.[3] They have also helped identify key genetic programs that are consistently activated (e.g., proliferation, migration, immunoevasion), inactivated (apoptosis, senescence), or frequently modulated (adhesion, angiogenesis, etc.) in tumorigenesis.[4,5] On the other hand, genome-wide studies of both heritable and somatic human variability have moved from theoretical concept to practical reality, opening a new window on both the heritable and the somatic components of cancer etiology. Yet, even as we achieve increased sensitivity in the identification of recurrent somatic alterations for several of the major tumor types, elucidation of the mechanistic role of genetic variability in cancer remains, overall, an elusive target.

Despite these advances, the relationship between genetic alterations and activation/inactivation of specific genetic programs contributing to cancer subtypes remains poorly understood, and the precise cascade of molecular events leading to tumorigenesis and progression is largely uncharted. For instance, although the mesenchymal subtype of glioblastoma is now universally accepted as a distinct subtype, only relatively rare mutations in the NF1 gene appear to co-segregate with it, and the mechanism by which NF1 drives the subtype has not been elucidated[6] (Figure 20-1). Similarly, despite massive sequencing efforts, many mutations discovered in diffuse large B-cell lymphoma fail to precisely co-segregate with its two main functional subtypes, the activated B-cell (ABC) and germinal center B-cell (GCB) phenotypes, which are associated with differential outcome.[7] Even in very common tumors, such as prostate cancer, the repertoire of genomic alterations that contribute to the indolent versus the more aggressive tumors is still unknown.[8] Critically, because of impractical requirements for cohort sizes[9] and lack of methodologies that maximize power for such detection, few epistatic interactions and low-penetrance variants have been identified so far.[10]

This chapter introduces a set of novel approaches and strategies, mostly developed over the past decade, for the elucidation of mechanisms associated with cancer initiation, progression, and chemosensitivity that, overall, go under the name of cancer systems biology. A fundamental departure from the previous methodologies is that, instead of being driven by the isolated analysis of a specific data modality, such as genomic alterations or gene expression profiles, the new discipline is both highly integrative and, more importantly, model driven. By the latter term, we mean that cancer-related datasets are analyzed using small- or large-scale models of the cellular machinery that is most likely to have generated it. These models are still in their infancy and are largely imperfect and incomplete. Yet, even in this embryonic state, they are starting to provide significant new insight and dissecting power, which is only going to increase as the models become more accurate and comprehensive.

Specifically, a key challenge for previous methods, such as genome-wide association studies (GWAS), is lack of statistical power once datasets become truly genome wide. Indeed, given the very large number of somatic events routinely discovered in cancer genomes, including mutations, translocations, gene fusions, aberrant copy number changes, and structural rearrangements,[11] distinguishing "drivers" from "passengers" is challenging and often impossible on a purely statistical basis (Figure 20-2). Not surprisingly, the tumors where greater progress has been made are those with somewhat more benign mutational landscapes, such as leukemias and lymphomas. Still, a significant fraction of these tumors lacks an appropriate causal genetic characterization or mechanistic elucidation of the relationship between genetic alterations and molecular phenotypes. The same can

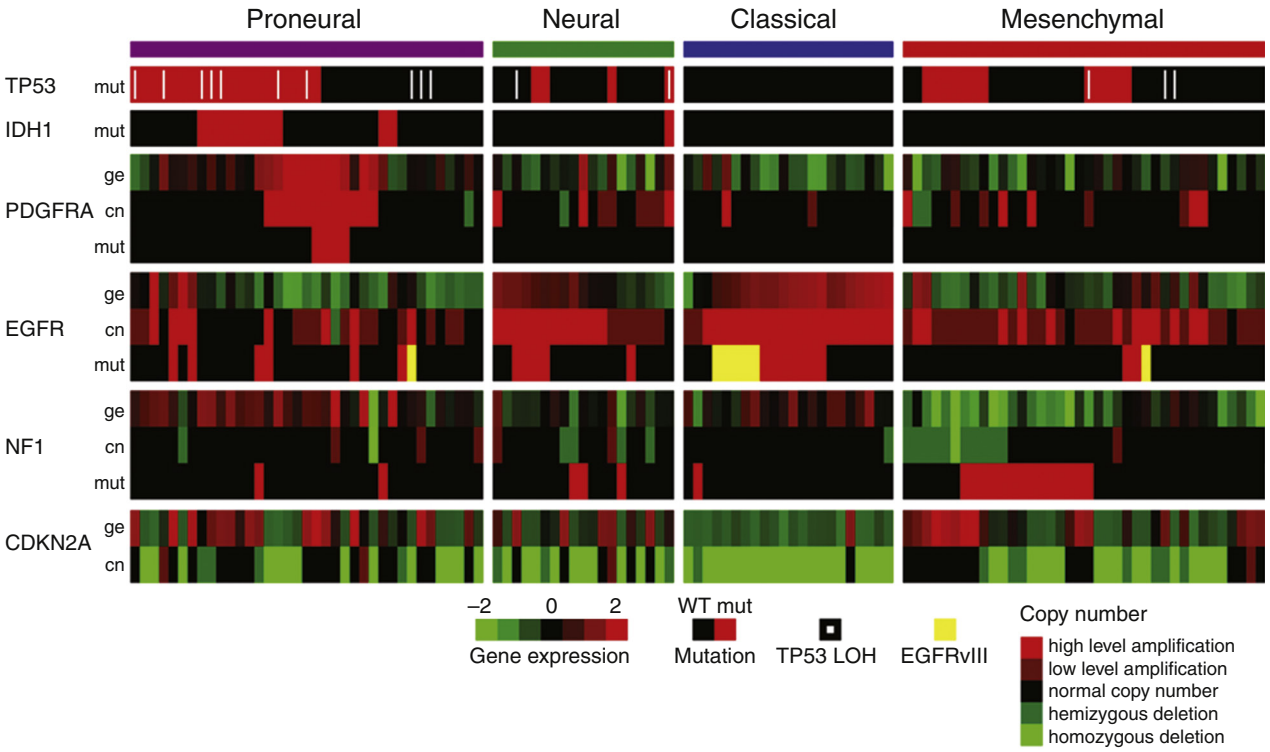

Figure 20-1 Genomic alterations in glioma co-segregate with only some of the identified molecular subtypes. *(With permission from Verhaak RG, Hoadley KA, Purdom E, et al. Integrated genomic analysis identifies clinically relevant subtypes of glioblastoma characterized by abnormalities in PDGFRA, IDH1, EGFR, and NF1.* Cancer Cell. *2010;17:98-110).*

be said for other genetic or epigenetic data modalities, from gene expression to DNA methylation profiles, which produce long lists of candidate genes with no intrinsic prioritization.

Recently, alternative approaches to those pursued using GWAS statistical approaches have started to emerge.[12] The rationale for these methods is that genome-wide regulatory models representing causal molecular interactions in the cell—for example, transcription factors regulating their transcriptional targets or protein kinases activating their substrates—may help us identify a relatively small number of candidate genes, upstream of genetic programs that are dysregulated, which may be tested for genetic and epigenetic alterations (Figure 20-3).

Variants of such a genetic genomics approach were pioneered in plants[13] and metabolic disease[14] and have been used successfully in cancer-related studies. For instance, identification of the novel HUWE1-MYCN-DLL3 cascade in brain tumors was possible by reverse engineering post-translational modulators of MYCN activity as well as its downstream targets using reverse engineering algorithms.[15] Similarly, the role of RUNX1 as a tumor suppressor mutated in T-cell acute lymphoblastic leukemia (T-ALL) was elucidated based on its most significant overlap with the TLX1 and TLX3 oncogene regulatory programs.[16] In some cases, a network-based view of cancer biology may allow elucidation of the dependency of a phenotype on an entire collection of genetic events, which would be virtually impossible to dissect using statistical approaches. For example, it was recently shown that deletion of any combination of 13 genetic loci distributed across the entire genome leads to functional inactivation of PTEN in glioma patients, via a novel interaction mechanism involving competitive endogenous RNA (ceRNA).[17] Indeed, cancer systems biology applications have exploded over the past 3 years, with studies ranging from the study of key drivers of tumorigenesis in melanoma[18,19] to the dissection of tyrosine kinase signals downstream of ERBB receptors.[20,21]

Such a regulatory-model–driven view of cancer biology is thus emerging as an important *systems-level* contribution to the study of this disease. By taking a more holistic view of tumor-related processes, anchored in gene regulatory mechanisms, cancer systems biology mediates the genetic and the genomic views of cancer to provide novel insight into its mechanisms. Specifically, the proponents of these approaches argue that among all genetic and epigenetic alterations in a tumor, those contributing to its initiation, progression, or drug sensitivity cannot affect regulatory interactions in a random way but must co-segregate within specific regulatory subnetworks that are thus globally dysregulated across different samples of a given tumor subtype. Hence, if the full complement of regulatory interactions regulating the behavior of a specific cancer cell population were known, then it

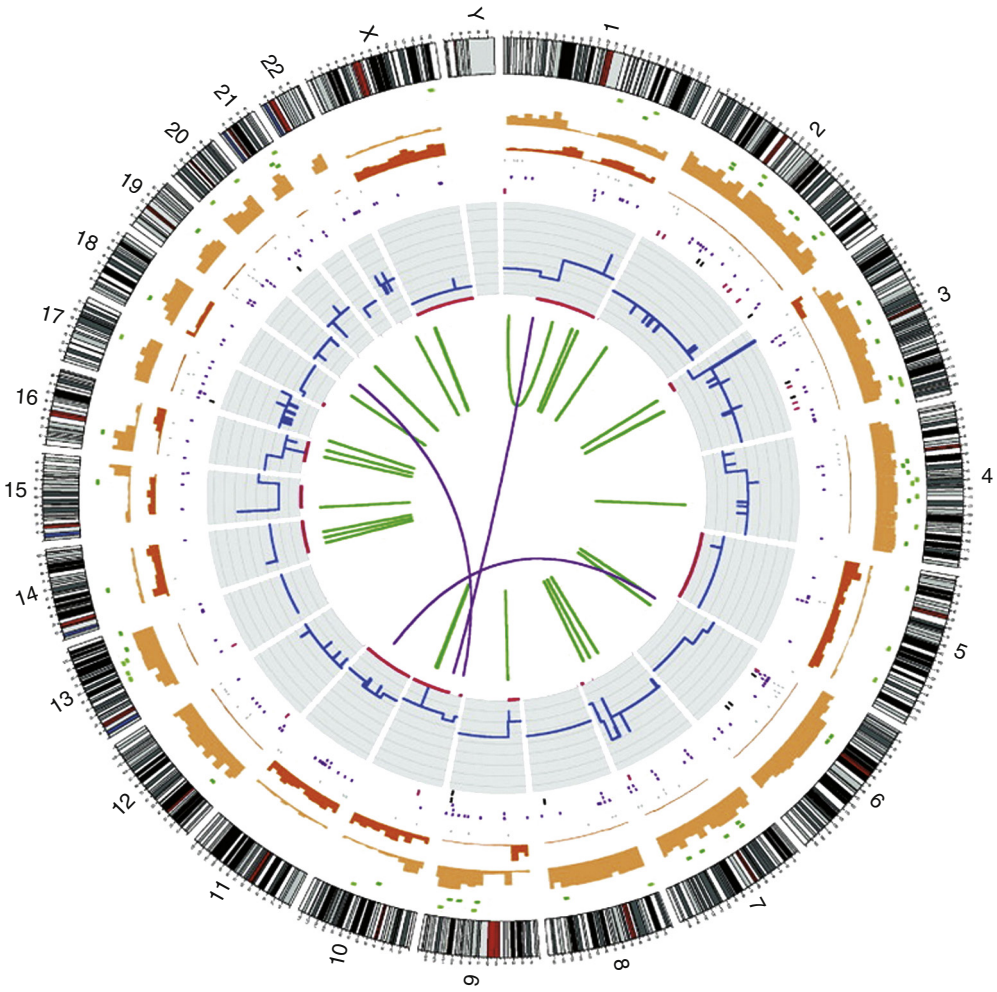

Figure 20-2 Circos plot showing the whole-genome catalogue of somatic mutations from the malignant melanoma cell line COLO-829 This genome has approximately 30,000 somatic base substitutions and 1000 somatic insertions and/or deletions. In coding exons, 272 somatic substitutions are present, including 155 missense changes, 16 nonsense changes, and 101 silent changes. The numbers and types of mutations are highly variable across different cancer genomes. Chromosome number and karyotype are indicated on the exterior of the plot. Key: *blue lines*, copy number across each chromosome; *red lines*, sites of loss of heterozygosity (LOH); *green lines*, intrachromosomal rearrangements; *purple lines*, interchromosomal rearrangements; *red spots*, nonsense mutations; *green spots*, missense mutations; *black spots*, silent mutations; *brown spots*, intronic and intergenic mutations (merged). *(With permission from Garnett M, McDermott U. Exploiting genetic complexity in cancer to improve therapeutic strategies.* Drug Discov Today. *2012;17:188-193).*

should be able to use its structure to separate driver from passenger alterations. The example of RUNX1 in T-ALL[16] is particularly revealing in this case. Here, the functional role of RUNX1 mutations could only be elucidated after determining that its targets are virtually overlapping with those of two previously established oncogenes, TLX1 and TLX3.[22] Without this regulatory insight, it would have been impossible to identify these mutations as statistically significant across the full repertoire of genes.

A key issue, then, is how to assemble accurate and comprehensive repertoires of molecular interactions to create a quantitative regulatory model that may be interrogated to elucidate drivers of tumor-related phenotypes. This is an important question, because virtually all cancer-related publications today contain appealing graphical presentations of molecular pathways in cancer. These bona fide models could provide a starting point for a systems-level study of cancer, as proposed, for instance, by pathway-wide association study (PWAS) strategies.[23]

Unfortunately, knowledge of molecular pathways governing physiological and tumor-related traits is still very poor. Indeed, canonical cancer pathways are more reflective of the researcher's desire to understand biological processes as a relatively linear and interpretable set of events than of the true complexity of cellular regulation. Specifically, these representations have two major limitations. First, they are not context specific. For instance, the EGFR pathway would be identically represented for a glioma and for a lung-cancer cell.

Second, they constitute a manually curated collection of published facts, of which several are actually incorrect, and which represents less than 1% of the total complement of regulatory interactions in the cell. Hence, their use introduces a strong bias toward what is already known (prior knowledge). Indeed, in the absence of a prior hypothesis, interrogation of canonical cancer pathways has been largely unsuccessful in the elucidation of novel tumor-related mechanisms. To understand the difference between a true regulatory network and a canonical cancer pathway, consider Figure 20-4, *A*, showing the differential phosphorylation of canonical EGFR pathway proteins in the H1650 cell line, where EGFR has an activating mutation, compared to the average of all cell

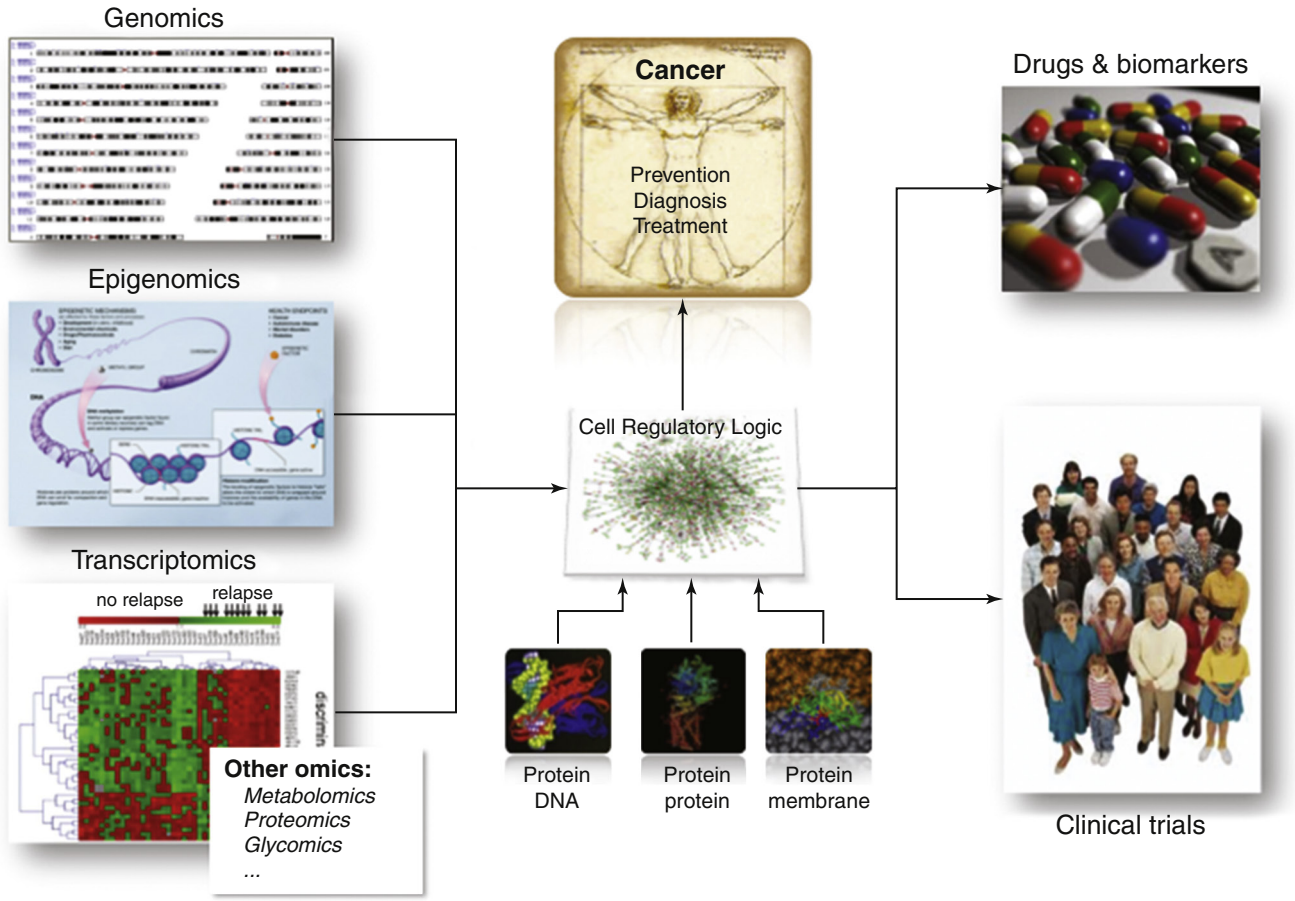

Figure 20-3 The -omics layers of the cell both encode and are processed by a context-specific regulatory logic. At the atomic level, this logic is implemented via molecular interactions, such as protein-DNA, protein-protein, protein-RNA, and RNA-RNA. Dissection and interrogation of this logic in context-specific fashion, using systems biology approaches, is starting to allow elucidation of driver genes responsible for the presentation of relevant cancer-related phenotypes.

lines. In contrast, Figure 20-4, *B*, shows the differentially phosphorylated proteins for the same cell lines in a signal transduction network, inferred de novo from a large-scale collection of phosphopeptide profiles of non–small-cell lung adenocarcinoma.[24] Whereas the pathway-based representation provides no clue that the EGFR pathway may be dysregulated, the network-based representation shows a clear hyperphosphorylated protein pattern surrounding both EGFR and MET.

In the following, we discuss the idea of a simultaneous, de novo reconstruction of context-specific gene regulatory networks from large-scale molecular profile data, and of the genetic and epigenetic variability they harbor and mediate. A classic systems biology workflow generally involves three steps: First is acquisition of molecular profiles for a variety of molecular species, several of which represent gene products, from mRNA to phosphopeptide abundance, as well as of genetic and epigenetic alterations. Second is data integration and reconstruction of the regulatory models for the specific cellular context of interest. The final step is regulatory model interrogation, using genetic and genomic signatures that represent the cellular states of interest. Given the abundance and prior coverage of molecular profile data for cancer, we concentrate on the two latter steps.

Reverse Engineering Regulatory Networks

From a systems biology perspective, cell behavior is driven by the processing of endogenous and exogenous signals and maintenance of homeostasis by a complex network of molecular interaction, that is, the regulatory model of the cell. The latter consists of several cross-interacting layers, including transcriptional, posttranscriptional, signal transduction, stable protein-complex formation, and metabolic interactions. Disruption of network topology or dynamics, within one of these layers or, more frequently, across layers, can aberrantly reprogram the cell by activating specific genetic programs, with the potential outcome of a stable phenotypic transformation such as is observed in tumorigenesis. Systems

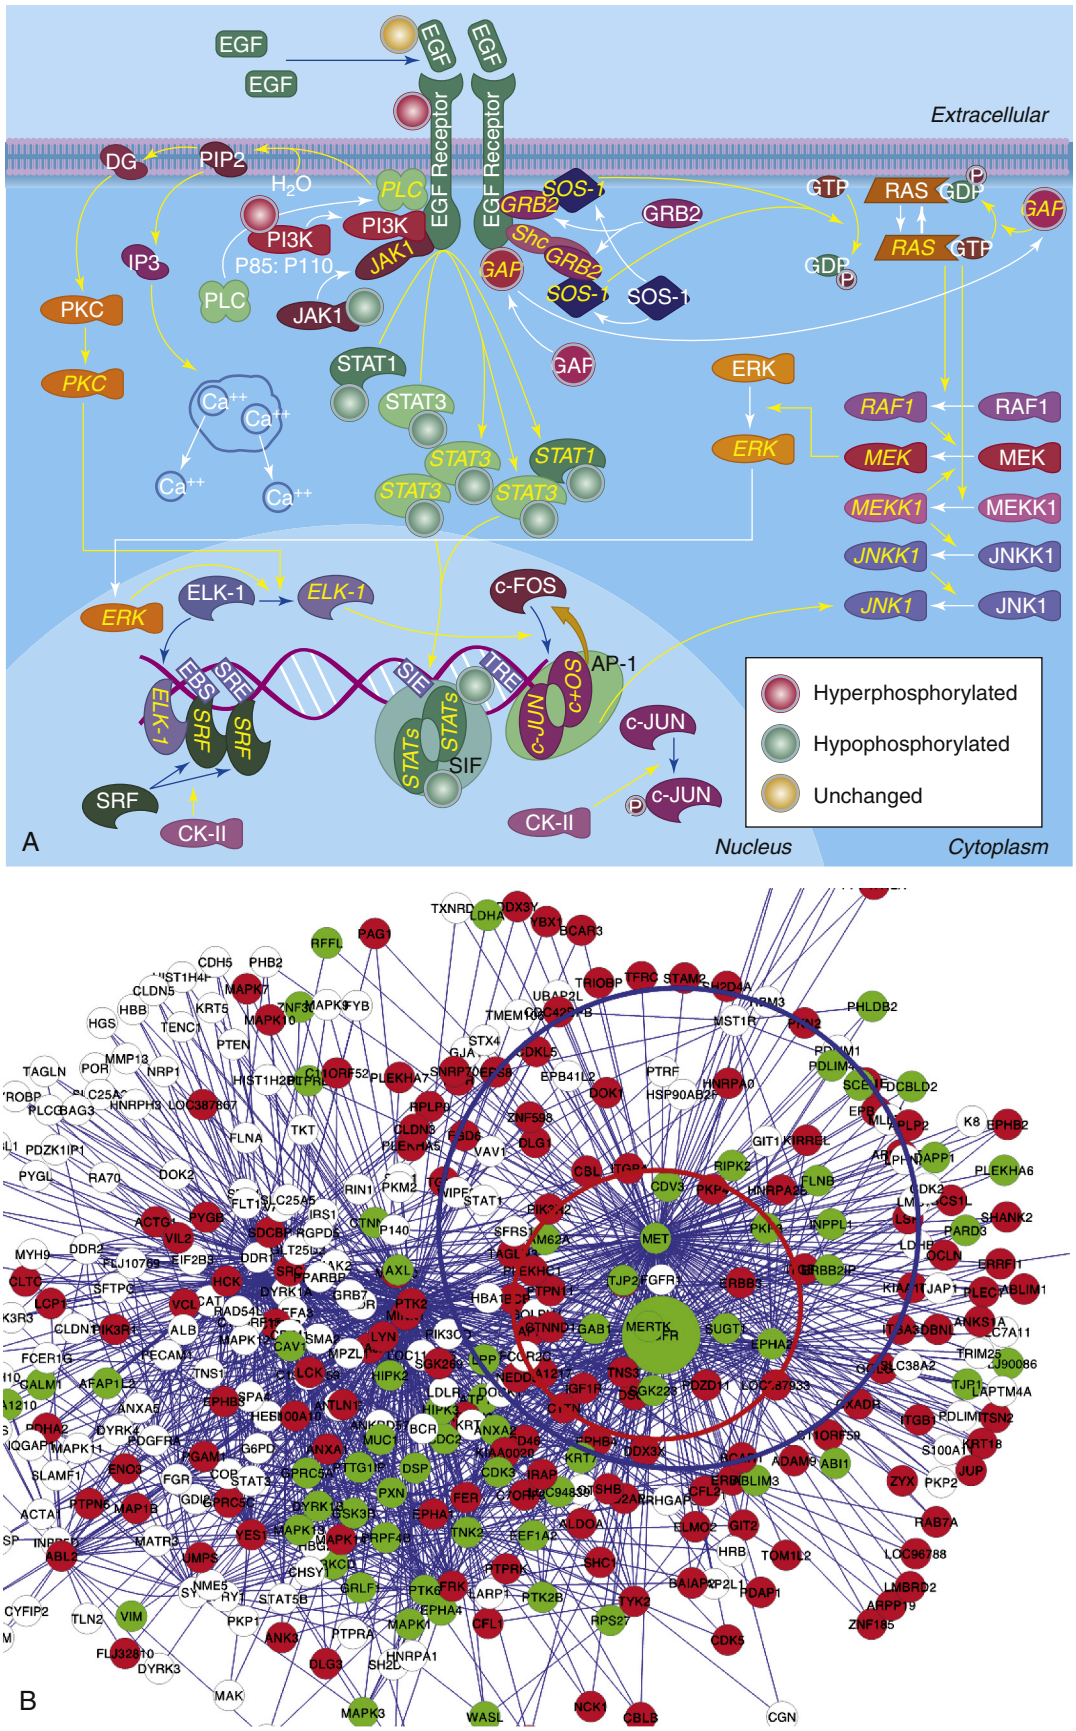

Figure 20-4 Pathway-based vs. network-based representation of differential protein phosphorylation in H1650 cells. (A) Pathway-based representation of differential EGFR pathway protein phosphorylation in H1650 cells, harboring an EGFR-activating mutation. Proteins tagged with a *red circle* are hyperphosphorylated, those tagged with a *green circle* are hypophosphorylated, and those with an *orange circle* are unchanged. Phosphopeptide abundance for the remaining proteins was not detected. **(B)** Network-based representation of differential protein phosphorylation in H1650 cells. Signal transduction network was inferred de novo from a large phospho-proteomic dataset[24] for non–small-cell adenocarcinoma. *Red* proteins are hyperphosphorylated, whereas those in *green* are hypophosphorylated. The *red* and *blue circles* represent EGFR and MET substrates, respectively.

biology, as a field, has evolved on the premise that these regulatory models, from simple kinetic models describing a handful of genes to probabilistic models of genome-wide regulation, could be dissected or "reverse engineered" from experimental data to infer their topology and behavior. One should be aware, however, that regulatory interactions in the cell are both dynamic and context dependent.[25] For instance, the Stat3 transcription factor must be phosphorylated to be transcriptionally active. Hence, the presence or absence of kinase activity or upstream signals may activate or inactivate its role as a transcriptional regulator in dynamic fashion. Of course, one could generate a fully representative, multivariate model of regulation that would represent both states of the transcription factor, but this requires the ability to detect changes in the pairwise interactions between the transcription factor and its targets, as the result of the presence or absence of other molecular species.[26] In addition, the complete model is likely so complex and unyielding that it may be more convenient to use simpler, contextualized models of regulation.

Over the past decade, multiple strategies have been developed by systems biologists to reconstruct the regulatory networks of living cells. Initially, these efforts have been driven by the study of yeast and bacteria as simple model organisms.[27-29] One advantage in these organisms is that regulatory regions on the genome, that is, regions where transcription factors and other chromatin binding proteins bind and regulate gene expression, are relatively short, allowing the efficient use of sequence information in reverse engineering. For instance, in yeast, promoter regions have an average length of 600 bp, whereas human genes may have distal regulatory elements hundreds of kilobases away from the transcription start site. In addition, gene regulation in higher eukaryotes is made dauntingly more complex by the presence of alternative splice variants, alternative start sites, and multiple poly-A tails.

Fortunately, as data generation technology and computational algorithms advance, regulatory models are becoming increasingly quantitative and predictive, thus capturing regulation of biological process more precisely. Currently, reverse-engineering methods can be mostly grouped into four categories. The following is not intended to provide a comprehensive description of all reverse engineering approaches in systems biology, but rather to provide a more general understanding of key differences between approaches.

Optimization-Driven Machine Learning Approaches

Because of the high-dimensional nature of the regulatory space covered by molecular profiles and the comparatively small number of distinct molecular profiles available in tumor repositories, such as those assembled by the Cancer Genome Atlas (TCGA) consortium[30] and the Catalogue of Somatic Mutations in Cancer (COSMIC),[31] classical methods such as maximum likelihood are not directly applicable to inferring causal relationships between regulators and regulated gene products. However, several assumptions, such as maximum parsimony, have allowed the successful use of machine learning (ML) approaches.[32] In this context, ML addresses this problem by asking what is the regulatory model with the largest posterior probability to have generated the observed molecular profile data. This cannot be addressed by enumerating all the possible models, of course. As a result, many approaches rely on greedy algorithms and underlying approximations, such as assuming that regulatory models can be effectively represented as directed acyclic graphs (DAG) that lack feedback loops.[27] The final model can then be used to infer systems behavior inferences with future data.[32] Examples of such methods include the analysis of regulators of gene expression modules,[33] as well as the use of Bayesian and dynamic Bayesian networks for reverse engineering transcriptional[27,34] and signal-transduction networks.[35] For a general review of these methods, see Refs. 36 through 38. Factors that affect the precision of the predictions by ML approaches include the dataset quality, feature preselection for single residues, and algorithm selection based on the purpose and data type.[39]

Integration of Prior Knowledge and Experimental Evidence

Rather than predicting interaction from a single data modality, such as gene expression profile data, systems biologists have embraced the vast number of repositories containing experimental data from high-throughput approaches. These range from gene expression profiles, to genome-wide chromatin immunoprecipitation data (GW-ChIP), to yeast-two-hybrids and nuclear pull-down assays. Although partial and often inaccurate in isolation, the knowledge contained in these repositories can be effectively integrated into a single unified model, using computational models to combine the probability about a specific event (e.g., the interaction between two molecular species) from a wealth of independent facts. For instance, transcriptional interactions may combine data from GW-ChIP, DNA binding site motif analysis, and co-expression, among a number of other relevant data types. Use of ML frameworks for the integration of multiple weak clues, from naïve Bayes classifiers,[40] to Bayesian networks,[41] to a variety of consensus scoring methods, has been very successful in generating more accurate and comprehensive molecular interaction models.[42,43] Recently, an intriguing result has been shown in the analysis

of the Dialogue on Reverse Engineering Assessment Methods (DREAM) challenges.[44] DREAM is an attempt to objectively measure the ability of computational approaches to correctly infer facts about regulatory network structure. Specifically, it was shown that integration of the results of many different inference algorithms performs generally better or at least as well as the best individual algorithm. This is an important result, as we often do not have a principled approach to objectively assess the quality of each given method and may instead want to use the integrative results of several of them. An additional value of integrative methods is that they allow the integration of completely heterogeneous types of data. For instance, it was recently shown that protein structure information from x-ray and nuclear magnetic resonance (NMR) crystallography can be effectively integrated with functional data to accurately predict protein-protein interactions.[45] For a more comprehensive review of integrative approaches, see Ref. 46.

Regression Analysis

Regression techniques have long been used to estimate parameters for kinetic models from experimental data and could, at least in theory, be extended to the inference of parameters for entire regulatory models. Various regression methods have been proposed for pathways or network inference, including maximum likelihood,[47,48] least squares,[49-51] and Bayesian inference,[52-54] to obtain estimates of model parameters.[55] Maximum likelihood approaches infer parameter values from a distribution, as those maximizing the posterior probability of the experimental data; least squares approaches determine the parameter values that minimize the sum of the squares of the residuals, that is, the difference between each experimental and model data point; and finally, Bayesian methods use a priori models for the unknown parameter distribution to compute their most likely values. A key problem of regression methods is that they are generally underdetermined. A determined problem is one where the number of independent observations of a system is equal to the number of parameters that must be estimated. Overdetermined problems—that is, those with more observations than parameters—have the advantage that estimates have some level of statistical robustness. When the number of parameters is much larger than the number of observations, however, an infinite number of parameter values becomes equally possible, thus requiring other heuristics. This is a common issue in real biological systems, as the number of parameters for a system with tens of thousands of interacting molecular species can be in the several hundred thousands, but few datasets with more than a few hundred independent experimental profiles are available for the same system. To address this problem, a number of dimensionality reduction approaches have been developed, which work by either splitting a single high-dimensional problem into a number of independent lower-dimensional ones, such as via singular value decomposition, or by penalizing models with a larger number of connections via sparsity constraints.[56]

Information Theory and Probabilistic Methods

Shannon's information theory provides a probabilistic model to characterize information flow in a system.[57] In recent years, information theory has become a staple of systems biology approaches,[58] for instance, by predicting the minimal machinery in the cell necessary to account for the globally observed information transfer between distinct molecular species characterized by a profile, such as mRNA,[26,59,60] mutational data,[61] and microRNAs.[17,62]

In general, these approaches view a regulatory process, such as a signaling pathway or a transcriptional regulatory circuit, as a flow of information carried by a cascade of molecular events, each one adding some noise to the process. Shannon entropies are estimated for each node of the cascade to quantify the information flow, and gain or loss of information is used as evidence to derive the structure of the information circuit. Specifically, the concept of mutual information (MI)[63] or conditional mutual information (CMI)[64] is usually applied to quantify two-way and three-way functional dependencies between variables, respectively. MI measures the mutual dependence of two random variables, without any linearity assumptions, for instance, between the mRNA of a transcription factor and one of its potential targets. CMI measures whether the information transfer between two variables is dependent on a third variable, for instance, the availability of a protein kinase affecting the ability of a transcription factor to regulate its targets. Various probabilistic and information-theoretic methods have been proposed for the reverse engineering of regulatory networks, of which some have been extensively experimentally validated, such as ARACNe,[59,65] MINDy,[26] Hermes,[66] minet,[67] and CLR.[68]

ARACNe and MINDy: A Case Study

These two algorithms are among those with the most extensive repertoire of experimental assays supporting their ability to dissect regulatory networks in cancer cells, as well as among the most adopted by the research community. We thus use them as a case study to illustrate several relevant concepts in the area of reverse engineering. Other examples of extensively validated algorithms with applications to the

study of cancer and other diseases include CONEXIC,[19] CLR,[18] and Bayesian networks[14,35]; see Refs. 12 and 69 for a more detailed review.

ARACNe has been widely applied to dissect transcriptional regulatory networks from gene expression profiles of multiple cancer subtypes, including B-cell lymphoma,[65] breast cancer,[70] glioma,[71] and T-cell leukemia.[16] ARACNe first estimates the statistical significance of the mutual information between every possible transcription factor and candidate target ($TF_A \rightarrow T$) and then removes candidate interactions that violate the data processing inequality, an information-theoretic property stating that information transferred via a direct interaction must exceed that transferred via any indirect path (e.g., $TF_A \rightarrow TF_B \rightarrow T$). Thus, if even one indirect path is found that exceeds the MI computed for a specific transcription factor–target pair, the candidate direct interaction is eliminated. ARACNe was experimentally validated by ChIP and GW-ChIP assays, as well as by silencing of transcription factors followed by gene expression profiling; see the papers referenced earlier.

This analysis was extended to higher-order interactions. Specifically, the Modulator Inference by Network Dynamics (MINDy) algorithm was developed to identify posttranslational modulators of transcription factor activity on their targets using the conditional mutual information.[26,72] These include both co-transcription factors and upstream signaling proteins regulating the transcription factor activity.[26] Genome-wide searches based on this methodology were successful in identifying the HUWE1 ubiquitin ligase as a key modulator of MYCN in neural stem cells,[15] as well as the serine threonine kinase STK38 as a key modulator of MYC in human B cells,[73] among several other interactions that were experimentally validated.

Interrogating Pathways and Networks

Once regulatory models such as pathways and networks are available, machine learning approaches can harness them to study cancer phenotypes. For example, a random forests algorithm was used to perform pathway-based SNP analysis to predict cancer-patient survival outcome.[74] Applied to multiple myeloma, using Affymetrix 500K SNP array data, the method connected informative SNPs and patient survival, thus identifying a candidate pathway involved in modulating patient survival and associated genetic variants.[74] A multitude of other machine learning algorithms have also been used to assist in GWAS analysis, such as SNP discovery,[75,76] SNP interaction,[77,78] cancer subtype classification,[79] survival outcome association,[80] and key genetic variant identification[81,82]; see Ref. 83 for a more comprehensive review. Yet, a common characteristic of these approaches is that the associations they identify are generally statistical in nature and not easy to relate to a specific molecular mechanism. This is mostly the result of using pathways that are universal, sparse generalizations of regulatory processes in human cells, rather than regulatory models that are cell specific.

Several approaches are now emerging that simultaneously address the reconstruction of context-specific cell regulatory models as well as their interrogation to identify drivers of both physiological and pathological phenotypes; see Refs. 12 and 69 for a more complete review. For instance, the Master Regulator Inference algorithm (MARINa; Figure 20-5)

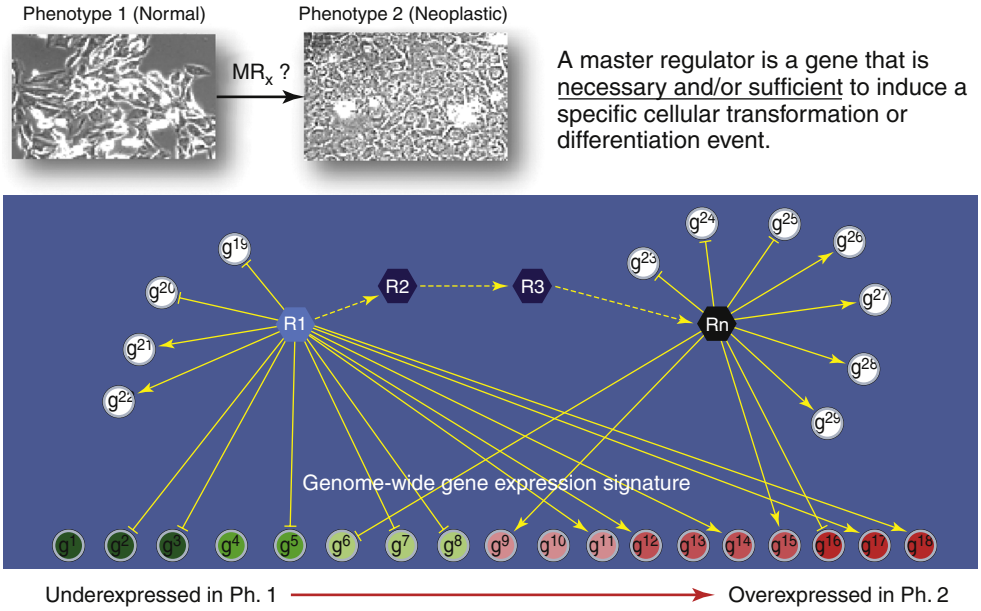

Figure 20-5 Discovery of master regulator genes using the MARINa algorithm Master regulators (e.g., R_1) are genes whose activated and repressed transcriptional targets are highly enriched in genes that are over- and underexpressed in the transition from the first to the second phenotype, respectively. Other regulators (e.g., R_n) have targets that are not enriched in differentially expressed genes.

was used to discover genes and associated mechanisms that are causally related to the implementation of a specific phenotype.[40,70,71] Specifically, rather than asking what genes are differentially expressed in a specific cellular phenotype, MARINa uses a context-specific, causal regulatory model to identify candidate master regulator (MR) genes that regulate the majority of genes that are differentially expressed. Given a small set of candidate MRs, experimental validation can then identify those both necessary and/or sufficient to implement the specific phenotype. This approach was used, for instance, to elucidate CEBPB/CEBPD and STAT3 as synergistic master regulators of the mesenchymal subtype of human glioblastoma, as well as FOXM1 and MYB as MRs of the germinal center reaction.

Similar approaches have led to the identification of NFκB as a key addiction point for the ABC subtype of diffuse B cell lymphoma tumors, associated with worst prognosis.[7,84] Indeed, while NFκB is never mutated in this phenotype, thus lacking the necessary prerequisites to elicit oncogene addiction,[85] it constitutes a natural functional bottleneck by integrating aberrant signals from several genetic alterations in upstream pathways, including the *Card11*, *Tnfaip3*, *Traf2*, *Traf5*, *Map3k7*, and *Trank1* genes, that induce cell addiction to its function. Here, we use the term *non-oncogene addiction* to indicate dependencies on genes that are not genetic drivers (i.e., mutated oncogenes) but are rather induced by upstream genetic alterations and aberrant signals.[86] Similarly, different integrative network-based systems biology approaches were used to identify drivers of tumor initiation[19] and differential patient survival[18] in melanoma. Although these constitute very recent developments, the availability of methods to assemble accurate and cancer-specific regulatory models will determine an explosion in this kind of approach.

Recent data[16,40,70,71] suggest that a majority of cancers present regulatory bottleneck structures, where aberrant signals from genomic alterations are integrated by a relatively small number of genes to implement specific downstream regulatory programs that contribute to define the cancer cell transcriptional identity and to ensure its survival and replicative potential (Figure 20-6). These programs are collectively known as the hallmarks of cancer.[87]

Causal Interactions: Reducing the Search Space for Genetic and Epigenetic Variability

One of the limitations of current associative methods is that the search space is so vast that the statistical correction required to account for testing so many hypotheses can mask all but the most obvious single genetic associations. In complex diseases such as cancer, where multiple genetic events are necessary to induce transformation and progression, this all but prevents testing for complex epistatic interactions. As a result, despite extensive sequencing of cancer genomes, most cancer cases lack a clear heritable or somatic explanation, and the co-factors contributing to tumorigenesis even when key oncogenes are elucidated are mostly unknown. For instance, although we know that MYC translocations, HER2 amplifications, and APC deletions contribute to tumor etiology in Burkitt's lymphoma, breast cancer, and colon cancer, respectively, these lesions are not sufficient to induce tumorigenesis and require a number of co-mutation events to induce transformation.

Systems biology approaches can help in this context by dramatically reducing the search space or by increasing the statistical significance using complementary, statistically independent evidence. This can be accomplished using two strategies. First, identification of functional master regulators of tumor-related phenotypes can dramatically reduce the search space for potential genetic and epigenetic alterations only to genes encoding proteins that interact with or modulate the activity of master regulators. Second, by integrating the probability of a gene having a functional effect on the phenotype, based on regulatory network analysis, with the probability deriving from GWAS-type studies, for instance. using Fisher's or Stouffer's method to integrate *p*-values, one can dramatically increase the statistical significance of

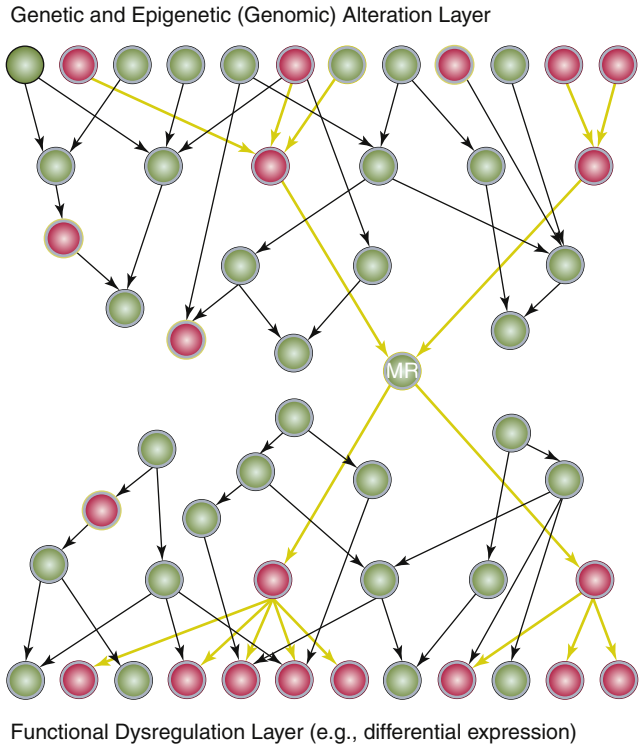

Figure 20-6 Master regulators implement the hall marks of cancer. One or more regulatory bottlenecks integrate aberrant signals from a spectrum of genetic alterations through key regulators (master regulators) that in turn implement the genetic programs necessary for tumor initiation and progression (cancer hallmarks).

relevant genes, thus exceeding the high bar determined by multiple hypothesis testing correction. A number of such methods have already been presented at cancer meetings, and more are likely to be published in the near future.

An illustrative example is the discovery of a new layer of regulation implemented by competitive endogenous RNAs (ceRNA). These are RNAs that compete through high-affinity RNA binding sites for recruitment of the same microRNA. When the abundance of one ceRNA in a pair decreases, the bound microRNAs are freed and can target the other species, thus repressing it. Although this regulatory layer was first hypothesized in plants,[88] its potential impact on human disease was only recently demonstrated when it was shown that the PTEN pseudogene is a tumor suppressor by regulating PTEN as its cognate ceRNA.[89] Moreover, by combined sequence and gene expression analysis,[90] as well as by extending the MINDy algorithm,[17] it was shown that ceRNA constitutes a vast regulatory network capable of dysregulating not only PTEN, but also the majority of oncogenes and tumor suppressors. For PTEN, in particular, this analysis reduced the number of regulators whose genetic deletion could affect PTEN abundance to about 500 loci, thus leading to the identification of 13 loci frequently deleted in TCGA glioma patients, such that co-deletion of any combination of these loci would lead to significant PTEN inactivation by microRNA-mediated repression.[17] These combinations of locus deletions could not possibly have been identified on a statistical basis, given the relatively small number of TCGA patients (approximately 500) in the glioblastoma cohort.

The powerful integrative nature of systems biology approaches requires multidimensional datasets and, more importantly, datasets in which multiple data modalities are profiled for the same samples, such as those assembled by recent, large consortia such as TCGA.[91] When used in integrative fashion with other large datasets containing GWAS and other data, such as the database of Genotypes and Phenotypes (dbGAP)[92] and the Gene Expression Omnibus (GEO), the real value of this new discipline can start to be fully harnessed.

Using Regulatory Networks to Elucidate Drug Activity

The naïve researcher may think of drugs as highly selective agents, affecting specific substrates that are relevant in equally specific disease-related contexts. For instance, imatinib is best known as a potent inhibitor of the BCR-ABL fusion protein in chronic myelogenous leukemia (CML), resulting from the Philadelphia chromosome translocation.[93] Yet, most drugs affect (directly or indirectly) a large repertoire of substrates by both high- and low-affinity interactions. Furthermore, drugs are metabolized by biological systems, resulting in a spectrum of metabolites, some inert and some having differential target affinity and potency. As a result, drug discovery and characterization could gain a tremendous advantage from systems biology approaches, which study a drug's activity and effects in the context of the full regulatory context that mediates compound activity. These approaches have the potential of transforming drug repositioning, identification of potential toxicity, drug sensitivity prediction, and combination therapy from trial-and-error efforts to a quantitative and predictive methodology.

Consider drug repositioning, for instance. Of the repertoire of more than 1500 distinct drugs approved by the U.S. Food and Drug Administration (FDA), it is likely that many could have far-ranging application in cancer, outside of the narrow disease confines they were originally approved for, frequently for non–cancer-related applications. For instance, imatinib, originally approved for CML, is now finding significant reuse as a C-KIT protein kinase inhibitor in gastrointestinal stromal tumors.[94] Indeed, repositioning of existing drugs in alternative disease systems is believed to have great potential to significantly shorten the drug development period and strengthen drug pipelines.[95,96] Similarly, in the context of combination therapy, testing the synergistic potential of just the 1500 FDA-approved drugs would require screening 1,125,000 combinations, a number that is far too vast to be efficiently tested across a broad base of tumor types and diseases.

Although the development of systems-biology–based methodologies for the study of drug-related phenotypes is far less developed than its use for elucidating driver genes, a handful of approaches have been proposed that suggest an important role for this area of research. For instance, experimental perturbations of the SOS pathway were used to elucidate drug mechanisms of action in *Escherichia coli*,[28] and chemogenomic profiles were analyzed to study antibiotic resistance using network-based approaches.[97] Similarly, network-based mechanisms of action of small compounds were elucidated using the Interactome-based Drug Enrichment Analysis (IDEA) algorithm,[98] while a library of gene expression profiles following drug perturbation was instrumental in the study of compounds that could induce a desired gene expression signature in the cell[99] and machine learning approaches were used to elucidate the molecular basis of drug resistance in yeast.[100] These are just some notable examples, as the literature on systems-level analysis of small-molecule activity is increasing exponentially.

In the context of drug repositioning, a Bayesian factor regression model was developed to perform off-target drug

repositioning based on transcriptional responses,[53] and a consensus analysis based on the connectivity map was successful in identifying experimentally validated analogs of existing drugs.[101] More recently, an elegant, small-scale kinetic model of signal transduction was used to elucidate a caspase-8–dependent mechanism inducing time-dependent synergy between erlotinib, an EGFR inhibitor, and doxorubicin in triple-negative breast cancers,[102] suggesting that regulatory models are becoming sufficiently mature to allow time- and dosage-dependent analysis.

Taken together, these early examples are illustrative of the great relevance that regulatory network–based analysis will have in the prediction of drug activity, in the rescue of drug sensitivity, and in the in silico exploration of combination therapy approaches.

Recent Trends and Future Perspectives

As discussed earlier, a variety of research strategies have emerged in cancer systems biology since the discipline's conceptual inception, about a decade ago.[103,104] Although the initial forays in this area were mostly of a theoretical nature, over the past 5 years these approaches have achieved significant success and gained considerable traction, especially in the elucidation of complex, multigene mechanisms that would not have been approachable using conventional molecular biology strategies. In its coming of age, systems biology has become one of the most powerful methods for the high-throughput generation of testable hypothesis, frequently achieving a greater than 50% likelihood of experimental validation, something that would have been previously unthinkable from purely computational approaches. For instance, validation of transcription factor targets, microRNA targets, and protein-protein interactions predicted by reverse engineering methods is frequently in the 80% range and thus competitive with high-throughput experimental approaches.[17,26,45,59] Similarly, a number of disease mechanisms have been recently elucidated, following validation of regulatory network–based predictions.* These are only a few representative examples from a now-vast literature.

In spite of these successes, concerns and skepticism are still pervasive in the biological community on the role and effectiveness of systems-biology approaches in dissecting complex diseases, such as cancer, and in elucidating novel therapeutic strategies for translational research. To address these concerns, this nascent discipline must make progress on two critical aspects. First, novel technologies are critically needed to interrogate cellular systems in integrative fashion; and, more importantly, translation of concepts emerging from systems approaches must lead to clinical applications. Indeed, these two aspects are critically related. For instance, although a genomic view of biology has now been around for more than 30 years, its translational applications have been largely the result of our newfound ability to exploit large-scale genomic information originating from the map of the human genome and from those of other organisms. Given the glacial times required for clinical experimentation, compared to molecular biology research in the lab, the first clinical applications of the genomic revolution are only now starting to appear, a full 10 years after the completion of the human genome map. Systems biology, as a discipline, is much more recent, and it would be unreasonable to expect immediate translation of its findings. Like genomics, this discipline could not achieve its true potential until appropriate datasets and technologies became available. As a result, the first attempts to translate cancer systems-biology discoveries are only now starting to percolate to the clinic. As in the case of genomic sciences, several years may be necessary before a compelling argument for clinical applications of systems biology can be made. For instance, the Cancer Target Discovery and Development (CTD^2) network,[86] a recent initiative to adopt a high-throughput, systems-biology–based approach to the discovery and validation of novel druggable targets for several tumor subtypes, associated biomarkers, and small-molecule modulators, has been very successful, producing dozens of new experimentally validated targets and small molecules that are now being prioritized for clinical research. The identification of a disease target, of associated biomarkers for population stratification, and of candidate small-molecule inhibitors has traditionally taken 10 years. Several CTD^2 projects were successful in achieving this target during the first 2 years of the program, dramatically accelerating the preclinical discovery process but also linking therapeutic strategies and biomarkers to specific biological mechanisms in vivo, thus ultimately increasing the probability of successful clinical translation.

Perhaps the most critical contribution to the ability to adopt a systems approach to accelerate preclinical discovery has derived from the development and introduction of novel technologies that allow us to both perturb and monitor cellular systems both in vitro and in vivo, as well as from single cells to tissues. These have produced both the comprehensive datasets that power systems biology approaches and the high-throughput validation methodologies to take full advantage of systems biology as an equally high-throughput hypothesis-generating science. Indeed, it is precisely the combination of high-throughput and integrative data acquisition,

* 14-16,22,40,69,71,73,105-107.

hypothesis generation, and experimental validation that has contributed most to the success of this discipline.

The Technologies of Cancer Systems Biology

We are currently experiencing dramatic acceleration in the ability to produce critically needed technologies to rapidly and accurately perturb cellular systems, monitor their changes at the molecular level, and experimentally validate molecular hypotheses. These technological improvements range from chemical biology approaches to perturb cellular systems in a controlled environment—including genome-wide libraries for RNAi-mediated gene silencing, ORF-based cDNA libraries for the genome-wide ectopic expression of genes, and small-molecule libraries of bioactive compounds—to the use of imaging for the detection of phenotypic changes in single cells, to the development of novel approaches to produce proteome-wide readout of peptide and phosphopeptide abundance, to the development of inexpensive approaches for monitoring the activity of hundreds of genes in cellular populations. Interestingly, many of these technologies have more than one use. For instance, pooled RNAi screens, where shRNA libraries are used in a cellular population such that each cell receives a single shRNA on average, are being used both to create datasets for the integrative discovery of cancer driver genes and, using smaller, more targeted libraries, to validate candidate driver genes both in vitro and in vivo.

The availability of data from cellular perturbation assays is critical for implementing systems-biology approaches to elucidating novel molecular mechanisms. This is because interactions for molecular species that are constant across multiple observations cannot be dissected using computational methods. On the other hand, when molecular species abundance is variable across samples, molecular interactions introduce constraints, resulting in highly nonrandom patterns in the data. These patterns can be analyzed and used to infer the most probable set of molecular interactions that originated them. Three distinct approaches to perturb molecular systems have been used in systems biology. The first and most effective one is based on the naturally occurring genotypic variability between individuals in a species or related cancer subtypes, further modulated by exogenous events such as temperature, nutrient intake, or chemical stressors. For instance, a set of gene expression profiles from approximately 400 samples of normal and tumor-related human B cells, covering 18 subtypes of lymphoma, were used to reverse engineer the first experimentally validated transcriptional network for a human cell.[59] The second type of variability arises from genetic manipulations aimed at silencing or expressing specific genes. For instance, profiles from yeast knockout libraries were successfully harnessed to reverse engineer yeast-specific regulatory networks; see Ref. 108 for an example. Finally, gene expression profiles following small-molecule perturbations, such as those in the connectivity map,[99] are also being used to reverse engineer human regulatory networks. Notably, regulatory models produced by analysis of naturally occurring variability in samples from primary tumor tissue are best suited to study driver genes, as they reflect regulation under the full context of autocrine, paracrine, endocrine, and contact signals that cancer cells receive. They also best reflect tumor heterogeneity. Conversely, models produced by chemical perturbations in vitro are optimally suited to dissect small-molecule mechanisms of action, effectors, and genes modulators of sensitivity. Indeed, several laboratories are actively attempting to match tumor dependencies elucidated from natural variability datasets with small-molecule activity and mechanisms elucidated from in vitro perturbations.

In the following paragraphs we discuss two of the most important and innovative technologies embraced and frequently developed by systems biologists, as well as their potential for the implementation of a predictive systems-level approach to cancer prevention, diagnosis, and therapy.

RNAi-Mediated Silencing

Traditional cancer research strategies focus on the use of molecular profiles to discover genes causally responsible for cancer initiation, progression, and drug sensitivity phenotypes, generally known as *driver* genes. Unfortunately, most genes identified by these methods are not causal; rather, these genes are just statistically associated with the specific cancer-related phenotype, also described as *passenger* genes. To simultaneously evaluate the relevance of a large number of genes in the context of a specific cancer-related phenotype, thus identifying a handful for further mechanistic elucidation, a variety of RNAi screening approaches have been developed.[109-111] These technologies, including siRNA and shRNA-based approaches, have provided powerful and efficient tools for screening a large number of genes. Importantly, when RNAi screens are integrated with additional experimental measurements, such as transcription factor activity, protein expression, and protein kinase/phosphatase activity, RNAi-based genetic screens can provide important clues about the structure and organization of regulatory networks, such as transcriptional and signaling networks, controlling a specific phenotype.[112]

shRNA-based RNAi screens are generally used for long-term culture assays, such as clonogenic assays and drug resistance assays. An increasingly popular approach is the pooling of multiple shRNA constructs—by using either multiple hairpins for the same genes, or a large hairpin library covering a fraction of or the complete expressed genome—to infect cells in a single assay.[113-115] This can, for instance, help in the identification of genes that confer sensitivity to a specific drug or in genes that constitute critical addiction point for the tumor cell. Large shRNA library screens have been successfully performed to identify tumor suppressors such as NF1 in neuroblastoma,[116] oncogenic MYD88 mutations in human lymphoma,[117] and haploinsufficient cancer gene RPS14 for 5q− syndrome in anemia and acute myelogenous leukemia.[118] Similarly, an siRNA-based synthetic lethality screen identified a repertoire of genes that sensitize lung cancer cells to paclitaxel, an approved cancer drug, but at 1000-fold lower concentration.[119]

RNAi screens are also well suited to high-content imaging analysis, where entire plates with 96 or 384 cell-silencing assays can be analyzed by high-throughput multicolor confocal microscopy to detect more complex phenotypes, such as cytoskeleton remodeling, cell morphology changes, and lineage differentiation.[119-121] For instance, a genome-wide siRNA screen for cell cycle, size, and proliferation, using quantitative fluorescence microscopy, identified more than 1000 cell-cycle–related genes.[122]

Project Achilles constitutes the most comprehensive attempt to use pooled RNAi technology to explore cellular dependencies in cancer.[123] It provides a summary of 102 cell lines perturbed with genome-wide pooled shRNA libraries representing 11,194 genes. Interestingly, when genetic screens are performed on such a diversity of cellular contexts, they achieve a more universal value that transcends that of the individual cell line analyses and provides a novel and highly compelling new paradigm for systems approaches. For instance, using data from Project Achilles and other related efforts, one may consider whether a specific gene dependency is detected repeatedly in the presence of a specific genetic alteration(s) across a large, heterogeneous panel of cell lines. This could be used to identify regulatory bottlenecks and to dissect the structure of transcriptional and signal transduction pathways. Similarly, by integrating such pooled approaches with chemosensitivity profiles across a number of cell lines, novel insight into small-molecule mechanisms of action, synergy, and genes that may modulate sensitivity could be gained.[3] Finally, by intersecting results from computational analysis of cancer driver genes with results from pooled screen assays, one could further identify small sets of candidate genes that would have a much higher probability of eliciting oncogene or non-oncogene addiction in vivo. Thus, the combination of genetic screens and computational approaches into an integrative systems-biology methodology has significant potential to increase the efficiency and specificity of target and biomarker discovery. For example, computationally inferred genetic backgrounds and gene regulatory networks in primary human tumors have been shown to greatly help in designing the genetic screen strategy and efficiently identifying malignant-state driving genes.[115]

Single-Cell Analysis and Tumor-Cell Heterogeneity

Traditional profiling techniques provide snapshots of molecular species' abundance averaged on populations containing thousands to millions of cells, thus capturing only average behavior. Unfortunately, cancer is a highly heterogeneous disease, both in cell type composition—because tumor cells are mixed with stroma, infiltrating leukocytes, and endothelial cells—and in terms of clonality of the tumor cells, with individual clones differing on a broad range of genetic and epigenetic alterations.[124] Intratumor heterogeneity is also due to differences in subclones, microenvironment, cell cycle stage, and stochastic fluctuations.[125] As a result, regulatory networks or gene signatures inferred from cellular populations may not be representative of any of the individual cells but only of their average common properties.[126,127]

Tumor heterogeneity greatly affects disease progression, transfection and infection rates, as well as drug response,[128] as subpopulations will be filtered over time, and even small clonal components presenting the most optimal fitness will grow exponentially over time, thus eventually dominating tumor composition. For instance, rather than presenting an even transduction efficiency across cells, some Jurkat cell clones consistently exhibit partially efficient RNAi-mediated silencing while others show complete inhibition of the target gene.[129] In such cases, the averaged population is a poor representative of the behavior of the individual clonal subpopulations. We thus need to port the tools of molecular biology for perturbing, profiling, and sensing to the single-cell context. Thanks to recent advances, it is now possible to isolate and profile genetic, genomic, proteomic, and metabolomic features in single cells. These technologies include microfluid-based cell culturing and profiling, high-performance cell sorting, super-resolution and high-content microscopy, single-cell next-generation sequencing, and antibody-based microchamber sensing devices, among many others. For example, whole-genome amplification (WGA) based on the multiple displacement amplification (MDA) method was adapted to single-cell exome sequencing to profile cells from JAK2-negative myeloproliferative neoplasm[130] and clear-cell renal-cell carcinoma.[131] These data showed surprising intratumor heterogeneity in the mutation spectra, significantly

more complex than expected, while providing candidate drivers of tumor progression. Importantly, several of these results could not have been identified from bulk analysis of cell populations.

Multiparameter flow cytometry has been commonly used in single-cell analysis for immunology, stem-cell, and cancer research. For example, causal signaling networks were inferred with a Bayesian network machine learning method by analyzing multiparameter flow-cytometry data from a large number of chemically perturbed immune system cells.[35] Similarly, single-cell measurements of phosphoproteins in acute myeloid leukemia cells obtained by multiparameter flow cytometry were used to differentiate tumor-cell populations in the same patient.[132] These approaches were successful in associating different genetic mutational backgrounds with specific drug response profiles and signal transduction patterns. These results are informative of tumor pathology and drug response mechanisms in tumor-cell subgroups.[132]

Fluorescence-based flow cytometry is limited to monitoring up to a dozen parameters in parallel, thus limiting the range of analytes for network reconstruction and interrogation. A novel mass spectrometry–based single-cell cytometry technique, which uses antibodies covalently bonded with a repertoire of rare earth isotopes (CyTOF), can currently measures up to 50 parameters in parallel at a rate of 100,000 cells per 3-minute interval[133] and will likely soon achieve higher multiplexing. CyTOF was successfully applied to profiling key proteins in cell cycle regulation[134] and to immunophenotyping individual tumor cells, including human leukemia cell lines and leukemia patient samples.[133] These accomplishments are widely regarded as the first forays of systems-level approaches into the domain of single-cell regulation and identity.

Other innovative single-cell profiling techniques have also been widely used to obtain genomic, genetic, proteomic, and metabolomic data. These techniques for nucleic acid profiling include microfluid-based "lab-on-a-chip" devices,[135] new high-throughput polymerase chain reaction (PCR) with or without preamplification,[136,137] and DNA/RNA-Seq.[138] The proteomic and metabolomic profiling techniques that were not discussed earlier include mass spectrometry–based methods (reviewed in Ref. 139) and fluorescence imaging coupled with flow cytometry that measures up to 1000 prelabeled targets.[128] Furthermore, a great range of new technologies is continuously emerging, providing ever finer detail to single-cell biology; see review articles.[140]

In summary, single-cell analysis is providing a new, previously inaccessible layer of information that is instrumental in elucidating the stochastic nature of molecular processes, population variability, and tumor heterogeneity using the quantitative tools of systems biology.

Personalized Systems Medicine: A Patient-centric View of Cancer Research

Extensive research efforts in past decades, especially following the introduction of high-throughput-omics profiling technologies, have clearly highlighted tumor heterogeneity as a result of the highly diverse repertoire of genetic and epigenetic alterations that define the disease. Although we have discussed heterogeneity at the level of single cells, an equally critical challenge of cancer research is patient-to-patient molecular heterogeneity, both in the tumor and in the patient background germline landscape, even when tumors are classified as morphologically indistinguishable. Two critical consequences of such heterogeneity are that patients with tumors that would be considered identical may have dramatically different outcome and response to therapy. For instance, the vast majority of prostate cancers never progresses to aggressive metastatic disease. Unfortunately, the small fraction that does can be indistinguishable from the majority that does not, prompting aggressive and often invasive therapy in patients who would not need it.

As a result, the development of personalized medicine approaches has become an almost inevitable trend in cancer research. Initially, the focus has been on identifying molecularly distinct subtypes of a major tumor class and associating them with equally distinct prognostics and therapeutics. For instance, tumor subtype and activation of specific pathways have been shown to be predictive of anticancer treatment in breast cancer and pancreatic ductal adenocarcinoma.[141,142] Unfortunately, individual tumor phenotypes appear increasingly as the intersection of several layers of regulatory control, including cell of origin, genetic and epigenetic alterations, distal endocrine signals, and the balance of distinct paracrine signals originating from the balance of cellular subpopulations that constitute the tumor microenvironment. As a result, with the possible exception of some leukemias, where somatic perturbation of lineage differentiation events plays a dominant role, a clear demarcation between tumor subtypes is becoming increasingly elusive, and much overlap between even relatively well-defined molecular subtypes is becoming evident, as demonstrated, for instance, by recent attempts to restructure established breast-cancer subtypes.[143] Indeed, for some large tumor classes, such as prostate cancer, a clear subtype distinction has been difficult, and only very recent results hypothesize different basal and luminal progenitor origins as a possible discriminating event.[144]

Now that full genomic and epigenomics characterization is achieving feasibility at the single-patient level, systems biology approaches are likely to help discriminate alterations and developmentally related states of the cancer cell of

each individual tumor. These analyses would be extremely difficult using only the tools of statistical genomics, which require a much larger sample size. Although success stories are still limited, there is now a realistic, albeit cautious, expectation that these tools will allow a new level of personalized cancer care, based on the individual's genetic background. For instance, at least in cell lines, it has now been possible to partially predict sensitivity to specific compounds on the basis of their genetic landscape,[3] and biomarkers have been shown to be predictive of response and disease-free survival in neoadjuvant breast cancer treatment.[145]

Integrative analysis, a staple of the cancer systems biology approach, is now also starting to be adopted in clinical practice. For instance, although most pathology labs now perform single mutation screens to inform therapeutic choices (e.g., KRAS mutation screen in colorectal carcinomas), whole-genome sequencing is starting to be adopted for genotype-specific therapeutics,[146] and the identification of drug-accessible fusion events in a small number of patients is likely to become an additional tool for cancer therapeutics. In a pilot study, whole-genome, exome, and transcriptome sequencing have been performed in several patients with advanced cancer.[147] These sequencing data were integrated to detect cancer mutations such as structural rearrangement, copy number variation, and somatic point mutation and identify aberrant pathways that are driven by these mutations. Finally, distinct rationales for clinical trials of two patients were suggested according to their backgrounds of genetic mutations and pathway dysregulation.[147] This framework of personalized therapy development, which integrates extensive genetic sequencing, genomic profiling, and causal network inferring, is expected to be tested on a larger scale in the near future.

Finally, although most personalized-medicine approaches have focused on cancer heterogeneity across patients, tumor clones evolve according to fitness landscapes that are frequently determined by therapeutic choices, thus acquiring mutations that confer drug resistance.[148,149] For instance, a mathematical model was built to simulate the genetic dynamics and cell heterogeneity in a tumor.[150] Multiple personalized therapeutic strategies were tested by simulation using this model, and clinical outcomes were inferred. This simulation suggested that nonstandard personalized medicine, which takes into account subclones and dynamic genetic and epigenetic mutations, should substantially improve the clinical outcome after personalized therapeutics. Although this is just a theoretical simulation, it does imply that traditional personalized medicine based on the averaged and static genetic genomics may not be enough to tackle the complexity of tumor progression in individual patients. There is still a long way to go toward achieving a mature view of personalized medicine that benefits cancer patients to the largest degree. Yet, cancer systems biology, as an integrative and cross-disciplinary science, offers a novel and promising avenue of research in this direction.

Biomarkers for Assessing Risk of Cancer

Cancer is a complex disease involving both environmental and genetic determinants. The majority of cancers are caused by environmental and lifestyle factors, including smoking, alcohol use, infectious agents, occupation, diet, obesity, and lack of physical activity. However, only a small number of cancers, such as lung cancer (smoking) and cervical cancer (human papillomavirus [HPV] infection), have a major environmental risk factor that accounts for the bulk of disease in the population. For most cancers, the exposures have weak effects, and how to better assess the exposures and their effects remains a challenge. On the other hand, even for those cancers with a predominant environmental risk factor, only a small fraction of exposed individuals develop the cancer. For example, it is estimated that only 1 in 10 smokers develops lung cancer, and the rate of developing cervical cancer in high-risk carriers of HPV is even lower. Our understanding of the etiology of cancer in terms of environmental factors and genetic susceptibility is still rather limited, and the interplay among these etiological constituents is poorly understood. In recent years, biomarkers have been playing an increasingly important role in cancer etiological study to help better determine exposures, evaluate effects, and assess susceptibility.[1-3]

Figure 21-1 shows the spectrum of biomarkers along the continuum of carcinogenic process from environmental exposure to cancer development. Biomarkers of cancer etiology can be classified into three broad categories: biomarkers of exposure, biomarkers of effect, and biomarkers of susceptibility.[1-4] Biomarkers of exposure indicate the presence of a carcinogenic compound or its biological interactions with cellular molecules, which can further be categorized into biomarkers of internal dose (e.g., carcinogens or their metabolites in bodily fluids, and circulating antibodies to infectious agents) and biomarkers of biologically effective dose (e.g., DNA and protein adducts).[5] Biomarkers of effect are biological indicators of the body's response to exposure and reflect the interaction between exposure and the human body. Biomarkers of effect encompass a broad array of early biological responses and altered structure and function of cells and tissues, such as chromosomal instability, gene mutation, epigenetic alteration (DNA methylation, histone modification, chromatin remodeling, and microRNA expression), changes in mRNA transcription and protein expression, and altered cell structure and function. Biomarkers of susceptibility (cancer risk) can be derived from each of the steps along the continuum of the carcinogenic process, reflecting interindividual variations in absorbing, distributing, metabolizing (activating and detoxifying), and excreting carcinogens; sensitivity to formation of macromolecule (DNA and protein) adducts; and ability to repair these adducts and eliminate damaged and premalignant cells. This categorization, however, is somewhat arbitrary, and the distinction among the three categories of biomarkers could be blurred. For instance, some chromosome instability biomarkers (e.g., micronuclei and chromosome aberrations) can be considered markers of effect as well as markers of susceptibility, because these markers not only indicate the early biological effect of exposure, but also reflect an individual's ability to metabolize carcinogens and repair DNA damage. Moreover, these markers have certain degrees of genetic heritability and can predict the risk of cancer independent of exposure level. Therefore, the interplay among these three categories of biomarkers is crucial for a complete understanding of cancer etiology. In the next few sections, we highlight some examples of biomarkers of exposure and biomarkers of effect. We also describe in more detail our current knowledge of biomarkers of cancer susceptibility.

Biomarkers of Exposure

Biomarkers of exposure can provide the most direct evidence of human exposure to a carcinogen as well as internal dose and biologically effective dose, affirm exposure-cancer associations established from traditional epidemiological approaches, and provide biological plausibility for the observed exposure-cancer association.

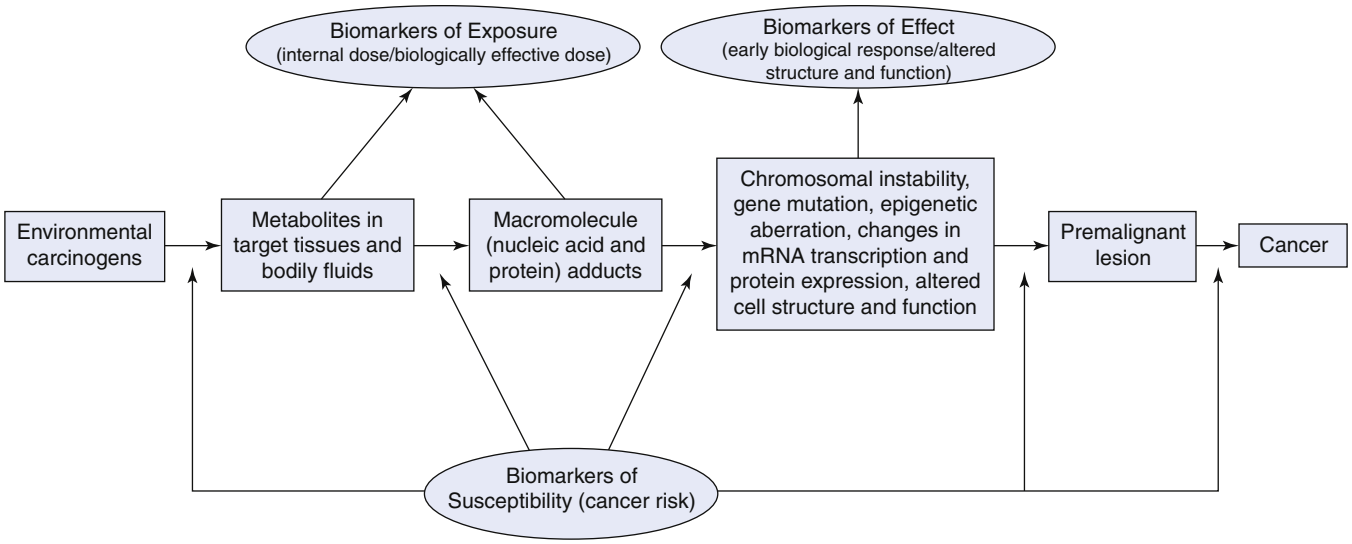

Figure 21-1 Biomarkers in cancer etiology Biomarkers in cancer etiologic studies can be classified into three broad categories: biomarkers of exposure, biomarkers of effect, and biomarkers of susceptibility. Biomarkers of susceptibility (cancer risk) can be derived from each of the steps along the continuum of the carcinogenic process, reflecting interindividual variations in absorption, distribution, metabolism (activating and detoxifying), and excretion of carcinogens; sensitivity to formation of macromolecule (DNA and protein) adducts; and ability to repair macromolecule damage, restore normal cellular functions, and eliminate premalignant cells.

Biomarkers of Internal Dose

Biomarkers of internal dose measure levels of a carcinogen or its metabolite in human tissues, bodily fluids, and excreta.[5] These biomarkers are not bound to cellular targets but provide a measure of exposure, absorption, metabolism, and excretion. There is generally a good correlation between external exposure and internal dose; however, the involvement of absorption and metabolism and interindividual variation in these processes suggest that the relationship may not always be simple. One of the classical examples of validated biomarkers of internal dose that contributed greatly to elucidate the environmental cause of human cancer is urinary aflatoxin and its metabolites. Aflatoxins have long been suspected to be human hepatic carcinogens, but the strongest evidence came from a prospective nested case-control study in which the authors measured urinary aflatoxin B1 (AFB1), its metabolites AFP1 and AFM1, and DNA adducts (AFB1-N7-Guanine) to assess the relation between aflatoxin exposure and liver cancer. Subjects with liver cancer were more likely to have detectable concentrations of any of the aflatoxin metabolites than controls, and the highest relative risk was for AFP1 (6.2-fold). Moreover, there was a strong interaction between chronic hepatitis B infection and aflatoxin exposure in liver cancer risk.[6] Tobacco-specific metabolites are the most studied biomarkers of internal dose. Cotinine is the main metabolite of nicotine, and the measurement of serum/plasma cotinine offers higher accuracy than self-reports in assessing tobacco smoking.[7] Two prospective studies have reported that higher levels of serum cotinine[8] and urinary cotinine[9] were associated with higher risk of lung cancer. The risk estimate of tobacco smoking and lung cancer from serum cotinine might be stronger than from questionnaire-based studies. The highest risk group had a 55-fold increased risk with no clear suggestion of a plateau in risk at high exposure levels, suggesting that analyzing the relationship between serum cotinine and lung cancer risk might contribute to a better quantitative assessment of tobacco-related lung carcinogenesis.[8] Additional prediagnostic urinary metabolites of tobacco carcinogens, such as NNAL (a metabolite of tobacco carcinogen NNK) and PheT (a metabolite of tobacco carcinogen polycyclic aromatic hydrocarbons [PAHs]), have also been associated with increased risk of lung cancer.[9,10] Other examples of biomarkers of internal dose include hormones or nutrients in body fluids and circulating antibodies to infectious agents (e.g., *Helicobacter pylori* in gastric cancer, hepatitis B virus [HBV] in liver cancer, and HPV in cervical cancer).[5]

Biomarkers of Biologically Effective Dose

Many carcinogens are metabolically activated and bind to DNA and/or protein to form adducts. DNA adducts have been the most evaluated biomarker of biologically effective dose, and a broad range of different DNA adducts have been measured in human samples using various approaches, including ^{32}P-postlabeling, immunoassays and immunohistochemistry, and mass spectrometry.[11,12] Because of the difficulty in measuring adducts in target tissues, almost all

of the population studies have used easily accessible surrogate samples, typically plasma/serum, white blood cells, or urine. The first prospective study showing a significant association between carcinogen-DNA adducts and subsequent cancer development was the aforementioned aflatoxin study in liver cancer.[6,13] Men with detectable urinary aflatoxin-DNA adduct (AFB1-N7-Guanine) and no HBV infection exhibited a ninefold increased liver cancer risk compared to men without detectable AFB1-N7-Guanine and no HBV infection. Tobacco smoke contains many different carcinogens, including PAHs, aromatic amines, and nitrosamines. Three prospective studies have evaluated the association of PAH-DNA or related aromatic-DNA adducts with the risk of lung cancer.[14-16] In a pioneering nested case-control study within the prospective Physicians' Health Study, the authors measured aromatic-DNA adducts in white blood cells (WBCs) at baseline and found current smokers who had higher levels of aromatic-DNA adducts in WBCs exhibited approximately threefold increased risk of lung cancer compared to current smokers with lower adduct concentrations. There were no associations in former and never smokers.[14] Two subsequent prospective studies, a pooled analysis of the three prospective studies, as well as a meta-analysis of nine studies (including retrospective case-control studies) recapitulated the main observation that bulky DNA adducts are associated with elevated lung cancer risk in current smokers after a follow-up of several years.[15-17] Protein adducts, such as hemoglobin (Hb) adducts of tobacco carcinogens and AFB1-albumin adducts, have also been used as biomarkers of biologically effective dose.[1,18,19]

Biomarkers of Effect

Biomarkers of effect measure early biological alterations that occur in the time frame between exposure and cancer development and are also known as biomarkers of intermediate endpoints or intermediate biomarkers. Historically, the most commonly studied biomarkers of effect in surrogate tissues are those related to genotoxicity endpoints, such as chromosome aberrations (CAs) and micronucleus (MN) formation in peripheral blood lymphocytes (PBLs). A number of prospective epidemiological studies have reported positive associations between elevated chromosomal aberrations in PBLs and increased cancer risk.[20-26] Importantly, a joint nested case-control study using subjects from two prospective cohort studies found that CA level in PBLs could predict future cancer development independent of environmental exposures (smoking and occupational exposure), supporting the notion that chromosomal instability markers could serve as both biomarkers of effect and biomarkers of susceptibility.[26] A few prospective studies showed that individuals with higher frequencies of MN in PBLs had 1.5- to 2-fold increased relative risk of cancer compared with the low-frequency subjects.[27,28]

Among various chromosome aberrations, chromosome translocation is one of the most well-established biomarkers of exposure and effect.[29] Translocations have been observed in nearly every cancer type,[30,31] and a single chromosome translocation can cause cancer—for example, Philadelphia translocation causes chronic myelogenous leukemia.[32,33] Chromosome translocation can survive mitosis and is the most persistent of all the different types of chromosome exchanges.[29] PBLs with radiation-induced translocations persisted for several decades in Japanese atomic bomb survivors. In contrast, other types of chromosome exchanges, for instance, dicentrics and acentric fragments, are unstable because they encounter difficulties during mitosis, which results in the affected cells being killed and eventually removed from the population, making them undetectable in long-term atomic bomb survivors.[34]

The mutational analyses of cancers with distinct environmental exposure provide elegant examples of biomarkers of effect. Exposure-specific mutational fingerprints in tumor suppressor genes have been known for many years.[35-39] The *TP53* gene is the most frequently mutated gene in human cancers, and its mutational spectrum varies substantially by tumor site, which is at least partially due to distinct environmental exposure.[36] For example, sunlight (UV exposure)-induced *TP53* mutations in skin cancer occur exclusively at dipyrimidine sites, including a high frequency of C-to-T transitions and unique CC-to-TT double base changes that do not happen in other malignancies.[37] In lung cancer, *TP53* mutational patterns are different between smokers and nonsmokers, with an excess of G-to-T transversions in smoking-associated cancers.[38] In liver cancer, a unique mutation (Arg249Ser) in *TP53* was linked to aflatoxin B1 exposure.[39,40] Moving beyond sequencing of candidate genes, the recent explosion of whole-genome sequencing (WGS) of cancer provides further evidence for profound effects of environmental exposure on the cancer genome.[41-44] In the first WGS of a solid tumor genome, Pleasance and colleagues[42] sequenced a malignant melanoma and a lymphoblastoid cell line from the same person. Consistent with observations in the *TP53* gene, of the more than 30,000 base substitutions found in the tumor genome compared to the lymphoblastoid genome, about 70% were C-to-T transitions. Of these, 92% occurred at the 3′ base of dipyrimidine sites, much higher than expected for chance occurrence. These mutations are characteristic of UVB-induced DNA lesions.[45] In the WGS of a small-cell lung cancer cell line[43] and a lung adenocarcinoma,[44] the mutational pattern (an excess of G-to-T mutations, an enrichment of CpG dinucleotides in the G-to-T

mutation sets, etc.) is also consistent with that of *TP53* and reflects the influences of tobacco carcinogens.[46]

With the breathtaking pace of technological advancements in the biomedical field, and with all the high-throughput "omics" technology, the list of potential biomarkers of effect is long and growing, encompassing molecular and functional changes in the epigenome, transcriptome, proteome, metabolome, and so on. There have been numerous investigations in exploring these technologies in epidemiological studies to identify biomarkers of effect in relation to cancer etiology; however, most of these studies are not validated, and the roles of the potential biomarkers in cancer causation are not clear. For biomarkers of effect (intermediate biomarkers), prospective studies are always preferred over retrospective case-control studies to avoid "reverse causation." Longitudinal evaluation of sequential samples should be the gold standard compared to cross-sectional and single time point analysis. There are many other issues in terms of study design, biospecimen collection and handling, assay reliability, and data reporting that are particularly important in the study of intermediate biomarkers to avoid spurious results.[3]

Biomarkers of Susceptibility

A major focus of cancer etiological study in recent years has been the determination of cancer susceptibility based on genetic variability. The earliest evidence for genetic susceptibility to cancer came from epidemiological observations of increased cancer risk among relatives of cancer patients. The existence of many rare inherited syndromes that predispose patients to increased risks of certain cancers provides other evidence for genetic susceptibility to cancer. A large classical twin study estimated the genetic heritability of most common cancers to be between 20% and 40%.[47] The identification of a large number of genetic susceptibility loci to common cancers by genome-wide association studies (GWAS) provides the strongest evidence for genetic susceptibility to common cancers.[48] Biomarkers of susceptibility have provided significant biological insight into cancer etiology and may become potential targets for preventive and therapeutic interventions. Biomarkers of susceptibility can also improve risk prediction and identify high-risk populations for targeted surveillance, screening, and prevention. Further investigation of gene-environment interactions is critical to advance the understanding of human carcinogenesis and improve the accuracy of cancer risk prediction.

Earlier analyses in cancer susceptibility have mostly focused on family-based linkage studies to identify high-penetrance genes whose mutations (mutation rate typically less than 0.1% in the general population) cause Mendelian cancer-predisposing syndromes. More recent efforts have mainly focused on association studies that compare variant allele frequencies of common single-nucleotide polymorphisms (SNPs) between a large number of cancer cases and unrelated controls. The underlying hypothesis for such an approach is the "common disease–common variant" (often abbreviated CD-CV) hypothesis, which postulates that genetic susceptibility to common diseases such as cancer is largely due to many common variants (typically having frequencies greater than 5% in the general population) with only modest effect conferred by each allele.[49] The competing hypothesis is the "common disease–rare variant" (CD-RV) hypothesis, which suggests that multiple rare variants (typically having frequencies that lie between approximately 0.1% and 1%, the upper limit for Mendelian mutations and the lower limit of SNPs, respectively) of larger effect cause common diseases.[50,51] However, recent evidence has suggested that these two hypotheses should not be viewed as an "either/or" choice, but rather that both common and rare variants may contribute to common diseases, and the degree of contribution by either variant depends on the particular disease phenotype.[50-52] In cancer, for example, and as described later, several rare susceptibility variants for breast cancer have been identified by candidate gene sequencing and genotyping. Furthermore, next-generation sequencing studies have identified novel rare susceptibility variants for other cancers.[53-57]

Depending on the population frequency of risk alleles and effect size, cancer genetic susceptibility markers can be roughly grouped into three classes: rare high-penetrance mutations, rare low- to moderate-penetrance disease-causing variants, and common low-penetrance SNPs (Table 21-1).[52]

Rare High-Penetrance Mutations

High-penetrance genes have been mostly identified by study of inherited Mendelian syndromes that predispose to cancer via linkage analysis followed by positional cloning. Such genes include *BRCA1* and *BRCA2* in hereditary breast/ovarian carcinoma; *RB1* in hereditary retinoblastoma; *APC* in familial adenomatous polyposis; mismatch repair genes, such as *MSH2*, *MLH1*, and *MSH6* in hereditary nonpoly posis colon carcinoma; and *VHL* in von Hippel–Lindau syndrome. Germline mutations in these high-penetrance genes confer high risk of respective cancers. However, because the population frequencies of these mutations are very rare (typically 0.1% or less), the population-attributable risk (PAR) is small.

Table 21-1 Three Classes of Biomarkers of Genetic Susceptibility to Cancer

	Rare High-Penetrance Mutations	Rare Low-to Moderate-Penetrance Variants	Common Low-Penetrance Variants
Population frequency	Rare, typically <0.1%	Rare, MAF typically between 0.1% and 2%	Common, MAF mostly >10%
Familial aggregation	Yes	No	No
Cancer risk (odds ratio)	≥10	Mostly ≥2	Mostly between 1.1 and 1.5
Population-attributable risk	Very small	Small	High
Functional significance	Direct effect (causal)	Direct effect (causal)	Mostly nonfunctional, in LD with causal variants
Approaches for identification	Linkage analysis followed by positional cloning, targeted sequencing of candidate genes	Candidate gene, exome, or whole genome sequencing of genetically enriched cases, followed by large-scale association study	Association study (candidate gene and GWAS) of unrelated cases and controls
Examples of genes	Breast cancer: BRCA1 and BRCA2; retinoblastoma: RB1; CRC: APC, mismatch repair genes (MSH2, MLH1, MSH6); kidney cancer: VHL	Breast cancer: ATM, CHEK2, BRIP1, PALB2, XRCC2; CRC: MUTYH; ovarian cancer: BRIP1; melanoma: MITF	Breast cancer: FGRF2, CASP8; lung cancer: CHRNA3-CHRNA5, TERT; CRC: TGFBR1, SMAD7, CDH1; bladder cancer: NAT2, GSTM1

CRC, Colorectal cancer; *GWAS*, genome-side association studies; *LD*, linkage disequilibrium; *MAF*, minor allele frequency.

Rare Low- to Moderate-Penetrance Variants

Rare low- to moderate-penetrance disease-causing variants are a relatively new territory in cancer susceptibility. However, the speed of identifying these variants is accelerating due to the ever-increasing application of next-generation sequencing (NGS) (whole exome or genome) in analysis of germline DNA. The earliest evidence for this class of variants came from rare variants in the *ATM* gene that increased breast cancer risk by two- to threefold,[58,59] whereas common SNPs in *ATM* were not associated with breast cancer.[60] Later on, rare variants in several *BRCA1-BRCA2* pathway genes, including *CHEK2*, *BRIP1*, and *PALB2*, were found to confer two- to threefold increased breast cancer risk.[61-63] In colorectal cancer (CRC), a large association study of 20,565 CRC cases and 15,524 controls uncovered that two rare variants, Gly396Asp (variant allele frequency, 0.7%) and Tyr179Cys (variant allele frequency, 0.2%), in the base excision repair gene *MUTYH* conferred extremely high risk of CRC: odds ratio (OR) = 23.1, 95% confidence interval [CI] 3.2 to 169; and OR = 4.1, 95% CI 0.9 to 18.5, respectively, for homozygous variant genotypes compared to the wild-type genotype.[64] Moreover, biallelic carriers of these two variants (i.e., homozygous at either site or heterozygous at both sites) exhibited a 28-fold (95% CI 6.9 to 115) increased CRC risk. This is currently the only example of a recessive model of inheritance for susceptibility to common cancers. Several recent studies have demonstrated the power of NGS in identifying novel rare cancer susceptibility variants.[53-55] In one study, Yokoyama and colleagues[53] first performed whole-exome sequencing (WES) of germline DNA from probands of several melanoma families and identified one novel variant (Glu318Lys) in the melanoma-lineage–specific oncogene *MITF*. Subsequently, they genotyped this rare variant in two large melanoma case-control studies conducted in the United States and Austria (a total of 3920 cases and 4036 controls) and found that in both studies carriers of the variant allele exhibited an over twofold increased risk of melanoma, with a combined OR of 2.19 (95% CI, 1.41 to 3.45). The variant allele frequency was 1.71% in cases compared to 0.79% in controls. Moreover, the variant allele was significantly overrepresented in cases with a family history of melanoma, multiple primary melanomas, or both. It was also associated with increased nevus count, non-blue eye color, and impaired *MITF* function in vitro, providing compelling evidence that *MITF* is a rare low-penetrance gene for melanoma. In another study, Park and co-workers[54] first performed WES of families with multiple cases of breast cancer and identified two families with *XRCC2* (a homologous recombination DNA repair gene) mutations. They then performed large-scale targeted sequencing of the *XRCC2* gene in a population-based case-control study (1308 cases with early-onset breast cancer and 1120 controls) that identified six probably pathogenic coding variants in cases but no variants in 1120 controls (*P* less than 0.02). Additional sequencing in 689 multiple-case families identified 10 families with protein-truncating or probably deleterious rare missense variants of *XRCC2*. Therefore, *XRCC2* is a novel rare low to moderately penetrant breast cancer susceptibility gene. A recent WES study of neuroblastoma found that rare, potentially pathogenic germline variants were significantly enriched in *ALK*, *CHEK2*, *PINK1*, and *BARD1*

genes.[57] WES-identified rare cancer susceptibility variants almost all have clear functional implications, and laboratory studies have been performed in many cases to confirm their functional effect. Thus, these markers are almost universally causal variants in causal genes.

WGS can provide enormous amounts of information (e.g., variants in regulatory regions such as noncoding RNAs) that are not available from WES. It can also open unprecedented opportunities in cancer association studies that will not only identify new cancer susceptibility loci but also facilitate the discovery of driver SNPs in regulatory regions. A recent study analyzed 32.5 million variants discovered by WGS of 1795 Icelanders and identified a new low-frequency variant at 8q24 that conferred a 2.9-fold increased risk of prostate cancer (PCa) ($P = 6.2 \times 10^{-34}$ in follow-up validation of more than 10,000 PCa cases and 62,000 controls of European origin).[65] Given the significantly reduced cost, WGS will be increasingly applied in cancer association studies.

Common Low-Penetrance SNPs

Accounting for 90% of naturally occurring genetic variations in the human genome, SNPs are the predominant marker of choice in current cancer association studies. By definition, SNPs have a minor allele frequency (MAF) of at least 1%. Most cancer association studies have examined common SNPs with an MAF of 5% or greater to allow for sufficient statistical power. Two approaches have been used to identify common SNPs as cancer susceptibility markers: the candidate gene approach and GWAS.

Candidate Gene Approach

The candidate gene approach stemmed from successful cellular phenotypic assays that were initiated before the development and application of genotyping techniques in epidemiological studies. Because of the important role of carcinogen metabolism and DNA repair pathways in determining cellular DNA adduct levels, it was natural to hypothesize that interindividual variations in these two cellular phenotypes may be associated with interindividual variation in exposure-induced cancer susceptibility. Therefore, cellular phenotypic assays in carcinogen metabolism and DNA repair capacity were initially used to determine interindividual variability in cancer susceptibility. Among such prototypic assays was evaluation of *N*-acetyltransferase (NAT) phenotypes based on NAT function as a phase II metabolizing enzyme involved in the detoxification of aromatic amines, which are known bladder carcinogens. The general population can be classified into rapid, intermediate, or slow acetylators, dependent on NAT activity, and an early phenotypic study suggested that slow acetylators were more susceptible to bladder cancer when exposed to bladder carcinogenic *N*-substituted aryl compounds.[66] Likewise, several different PBL-based DNA repair assays were widely applied in cancer association studies and yielded positive and consistent association between DNA repair capacity and cancer risk.[67] Starting from the early 1990s, with the development of low-throughput genotyping techniques, genetic association studies of cancer risk using a candidate gene approach exploded, initially focusing on carcinogen metabolism and DNA repair genes and later expanding to include other important cellular pathways. Numerous associations have been reported. However, most of these candidate gene studies involved small numbers of cases and controls, and very few of the initially reported positive susceptibility alleles have been replicated in subsequent validation studies.[68] Nevertheless, *NAT2* is among the very few validated cancer susceptibility loci derived from the candidate gene approach. As described earlier, NAT acetylator phenotypes are associated with bladder cancer risk, and these phenotypes can be tagged by genotypes composed of several SNPs in the *NAT2* gene. Numerous candidate gene studies and a meta-analysis have unequivocally confirmed that the *NAT2* slow acetylator genotype confers an approximately 50% increased risk of bladder cancer.[69] Other confirmed cancer susceptibility alleles from the candidate gene approach include the *GSTM1* null genotype in bladder cancer,[69] multiple SNPs of alcohol dehydrogenase genes (*ADH*) in upper aerodigestive cancers,[70] and a *CASP8* SNP (D302H) in breast cancer.[71] Besides carcinogen metabolism and DNA repair pathways, SNPs in other critical cellular pathways with obvious biological links to tumor development—for example, tumor microenvironment-related pathways such as immune surveillance and angiogenesis—have been extensively studied in relation to cancer susceptibility.[72-74] However, like most candidate gene studies, no SNP in these pathways has been unequivocally associated with cancer risks through a candidate gene approach.

Genome-Wide Association Studies

In the past 5 years, GWAS have revolutionized the study of cancer association and identified thousands of SNPs that are associated with the risk of many human diseases.[48] The GWAS approach tests hundreds of thousands of common SNP markers as surrogates to tag a much larger set of variants that are in strong linkage disequilibrium (LD) with the genotyped SNPs. Therefore, GWAS is discovery driven, in contrast to the hypothesis-driven candidate gene approach. The agnostic nature of GWAS allows identification of completely novel cancer susceptibility loci that would have been overlooked using the candidate gene approach. To date, more than 200 common susceptibility SNPs have been identified

for about two dozen cancer types.[48] These common susceptibility SNPs spread across all the chromosomes except the Y chromosome. A few regions, most notably 5p15.33 and 8q24, contain susceptibility SNPs for multiple cancer types (Figure 21-2). As expected from a tagging SNP-based approach, the vast majority of the identified SNPs are either intronic (39%) or intergenic (52%), and the functional implications of most SNPs are unclear.[75] Effect size associated with these common SNPs is modest (OR typically between 1.1 and 1.5).[75] Moreover, very few SNPs have an OR greater than 2, and the largest OR (over 2.5) has been observed for an SNP in the *KITLG* gene in testicular cancer, a malignancy with substantial familial risk but with little evidence for Mendelian predisposition.[76,77]

Most GWAS-identified SNPs are cancer-type specific and sometimes subtype specific. One example of a subtype-specific locus is in lung cancer, where 5p15.33 (*TERT-CLPTM1L* locus) is associated with adenocarcinoma but not squamous cell carcinoma.[78] However, there are at least seven regions that have been associated with more than one cancer type. For example, chromosome 8q24 flanking the *MYC* oncogene harbors susceptibility loci for prostate (five independent loci), breast, colon, bladder, and ovarian cancers as well as for chronic lymphocytic leukemia.[79] Although the *MYC* oncogene is the most likely plausible gene, these SNPs are relatively distant and are not in LD with any SNPs within the *MYC* gene or proximal promoter. Thus, just how these variants affect *MYC* function has been under extensive study. At least one CRC susceptibility SNP (rs6983267) in this region has been reported by two independent studies to be located within a transcriptional enhancer, bind differentially to transcription factor TCF7L2/TCF4, and either physically interact with the *MYC* gene[80] or enhance responsiveness of Wnt signaling, a key pathway in CRC.[81] Chromosome 5p15.33 (*TERT-CLPTM1L* locus) contains susceptibility loci for at least seven cancers, including melanoma, basal cell carcinoma, and bladder, brain, lung, pancreatic, and testicular cancer. In another example, a region on chromosome 11q13 harbors susceptibility SNPs for prostate, renal, and breast cancer.[79] In addition to these pleiotropic cancer susceptibility loci, a more interesting observation from GWAS is the pleiotropic susceptibility for seemingly unrelated genetic traits. However, at least some of these pleiotropic loci have biological plausibility. For example, an SNP in *TCF2* (a gene known to be involved in diabetes) was associated with a reduced risk of prostate cancer but an increased risk of type 2 diabetes (T2D),[82] consistent with previous epidemiological observation that individuals with T2D have a lower risk of developing prostate cancer.[83] An SNP in *ITPR2* was associated with an increased waist-hip ratio (WHR)[84] and increased risk of renal cell carcinoma (RCC).[85] Obesity is an established risk factor for RCC, and WHR has been suggested as a better measure of obesity than BMI. Other examples of pleiotropic loci in cancer and other genetic traits include the *JAZF1* locus with height,[86] T2D,[87] and prostate cancer[88] and the 9p21.3 (*CDKN2A/2B*) locus with T2D,[87] myocardial infarction,[89] nevus density,[90] melanoma,[91] and glioma.[92]

Identification of cancer-specific loci through GWAS has provided significant insight into the distinct genetic

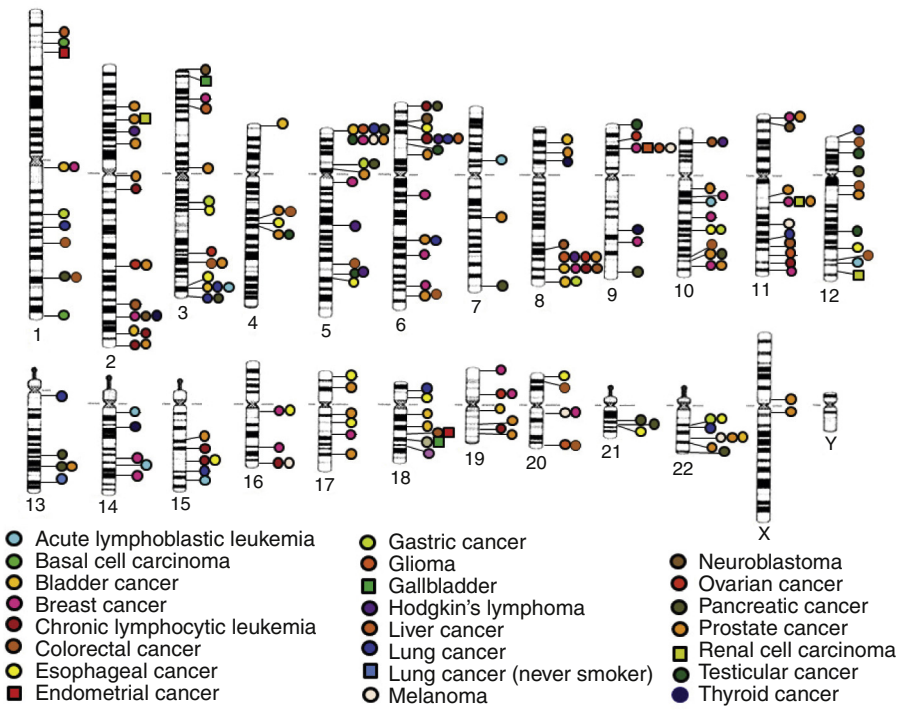

Figure 21-2 Genome-wide distribution of GWAS-identified cancer susceptibility loci Over 200 cancer susceptibility SNPs have been identified and these SNPs spread across all the chromosomes except the Y chromosome. The SNP data were obtained from the National Human Genome Research Institute (NHGRI) GWAS Catalog (http://www.genome.gov/gwastudies/).[48]

architecture of different cancers.[52,75] For example, PCa has the most susceptibility SNPs (over 70) identified to date, explaining about 30% of the familial risk in this disease.[93-95] Previously a classical twin study estimated a genetic heritability of 42% for PCa, the highest among common cancers[47]; however, a high-penetrance gene has yet to be identified and confirmed. One needs to reflect on underlying reasons for the high number of susceptibility SNPs discovered by GWAS in PCa. Whereas this could reflect the true genetic architecture of PCa wherein common variants with modest effect sizes play more prominent roles in PCa etiology, it is also possible that PCa may be more amenable to GWAS, possibly because of large sample size and limited confounding effects by environmental exposure and histological heterogeneity. In contrast to PCa, which does not have an obvious environmental risk factor, lung cancer is a strongly induced by environmental exposure. Perhaps reflecting the predominant effect of smoking, lung cancer is one of the malignancies with the least number of identified susceptibility SNPs. Multiple independent GWAS with very large sample sizes (13,300 cases and 19,666 controls in one study) have only unequivocally identified three susceptibility loci (15q25, 5p15, and 6p21) for lung cancer in individuals of European descent by stringent GWAS standards.[78,96-100] Importantly, the 15q25 variants were strongly associated with objective measures of tobacco exposure, suggesting that the association of these variants with lung cancer risk is likely to be mediated largely via tobacco exposure.[101] Bladder cancer lies in between PCa and lung cancer in terms of environmental exposure and genetic susceptibility and therefore is an excellent model for studying gene-environment interactions in cancer etiology. Smoking accounts for about half of all bladder cancers, and occupational exposure explains another one fifth. A large twin study estimated that inherited genetic susceptibility contributes to 31% of bladder cancer risk.[47] Eleven susceptibility loci have been validated for bladder cancer, and most of these loci have biological plausibility: three carcinogen-metabolizing genes, *GSTM1* on 1p13.3,[69,102] *NAT2* on 8p22,[69,103] and *UGT1A1* on 2q37.1[104]; a urea transporter gene *SLC14A1* on 18q12.3[105,106]; a cell cycle control gene *CCNE1* on 19q12[104]; and several oncogene, tumor-suppressor, or cell growth–related genes including *TP63* on 3q28,[107] *FGFR3* on 4p16.3,[108] *PSCA* on 8q24.3,[109] *TERT-CLPTM1L* on 5p15.33,[104,110] and a locus at 8q24.21, near *MYC*.[107] More importantly, there was a significant gene-smoking interaction between *NAT2* genotypes and smoking status, with the *NAT2* slow-acetylator genotype increasing bladder cancer risk, particularly among cigarette smokers.[69] This observation has become one of the classic examples of a gene-environment interaction in cancer etiology supported by a strong biological basis.

Based on the substantial number of cases and controls with both GWAS and exposure data, gene-environment interactions will be a hot topic in cancer etiology studies in the coming years. Indeed, a recent large-scale analysis of breast cancer highlighted the value of GWAS data together with exposure data.[111] A total of 34,793 invasive breast cancers and 41,099 controls of European ancestry from 24 studies of the Breast Cancer Association Consortium were analyzed for the modifying effect of 10 established environmental risk factors (age at menarche, parity, breastfeeding, body mass index, height, oral contraceptive use, menopausal hormone therapy use, alcohol consumption, cigarette smoking, and physical activity) on the association of 23 GWAS-identified SNPs with breast cancer risk. An SNP (rs3817198) in the *LSP1* gene showed strong interaction with parity (P for interaction = 2.4×10^{-6}): the per-allele OR (95% CI) was 1.08 (1.01 to 1.16) in nulliparous women and ranged from 1.03 (0.96 to 1.10) in parous women with one birth to 1.26 (1.16 to 1.37) in parous women with four or more births. Another SNP (rs17468277) in *CASP8* exhibited significant interaction with alcohol consumption (P for interaction = 3.1×10^{-4}): the per-allele OR (95% CI) was 0.91 (0.85 to 0.98) in those who drank less than 20 g/day and 1.45 (1.14 20 1.85) in those with an alcohol intake of at least 20 g/day.

Cellular Phenotypic Assays of Susceptibility

As introduced in earlier sections, cellular phenotypic assays in carcinogen metabolism and DNA repair capacity were initially used to determine interindividual variability in cancer susceptibility before the wide application of genotyping in cancer epidemiological studies. There is substantial interindividual variation in DNA repair capacity (DRC) in the human population. At the extreme end of this spectrum are patients with xeroderma pigmentosum, who have a defect in nucleotide excision repair and who exhibit a 1000-fold increased risk of skin cancer. There is a larger subgroup with suboptimal DRC who are phenotypically normal but may be at increased cancer risk if exposed to carcinogen. Various DNA repair assays in PBLs are still being used in assessing cancer risk. These assays include tests based on DNA damage induced by chemical or physical mutagen challenge, such as the mutagen sensitivity, induced micronuclei, and Comet assays; indirect tests of repair, such as unscheduled DNA synthesis; and direct measures of DNA repair capacity, such as the host cell reactivation assay.[67]

The mutagen sensitivity assay was the first DNA repair–related phenotypic assay to be widely applied in cancer epidemiological studies. Developed by Hsu and associates,[112] this assay cytogenetically quantifies the frequency of chromatid breaks induced by bleomycin in cultured PBLs as an indirect measure of DRC. The assay has since been expanded to employ other etiologically relevant mutagens

to assess genetic susceptibility to different cancers, such as benzo(a)pyrene [B(a)P] diolepoxide (BPDE) and NNK for smoking-related cancers, UV light for skin cancer, and γ-radiation for breast and brain cancer.[113] Numerous epidemiological studies, including a few prospective studies, have shown mutagen-sensitive phenotypes to be associated with increased risks of a variety of cancers.[113] Furthermore, classical twin studies have demonstrated that mutagen sensitivity is a genetic trait with heritability estimates ranging from 40% to 75%,[113,114] and a GWAS identified the first common SNP predictive of bleomycin-sensitive phenotype.[115] The data are compelling and support assay of mutagen sensitivity as a biomarker of cancer susceptibility.

The mutagen-challenged cytokinesis-blocked micronucleus (CBMN) assay in PBLs is another related and commonly used cytogenetic assay for DNA damage.[116] Micronuclei (MN) originate from chromosome fragments or whole chromosomes that fail to engage with the mitotic spindle and therefore lag behind when the cell divides. Because cells are blocked in the binucleated stage, it is also possible to measure nucleoplasmic bridges (NPBs) originating from asymmetrical chromosome rearrangements and/or telomere end fusions, and nuclear buds (NBUDs), the latter considered a marker of possible gene amplification. The CBMN assay has been used in assessment of cellular radiosensitivity to determine breast cancer predisposition and as a biomarker of susceptibility in tobacco-induced carcinogenesis.[116] A provocative retrospective case-control study showed that NNK-induced MN, NPBs, and NBUDs in PBLs were associated with a 2.3-, 45.5-, and 10.0-fold increased risk of lung cancer in smokers, respectively.[117] Whether such dramatic increases in risk hold up in prospective studies employing NNK-induced NPBs and NBUDs as biomarkers remains to be seen. Nevertheless, the simplicity, rapidity, and sensitivity of the CBMN assay make it a valuable tool for cancer risk assessment.

Unlike the cytogenetic assays that indirectly infer DNA repair, the host cell reactivation (HCR) assay is a direct measure of intrinsic DNA repair kinetics in intact cells. To perform this in vitro assay, PBLs are transfected with a damaged (treated by different mutagens) recombinant plasmid construct containing a reporter gene. The reporter gene's expression level directly reflects the PBLs' DRC to specific mutagens. The low DRC phenotype measured by HCR has been shown to be an independent risk factor for a variety of epithelial cancers in retrospective case-control studies.[118] Prospective studies are warranted to validate the HCR-measured DRC as valuable biomarkers of susceptibility.

In addition to DNA repair–related assays, telomere length in leukocytes, an indicator of biological aging and genomic instability, has been extensively evaluated as a cancer susceptibility marker in the past decade. The association appears to be cancer type–dependent. The majority of studies have shown significant associations between short telomeres in leukocytes and increased risks of cancers, including bladder, esophageal, gastric, head and neck, ovarian, and renal cancer; however, there were no significant associations reported in prostate, breast, and colorectal cancers from several large prospective studies.[119-122] Interestingly, two prospective studies reported that long telomeres were associated with increased risks of melanoma and non-Hodgkin lymphoma, respectively.[123,124] These cancer type–specific associations between telomere length and cancer risk warrant further validation and biological investigation.

Mouse Models for Cancer Susceptibility Study

Mouse models that cross tumor-resistant with tumor-susceptible strains have been instrumental in mapping several candidate cancer susceptibility loci and expression quantitative trait loci (eQTLs)[125-131] before the wide application of GWAS in human cancers. Although hundreds of cancer susceptibility loci have been identified through GWAS, the majority of the heritable risk of cancer cannot be explained by the main effects of common alleles. Gene-gene and gene-environment interaction clearly play important roles in cancer development, which is challenging in human studies because of the heterogeneity of human cancers. Mouse models have a defined genetic background that does not possess the genetic heterogeneity characteristic of human cancers. Crossing genetically distinct mouse strains can allow the analysis of the combinatorial effects of host genetic background and somatic events at different stages of cancer development. A recent study applied a network analysis in a mouse model of skin cancer that produces both benign tumors and malignant carcinomas and identified a genetic architecture affecting inflammation and tumor susceptibility.[132] Gene–environment interactions can also be investigated using mouse models to identify how genetic modifiers of tumor initiation interact with specific environmental effects identified through epidemiological studies. Mouse models will also be a major tool for mechanistic studies of cancer susceptibility loci.

Genetic Susceptibility to Cancer Outcomes

Genetic susceptibility plays a significant role not only in the initiation of cancer, but also in the outcomes of cancer treatment. Pharmacogenetics/pharmacogenomics is the study of the role of inherited and acquired genetic variation in drug response (efficacy and toxicity). Acquired somatic mutations and other types of abnormalities obviously play a determining role in patients' responses to therapeutic drugs—for instance, in the case of *HER2* overexpression in breast cancer and *EGFR* mutation in lung cancer. On the other hand, germline genetics may also modulate drug response, particularly systemic toxicities

associated with specific drugs. The most prominent example in this field is the effect of thiopurine *S*-methyltransferase (*TPMT*) gene variants on the toxicity of 6-mercaptopurine (6-MP), a drug used for the treatment of acute lymphoblastic leukemia (ALL). A standard dose of 6-MP would cause life-threatening toxicity to patients with certain variant alleles of *TPMT* that results in exceptionally low TPMT activity.[133,134] The U.S. Food and Drug Administration (FDA) has recommended *TPMT* genotyping and dosage reduction for those with low-activity alleles.[135] GWAS has also begun to be applied to pharmacogenomics research, although the sample size remains a major challenge. Ingle and colleagues presented an example of GWAS for outcomes.[136] Aromatase inhibitors have been used in estrogen-positive breast cancers to reduce recurrence. However, the administration of an aromatase inhibitor can also cause severe musculoskeletal pain in 10% to 20% of patients that may lead to therapy termination. Ingle and co-workers performed a small-scale GWAS using DNA samples from a large clinical trial of aromatase inhibitors in breast cancer patients and found a strong association—although not reaching genome-wide significance, likely because of small sample size—between musculoskeletal pain and variants in the gene cluster encoding T-cell leukemia lymphoma (TCL) proteins. Functional genomic studies showed that SNPs with the strongest association created an estrogen response element and that *TCL1A* expression was estrogen dependent and directly related to interleukin 17 receptor A (*IL17RA*) expression.[136] IL17RA is an experimental target for the treatment of patients with rheumatoid arthritis.[137] This provocative study illustrates the major challenge for GWAS of treatment responses: the difficulty of finding a large number of patients undergoing a specific drug treatment. Nevertheless, functional validation could increase the confidence that the observed genetic association (not reaching genome-wide significance) represents a true biological link rather than a chance finding. There have been increasing reports that applied GWAS to identify SNP association with the prognosis of common cancers[138-142]; however, there has not been a consistent susceptibility locus for any cancer outcome that is replicated by different groups. Future studies with large sample sizes and relatively homogeneous patient populations in terms of stage and treatment are warranted for GWAS of clinical outcomes. A detailed summary of cancer pharmacogenomics is outside the scope of this chapter, and readers are referred to other recent excellent review articles.[143,144]

Integrative Multifactor Risk Prediction

The ultimate goal of identifying biomarkers of cancer risk is to incorporate validated biomarkers into a comprehensive risk assessment model, with integration of environmental, behavioral, and genetic risk factors. The risk of cancer in the general population varies dramatically among different individuals, from average, to moderate, to high risk. For individuals with different cancer risks, there are different risk-reduction options. These include lifestyle changes for an average-risk person, and frequent screening and chemoprevention for moderate- and high-risk individuals. Cancer risk prediction models with high discriminatory accuracy can have significant applications in planning intervention trials, estimating the population burden of disease, creating benefit/risk indices and clinical decision-making processes, and designing prevention strategies. The currently developed cancer risk prediction models rely mostly on environmental risk factors and have modest discriminatory accuracy, which has limited clinical or public health utility. For example, heavy smoking confers an over 30-fold increased risk of lung cancer; however, consideration of smoking alone is insufficient to identify a high-risk population for cost-effective surveillance and screening. Indeed, the National Lung Screening Trial (NLST) showed that although low-dose computed tomography screening of heavy smokers can reduce lung cancer mortality by 20%, the feasibility of large-scale screening is limited by a false-positive rate of greater than 95%.[145,146] Improved risk prediction for lung cancer is critical to reduce false positives and shift the balance toward higher cost effectiveness for surveillance and screening. The best known cancer risk model, the Gail model for breast cancer, has a discriminatory accuracy of 0.58, measured as the area under the receiver operating characteristic curve (AUC), indicating that the distribution of projected risks among women who developed breast cancer overlapped considerably with that among women who did not develop breast cancer.[147] There have been many attempts to improve the modest discriminatory accuracy of the Gail model—for example, adding breast density in the BCRAT (*B*reast *C*ancer *R*isk *A*ssessment *T*ool of NCI, or Gail Model 2) modestly improved the discriminatory accuracy by 0.047.[148] Recent identification of multiple genetic predisposing loci for cancers by GWAS has generated great interest and raised hopes that these SNPs may improve risk prediction if incorporated into available risk-prediction models. However, the results have been somewhat disappointing. Addition of 7 and 11 GWAS-validated breast cancer susceptibility SNPs to the BCRAT model only improved the AUC by 0.025 and 0.030, respectively.[149,150] Also, adding three GWAS-validated SNPs to a lung cancer prediction model increased the AUC by 0.012.[151] As more and more common cancer susceptibility SNPs are identified through GWAS, there is clearly a potential to improve risk-prediction accuracy as more SNPs are incorporated. More importantly, gene–environment interactions have not been fully explored and integrated into

risk-prediction models, and this approach would probably add more discriminatory accuracy than integration of SNPs alone. Cellular phenotypic biomarkers (e.g., mutagen sensitivity and MN) are believed to measure the sum results of multiple genetic variations and thus, in theory, should provide more predictive power than individual SNPs. In the first attempt to incorporate cellular phenotypic biomarkers into a risk-prediction model, adding mutagen-sensitive phenotypes to a basic epidemiological risk prediction model for bladder cancer improved the AUC from 0.70 to 0.80.[152,153] This scale of increase is much higher than that reported from adding SNPs, demonstrating the potential of phenotypic biomarkers in improving cancer-risk prediction models.

Conclusion

Over the past two decades, enormous strides have been made in identifying biomarkers of cancer risk, and these discoveries have paralleled the evolution of the discipline of molecular epidemiology. Whereas the currently identified biomarkers have contributed greatly to our understanding of environmental exposure and cancer susceptibility, rapid advances in technology have greatly expanded the repertoire of biomarkers at all levels. We have already witnessed the revolution of GWAS in identifying novel cancer susceptibility factors. Although it is likely that most SNPs with larger ORs for common cancers have already been identified, given the large sample sizes of published studies, we will see continued application of GWAS in cancer risk assessment. Future GWAS will query cancer subtypes, population subgroups such as those categorized by exposure, and diverse populations. Exploring cancer susceptibility in diverse populations could further the understanding of disease pathways and assist in fine mapping of genetic associations by exploiting the differences in LD among different populations. Fine mapping and functional characterization of causal SNPs is a necessary step to move GWAS forward. GWAS will also be increasingly applied to identify genetic predictors of clinical outcomes. There is growing interest in the use of GWAS data for copy-number variation (CNV) analysis.[154] Moreover, the trend in performing WES and WGS to identify rare variants for cancer susceptibility will no doubt lead to an explosion of data reporting novel rare low- to moderate-penetrance variants, which would account for some of the missing heritability and provide enormous biological insight into human carcinogenesis. In the coming years, we will also see increasing use of various high-throughput "omics" technologies in cancer biomarker discovery. Unlike genotyping and sequencing, the techniques of epigenomics, transcriptomics, proteomics, and metabolomics are subjected to concerns of sample heterogeneity, technical reproducibility, and, if performed in retrospective case-control studies, "reverse causation." Longitudinal evaluation of these markers should always be preferred. Finally, validation is the key for any biomarkers, particularly those identified from high-throughput technologies. In conclusion, the overarching goal is to integrate different levels of biomarkers of cancer risk into comprehensive risk-prediction models for specific cancer types in order to benefit public health.

Protein Biomarkers for Detecting Cancer: Molecular Screening

No matter how many mistakes you make or how slow you progress, you are still way ahead of everyone who isn't trying.

(http://www.marcandangel.com/2012/06/08/60-quotes-change-the-way-you-think/)

Biomarkers of early cancer detection, specific markers of a malignancy type, and predictive markers of response to treatment will aid in the early diagnosis and selection of the most efficient therapies. An exponential growth in technologies has been achieved toward this goal in the past decade. However, it is safe to say that the field of disease biomarkers produced many more publications on the subject than actual "clinically actionable" targets. By no means a criticism, this statement reflects on the status quo of a discipline that has been "trying really hard" but finding the goal more elusive with each step forward.[1] Why has the progress been slow? Is it just the technology that is not on par with the complexity of human biology? Or perhaps, by focusing mainly on a paradigm of "DNA-mRNA-protein" as a fundamental driving force that defines a phenotype, are we oversimplifying and hence misinterpreting a system?[2,3] We bring these very general questions to the attention of the reader for two reasons: first to spark a debate on the fundamental issues that biomarker discovery entails and second to put our detailed proteomics discussion into the perspective within the larger context of biomarker discovery.

Establishing a panel of biomarkers for early diagnosis of cancer holds tremendous promise but also faces daunting obstacles. The major challenge stems from the very nature of a biological system, its complexity, dynamics, variability, and versatility all making it difficult to draw clear lines between a state that would be considered normal and one that appears to be slightly different and in danger of becoming abnormal. Then come barriers of logistics, such as a dichotomy between a need to mainly rely on population studies while facing tremendous intra- and interpersonal phenotypic variability, defining adequate controls, availability of specimens, and the danger of their potential adulteration before analysis (i.e., in the course of collection, processing, and storage). Last but not least is the requirement for sensitive technologies capable of measuring target compounds directly from a biological milieu with a level of specificity and selectivity that allows differentiation among discrete cohorts of individuals/patients that is reliable enough to justify the risk of acting on specific clinical modalities. There is a growing recognition that achieving true breakthroughs in the use of biomarkers to improve human conditions, while delivering health care in an economically sustainable way, requires concerted and coordinated efforts of stakeholders across disciplines and across borders. A large consortium of authors has recently published an in-depth analysis of the status of implementation of proteomics biomarkers of disease with a focus on postdiscovery/postvalidation barriers and outlined a need for a roadmap to biomarker implementation.[4] In our review, we concentrate on the preimplementation stages of the biomarker pipeline from the perspective of technologies that are currently available for biomarker discovery and validation, with a focus on protein biomarkers for which mass spectrometry (MS) plays a primary role.

The discipline of MS-based proteomics[5] emerged through a serendipitous convergence of major technological developments in DNA sequencing, MS analysis of proteins/peptides and bioinformatics. In the enthusiasm that followed the success of the Human Genome Project, it appeared that understanding how the functional phenotype of a cell/tissue/organism relates to its protein/peptide repertoire was imminent, leading to exaggerated expectations that the new technology of proteomics would deliver meaningful results in a short time. A rush for quick success resulted in controversies and disappointments, and unavoidably triggered questions as to the fundamental validity and practical usefulness of proteomics approaches.[6-8] The involvement of funding agencies (e.g., the National Cancer Institute [NCI]), which funded programs aimed at addressing various stumbling blocks of

proteomics technologies (e.g., the Clinical Proteomics Technologies for Cancer),[9-15] and of professional organizations and consortia (e.g., the Human Proteome Organization [HUPO][16-20] and the Proteomics Specification in Time and Space [PROSPECTS] Network[21]) has been crucial, providing funding and building foundations and collaborations among various disciplines to ensure future success in developing protein-based biomarkers of disease. Now, after more than a decade of intense effort, the promise of proteomics remains valid. Accumulated experience, however, required reassessment of the prospects of achieving quick payoffs—especially in the context of translational research, as illustrated by a recent breast cancer biomarker study using an animal model that is reviewed at the end of this chapter. Nevertheless, the field is progressing steadily, and the lessons learned in the early days of the proteomics bonanza are informing the directions of new developments.[22-30] Thousands of papers on the subject have been published to date. Here we focus on selected aspects of method development that, in our opinion, will play a significant role in moving this effort toward its eventual success.

Before discussing different aspects of technology for protein biomarker discovery, it is important to ponder the nature of the objects of inquiry, that is, a protein and a proteome, in the context of the goal of finding biomarkers of physiological processes leading to tumorigenesis. At first approximation, a protein can be viewed as a gene that has been realized in a dimension defined by the available amino acid building blocks. With this simple though simplistic concept of a protein-gene equivalence in mind, the proteome can be reduced to a catalogue of gene products present in a cell. From this perspective, experiments aimed at monitoring gross changes in the repertoire of "protein parts"—that is, the presence or absence of a specific gene product, or significant differences in protein levels—would lead to the detection of robust biomarkers. Most protein biomarker discovery studies to date were based on these operational definitions of a protein and a proteome. The adopted strategies represented a natural extension of familiar approaches used in functional genomics and took advantage of the availability of the required, albeit imperfect, experimental tools. However, although proteins start their lives as strings of amino acid residues arranged in an order prescribed by DNA, they further acquire a multitude of attributes that endow them with functional competence: they fold into specific shapes; they might need to be "cut to order" by proteolytic enzymes; they are decorated with modifications, many of which are transient by design; they are localized to the proper compartment of a cell; they interact with other cell components, including other proteins, to form "molecular machines"; and, once their mission has been fulfilled, they need to be disposed of in an orderly fashion. Defects in any of these processes could lead to, or result from, disease and hence could be used as valuable biomarkers.[31-36] However, because of the very nature of experimental design and confounding factors of system complexity and limitations of technology, these types of biomarker candidates are likely to be missed in studies geared solely toward detecting changes in peptide/protein concentration. Although technically more challenging, approaches that target specific attributes of protein structure and function, including but not limited to the examples listed earlier, are gaining importance in the biomarker discovery field. Of note, systems biology–based predictions are still far from being able to model all aspects of protein "life." Thus the analysis of a final protein product is the only approach currently available for characterization of protein-driven cell processes. As we discuss in this chapter, MS-based proteomics approaches enable exploration of biomarkers in various contexts.

Defining "Normal"

"Always remember that you are absolutely unique. Just like everyone else." This maxim, attributed to Margaret Mead, is also an excellent comment on the challenges intrinsic to biomarker discovery. What is normal for one person might be outside the norm for another. Hence, the "perfect world" scenario of early detection of malignancy, or any other malady, would use "self" as a control and rely on serial analyses of specimens collected at different time points, thus focusing on changes in, rather than absolute levels of, putative markers of health or disease. For a variety of reasons, longitudinal collection of specimens for the population at large is not feasible. Therefore, we are limited to epidemiological approaches. In this context, assessing the level of variability within a population is vital to provide a baseline/reference point for evaluating disease consequences in terms of biomarkers.[37] To this end, a number of tools have been proposed and/or are being developed. A protein equivalent to the HapMap,[38] and repositories of human DNA sequences,[39-41] is the foundation on which disease-related changes in protein repertoire will need to be built. Databases of MS-identified peptides are being generated for human[42] and model organisms (e.g., mouse[43]). In addition, the normal range of post-translational modifications (PTMs) should be considered.[44] For example, population proteomics proposes using targeted affinity capture approaches combined with high-throughput MS to screen large numbers of samples for a broad array of modifications.[45] Antibodies or lectins could be used for enrichment. In this regard, the Human Protein Atlas is a valuable resource with respect to antibodies,[46,47] and it will be important to generate the lectin equivalent.[48,49] Examples of these datasets include publications on the normal urine,[50]

breast,[51] oral epithelium,[52] liver,[53,54] and brain[55] proteomes and PTMs in various settings.[56] These catalogues of normal proteomes and PTMs will be crucial for identifying disease-related changes—that is, candidate biomarkers.

MS Proteomics for Biomarker Discovery and Validation: An Overview of Basic Methods

The ideal biomarker discovery methods should be comprehensive to sift through as many potential targets as possible; verification/validation methods should be specific and accurate to filter out all false positives. The "open-mindedness" of MS in detecting all species that are ionizable, transferable to the gas phase, and produce discernible signals under the chosen experimental conditions, makes it an excellent biomarker discovery tool (Figure 22-1). Because it is not necessary to know beforehand the identities of compounds to be monitored, untargeted (shotgun) approaches can generate extensive information on sample content.[57-59] Conversely, MS assays can also be executed in a targeted fashion by focusing data acquisition on prespecified compounds of interest,[60] thus providing the high level of selectivity required for biomarker validation experiments. In their most sophisticated format, verification/validation assays employ standards labeled with stable isotopes to enable high-sensitivity

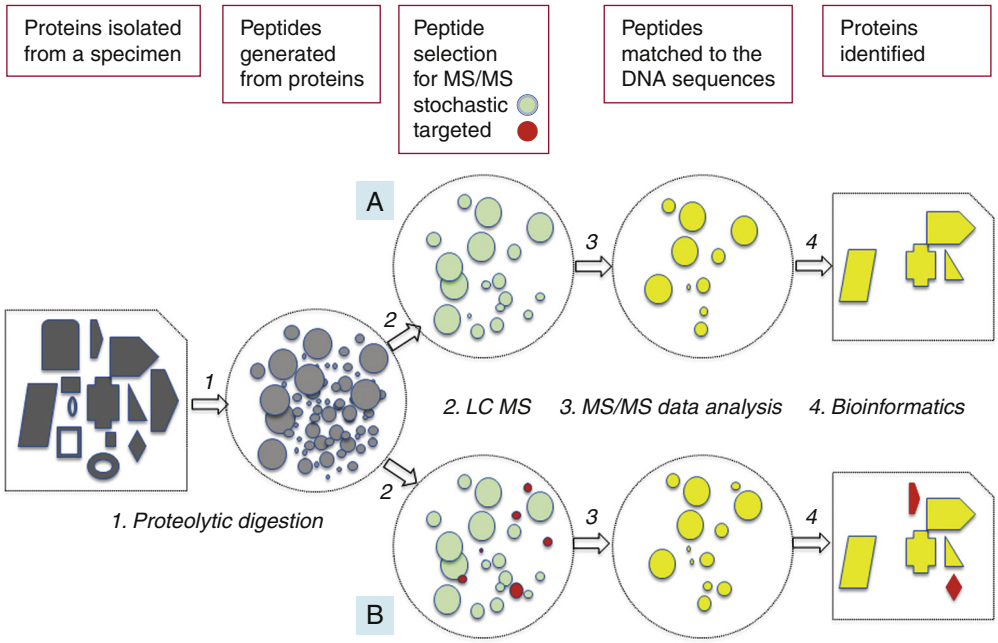

Figure 22-1 Shotgun **(A)** and hybrid **(B)** proteomics discovery workflows. A protein mixture isolated from a specimen consists of a great variety of species present at different concentrations (the size of a "protein shape" reflects its relative abundance). In either workflow, only a fraction of proteins/peptides that are present in the sample are identified. At step 1, proteins are cut to smaller, manageable pieces using proteolytic enzyme(s), most commonly trypsin, to generate peptides (*circles;* different sizes represent relative concentrations). The resulting peptide mixtures, which typically contain hundreds of thousands of species, are prefractionated using chromatography (not shown) and then submitted to LC MS analysis (step 2). To identify a peptide, and hence the protein from which it was derived, peptide ions must be fragmented into smaller, sequence-dependent parts. Peptide fragmentation is performed within the mass spectrometer and is referred to as *tandem mass spectrometry* (MS/MS). Most of the MS/MS approaches currently used rely on analyzing each peptide molecular ion (precursor) one by one. Given the complexity of a sample, at any given time the mass spectrometer is presented with many more precursors than it can possibly analyze by MS/MS. Hence, ion prioritization for further MS/MS analysis is necessary. In an untargeted, shotgun workflow **(A)**, selection of a peptide molecular ion for fragmentation is based on signal intensity, leading to a stochastic choice of precursors from within a large array of potential contenders. Predictably, shotgun analysis is biased toward selecting highly abundant peptides at the expense of less abundant ones. In the hybrid workflow **(B)**, a predefined set of precursor ions of interest is selected for MS/MS (step 1) followed by a shotgun signal intensity-based acquisition routine (step 2), as described for **(A)**. The targeted ions are analyzed by MS/MS regardless of their relative abundance, as long as they meet the analysis-wide signal-to-noise threshold for precursor ion intensity (note the small size of the *red* dots representing target peptides selected for MS/MS in workflow B). In step 3, the experimental MS/MS spectra are compared to the theoretical in situ generated mock spectra predicted for peptides representing all proteins for which DNA sequences are known. In this process, the peptide identities and hence proteins are not derived de novo from the MS/MS data. Rather, they represent the best matches between the observed and theoretically predicted spectra. Of note, typically some of the molecular ions selected for MS/MS analysis do not generate reliable matches, and hence the number of identified peptides is always lower than the number of acquired MS/MS spectra. In step 4, bioinformatics tools are used to combine peptide-based matches to generate a list of proteins that are most likely present in the mixture. Because of the targeted nature of workflow **B**, low-abundance proteins *(red)* that are missed by the shotgun workflow **(A)** can now be identified. Thus, using a targeted approach for discovery overcomes the limitations of stochastic ion selection. Hence, to compare the compositions of two samples it is necessary to target the species of interest in both samples rather than rely on the unbiased nature of the stochastic shotgun workflow.

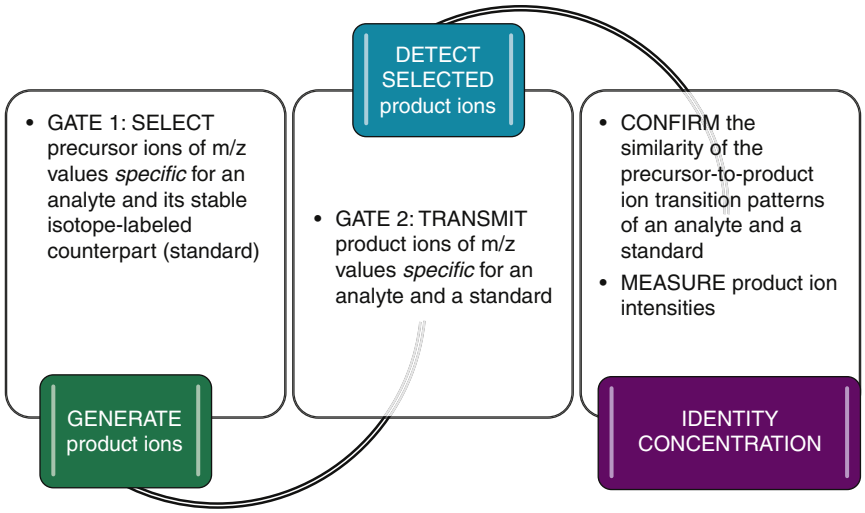

Figure 22-2 Outline of stable isotope dilution multiple reaction monitoring mass spectrometry (SID MRM MS) experiments SID MRM MS workflows provide highly reliable and sensitive detection and accurate measurement of absolute concentrations of endogenous analytes such as proteins. The assay is reliable because double-gated filtering is used at both the precursor-ion (gate 1) and the product-ion (gate 2) stages of analysis. This method is very sensitive because the mass spectrometer exclusively monitors ions of interest without interference from others present in the sample. Analyte concentrations are measured with high accuracy by using stable-isotope (SI)-labeled internal standards that have identical chemistry to the endogenous analytes. Typically, SI-labeled internal standards are spiked into the sample at known levels early on in the experimental workflow to account for losses encountered during sample processing. The ability to measure absolute concentrations of analytes provides a high level of confidence when comparing compositions of specimens obtained from different patient cohorts in biomarker verification and validation studies.

detection, structure confirmation, and absolute quantification of selected protein targets (Figure 22-2). In contrast to classical immunochemistry-based approaches, MS-based biomarker validation assays—that is, *stable isotope dilution (SID) multiple reaction monitoring (MRM)* MS (also called *selected reaction monitoring* [SRM] MS)—do not rely on protein-specific antibodies, and offer high multiplexing capabilities.[9,61-64] To achieve ultimate sensitivity in detecting and quantifying selected proteins, immunoaffinity isolation of representative target peptides followed by MRM is used and is referred to as *stable isotope standards with capture by anti-peptide antibodies* (SISCAPA).[65] Last, recent developments in MS technology—that is, improvements in mass resolution leading to significantly higher accuracy in detecting true targets[66,67]—and greatly enhanced scan rates, enabled hybrid MS discovery workflows in which the targeted and untargeted methods are executed in a single analysis. These hybrid workflows allow for the preferential analysis of predetermined ions while the excess capacity is used to analyze "unknowns" (see Figure 22-1, *B*).

Discovery and verification/validation platforms share a number of analytical steps albeit their modes of execution can differ significantly. Typically, liquid chromatography (LC) is used to fractionate a sample before MS analysis. Eluting compounds are either transferred online in a continuous fashion to the mass spectrometer for electrospray ionization (ESI) MS[68] or collected offline in discrete fractions for subsequent matrix-assisted laser desorption ionization (MALDI) MS.[69] The classical experimental approach to proteomics MS data acquisition, which still dominates the field, involves rapidly toggling between two distinct automatically executed modes of operation: MS and tandem MS (MS/MS). The MS mode operates under conditions that maintain the molecular integrity of analytes and delivers a survey of mass-to-charge ratios (m/z) and relative intensities of the detected molecular ions (precursors). During MS/MS, a subset of precursor ions are transferred, one by one, to a collision cell where they are dissociated under controlled conditions into a series of fragment (product) ions whose m/z values and relative intensities carry structure-specific information. Although the elemental steps are common for both verification/validation and discovery platforms, the paradigms of data acquisition and analysis differ significantly. In the former case, precursor ion selection before MS/MS is centered on predetermined masses of the components of interest; all other species in the sample are ignored. In the latter case, the targets are yet to be discovered and, hence, precursors are selected in a stochastic fashion. As to data analysis, in discovery assays, the experimental MS/MS spectra are compared to the theoretical in situ generated mock spectra predicted for peptides representing all proteins for which DNA sequences are known. In verification/validation assays (SID MRM MS), confirmation of analyte identity is based on matching the MS/MS data to the previously experimentally established, rather than predicted, MS/MS fragmentation features (i.e., types and relative intensities of product ions).

Completeness of Shotgun Biomarker Discovery Proteomics

Limitations Inherent to Peptide-Centric Strategies for Protein Biomarker Discovery

With the exception of protein profiling, described later, the great majority of workflows that are currently used for protein biomarker discovery and validation rely on the analysis of peptides generated from proteins via enzymatic or chemical digestion. Consequently, the information about the structure of a protein identified in the sample is limited to a portion of amino acid sequence that is encompassed by the observed peptides (Figure 22-3). When the goal of analysis is to detect differences in relative protein concentration, limited sequence coverage by detected peptides often leads to ambiguity in identifying highly homologous proteins. Most importantly, any subtle but functionally relevant disease-related structural modifications resulting from posttranscriptional/posttranslational processing are likely to remain invisible when shotgun approaches are used (see Figure 22-3). To remedy this problem, a number of specialized methods based on either chemical or biochemical characteristics of specific modifications (e.g., affinity capture using antibodies or lectins) are being developed to increase the chances of detecting biomarkers that reflect proteome alterations extending beyond changes in protein expression and/or degradation. The ideal solution would be to use a protein-centric approach: to analyze intact proteins by MS to directly reveal potential changes in highly heterogeneous protein populations. Presently, high-resolution MS and MS/MS analysis of intact proteins in biological samples remains technically challenging. However, great strides in instrument design, along with novel method development, continue to advance this area of proteomics research.[70-72]

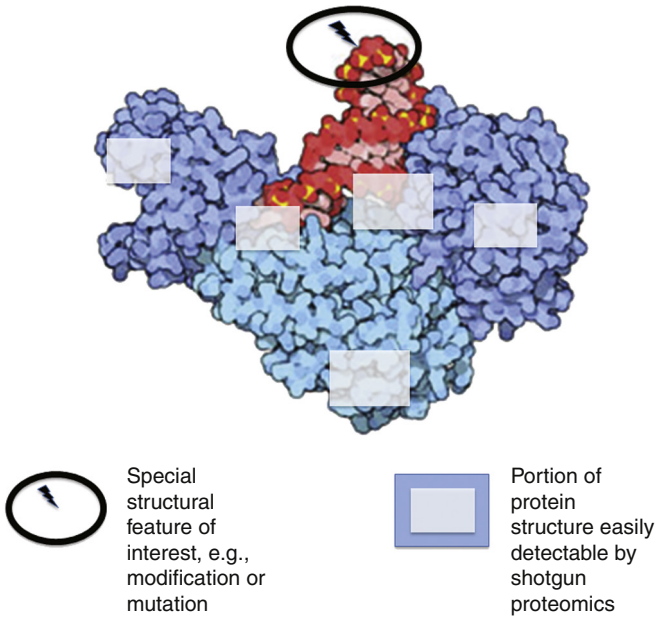

Figure 22-3 Challenges and opportunities presented by special features of protein structure, e.g., protein posttranslational modifications in proteomics analysis There is no guarantee that an untargeted shotgun analysis will detect the portion of the protein structure that carries a modification (*oval;* parts of protein sequence covered by identified peptides are shown by *gray rectangles*). Importantly, even if a peptide carrying a modification is seen, it might not be identified, that is, matched to a DNA sequence by using currently available software algorithms. Hence, if detection of a specific modification is a primary goal, specialized methods that target specific chemical/biochemical features of the modification need to be used. For example, affinity capture of glycoproteins using lectins or capture of phosphotyrosine residues using antibodies can be performed. Use of affinity capture or other specialized methods allows enrichment of subsets of proteins/peptides carrying specific modifications, thus enabling identification of protein scaffolds present at very low levels. *The figure template is based on David Goodsell's rendering of Aconitase and Iron Regulatory Protein 1 (May 2007 Molecule of the Month) by David Goodsell, retrieved from the RCSB Protein Data Bank at* http://www.rcsb.org/pdb/pdb/101/motm.do?momID=42*; doi: 10.2210/rcsb_pdb/mom_2007_5.*

Technical Limitations of Data Generation

The great complexity and large dynamic range of protein concentrations in biological samples present major challenges to all MS proteomics workflows because of a mismatch between the number of molecular ions generated and the MS analyzer's capacity to process them by MS/MS. As a result, a large fraction of the detectable ions are not identified in a single MS/MS experiment (see Figure 22-1). Furthermore, because of the combination of the inherent nonlinearity of the system, and stochastic selection of precursors, subsets of ions analyzed by MS/MS will not be identical across replicate experiments, generating dissimilar, albeit overlapping, protein/peptide lists.[15] Adverse effects of crowding-related competition lead to undersampling,[73] affecting untargeted discovery platforms to a much higher degree than targeted approaches. The actual extent of these limitations was demonstrated through a series of controlled, parallel benchmarking experiments, which established that prior knowledge of signature peptides (i.e., peptides having sequenced that are unique to targeted proteins) markedly improves overall detection sensitivity and reliability of quantification.[74] Performing replicate LC MS runs increases the number of identified m/z features. To maximize efficiency and information content, it is advantageous to set up replicate analyses in an intelligent fashion to ensure that the same set of molecular ions will be interrogated across all samples, while allowing room for new discoveries in the course of each iteration. To this end, the hybrid untargeted/targeted workflows described earlier are best suited to monitor specific molecular ions that were missed in parallel analyses, thus minimizing information gaps in sample sets.[75,76] Undersampling tends to skew the results in favor of the most abundant

species, especially when ion intensity is used as the sole criterion for precursor selection—that is, when "data-dependent" routines are used. Thus, novel iterative "information-dependent" data acquisition routines are being developed that intelligently prioritize targets for tandem MS on the basis of previously collected data.[77-81]

Limitations in Data Analysis

Currently, protein identification is based on matching the experimentally acquired peptide MS/MS spectra to theoretical in silico predictions derived from DNA sequences, rather than on inferring the sequence information by de novo interpretation of the observed signature fragment ions.[82] Hence, the success of analysis—assignment of peptide MS/MS spectra to specific proteins—relies to a great extent on the selection and quality of the protein sequence database that is being interrogated. Important parameters include relevance to the experimental design and the completeness and accuracy of the underlying DNA sequencing data. The need for the selection of a representative database cannot be overstated. First, proteins that are not included in the database will not be identified. Second, when there is a mismatch between sample composition and the database that is searched, there exists a serious danger of generating false-positive identifications. The example of identifying iridovirus and the microsporidian *Nosema* as purported reasons for bee colony collapse offers an important cautionary tale.[83] The authors performed proteomics analysis of material isolated from bees, but restricted the database to sequences of potential pathogenic organisms while excluding those of the host. Independent analyses of the data clearly demonstrated that MS/MS spectra originally assigned to iridovirus and *Nosema* were actually matched to the bee protein sequences with much higher probability.[84]

MS Protein Profiling

In addition to the high-resolution MS-based methods described earlier, *protein profiling* based on low-resolution MS analysis of mixtures of intact proteins in body fluids has been extensively used in biomarker discovery research.[85] In its most common format of surface enhanced laser desorption/ionization (SELDI) MS,[86,87] proteins from body fluids such as serum or plasma are affinity captured by surfaces with various chemical properties and, following the addition of a matrix, ionized under MALDI conditions and surveyed using a time-of-flight (TOF) mass analyzer. The resulting mass spectra show a series of *m/z* features (peaks) of various intensities. The premise of this method is that the SELDI pattern will reliably discriminate among samples of various biological fluids/cells/tissues that are collected in normal versus disease states without invoking the need for identifying the diagnostic features. Intrinsic to this approach is the concept of developing biomarker panels rather than single protein sentinels, which is appealing given the multifactorial nature of neoplastic diseases. Although attractive because of the simplicity of concept and methods, and its high-throughput potential, SELDI MS protein profiling is plagued by a number of problems. First, the identities of proteins on which the diagnostic pattern is based are not known. Second, in view of the limitations of mass resolution, it is impossible to tell whether each peak represents a single protein or a mixture of species of similar molecular masses. A combination of these two factors makes it difficult to control method reproducibility. Third, even small changes in sample composition greatly affect the efficiencies of molecular ion generation under MALDI conditions. Hence, altered relative intensities of the same peak in different samples might be due to secondary effects rather than a reflection of differences in concentration.[88] Last, SELDI is unlikely to capture low-abundance proteins. For example, many of the discriminatory proteins reported for ovarian cancer, such as apolipoprotein A, haptoglobin, and complement component 3, were also found to be affected in a number of different types of cancers. Nevertheless, the first proteomics-derived protein test for cancer biomarkers that was approved by the U.S. Food and Drug Administration (FDA) originated from SELDI technology, although its final format is based on a standard immunoassay, rather than an MS platform. The OVA1 test for ovarian cancer diagnosis (21 CFR 866.6050, ovarian adnexal mass assessment score test system) was developed by Vermillion, Inc.,[89] approved by the FDA in 2009, and launched commercially by Quest Diagnostics in 2010. This assay quantifies five serum proteins: beta-2-microglobulin, prealbumin, apolipoprotein A-1, transferrin, and CA125. The results are scored from 1 to 10 to classify the likelihood that a woman's pelvic mass is cancerous or benign.[90] Of note, a recent SELDI-based study that monitored seven serum proteins (some of them included in the OVA1 test) in addition to CA125 in prediagnostic specimens did not demonstrate any improvements in sensitivity for preclinical diagnosis of ovarian cancer when compared to using CA125 as the only factor.[91] In a recent paper evaluating SELDI technology, the authors reviewed 34 SELDI studies focused on ovarian cancer and compared the published data to their own analysis of plasma from ovarian cancer patients using MALDI techniques.[92] They found nearly a 50% overlap among all the detected *m/z* features and a 34% overlap in a subset of discriminating peaks, concluding that the results "indicate convergence toward a set of common discriminating, reproducible peaks for (identifying) ovarian cancer." Hence, although the SELDI

or MALDI protein profiling platforms are not adequate for biomarker validation and clinical diagnosis, they might still have a niche at the discovery stage of biomarker development, particularly when they are used in combination with MALDI methods of identification. However, the serious limitations of SELDI technology discussed earlier should be fully taken into consideration before choosing this path.

The Proteomics Toolbox for Biomarker Discovery and Validation

Developments in Mass Spectrometry Instrumentation and Acquisition Methods

As previously noted, undersampling is one of the bottlenecks in achieving increased breadth of proteome interrogation. In addition to the information-dependent modes of precursor ion selection that were discussed earlier, a number of other ideas for maximizing the generation of structural information from detected peptides are being pursued. An obvious way to increase the number of precursor ions that can be analyzed on the time scale of their introduction to the mass spectrometer is to significantly increase the speed of MS/MS acquisition. MS vendors are moving quickly in this direction. A paradigm shift in thinking about MS/MS experiments brought about revolutionary approaches that eliminate precursor ion selection altogether (parallel acquisition[93]). In these strategies, such as MS^{E}[94,95] and SWATH,[96,97] molecular ions introduced into the mass spectrometer are subjected to gas-phase fragmentations en masse in the source.[95-97] Software tools are used to disentangle the resulting spectra, linking product ions to their precursors, and thus assigning peptide identities to precursor ions. This brute-force approach has become feasible because of the high accuracy of product ion mass measurements afforded by the current instrumentation and the ability to capitalize on shared product and precursor ion elution profiles to facilitate the analysis.[93,94]

Another way of overcoming the crowding problem is to minimize the load of precursors that need to be processed by the mass spectrometer within a unit of time. Sample simplification via increased fractionation is being extensively used, with myriad variations that might include protein separation before protein digestion and/or extensive separation of peptide mixtures via a combination of orthogonal LC or capillary electrophoresis methods.[98] Other improvements in increasing the efficiency of MS protein identification are likely to come from the recently commercialized technology of ion mobility separation (IMS).[99-101] IMS fractionates ions in the gas phase on the basis of the ratio of their collision cross-section to their charge—that is, "shape"-to-charge ratios—thus providing an additional dimension of molecular ion separation *after* sample introduction into the mass spectrometer. Mass spectrometers equipped with IMS analyzers are capable of separating species of the same nominal mass that have different higher-order structures, thus increasing the visibility of ions that might have otherwise been missed and hence not considered for MS/MS analysis. Last but not least, samples can be simplified by removing interfering species and/or enriching for proteins/peptides of interest, as discussed later.

Targeted MS Assays for Biomarker Discovery and Qualification for Analysis of Splice Variants

Alternative splicing has long been considered a hallmark of malignant transformation,[102-105] and recent progress in RNA-Seq technologies revealed thousands of aberrant transcripts in tumor tissues. However, in the great majority of cases, nothing is known about the functional implications of these alterations. Indeed, only a small fraction of potential splice variants have been observed at the protein level. The task of unambiguous identification of a splice variant is not trivial.[106] It requires the ability to differentiate the aberrant protein from other variant and normal isoforms that are likely to be present in the same sample. Whereas proving the presence of a gene product requires identification of any peptide from any part of a protein sequence, the diagnostic field of opportunity for a splice variant detection often is restricted to a very small portion of the protein sequence that encompasses the splice junction. Peptides diagnostic for splice forms stand the same chance of being selected for MS/MS in untargeted workflows as any other peptides of similar properties and abundance, as evidenced by a number of successful studies.[104,107-109] However, we posit that use of targeted workflows might prove much more productive in detecting specific splice variants. It is important to note that not every splice junction will be represented by a tryptic peptide that generates a precursor that can be analyzed by MS. Hence, use of various proteolytic strategies and complementary MS ionization modes—that is, MALDI and ESI—will likely increase the number of identified splice variants.

General Affinity-Based Methods to Access Low-Abundance Proteins

Body fluids, especially blood, are considered the primary source of cancer biomarkers because of their diagnostic availability and high likelihood that they contain a cancer fingerprint that represents proteins secreted, shed, or otherwise deposited into circulation from distant tumor locations. At the same time, plasma and serum present with formidable
