Pediatric Allergy

Principles and Practice

Third Edition

ELSEVIER

https://CafePezeshki.IR

To our families and patients who have supported our efforts to advance the care of asthma, allergy, and immunology treatment for children. We would also like to thank those children and families who participated in studies that allowed us to make the changes in care emphasized in this update.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

PREFACE

These are exciting times for physicians who treat children with allergic and immunologically-mediated diseases. Microbial infection and treatment of allergic reactions are common problems seen by the practicing pediatrician. Recent studies have provided new insights into mechanisms underlying diseases in the area of pediatric allergy, asthma and clinical immunology. As a result, new therapies are targeting key immune pathways. Management guidelines for various diseases have also been developed based on evidence-based approaches. In addition, the National Institutes of Health have formed networks and collaborative studies to investigate allergic/immunologic diseases, such as food allergy, atopic dermatitis, asthma and immunodeficiency. We are now witnessing the introduction of new medications that resulted from improved understanding of the biology of allergic and immunologic diseases. The need to document and summarize this recent remarkable increase in information justifies the third edition of our textbook in the field of pediatric allergy and clinical immunology for practicing physicians and investigators interested in this area.

It is often said, 'Children are not simply small adults.' In no other subspecialty is this truer than in pediatric allergy and immunology, where the immune system and allergic responses are developing in different organs of the child. Earlier identification of disease onset offers special opportunities for prevention and intervention, which cannot be carried out once disease processes have been established in the older child and adult. Indeed, many diseases that pediatricians see in clinical practice are complex and are thought to result from a multigenic predisposition in combination with exposure to environmental triggers. However, the age at which the host is exposed to a particular environmental agent and the resultant immune response are increasingly being recognized as important factors. Furthermore, determining the appropriate time for intervention will be critical for defining a window of opportunity to induce disease remission. For example, microbes are a known trigger of established asthma in adults but the 'hygiene hypothesis' in children suggests that early exposure to certain microbes prior to the onset of allergies may actually prevent allergic responses and thus account for the low prevalence of allergic disease in children living on farms. New information is available on controlling asthma in early childhood, however our current treatment does not alter the natural history of the disease. This concept will now reach clinical care as we draw attention to population health and prevention.

Pediatric Allergy: Principles and Practice is aimed at updating the reader on the pathophysiology of allergic responses, and allergic diseases including asthma, food allergy, allergic rhinitis, and atopic dermatitis; their socioeconomic impact and new treatment approaches that take advantage of emerging concepts of the pathobiology of these diseases. An outstanding group of authors who are acknowledged leaders in their fields has been assembled because of their personal knowledge, expertise, and involvement with their subject matter in children. Every effort has been made to achieve prompt publication of this book, thus ensuring that the content of each chapter is 'state of the art.'

Section A presents general concepts critical to an understanding of the impact and causes of allergic diseases. These include reviews of the epidemiology and natural history of allergic disease, genetics of allergic disease and asthma, biology of inflammatory-effector cells, regulation of IgE synthesis, and the developing immune system and allergy. Section B reviews an approach to the child with recurrent infection and specific immunodeficiency and autoimmune diseases that pediatricians frequently encounter. Section C updates the reader on a number of important and emerging immune-directed therapies including immunizations, immunoglobulin therapy, stem cell therapy, and gene therapy. Section D examines the diagnosis and treatment of allergic disease. The remainder of the book is devoted to the management and treatment of asthma and a number of specific allergic diseases such as upper airway disease, food allergy, allergic skin and eye diseases, drug allergy, latex allergy, insect hypersensitivity, and anaphylaxis. In each chapter, the disease is discussed in the context of its differential diagnoses, key concepts, evaluations, environmental triggers, and concepts of emerging and established treatments.

Major advances in this third edition include updates on genetics and biomarkers of allergy, inflammatory conditions and immunodeficiencies, recent guidelines in the treatment of asthma, food allergy, atopic dermatitis, urticaria-angioedema, and immunodeficiencies, population health, school-centered asthma programs, prevention strategies, appropriate evaluation of drug allergy and a better understanding of drug cross-reactivity to eliminate the difficulty prescribing antibiotics in the pediatric population, the role of new biologics and immunomodulatory therapy in the treatment of inflammatory diseases and emerging evidence that epithelial barrier dysfunction can drive allergic disease.

We would like to thank each of the contributors for their time and invaluable expertise, which were vital to the success of this book. The editors are also grateful to Belinda Kuhn (Senior Content Strategist), Joanna Souch (Project Manager) and Nani Clansey (Senior Content Development Specialist), who have played a major role in editing and organizing this textbook, as well as the production staff at Elsevier Ltd for their help in the preparation of this book.

1 Epidemiology of Allergic Diseases

ERIKA VON MUTIUS

KEY POINTS

- Large geographical variations in the prevalence of allergic diseases exist worldwide among children and adults.
- Lower prevalences have been reported from developing countries, eastern European areas, rural areas in Africa and Asia, and farm populations in Europe.
- The prevalence of asthma and allergies has increased over the last few decades. This trend seems to have reached a plateau in affluent countries, but not in low- to mid-income countries.
- Allergic diseases are multifactorial illnesses determined by a complex interplay between genetic and environmental factors.

Introduction

Traditionally, asthma, allergic rhinitis and hay fever as well as atopic dermatitis and food allergy have been categorized as atopic diseases, yet the relation between clinical manifestations of these diseases and the production of IgE antibodies has not been fully clarified. Although in many patients high levels of total and specific IgE antibodies are found, many individuals in the general population will not show any signs of illness despite elevated total and specific IgE levels. In some individuals various atopic illnesses can be co-expressed, whereas in others only one manifestation of an atopic illness is present. The prevalence of these four atopic entities therefore only partially overlaps in the general population (Figure 1-1). Risk factors and determinants of atopy, defined as the presence of IgE antibodies, differ from those associated with asthma, atopic dermatitis and hay fever.

Asthma, atopic dermatitis and hay fever are complex diseases and their incidence is determined by an intricate interplay of genetic and environmental factors. Environmental exposures may affect susceptible individuals during certain time windows in which particular organ systems are vulnerable to extrinsic influences such as early in life. Moreover, most allergic illnesses are likely to represent syndromes with many different phenotypes rather than single disease entities. The search for determinants of allergic illnesses must therefore take phenotypes, genes, environmental exposures and the timing (developmental aspect) of these exposures into account.

Prevalence of Childhood Asthma and Allergies

Asthma is a complex syndrome rather than a single disease entity. Different phenotypes with varying prognosis and determinants have been described, particularly over childhood years, using hypothesis and data-driven approaches.[1] Transient wheezing is characterized by the occurrence of wheezing in infants up to the age of 2 to 3 years which disappears thereafter and does not progress to childhood asthma. There are epidemiological observations suggesting that these children may be at risk of developing chronic obstructive pulmonary disease (COPD) in adulthood. The main predictor of transient wheeze is premorbid reduced lung function, in part determined by passive smoke exposure in utero.[1–4] Wheeze among school-aged children can be classified into an atopic and nonatopic phenotype.[5] This differentiation has clinical implications as nonatopic children with wheeze outgrow their symptoms and retain normal lung function at school age. In turn, among atopic wheezy children, the time of new onset of atopic sensitization and the severity of airway responsiveness determine the progression of this wheezing phenotype over school and adolescent years.[6]

Data-driven latent class analyses of birth cohort studies have consistently shown a persistent phenotype with symptoms starting very early in life and progressing into school age and beyond.[7] Late onset and intermediate phenotypes have also been described. These phenotypes can only be identified in prospective studies following infants from birth, up to school age and through adolescence, enabling the differential analysis of risk factors and determinants for distinct wheezing phenotypes over time. These limitations must be borne in mind when discussing and interpreting findings from cross-sectional surveys. The relative proportion of different wheezing phenotypes is likely to vary among age groups and therefore the strength of association between different risk factors and wheeze is also likely to vary across age groups.

Similarly, limitations apply with respect to the epidemiology of atopic dermatitis.[8] The definition of atopic eczema varies from study to study and validations of questionnaire-based estimates have been few. Skin examinations by trained field workers, adding an objective parameter to questionnaire-based data, reflect a point prevalence of skin symptoms at the time of examination and can therefore, in only a limited way, corroborate estimates of lifetime prevalence.

Lastly, identified risk factors in all cross-sectional surveys relate to the prevalence of the condition. The prevalence in turn reflects the incidence and the persistence of a disease. It is therefore often difficult to disentangle aggravating from causal factors in such studies. Only prospective surveys can identify environmental exposures prior to the onset of an atopic illness and thus infer a potentially causal relationship to the new onset of disease.

WESTERN VERSUS DEVELOPING COUNTRIES

In general, reported rates of asthma, hay fever and atopic dermatitis are higher in affluent, western countries than in developing countries. The worldwide prevalence of allergic diseases was assessed in the 1990s by the large scale International Study of

https://CafePezeshki.IR

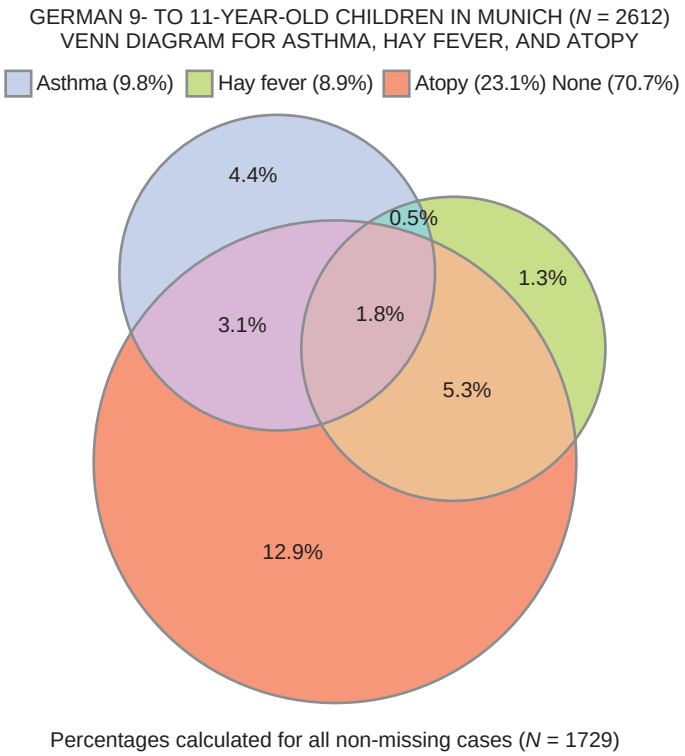

Figure 1-1 The prevalence of asthma, hay fever and atopic sensitization only partially overlaps on a population level. Description of findings from the ISAAC Phase II study in Munich, of German children aged 9 to 11 years. *(From The International Study of Asthma and Allergies in Childhood [ISAAC]. Lancet 1998;351:1225.)*

Asthma and Allergy in Childhood (ISAAC).[9] A total of 463,801 children in 155 collaborating centers in 56 countries were studied. Between 20-fold and 60-fold differences were found between centers in the prevalence of symptoms of asthma, allergic rhinoconjunctivitis and atopic eczema (Figure 1-2).

The European Community Respiratory Health Survey (ECRHS) studied young adults aged 20 to 44 years.[10] A highly standardized and comprehensive study instrument including questionnaires, lung function and allergy testing was used by 35 to 48 centers in 22 countries, predominantly in Western Europe, but also in Australia, New Zealand and the USA. The ECRHS has shown large geographical differences in the prevalence of respiratory symptoms, asthma, bronchial responsiveness and atopic sensitization with high prevalence in English speaking countries and low prevalence rates in the Mediterranean region and Eastern Europe.[11] The geographical pattern emerging from questionnaire findings was consistent with the distribution of atopy and bronchial hyperresponsiveness, supporting the conclusion that the geographical variation in asthma is true and not attributable to methodological factors such as the questionnaire phrasing, the skin testing technique or the type of assay for the measurement of specific IgE.

A strong correlation was found between the findings from children as assessed by the ISAAC Study and the rates in adults as reported by the ECRHS questionnaire.[12] Although there were differences in the absolute prevalences observed in the two surveys, there was good overall agreement, adding support to the validity of both studies.

Dissociations between the prevalence of asthma and atopy have, however, been documented in developing countries.[1,13,14] The ISAAC Phase II Study[15] has demonstrated that the fractions and prevalence rates of wheeze attributable to skin test reactivity correlated strongly with the gross national income of the respective country. These findings suggest that the strength of association between atopy and asthma across the world is determined by affluence and factors relating to affluence.

THE EAST-WEST GRADIENT ACROSS EUROPE

A number of reports have been published demonstrating large differences in the prevalence of asthma, airway hyperresponsiveness, hay fever and atopy in children and adults between east and west European areas.[16–20] The prevalence of asthma was significantly lower in all study areas in eastern Europe compared to western Europe.[17] Among the older age group of 13- to 14-year-old children, the prevalence of wheezing was 11.2% to 19.7% in Finland and Sweden, 7.6% to 8.5% in Estonia, Latvia and Poland, and 2.6% to 5.9% in Albania, Romania, Russia, Georgia and Uzbekistan (except Samarkand).

The rates of allergic illnesses have been rising rapidly. After reunification of Germany in 1989 a significantly lower prevalence of allergic diseases was found in East Germany.[16] Only a few years later (2003–2006) differences in the prevalence rates between East and West Germany were no longer observed.[21] The causes underlying the increase in prevalence in East Germany are not fully understood. The drastic decrease in family size after reunification, changes in dietary habits or indoor exposures may have contributed to this trend. Likewise, Poland's accession to the European Union was followed by a rapid and striking increase in the prevalence of atopy in rural areas.[22] This increase may in part be attributable to loss of traditional farming exposures.

DIFFERENCES BETWEEN RURAL AND URBAN POPULATIONS

The prevalence of asthma and allergies is not only increasing with westernization and affluence, but also with urbanization. The rates of asthma and atopy among children living in Hong Kong are similar to European figures. In rural China, asthma is almost nonexistent with a prevalence of less than 1%.[23] In Mongolia, a country in transition from rural, farming lifestyles to an industrial society, marked differences in the prevalence of asthma, allergic rhinoconjunctivitis and atopy exist.[24] Inhabitants of small rural villages are least affected, whereas residents of the capital city, Ulaanbaatar, have high rates of allergic diseases comparable to affluent western countries.

Across Europe, differences between urban and rural areas are less clear. However, strong contrasts exist on a lower spatial scale, i.e. among children raised on a farm in comparison to their neighbours living in the same rural area but not on a farm.[25] Since 1999, more than 30 studies have corroborated these findings.[26] Children raised on farms retain their protection from allergy at least into adulthood.[27–29]

The timing and duration of exposure seem to play a critical role. The largest reduction in risk of developing respiratory allergies is seen among those who are exposed prenatally and continue to be exposed throughout their life.[30] The protective factors in these farming environments have not been completely unraveled. Contact with farm animals, particularly cattle, confers protection. Also the consumption of unprocessed cow's milk has been shown to be beneficial with respect to childhood

https://CafePezeshki.IR

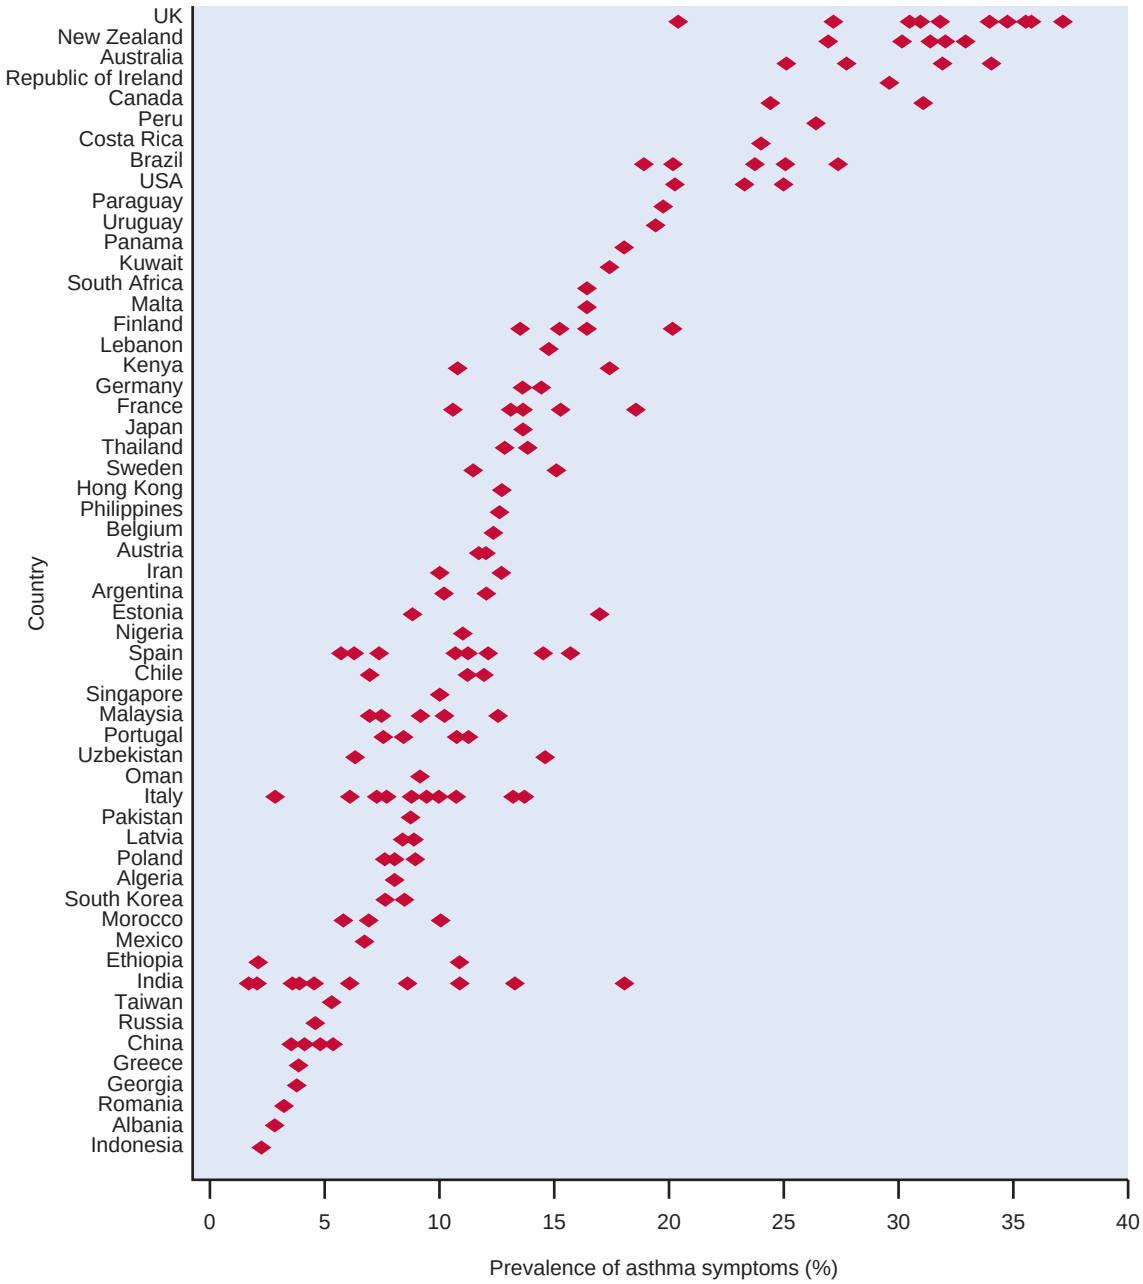

Figure 1-2 Prevalence of asthma symptoms worldwide according to the ISAAC Phase I study. *(From The International Study of Asthma and Allergies in Childhood [ISAAC]. Lancet 1998;351:1225.)*

asthma and allergies. Increased levels and diversity of microbial exposures also contribute to the protective effects.[31]

INNER CITY AREAS OF THE USA

Living conditions in inner city areas in the USA are associated with a markedly increased risk of asthma.[32] Several potential risk factors are being investigated, such as race and poverty, adherence to asthma treatment[33] and factors related to the disproportionate exposures associated with socioeconomic disadvantage such as indoor and outdoor exposure to pollution and cockroach infestation.[4] Cockroach exposure, at least in early life, has been associated with the development of sensitization to cockroach allergen[34] and wheeze[35] in infants living in inner city areas of the USA. Problems relating to inner city asthma will be discussed in more detail in Chapter 33.

Time Trends in the Prevalence of Allergic Diseases

Data collected over the last 40 years in industrialized countries indicate a significant increase in the prevalence of asthma, hay fever and atopic dermatitis in repeated cross-sectional surveys using identical questionnaires.[36] Most studies from industrialized countries suggest an overall increase in the prevalence of asthma and wheezing between 1960 and 1990. Many studies have been performed among children and little is

https://CafePezeshki.IR

known about time trends in adults. Twenty-year trends of the prevalence of treated asthma among pediatric and adult members of a large US health maintenance organization were reported.[37] During the period 1967–1987, the treated prevalence of asthma increased significantly in all age-sex categories except males aged 65 and older. In the USA, the greatest increase was detected among children and young adults living in inner cities.[38]

Recent studies suggest that in some areas this trend may have reached a plateau. Studies from Italy showed that among school children surveyed in 1974, 1992 and 1998 the prevalence of asthma had increased significantly during the 1974–1992 period, whereas it remained stable from 1992 to 1998.[39] Similar findings have been reported from Germany and Switzerland, where prevalence rates have been on a plateau since the 1990s.[40,41] On a global scale, time trends in the prevalence of asthma and allergic rhinoconjunctivitis have been assessed in ISAAC Phase III.[42] The findings indicate that international differences in symptom prevalence have reduced with decreases in prevalence in English-speaking countries and Western Europe and increases in prevalence in regions where prevalence was previously low, i.e. in low- to mid-income countries.

Environmental Risk Factors for Allergic Diseases

AIR POLLUTION

There is considerable evidence showing that increased exposure to air pollutants is a risk factor for increased morbidity of asthma with worsening of symptoms and lung function.[43] Air pollution is a complex mixture of particulate matter of variable size and various gases. As particulates and polluting gases often co-occur, their individual contribution to worsening of asthma is hard to disentangle. In panel and time-series studies, air pollutants such as fine particles and ozone reduce lung function in children already affected by asthma and increase symptoms and medication use. Likewise, emergency room visits, general practitioner activities and hospital admissions for asthma and wheeze are positively associated with ambient air pollution levels.

Mixes of particulate matter, especially those seen with traffic related exposures, seem to have the most adverse effects. Traffic related air pollution is a complex mix of particulate matter and primary gaseous emissions including nitrogen oxides, which lead to the generation of secondary pollutants such as ozone, nitrates and organic aerosol. Traffic related pollution decreases quickly with distance from roadways. For adverse effects, distance within 300–500 m of roadways seems to be most significant. In large North American cities, 30–45% of people live within this distance and so the impact of traffic related air pollution is significant. The closeness to major roadways may be even greater in cities in Europe and the developing world. Given that disadvantaged families live close to major roadways, other risk factors such as poverty, stress and cigarette smoking may aggravate the effects.[44]

The role of air pollution in the new onset of asthma and allergic sensitization is less well understood.[43] There is however a growing body of prospective studies suggesting a causal role for the incidence of asthma among children and adults. In particular, long-term exposure to traffic related air pollution may again play a significant role.

ENVIRONMENTAL TOBACCO SMOKE

Numerous surveys have consistently reported an association between environmental tobacco smoke (ETS) exposure and respiratory diseases. Strong evidence exists that passive smoking increases the risk of lower respiratory tract illnesses such as bronchitis, wheezy bronchitis and pneumonia in infants and young children. Maternal smoking during pregnancy and early childhood has been shown to be strongly associated with impaired lung growth and diminished lung function,[2,3] which in turn may predispose infants to develop transient early wheezing. In children with asthma, parental smoking increases symptoms and the frequency of asthma attacks. Banning tobacco smoke in public places has been shown in a number of countries to result in a significant reduction in hospital admissions for asthma.[45]

A series of epidemiological studies has also been performed to determine the effect of ETS exposure on the new onset of asthma. In most cross-sectional and longitudinal studies, passive and more importantly active smoking appears to be an important risk factor for the development of childhood, adolescent and adult asthma. In turn, no unequivocal association between ETS exposure, atopic sensitization and atopic dermatitis was found.

WATER HARDNESS AND DAMPNESS

The domestic water supply may be relevant for the inception of atopic dermatitis. An ecological study of the relation between domestic water hardness and the prevalence of atopic eczema among British school children was performed.[46] Geographical information systems were used to link the geographical distribution of eczema in the study area to four categories of domestic water-hardness data. Among school children aged 4 to 16 years, a significant relation was found between the prevalence of atopic eczema and water hardness, both before and after adjustment for potential confounding factors. The effect on recent eczema symptoms was stronger than on lifetime prevalence, which may indicate that water hardness acts more on existing dermatitis by exacerbating the disorder or prolonging its duration rather than as a cause of new cases. These observations await replication by other studies.

In 2004 a report by the Institutes of Medicine Committee on Damp Indoor Spaces and Health in the USA concluded that there is sufficient evidence of an association between exposure to a damp indoor environment and worsening of asthma symptoms, and that there is suggestive evidence of an association between exposure to a damp indoor environment and the development of asthma in children and adults. Dampness can elicit a number of different exposures such as fungi, bacteria or their constituents and emissions, or other agents related to damp indoor environments such as house dust mites and cockroaches. The responsible factors are not known but may vary among individuals or be potentiated in complex mixtures.[47]

NUTRITION

Breastfeeding has long been recommended for the prevention of allergic diseases. The epidemiological evidence is, however, highly controversial.[48] Some studies even suggest that breastfeeding may result in risk of asthma and atopy, but these studies may reflect adherence to recommendations. Likewise, the age at introduction of solid foods has been fiercely debated and no

https://CafePezeshki.IR

conclusive evidence has been reached that would allow general recommendations. Recently, the diversity of solid foods introduced in the first year of life has been linked to less atopic dermatitis and asthma later in life.[49]

There is increasing evidence relating body mass index to the prevalence and incidence of asthma in children and adults, males, and, more consistently, in adolescent females.[50] It is unlikely that the association is attributable to reverse causation, i.e. that asthma precedes obesity because of exercise-induced symptoms. Rather, weight gain can antedate the development of asthma. Weight reduction among asthmatic patients can result in improvements in lung function.[50] Obesity has been associated with inflammatory processes, which may contribute to asthma development. Other potential explanations are that mechanical factors promote asthma symptoms in obese individuals, or that gastroesophageal reflux as a result of obesity induces asthma. Furthermore, physical inactivity may promote both obesity and asthma.

Fruit, vegetable, cereal and starch consumption and intake of various fatty acids, vitamins A, C, D, E, minerals and antioxidants have all been studied.[36] However, diet is complex and difficult to measure, and standardized tools are still lacking. All methods pertaining to food frequency, individual food items, food patterns and serum nutrients can introduce substantial misclassification, and the close correlation of many nutrients presents problems when trying to identify independent effects. The evidence from prospective studies and randomized clinical trials for individual food items has been disappointing.[51] Thus, measures such as Mediterranean diet may better reflect real world exposures. A Mediterranean diet has in turn been linked to protection from asthma.[52]

ALLERGEN EXPOSURE

Although in some studies a clear, almost linear dose-response relation between allergen exposure and sensitization has been found,[53] others describe a bell-shaped association with higher levels of exposures relating to lower rates of atopic sensitization.[54] Part of the discrepancy may relate to the type of allergen, since mostly cat but not house dust mite allergen exposure has been shown, in some studies, to exert protective effects at higher levels of exposure. Furthermore, there is some evidence that the presence of a dog or a cat, or both, protects from the development of allergic sensitization, indicating that the presence of an animal is more important than just exposure to its allergens.

The relationship between allergens, particularly house dust mite exposure, and asthma has been studied for many years. Overall, there is little evidence to suggest a positive association between house dust mite exposure and the new onset of childhood asthma.[55] Intervention studies have failed to show convincing evidence of a reduction in asthma risk after the implementation of avoidance strategies.[56] Other co-factors of exposure should, however, also be taken into account, such as exposure to microbial compounds. For example, levels of endotoxin and other microbial exposures have been shown to modify the effect of allergen exposure[57–59]

FAMILY SIZE, INFECTIONS AND HYGIENE

Strachan first reported that sibship size, the number of children produced by a pair of parents, is inversely related to the prevalence of childhood atopic diseases and thereby proposed the 'hygiene hypothesis'.[60] This observation has since been confirmed by numerous studies, all showing that atopy, hay fever and atopic eczema were inversely related to increasing numbers of siblings. In contrast, the relation between family size and childhood asthma and airway hyperresponsiveness is less clear. However, the underlying causes of this consistent protective effect remain unknown.

Viral infections of the respiratory tract are the major precipitants of acute exacerbations of wheezing illness at any age, yet viral respiratory infections are very common during infancy and early childhood and most children do not suffer any aftermath relating to these infections, including infections with respiratory syncytial virus and rhinovirus.[61] Thus, host factors in children susceptible to the development of wheezing illnesses and asthma are likely to play a major role. Deficiencies in innate immune responses have been shown to contribute to a subject's susceptibility to rhinovirus infections, the most prevalent cause of lower respiratory tract viral infections in infants associated with asthma development.[62] Interactions between viral lower respiratory tract infections and early atopic sensitization may play a role: only among children with early onset of atopy may repeated viral infections become a risk factor for developing asthma.[63]

However, an inverse relation between asthma and the overall burden of respiratory infections may also exist. Several studies investigating children in daycare have rather consistently shown that exposure to a daycare environment in the first months of life is associated with a significantly reduced risk of wheezing, hay fever and atopic sensitization at school age and adolescence.[64,65] It remains, however, unclear whether the burden of infections or other exposures in daycare early in life account for this protective effect. Several reports have shown that children who are sero-positive for hepatitis A, *Toxoplasma gondii* or *Helicobacter pylori* have a significantly lower prevalence of atopic sensitization, allergic rhinitis and allergic asthma as compared to their sero-negative peers.[66]

The use of antibiotics has been proposed as a risk factor for asthma and allergic diseases. In most cross-sectional studies a positive relation between antibiotics and asthma has been found which is, however, most likely to be attributable to reverse causation. Early in life, when it is difficult to diagnose asthma, antibiotics are often prescribed for respiratory symptoms in wheezy children and thus are positively associated with asthma later in life. Most studies using a prospective design have, however, failed to identify antibiotics as a risk factor antedating the new onset of asthma.[67] Similar problems arise when interpreting the positive relation between paracetamol use and asthma seen in cross-sectional studies.[68] Intervention trials are needed to come to firm conclusions.

Active and chronic helminthic infections were reported to be protective from atopy, but findings are less consistent for wheeze and asthma.[69] Part of the discrepancies in the literature reporting associations between helminths and allergic diseases may be the load of parasitic infestation and the type of helminths in a particular area. Microbial stimulation, both from normal commensals and pathogens through the gut, may be another route of exposure which may have altered the normal intestinal colonization pattern in infancy. Thereby, the induction and maintenance of oral tolerance of innocuous antigens such as food proteins and inhaled allergens may be substantially hampered. These hypotheses, though intriguing, have to date not been supported by epidemiological evidence since significant methodological difficulties arise when attempting to measure the microbial pattern of the intestinal flora.

https://CafePezeshki.IR

Exposure to microbes does not only occur through invasive infection of human tissues. Viable germs and nonviable parts of microbial organisms are ubiquitous in nature and can be found in varying concentrations in our daily indoor and outdoor environments, and also in urban areas. These microbial products are recognized by the innate immune system and induce an inflammatory response. Therefore, environmental exposure to microbial products may play a crucial role in the maturation of a child's immune response, enabling tolerance of other components of its natural environment such as pollen and animal dander.

A number of studies have in fact shown that environmental exposure to endotoxin, a component of the cell wall of Gram negative bacteria, is inversely related to the development of atopic sensitization and atopic dermatitis[70]; yet endotoxin exposure is a risk factor for wheezing and asthma as shown in a number of studies.[71] Muramic acid, a component of the cell wall of all bacteria, but more abundant in Gram positive bacteria, has been inversely related to asthma and wheeze, but not atopy.[72] Compounds related to fungal exposures, such as extracellular polysaccharides derived from *Penicillium* spp. and *Aspergillus* spp., have also been inversely associated with asthma.[73] These microbial compounds are found in higher abundance in farming than nonfarming environments. Recent findings using culture based and DNA based analyses suggest that the diversity in environmental microbial (bacterial and fungal) exposures explains at least in part the 'farm effect' on childhood asthma.[31]

These environmental microbial exposures may shape a subject's microbiome at mucosal surfaces. Thus, the true intermediary between the environment and the host may be the microbiota. While there exists intriguing evidence in experimental studies in mice, the precise role of the microbiome for developing allergic diseases on a population level has not been determined.

Gene-Environment Interactions

The genetics of asthma will be discussed in Chapter 3 and are touched on here only in the context of environmental exposures. In general, the identification of novel genes for asthma suggests that many genes with small effects, rather than a few genes with strong effects, contribute to the development of asthma and atopy.[74] These genetic effects may, in part, differ with respect to a subject's environmental exposures, although some genes may also exert their effect independently of the environment.

A number of gene-environment interactions have been found, which are discussed in detail by von Mutius[74] and Le Souef.[75] These interactions confer additional biologic plausibility for the identified environmental exposures in the inception of asthma and allergic diseases. For example, the interaction of polymorphisms in the *TLR2* gene with a farming environment or daycare settings is highly suggestive of microbial exposures underlying this observation. Conversely, the more detrimental effects of passive smoking in people with genetically determined insufficient detoxification (e.g. GST Null genotypes) highlight the importance of taking a host's susceptibility into account when estimating the effect size of harmful exposures.[76] Thereby, the analysis of gene-environment interactions may result in the identification of individuals who are particularly vulnerable to certain environmental exposures.

Conclusions

Large variations in the prevalence of childhood and adult asthma and allergies have been reported. In affluent, urbanized centers, prevalences are generally higher than in poorer centers with the exception of the inner city environments in the USA, where prevalences are particularly high. Lower levels are seen, especially in some rural areas in Africa and Asia and among farmers' children in Europe. Numerous environmental factors have been scrutinized, but no conclusive explanation for the rising trends has been found. Future challenges are to tackle the complex interplay between environmental factors and genetic determinants.

2 Natural History of Allergic Diseases and Asthma

ANDREW H. LIU | FERNANDO D. MARTINEZ

KEY POINTS

- The atopic disorders – atopic dermatitis, food and inhalant allergies, allergic rhinoconjunctivitis and asthma – tend to cluster in individuals, families and locales
- A developmental 'allergic march' of childhood begins with atopic dermatitis, food allergies and bronchiolitis episodes in the first few years of life, and progresses to inhalant allergic sensitization, allergic rhinoconjunctivitis and atopic asthma.
- Although persistent asthma commonly begins in the first few years of life, most infants and toddlers who have recurrent bronchiolitis episodes do not go on to have persistent asthma in later childhood and adulthood. Early life predictive factors for disease persistence include allergic march manifestations (atopic dermatitis, food allergy, allergic sensitization to inhalant allergens), recurrent bronchiolitis episodes triggered by common rhinoviruses, and parental asthma.
- Epidemiologic evidence suggests that atopic disorders are caused by environmental and lifestyle factors in the susceptible host.
- While atopy is a common feature of childhood asthma, additional factors appear to contribute to severe, persistent disease expression, including early onset, chronic exposure to sensitized allergen in the home and a dysregulated 'Th2-high' immunopathology.

Natural history studies of allergic diseases and asthma are fundamental for predicting disease onset and prognosis. Such studies reveal a developmental 'allergic march' in childhood, from the early onset of atopic dermatitis (AD) and food allergies in infancy, to asthma, allergic rhinitis (AR) and inhalant allergen sensitization in later childhood. Allergy and asthma of earlier onset and greater severity are generally associated with disease persistence. Therefore, allergy and asthma commonly develop during the early childhood years, the period of greatest immune maturation and lung growth. This highlights the importance of growth and development in a conceptual framework for allergy and asthma pathogenesis.

This chapter reviews the allergic march of childhood and its different clinical manifestations: food allergies, AD, inhalant allergies, AR and asthma. The natural history of anaphylaxis, an allergic condition not currently implicated in the allergic march, is also covered. Interventions that reduce the prevalence of allergy and asthma are reviewed toward the end of the chapter. The findings and conclusions presented in this chapter are largely based on long-term prospective (i.e. 'natural history') studies. Complementary reviews of the epidemiology of allergic diseases in childhood can be found in Chapter 1, and the prevention and natural history of food allergy in Chapter 43.

Allergic March of Childhood

Three prospective, longitudinal, birth cohort studies exemplify optimized natural history studies that are rich resources for our current understanding of the development and outcome of allergy and asthma in childhood: (1) the Tucson Children's Respiratory Study (CRS) in Tucson, Arizona (begun in 1980); (2) a Kaiser-based study in San Diego, California (begun in 1981); and the German Multicentre Allergy Study (MAS) in Germany (begun in 1990). The major findings of these studies have been consistent and reveal a common pattern of allergy and asthma development that begins in infancy.

1. The highest incidence of AD and food allergies is in the first 2 years of life (Figure 2-1). It is generally believed that infants rarely manifest allergic symptoms in the first month of life. By 3 months of age, however, AD, food allergies and wheezing problems are common.
2. This is paralleled by a high prevalence of food allergen sensitization in the first 2 years of life.[1] Early food allergen sensitization is an important risk factor for food allergies, AD and asthma.
3. Allergic airways diseases generally begin slightly later in childhood (see Figure 2-1). Childhood asthma often initially manifests with a lower respiratory tract infection or bronchiolitis episodes in the first few years of life.
4. AR commonly begins in childhood, although there is also good evidence that it often develops in early adulthood.[2,3]
5. The development of AR and persistent asthma is paralleled by a rise in inhalant allergen sensitization. Perennial inhalant allergen sensitization (i.e. cat dander, dust mites) emerges between 2 and 5 years of age, and seasonal inhalant allergen sensitization becomes apparent slightly later in life (ages 3 to 5 years).

Early Immune Development Underlying Allergies

A paradigm of immune development underlies allergy development and progression in early childhood (see Chapter 6). Briefly, the immune system of the fetus is maintained in a tolerogenic state, preventing adverse immune responses and rejection between the mother and fetus. Placental interleukin-10 (IL-10) suppresses the production of immune-potentiating interferon gamma (IFN-γ) by fetal immune cells. IFN-γ downregulates the production of pro-allergic cytokines, such as IL-4

https://CafePezeshki.IR

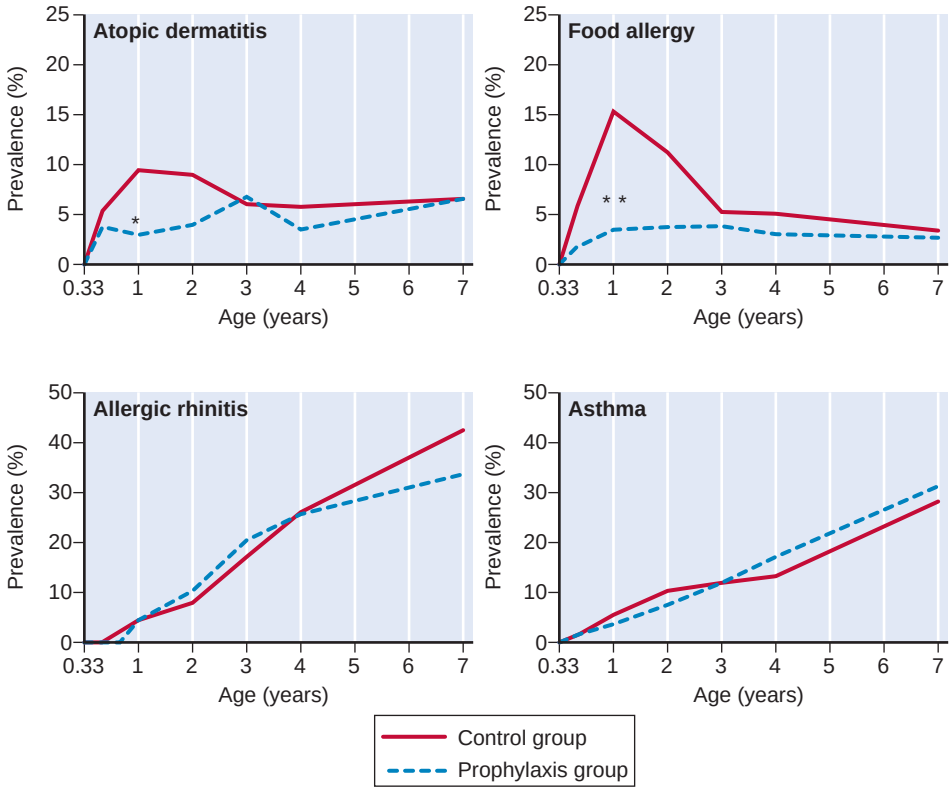

Figure 2-1 Allergic march of early childhood. Period prevalence of atopic dermatitis, food allergy, allergic rhinitis and asthma from birth to 7 years in prophylactic-treated (allergenic food avoidance) and untreated (control) groups (Kaiser Permanente; San Diego). *$P \leq .05$; **$P < .01$. *(Data from Zeiger RS, Heller S, J Allergy Clin Immunol 1995;95:1179–90; and Zeiger RS, Heller S, Mellon MH, et al. J Allergy Clin Immunol 1989;84:72–89.)*

and IL-13. The reciprocal relationship between these cytokines and the immune cells that produce them defines 'T-helper 2' (Th2), pro-allergic immune responses (i.e. IL-4, IL-13), and antiallergic 'T-helper 1' (Th1) immune development (i.e. IFN-γ). Thus the conditions that favor immune tolerance in utero may also foster allergic immune responses, such that newborn immune responses to ubiquitous ingested and inhaled proteins are Th2 biased.[4] Postnatally, encounters with these common allergenic proteins lead to the development of mature immune responses to them. The underlying immune characteristics of allergic diseases – allergen-specific memory Th2 cells and immunoglobulin E (IgE) – can be viewed as aberrant manifestations of immune maturation that typically develop during these early years, and might have their roots in the inadequate or delayed development of regulatory T lymphocytes that can inhibit them.

TOTAL SERUM IgE LEVELS

At birth, cord blood IgE levels are almost undetectable; these levels increase during the first 6 years of life. Elevated serum IgE levels in infancy have been associated with persistent asthma in later childhood.[5] High serum IgE levels in later childhood (i.e. after 11 years of age) have also been well correlated with bronchial hyperresponsiveness (BHR) and asthma.[6,7]

ALLERGEN-SPECIFIC IgE

In two birth cohort (up to 5 years old) studies of IgG and IgE antibody development to common food and inhalant allergens, IgG antibodies to milk and egg proteins were detectable in nearly all subjects in the first 12 months of life, implying that the infant immune system sees and responds to commonly ingested proteins.[8,9] In comparison, food allergen-specific IgE (especially to egg) was measurable in approximately 30% of subjects at 1 year of age. Low-level IgE responses to food allergens in infancy were common and transient, and sometimes occurred before introduction of the foods into the diet. In children who developed clinical allergic conditions, higher levels and persistence of food allergen-specific IgE were typical.

Of seasonal inhalant allergens, ragweed and grass allergen-specific IgGs were detectable in approximately 25% of subjects at 3 to 6 months of age, and steadily increased to 40% to 50% by 5 years of age.[10,11] In comparison, allergen-specific IgE was detected in <5% of subjects from 3 to 12 months of age, and increased in prevalence to approximately 20% by 5 years of age. Therefore, allergen-specific IgE production emerges in the preschool years and persists in those who develop clinical allergies.

ALLERGEN-SPECIFIC TH2 LYMPHOCYTES, AND THEIR REGULATION BY TH1 AND TREG LYMPHOCYTES

The development of allergen-specific antibody production is indicative of allergen-specific T lymphocytes that are guiding the development and differentiation of B lymphocytes to produce IgE through secreted Th2-type cytokines (i.e. IL-4, IL-13) and cell surface molecular interactions (i.e. CD40/CD40

https://CafePezeshki.IR

ligand). T cell-derived IL-4, IL-5 and GM-CSF also support eosinophil and mast cell development and differentiation in allergic inflammation. A current paradigm for allergic disease suggests that pro-allergic Th2 cells are (1) differentiated to produce cytokines that direct allergic responses and inflammation, (2) opposed by Th1 cells that produce counter-regulatory cytokines (e.g. IFN-γ) that inhibit Th2 differentiation, and (3) suppressed by regulatory T lymphocytes. As an example of this Th2/Th1/TREG paradigm, peripheral blood mononuclear cells from infants who have milk allergy or peanut sensitization, or ultimately manifest allergic disease at 2 years of age, produce more pro-allergic Th2 cytokines (i.e. IL-4) to allergen-specific stimulation in vitro.[10,12] In comparison, infants who continue to be nonallergic (i.e. no allergic disease and/or no allergen sensitization in later childhood) produce more counter-regulatory IFN-γ to nonspecific[5,11] and allergen-specific[10] stimuli. Infants with reduced allergic sensitization also have increased IL-10-producing T lymphocyte numbers and suppressive function.[13]

Infants with diminished Th1 responses may be more susceptible to developing asthma for additional reasons. Bronchiolitic infants who continue to have persistent wheezing and airflow obstruction also produce less IFN-γ.[14] This suggests that infants who produce less IFN-γ to ubiquitous allergens and to airway viral infections are susceptible to chronic allergic diseases and asthma because (1) they are less able to impede the development of allergen-specific T cells and IgE, and (2) they are more likely to manifest persistent airways abnormalities following respiratory viral infections.

Childhood Asthma

Approximately 80% of asthmatic patients report disease onset before 6 years of age.[15] However, of all young children who experience recurrent wheezing, only a minority will go on to have persistent asthma in later life. The most common form of recurrent wheezing in preschool children occurs primarily with viral infections (Box 2-1). These 'transient wheezers' or 'wheezy bronchitics' are not at an increased risk of having asthma in later life. Transient wheezing is associated with airways viral infections, smaller airways and lung size, male gender, low birth weight, and prenatal environmental tobacco smoke (ETS) exposure.

BOX 2-1 KEY CONCEPTS

Childhood Wheezing and Asthma Phenotypes

- Transient early wheezing or wheezy bronchitis: most common in infancy and preschool years
- Persistent allergy-associated asthma: most common phenotype in school-age children, adults and elderly
- Nonallergic wheezing: associated with bronchial hyperresponsiveness at birth; continues into childhood
- Asthma associated with obesity, female gender and early-onset puberty: emerges between 6 and 11 years of age
- Asthma mediated by occupational-type exposures: a probable type of childhood asthma in children living in particular locales, although not yet demonstrated
- Triad asthma: asthma associated with chronic sinusitis, nasal polyposis and/or hypersensitivity to nonsteroidal antiinflammatory medications (e.g. aspirin, ibuprofen); rarely begins in childhood

Persistent asthma commonly begins and co-exists with the large population of transient wheezers (see Box 2-1). Persistent asthma is strongly associated with allergy, which is evident in the early childhood years as clinical conditions (i.e. AD, AR, food allergies) or by testing for allergen sensitization to inhalant and food allergens (e.g. IgE, allergy skin testing). Severity of childhood asthma, determined clinically or by lung function impairment, also predicts asthma persistence into adulthood.

Early Childhood: Transient vs Persistent Asthma

In the Tucson CRS study, approximately 50% of young children experienced a period of recurrent wheezing and/or coughing in the first 6 years of life.[16] These early-childhood wheezers were further subdivided into: (1) 'transient early wheezers,' with wheezing only <3 years; (2) 'persistent wheezers,' with manifestations through the first 6 years; and (3) 'late-onset wheezers,' with manifestations only after 3 years. Transient wheezers comprised the largest proportion of the group, at 20%; persistent and late-onset wheezers made up slightly smaller proportions (14% and 15%, respectively). Of the three groups, persistent wheezers had the greatest likelihood of persistent asthma in later childhood (Figure 2-2). By age 16 years, approximately 50% of those with persistent or late-onset wheezing in early life continued to have recurrent wheezing/coughing episodes.[17] In contrast, the prevalence of persistent asthma in the transient wheezer group was approximately 20% and not different from nonwheezers.

Lung function in the Tucson CRS was measured in the first year of life (before the occurrence of lower respiratory tract infections) and at 6 years of age. Interestingly, transient wheezers had the lowest airflow measures in infancy, suggesting that they had the narrowest airways and/or the smallest lungs at birth.[16] Their reduced lung function improved significantly by age 6 years, but continued to be lower than normal at age 16 years.[17]

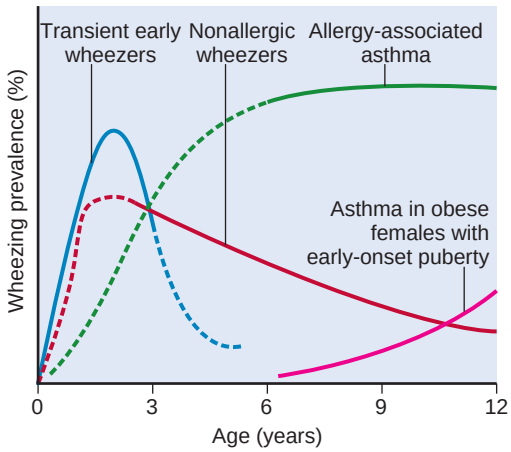

Figure 2-2 Hypothetical yearly prevalence for recurrent wheezing phenotypes in childhood (Tucson Children's Respiratory Study, Tucson, Arizona). This classification does not imply that the groups are exclusive. Dashed lines suggest that wheezing can be represented by different curve shapes resulting from many different factors, including overlap of groups. *(Modified from Stein RT, Holberg CJ, Morgan WJ, et al. Thorax 1997;52:946–52.)*

https://CafePezeshki.IR

In comparison, persistent wheezers demonstrated normal lung function in the first few months of life but a significant decline in airflow measures by 6 years of age that persisted as lower than normal at age 16 years.[17] Therefore, lung function in transient early and persistent wheezers remained lower than normal non-wheezers through age 16 years, indicating two different clinical patterns of recurrent wheezing in early childhood that are associated with persistently low lung function established early in life.

Some children with BHR in early life are also more likely to have persistent asthma. Investigators of a birth cohort in Perth, Australia, found that BHR at 1 month of age was associated with lower lung function (i.e. FEV_1 and FVC) and a higher likelihood of asthma at 6 years of age.[18] Interestingly, congenital BHR was not associated with total serum IgE, eosinophilia, allergen sensitization or BHR at 6 years of age and was independent of gender, family history of asthma and maternal smoking. In the Tucson CRS study, BHR measured at age 6 years predicted chronic and newly diagnosed asthma at age 22 years.[19]

Asthma from Childhood to Adulthood

A cohort of 7-year-old children with asthma living in Melbourne, Australia, was restudied for persistence and severity of asthma at 10, 14, 21, 28, 35 and 42 years of age. At 42 years of age, 71% of the asthmatics and 89% of the severe asthmatics continued to have asthma symptoms; 76% of the severe asthmatics reported frequent or persistent asthma.[20] In comparison, 15% of 'mild wheezy bronchitics' (i.e. wheezing only with colds at 7 years of age) and 28% of 'wheezy bronchitics' (i.e. at least five episodes of wheezing with colds) reported frequent or persistent asthma. These observations – that many children with asthma experience disease remission or improvement in early adulthood but that severe asthma persists with age – are remarkably similar to those of several other natural history studies of childhood asthma into adulthood.[21–24]

Spirometric measures of lung function of the Melbourne study children initially revealed that asthmatics (especially severe asthmatics) had lung function impairment, whereas wheezy bronchitics (i.e. 'transient' wheezers) had lung function that was not different from that of nonasthmatics. Over the ensuing years these differences in lung function impairment between groups persisted in parallel, without a greater rate of decline in lung function in any group (Figure 2-3).[20,25] Beginning from birth, in the Tucson CRS, low lung function in infancy also persisted through ages 11, 16 and 22 years.[26] However, some children with persistent asthma demonstrated progressive decline in lung function. In the longitudinal CAMP study, approximately 25% of elementary school-age children with persistent asthma manifested progressive decline in lung function annually for 4 years.[27] Risk factors for progressive decline in lung function included male gender, younger age and hyperinflation. These findings support the importance of the early childhood years in lung and asthma development. The establishment of chronic disease and lung function impairment in early life appears to predict persistent asthma and lung dysfunction well into adulthood; however, progressive decline in lung function can occur in some children during school-age years.

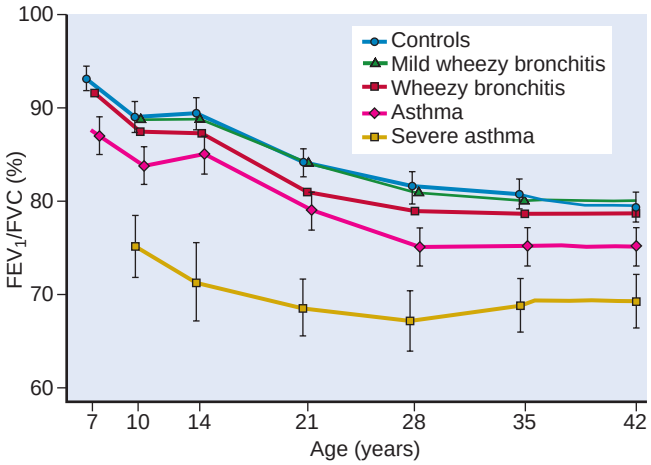

Figure 2-3 Natural history of lung function from childhood to adulthood (Melbourne Longitudinal Study of Asthma, Melbourne, Australia). Subjects were classified according to their diagnosis at time of enrollment: nonwheezing control; mild wheezy bronchitis; wheezy bronchitis; asthma; and severe asthma. Lung function is represented as FEV_1 corrected for lung volume (FEV_1/FVC ratio). Mean values and standard error bars are shown. *(Adapted from Oswald H, Phelan PD, Lanigan A, et al. Pediatr Pulmonol 1997;23:14–20; with data for age 42 years from Horak E, Lanigan A, Roberts M, et al. BMJ 2003; 326(7386):422–3.)*

BOX 2-2 KEY CONCEPTS

Risk Factors for Persistent Asthma

ALLERGY

Atopic dermatitis
Allergic rhinitis
Elevated total serum IgE levels (first year of life)
Peripheral blood eosinophilia >4% (2 to 3 years of age)
Inhalant and food allergen sensitization

GENDER

Males

- Transient wheezing
- Persistent allergy-associated asthma

Females

- Asthma associated with obesity and early-onset puberty
- 'Triad' asthma (adulthood)

PARENTAL ASTHMA

LOWER RESPIRATORY TRACT INFECTIONS

Rhinovirus, respiratory syncytial virus
Severe bronchiolitis (i.e. requiring hospitalization)
Pneumonia

ENVIRONMENTAL TOBACCO SMOKE EXPOSURE (INCLUDING PRENATAL)

Risk Factors for Persistent Asthma

Natural history studies of asthma have identified biologic, genetic and environmental risk factors for persistent asthma (Box 2-2). From the Tucson CRS, a statistical optimization of the major risk factors for persistent childhood asthma provided 97% specificity and 77% positive predictive value for persistent asthma in later childhood (Figure 2-4).[28]

https://CafePezeshki.IR

At least 4 wheezing episodes, plus:	
1 Major criterion	**or 2 Minor criteria**
Parental asthma	Allergic rhinitis
Eczema	Wheezing apart from colds
Inhalant allergen sensitization	Eosinophils ≥ 4%
	Food allergen sensitization

Figure 2-4 Modified Asthma Predictive Index for children (Tucson Children's Respiratory Study, Tucson, Arizona). Through a statistically optimized model for 2- to 3-year-old children with frequent wheezing in the past year, one major criterion or two minor criteria provided 77% positive predictive value and 97% specificity for persistent asthma in later childhood. *(Adapted from Castro-Rodriguez JA, Holberg CH, Wright AL, et al. Am J Respir Crit Care 2000;162:1403–6; and Guilbert TW, Morgan WJ, Zeiger RS, et al. J Allergy Clin Immunol 2004;114:1282–7.)*

ALLERGY

Essentially all of the current natural history studies have found that allergic disease and evidence of pro-allergic immune development are significant risk factors for persistent asthma. For example, in the Tucson CRS, early AD, AR, elevated serum IgE levels in the first year of life and peripheral blood eosinophilia were all significant risk factors for persistent asthma.[16,28] In the Berlin MAS study, additional risk factors for asthma and BHR at age 7 years included persistent sensitization to foods (i.e. hen's egg, cow's milk, wheat and/or soy) and perennial inhalant allergens (i.e. dust mite, cat dander), especially in early life.[29,30] The combination of allergic sensitization to major indoor allergens (dog, cat and/or mite) by age 3 years with higher levels of allergen exposure in the home was associated with persistent wheezing and lower lung function into adolescence.[31] In the Kaiser San Diego study, milk or peanut allergen sensitization was a risk factor for asthma.[32] Natural history studies of asthma that have extended into adulthood continue to find allergy to be a risk factor for persistent asthma.[22,23] Since the eight-center Childhood Asthma Management Program (CAMP) study of 1,041 asthmatic children ages 5 to 12 years found that 88% were sensitized to at least one inhalant allergen at study enrollment, allergy-associated asthma appears to be the most common form of asthma in elementary school-age children in the USA.[33] Furthermore, in the International Study of Asthma and Allergies in Childhood (ISAAC), strong correlations between high asthma prevalence and both high allergic rhinoconjunctivitis and high AD prevalence in different sites throughout the world suggest that allergy-associated asthma is also the most common form of asthma worldwide.[34] In children with recurrent cough or wheeze in early life, early manifestations of atopy are well-regarded predictive risk factors for persistent lung dysfunction and clinical disease (Figure 2-4).[35,36]

GENDER

Male gender is a risk factor for both transient wheezing and persistent asthma in childhood.[16,32] This is generally believed to be caused by the smaller airways of young boys when compared with girls.[37,38] Later in childhood, BHR and inhalant allergen sensitization are more prevalent in boys than in girls.[39,40] For asthma persistence from childhood to adulthood, female gender is a risk factor for greater asthma severity[22] and BHR.[21] Female children who become overweight and have early-onset puberty are also more likely to develop asthma in adolescence, an association not appreciated in males (see Figure 2-2).[41] These observations are consistent with the gender 'flip' in asthma prevalence – higher in males in childhood, and in females by adulthood.[15]

PARENTAL HISTORY OF ASTHMA

Infants whose parents report a history of childhood asthma have lower lung function and are more likely to wheeze in early life,[42,43] in later childhood[16,32] and in adulthood.[22] However, in a two-generation, longitudinal study in Aberdeen, Scotland, the children of well-characterized subjects without atopy or asthma were found to have a surprisingly high prevalence of allergen sensitization (56%) and wheezing (33%).[44] Similarly, in the MAS study, the majority of children with AD and/or asthma in early childhood were born to nonallergic parents.[45] For example, of the study's asthmatic children at 5 years of age, 57% were born to parents without an atopic history. Therefore allergen sensitization and asthma seem to be occurring at high rates, even in persons considered to be at low genetic risk for allergy and asthma.

LOWER RESPIRATORY TRACT INFECTIONS

Certain respiratory viruses have been associated with persistent wheezing problems in children. It is not known if persistent airways abnormalities are primarily the result of virus-induced damage, vulnerable individuals revealing their airway susceptibility to virus-induced airflow obstruction, or airways injury with aberrant repair. In long-term studies, infants hospitalized with respiratory syncytial virus (RSV) bronchiolitis (most occurred by 4 months of age) were significantly more likely to have asthma and lung dysfunction through age 13 years.[46] In the Tucson CRS birth cohort, 91% of lower respiratory tract infections (LRTIs) in the first 3 years of life were cultured for common pathogens: 44% were RSV-positive, 14% were parainfluenza-positive, 14% were culture-positive for other respiratory pathogens, and 27% were culture-negative.[47] Followed prospectively, infants with RSV LRTI were more likely to have wheezing symptoms at 6 years of age but not at later ages (i.e. 11 and 13 years old). However, young children who had radiographic evidence of pneumonia or croup symptoms accompanying wheezing were more likely to have persistent asthma symptoms and lung function impairment at 6 and 11 years of age.[48,49]

Improved PCR-based detection methods have affirmed a strong association between rhinovirus infection and asthma exacerbations, such that approximately 40% to 70% of wheezing illnesses and asthma exacerbations in children can be attributed to rhinovirus.[50–52] People with asthma do not appear to be more susceptible to rhinovirus infection, but they are more likely to develop an LRTI with symptoms that are more severe and longer lasting.[53] In the Childhood Origins of Asthma (COAST) birth cohort study, 90% of children with rhinovirus-associated wheezing episodes at age 3 years had asthma at age 6 years, such that a rhinovirus-associated wheezing episode at age 3 years was a stronger predictor of subsequent asthma than

https://CafePezeshki.IR

aeroallergen sensitization (odds ratios 25.6 vs 3.4).[54] This supports the premise that individuals with lower airway vulnerability to common respiratory viruses are at risk for wheezing episodes and persistent asthma.

ENVIRONMENTAL TOBACCO SMOKE EXPOSURE

ETS exposure is a risk factor for wheezing problems at all ages. Prenatal ETS exposure is associated, in a dose-dependent manner, with wheezing manifestations and decreased lung function in infancy and early childhood.[55,56] Postnatal ETS exposure is associated with a greater likelihood of wheezing in infancy,[43] transient wheezing, and persistent asthma in childhood.[16] Cigarette smoking has also been strongly associated with persistent asthma and asthma relapses in adulthood.[23]

ETS exposure is also associated with food allergen sensitization,[57] AR, hospitalization for LRTIs, BHR and elevated serum IgE levels.[58,59] In a 7-year prospective study, ETS exposure was associated with greater inhalant allergen sensitization and reduced lung function.[32]

Asthma- and Allergy-Protective Influences

Some lifestyle differences may impart asthma- and/or allergy-protective effects. Natural history studies have started to contribute some epidemiologic evidence in support of these hypotheses.

BREASTFEEDING

Numerous studies have investigated the potential of early breastfeeding as a protective influence against the development of allergy and asthma. Meta-analyses of prospective studies of exclusive breastfeeding for 4 or more months from birth have been associated with less AD and asthma (summary odds ratios of 0.68 and 0.70, respectively).[60,61]

MICROBIAL EXPOSURES

Numerous epidemiologic studies have found that a variety of microbial exposures are associated with a lower likelihood of allergen sensitization, allergic disease and asthma. This has led to a 'hygiene' hypothesis, which proposes that the reduction of microbial exposures in childhood in modernized locales has led to the rise in allergy and asthma.[62] Microbes and their molecular components are believed to influence early childhood development by inducing Th1-type and regulatory immune development and immune memory, thereby preventing the development of allergen sensitization and diseases, while strengthening the immune response and controlling inflammation to common respiratory viral infections.

To address this hypothesis, natural history studies have begun to explore the relationships between microbes and their components (e.g. home environmental bacterial endotoxin) to the development of allergies and asthma:

1. In the Tucson CRS, children raised in larger families or in daycare from an early age (believed to be surrogate measures for more respiratory infections and microbial exposures) were less likely to have asthma symptoms in later childhood.[63] In the German MAS study, more runny nose colds in the first 3 years of life were associated with a lower likelihood of allergen sensitization, asthma and BHR at 7 years of age.[64] A dose-dependent effect was observed, such that children who experienced at least eight colds by age 3 years had an adjusted odds ratio of 0.16 for asthma at age 7 years.
2. In infants and children, higher house dust endotoxin levels were associated with less AD,[65–67] inhalant allergen sensitization,[68–71] AR and asthma.[72,73] Complementary immunologic studies reveal that higher house dust endotoxin levels were associated with increased proportions of Th1-type cells,[68] higher levels of IFN-γ from stimulated peripheral blood samples[74,75] and immune down-regulation of endotoxin-stimulated blood samples.[72] In contrast to these atopy-protective influences, higher endotoxin levels were associated with more wheezing, even when a protective effect on atopy in early life was concurrently observed.[65,67,69,72,76]
3. Gastrointestinal (GI) microbiota shape early immune development, and some investigators identified differences in stool bacteria from newborns and infants who ultimately go on to develop allergic disease as being less diverse and having more clostridia and *Staphylococcus aureus*, while nonallergic infants had more enterococci, bifidobacteria, lactobacilli and *Bacteroides*.[77–81] Alterations in the gut microbiome of infants from dietary and environmental differences (e.g. breastfeeding, semi-sterile food, infections, antibiotic use, siblings, pets) may influence the developing immune system and allergy outcomes.
4. Diverse environmental microbiomes associated with animal exposures may exert a protective influence on the development of asthma. In Europe, farm versus non-farm children were exposed to a greater diversity of bacteria and fungi in their mattress dust, and diversity of microbial exposure was inversely related to asthma risk.[82] Interestingly, in US inner city locales known for a higher prevalence of severe asthma, cockroach, mouse and cat allergen exposure in the first year of life was inversely associated with recurrent wheeze (odds ratios 0.60–0.75).[83] Cockroach and mouse exposure were associated with bacterial Bacteroidetes and Firmicutes phyla in house dust samples, which were associated with lack of atopy and wheeze.

Conversely, some microbial exposures have been associated with the development of persistent asthma. Nasopharyngeal carriage of common respiratory pathogens (*Streptococcus pneumoniae, Moraxella catarrhalis, Haemophilus influenzae*) in infancy, and in children with asthma in later childhood (*S. pneumoniae, M. catarrhalis*), was associated with asthma exacerbations, implicating these respiratory pathogens as co-exposures in the pathogenesis of asthma persistence and exacerbations.[84,85]

PET OWNERSHIP

Multiple longitudinal birth cohort studies have observed dog and/or cat ownership to be associated with a lower likelihood of AD, allergen sensitization and asthma.[86–88] Similarly, in farming and rural locales, a lower likelihood of allergy and asthma has been associated with animal contact or the keeping

https://CafePezeshki.IR

of domestic animals in the home.[89] Two meta-analyses of numerous studies of domestic animal exposure and allergy and asthma outcomes generally found a protective effect.[90,91] Although the mechanism(s) for this protective association is unclear, one possibility is that greater bacterial exposure occurs with animal contact and/or animal/petkeeping in the home. Indoor pets are a major factor associated with higher indoor endotoxin levels in metropolitan homes.[89] Bacterial community diversity in house dust samples from households with pet dogs, and some with cats, is increased.[92]

VITAMIN D

There is current conjecture that vitamin D supplementation can prevent allergy and asthma. It has been hypothesized that modern lifestyles with greater time spent indoors have fostered more vitamin D deficiency, resulting in more asthma and allergy.[93,94] The scientific rationale is appealing: vitamin D has been shown to bolster innate antimicrobial and regulatory T lymphocyte responses.[93] Complementing this mechanistic science, three birth cohort studies have observed that high maternal vitamin D intake during pregnancy was associated with a lower risk of recurrent/persistent wheeze or asthma in preschool childhood.[95–97] Clinical trials to determine the potential preventive benefits of vitamin D supplementation on allergy and asthma are ongoing.

Childhood Asthma Phenotypes

Different severity phenotypes of children with persistent asthma have recently been characterized using cluster analysis. In the Childhood Asthma Management Program (CAMP) study, five main phenotypes were distinguished: (1) 'mild asthma' with low atopy, airways obstruction and exacerbation rate; (2) atopic asthma with atopic dermatitis/allergic rhinitis/allergic sensitization, normal lung function and low exacerbation rates; (3) high allergic rhinitis/allergic sensitization, reduced lung function and moderate exacerbation rates; (4) reduced lung function and high bronchodilator responses, BHR and exacerbation/hospitalization rates; and (5) the highest atopy/serum IgE/eosinophilia, reduced lung function, high bronchodilator responses/BHR, and the highest exacerbation and hospitalization rates.[98] Children in these different clusters appeared to be temporally stable over the 5 years of the CAMP study, with mild versus severe diverging over time. These clusters were consistent with those identified in the Severe Asthma Research Program (SARP).[99] The most severe phenotype in children appears consistent with a severe 'Th2-high' phenotype in adults, with IL-13-induced epithelial gene expression (e.g. periostin), atopic airways inflammation and exacerbation risk.[100]

Asthma mediated by occupational-type exposures is often not considered in children, and yet some children are raised in settings where occupational-type exposures can mediate asthma in adults (e.g. on farms or with farm animals in the home). Children with hypersensitivity and exposure to other common airways irritants or air pollutants such as ETS, endotoxin, ozone, sulfur dioxide or cold air may also contribute to the pool of nonatopic children with persistent asthma. 'Triad' asthma, characteristically associated with hyperplastic sinusitis/nasal polyposis and/or hypersensitivity to nonsteroidal antiinflammatory medications (e.g. aspirin, ibuprofen), rarely occurs in childhood.

Atopic Dermatitis

AD usually begins during the preschool years and persists throughout childhood. Two prospective birth cohort studies have found the peak incidence of AD to be in the first 2 years of life (see Figure 2-1).[32,101] Although 66% to 90% of patients with AD have clinical manifestations before 7 years of age,[102,103] eczematous lesions in the first 2 months of life are rare. Natural history studies of AD have reported a wide variation (35% to 82%) in disease persistence throughout childhood.[103,104] The greatest remission in AD seems to occur between 8 and 11 years of age and, to a lesser extent, between 12 and 16 years.[103] Natural history studies of AD may have underestimated the persistent nature of the disease for reasons that include (1) AD definition – some studies have included other forms of dermatitis that have a better prognosis over time (i.e. seborrheic dermatitis),[105] (2) AD recurrence – a recent 23-year birth cohort study found that many patients who went into disease remission in childhood had an AD recurrence in early adulthood,[103] and (3) AD manifestation – it is generally believed that patients with childhood AD will often evolve to manifest hand and/or foot dermatitis as adults.

Parental history of AD is an important risk factor for childhood AD. This apparent heritability complements studies revealing a high concordance rate of AD among monozygotic versus dizygotic twins (0.72 vs 0.23, respectively).[106] In a risk factor assessment for AD in the first 2 years of life, higher levels of maternal education and living in less crowded homes were risk factors for early-onset AD.[107] The environmental/lifestyle risk factors reported for AR and asthma are similar. A meta-analysis of prospective breastfeeding studies concluded that exclusive breastfeeding of infants with a family history of atopy for at least the first 3 months of life is associated with a lower likelihood of childhood AD (odds ratio 0.58). This protective effect was not observed, however, in children without a family history of atopy.[60]

Initial AD disease severity seems predictive of later disease severity and persistence. Of adolescents with moderate to severe AD, 77% to 91% continued to have persistent disease in adulthood.[108] In comparison, of adolescents with mild AD, 50% had AD in adulthood. Food allergen sensitization and exposure in early childhood also contribute to AD development and disease severity. Food allergen sensitization is associated with greater AD severity.[32,109] Furthermore, elimination of common allergenic foods in infancy (i.e. soy, milk, egg, peanuts) is associated with a lower prevalence of allergic skin conditions up to age 2 years (see Figure 2-1).[32]

Natural history studies have found early childhood AD to be a major risk factor for food allergen sensitization in infancy,[110] inhalant allergen sensitization[110,111] and persistent asthma in later childhood.[16,28] In particular, severe AD in early childhood is associated with a high prevalence of allergen sensitization and airways allergic disease in later childhood (i.e. 4 years later; Figure 2-5). Indeed, in young patients with severe AD, 100% developed inhalant allergen sensitization and 75% developed an allergic respiratory disease (mostly asthma) over 4 years. In contrast to severe AD, patients with mild to moderate AD were not as likely to develop allergen sensitization (36%) or an allergic respiratory disease (26%). More information on current concepts of barrier and immune dysfunction in AD, and the role of food hypersensitivity, can be found in Chapters 50 and 47, respectively.

https://CafePezeshki.IR

	Initial examination		4 years later		
AD severity	Inhalant ± food	Food only	Inhalant ± food	Food only	Asthma and/or AR
Mild	15%	20%	31%	6%	15%
Moderate	18%	26%	52%	6%	32%
Severe	20%	45%	100%	0%	75%

Figure 2-5 Atopic dermatitis *(AD)* in young children (2 months to 3 years of age) and allergen sensitization (to food and inhalant allergens), asthma and allergic rhinoconjunctivitis *(AR)* 4 years later. At enrollment, AD severity was determined, and no subjects had AR or asthma. Four years later, 88% of subjects had a marked improvement or complete resolution of AD. However, all children with severe AD at enrollment were sensitized to inhalant allergens, and 75% had asthma and/or AR. *(From Patrizi A, Guerrini V, Ricci G, et al. Pediatr Dermatol 2000; 17:261–5.)*

Allergic Rhinitis

Many people develop AR during childhood. Two prospective birth cohort studies reported a steady rise in total (i.e. seasonal and perennial) AR prevalence, reaching 35% to 40% by age 7 years.[32,112] Seasonal AR emerged after 2 years of age and increased steadily to 15% by age 7 years.[112]

AR also commonly begins in early adulthood. In a 23-year cohort study of Brown University students, beginning in their freshman year, perennial AR developed in 4.8% at 7 years and 14% at 23 years of follow-up.[2,3] The incidence increase for seasonal AR was substantially greater: 13% at 7 years and 41% at 23 years of follow-up.[2,3] Allergen skin test sensitization and asthma were prognostic risk factors for the development of AR.

AR persistence has been evaluated in adult patients. Three follow-up studies of adult AR patients found a disease remission rate of 5% to 10% by 4 years[113] and 23% by 23 years.[2] In the 23-year follow-up study, 55% of the follow-up subjects reported improvement in rhinitis. Onset of disease in early childhood was associated with greater improvement.[2]

Food Allergy

Food-adverse reactions in childhood include food hypersensitivity that is IgE mediated and manifests as classic allergic symptoms of immediate onset. Other food-allergic reactions, such as eosinophilic gastroenteropathy and food protein-induced enterocolitis syndrome, have variable associations with foods and lack natural history studies.

Natural history studies reveal that the prevalence of food hypersensitivity is greatest in the first few years of life, affecting 5% to 15% of children in their first year of life.[114,115] Most children become tolerant of or seem to 'outgrow' their food allergies to milk, soy and egg within a few years. In a prospective study of young children with milk allergy, most became nonallergic within a few years: 50% by 1 year of age, 70% by 2 years, and 85% by 3 years.[116] Older children and adults with food allergies are less likely to become tolerant (26% to 33%).[117,118] Long-term follow-up studies of peanut-allergic children found that loss of clinical hypersensitivity was uncommon, especially in children with anaphylactic symptoms in addition to urticaria and/or AD.[119,120] Allergies to other nuts, fish and shellfish are also believed to be more persistent. It is purported that allergen avoidance diets in food-allergic children increase their likelihood of losing clinical hypersensitivity, but this has not been well studied.[118]

Hypersensitivity to milk at 1 year of age was a risk factor for additional food allergies in later childhood.[121,122] Furthermore, food hypersensitivity in early life (i.e. to milk, egg, peanut) was found to be a risk factor for AD[123,124] and, later, asthma.[29,32] More information on the natural history and prevention of food allergy can be found in Chapter 43.

Anaphylaxis

Anaphylaxis in children can result from numerous possible exposures (e.g. foods, antibiotics, insulin, insect venoms, latex) and is sometimes anaphylactoid (a clinically similar but non-IgE-mediated reaction, such as occurs with radio-contrast media and aspirin/nonsteroidal antiinflammatory drugs) or idiopathic. In a retrospective medical records review of 601 cases, causes of anaphylaxis were determined in 41%: foods 22%, medications 11% and exercise 5%. Episodes tended to become less frequent over time.[125] A history of AR or asthma is a risk factor for anaphylaxis to foods and latex.[126] Surprisingly, a history of asthma, pollenosis or food and/or drug allergy is a risk factor for anaphylactoid reactions to radio-contrast media, with a higher prevalence of adverse reactions to ionic versus nonionic contrast media observed.[127] In contrast, atopy is not a risk factor for anaphylaxis to insulin,[128] penicillin[129] or insect stings.[130] The natural history of anaphylactic reactions in children has been studied prospectively only for food-induced anaphylaxis (described previously) and bee sting anaphylaxis.

In a Johns Hopkins study examining the natural history of bee venom allergy in children, venom-allergic children with a history of mild generalized reactions were randomly assigned to venom immunotherapy or no treatment and then subjected to a repeat sting in a medical setting 4 years later.[131] Systemic allergic reactions occurred in 1.2% of the treated group and 9.2% of the untreated group. Moreover, systemic reactions that occurred were no more severe than the original incidents. In a smaller study of children and adults with venom hypersensitivity, repeat sting challenges, at least 5 years after the original incidents, induced no systemic reactions in those who originally presented with only urticaria/angioedema but did induce systemic reactions in 21% of those who originally had respiratory and/or cardiovascular complications.[132]

These studies suggest that insect sting anaphylaxis is often self-limited in children, with spontaneous remission usually occurring within 4 years. Those at greatest risk of persistent hypersensitivity include those with previous severe anaphylactic episodes. Conversely, those children with mild systemic reactions to bee stings are less likely to have an allergic reaction on re-sting, and any future anaphylactic episodes from bee stings are not likely to be severe. Finally, in a re-challenge study of subjects with no clinical response to a first sting challenge, 21% experienced anaphylaxis to the second challenge, and, of those, one half developed symptomatic hypotension requiring epinephrine.[133]

Gene-Environment Interactions

Gene-environment interactions validate the central paradigm that allergy and asthma development results from common environmental exposures affecting the inherently susceptible host. There are two notable examples related to childhood asthma:

https://CafePezeshki.IR

1. *CD14, endotoxin and dogs:* Polymorphisms in genes encoding proteins that mediate endotoxin recognition can modify endotoxin responsiveness. A common polymorphism in the promoter region (-260C-to-T) of the CD14 gene (endotoxin promoter/enhancer protein) has been one of the most studied polymorphisms with regard to asthma and allergies. Functionally, the -260CT CD14 promoter polymorphism alters the transcriptional regulation of CD14; the T allele increases CD14 transcription by reducing the binding of proteins that inhibit gene transcription.[134] Some studies have found that the C allele of the -260 CD14 promoter polymorphism increases the risk for allergic sensitization,[135,136] while others have not.[137,138] Furthermore, some studies show this allele to have either protective or risk effects, depending on the type of environment in which the individual lives. These discrepancies are likely to be a consequence of different levels of exposure to endotoxin or similar microbial components. For example, in a birth cohort study, only the low-responder, 'CC' homozygous group demonstrated strong dose-response relationships between higher house dust endotoxin levels and less subsequent allergic sensitization to inhalant allergens, less AD and more nonatopic wheeze.[139] Similarly, the C allele was found to be protective in children living in a subset of homes where measured endotoxin levels were high.[140] In another birth cohort study, the protective effect of dog ownership on AD in infancy occurred only in those who were of the CD14 'TT' genotype.[88]
2. *Glutathione S-transferases (GSTs), environmental tobacco smoke (ETS) and diesel exhaust*: Genetic susceptibility to common air pollutant exposures increases the risk of childhood asthma. For example, polymorphisms in the endogenous antioxidant GST genes (e.g. *GST-M1* null) were associated with less asthma in children; these associations were strengthened when genetic GST susceptibility was combined with maternal smoking.[141–143] In a longitudinal birth cohort study, diesel exhaust particulate exposure was associated with persistent wheezing only in those children carrying a specific genotypic variant in GST-P1 (valine at position 105).[144] Similar to the GST polymorphisms, genetic variants in chromosome 17q21 increased the risk of early-onset asthma; this risk was further increased by early ETS exposure.[145]

These findings demonstrate how ordinary environmental exposures conspire with genetic susceptibilities to exert stronger effects on the development of asthma and allergy than either genes or environmental exposures alone.

Prevention Studies

Early-intervention studies to prevent the development of allergic disease and asthma have had limited success so far. Nevertheless, because of their prospective design, such studies can add valuable insights to the natural history of allergic diseases.

AVOIDANCE VERSUS EARLY INTRODUCTION OF ALLERGENIC FOODS

In a 7-year randomized, controlled intervention study (Kaiser Permanente San Diego), in which the common allergenic foods (cow's milk, peanut, egg, fish) were eliminated from the diets of at-risk infants (i.e. one parent with an atopic disorder and allergen sensitization) from the third trimester of pregnancy to 24 months of life, the prevalence of food allergen sensitization, AD and urticarial rash was reduced in the first year of life,[115] but did not persist at either age 4 or 7 years, and no effect was observed on inhalant allergen sensitization or allergic airways conditions[32] (see Figure 2-1).

In contrast, in observational studies, introduction of allergenic foods in early infancy has been associated with a lower prevalence of specific food allergy. Infants introduced to egg at 4 to 6 months of age had a significantly lower risk of egg allergy, especially if first exposed to cooked egg (as opposed to egg in baked goods).[146] A 10-fold higher prevalence of peanut allergy in Jewish children in the UK versus Israel was linked to dietary differences: Israeli infants consume peanuts in a teething biscuit, while UK infants avoid peanuts.[147] A clinical trial to determine if early introduction of peanut in infants' diets can prevent peanut allergy by oral tolerance induction is ongoing (Learning Early About Peanut Allergy [LEAP] study).[148]

INHALANT ALLERGEN ELIMINATION/REDUCTION

Randomized clinical trials of home inhalant allergen reduction beginning pre birth have had mixed results. An intensive indoor allergen reduction intervention did not affect the risk of respiratory symptoms, wheeze, rhinitis or AD at age 3 years; although intervention was associated with a higher prevalence of allergic sensitization, it was conversely associated with better lung function, i.e. lower airways resistance.[149] Addition of thorough dust mite reduction measures to food allergen avoidance for 1 year reduced the likelihood of AD from 1 to 4 years of age and reduced the incidence of allergen sensitization at age 4 years.[150–152] Decreased asthma was observed in the first year of life but not at age 2 or 4 years. An intervention including house dust, pets and ETS avoidance, breastfeeding and delayed introduction of solid foods was associated with a lower risk of asthma at age 7 years; BHR, allergic sensitization, AR and AD were not affected.[153] A systematic review and meta-analysis of three multifaceted and six monofaceted allergen reduction trials suggested that reduction in exposure to multiple indoor allergens, but not monoallergen interventions, modestly reduced the likelihood of asthma in children.[154] The modest effect of these allergen reduction interventions may be attributable to the partial effectiveness of these specific interventions in lowering home allergen levels, allergen exposure that occurs outside of the home, and the potential unintended effect of the interventions on other environmental disease modifiers (e.g. endotoxin). Improving allergen reduction/elimination (i.e. dehumidification[155]) could potentially be more effective. Dust mite-sensitive children with asthma who have been moved to high-altitude locales without dust mite allergen,[156,157] or whose bedrooms have undergone extensive mite reduction measures,[60,61,158] experience significant asthma improvement, sometimes dramatically.

BREASTFEEDING

This has been addressed in prospective studies discussed earlier in this chapter.

ENVIRONMENTAL TOBACCO SMOKE ELIMINATION/REDUCTION

The acquisition of definitive proof of the preventive value of reducing or eliminating ETS exposure in infancy and childhood

https://CafePezeshki.IR

has been hindered by the difficulties in achieving long-term smoking cessation in randomized, controlled studies. ETS exposure at all ages, from prenatal exposure of mothers to smoking in asthmatic adults, is associated with more wheezing problems and more severe disease and is discussed earlier in this chapter. When considered with other health benefits of ETS exposure avoidance, this is strongly recommended.

Pharmacologic Intervention

Several studies have attempted to determine if conventional therapy for allergy and asthma may be able to alter the natural course of the allergic march or to prevent persistent allergic disease and chronic asthma.

ANTIHISTAMINES

In the Early Treatment of the Atopic Child (ETAC) study, the antihistamine cetirizine was administered for 18 months to young children at high risk for asthma. Of subjects receiving cetirizine, only young children with early allergen sensitization to mites or grass pollen were less likely to develop asthma symptoms.[159,160]

CONVENTIONAL 'CONTROLLER' PHARMACOTHERAPY FOR ASTHMA

In the CAMP study, 5- to 12-year-old children were treated with daily inhaled corticosteroid (ICS, budesonide), daily inhaled nonsteroidal antiinflammatory medication (nedocromil) or placebo for more than 4 years; treatment was then discontinued.[29] During treatment, the ICS-treated subjects demonstrated significant improvement in most of the clinical outcomes and lung function measures of asthma. After ICS discontinuation, however, the ICS-treated group regressed to that of the placebo group. Nedocromil-treated subjects did not improve. This suggests that, although long-term ICS administration in school-age children with asthma improves asthma severity, it does not alter its natural course.

Similarly, randomized controlled trials with ICS administered earlier in life have not demonstrated a preventive effect on persistent asthma. Daily or intermittent 2-week ICS courses administered to infants for episodic wheezing did not improve asthma, wheeze or lung function outcomes in later childhood.[161,162] Daily ICS administered for 2 years to toddler-age children meeting modified asthma predictive indices for persistent asthma (Figure 2-4) improved clinical asthma while on treatment, but did not affect asthma persistence during a third treatment-free year.[163] As a meta-analysis of 29 studies of infants and preschoolers with recurrent wheezing or asthma concluded, daily ICS improves respiratory symptoms, exacerbations and lung function, but does not appear to improve the natural course of asthma.[164]

ALLERGEN-SPECIFIC IMMUNOTHERAPY

Allergen-specific immunotherapy (AIT) has been studied to determine if it can reduce the likelihood of asthma development in children with AR. A recently published randomized, controlled study found that a 3-year AIT course administered to children with birch and/or grass pollen AR reduced rhinoconjunctivitis severity, conjunctival sensitivity to allergen and the likelihood of developing asthma at 2 and 7 years after AIT discontinuation.[165,166] AIT also prevents the development of new sensitization to inhalant allergens.[167,168] These studies suggest that AIT may alter the allergic march of inhalant allergen sensitization and asthma, but the difficulties and risks of conventional AIT in children warrant careful consideration.

PROBIOTICS

Some studies suggest that oral probiotic supplementation in infancy may prevent atopy by promoting Th1-type and/or regulatory T lymphocyte immune development. In breastfeeding mothers who received lactobacillus supplementation, breast milk had higher concentrations of the antiinflammatory cytokine TGF-β, and their infants had a reduced risk of AD of 0.32.[169] Lactobacillus ingestion has also been associated with increased infant peripheral blood IL-10 production and serum IL-10 levels.[170] A meta-analysis of six randomized controlled trials to prevent AD in children, usually beginning with maternal intake before birth, reported less AD in the probiotic-treated group.[171] Other clinical trials with lactobacillus or combined pro-/prebiotics demonstrated reduced respiratory infection illnesses in young children.[172–174] A large randomized controlled trial ($N = 1,018$) of pre-/probiotic supplementation to prevent allergies found no significant differences in allergic sensitization, AD, AR or asthma at 5 years of age; however, it significantly reduced the odds ratio (0.47) of IgE-associated allergic disease in cesarean-delivered children.[175] Differences in the specific probiotic strains used in the different clinical trials may contribute to the differences in findings between studies.

Conclusions

To summarize, allergic diseases and asthma commonly develop in the early childhood years. Current paradigms of immune development and lung growth shape the understanding of disease pathogenesis. The systemic nature of these conditions is such that manifestations of one allergic condition are often risk factors for others (e.g. AD and allergen sensitization are risk factors for persistent asthma). Although many allergy and asthma sufferers improve and can even become disease-free as adults, those with severe disease and some particular conditions (e.g. peanut allergy) are likely to have lifelong disease.

ACKNOWLEDGMENT

Our sincere gratitude to our colleague, Dr. Lynn Taussig, for his previous authorship of this chapter and his legacy of natural history investigation in childhood asthma.

The Genetics of Allergic Disease and Asthma

SAMUEL A. COLLINS | GABRIELLE A. LOCKETT | JOHN W. HOLLOWAY

KEY POINTS

- Asthma and atopy are examples of complex genetic diseases that, despite a strong genetic component, do not exhibit simple Mendelian inheritance.
- The many genes involved have 'mild' mutations with small phenotypic effects that combine to influence disease phenotype.
- Numerous genes have been identified that are associated with asthma, atopy, atopic dermatitis and allergic rhinitis. Recent advances have largely been due to improvements in whole genome approaches.
- Research has now moved on to the modifying effects of environment on these genetic susceptibilities including the role of epigenetic changes.
- The hope is that we are now moving into an era of clinical application of these genetic findings such as the use of pharmacogenetics to tailor asthma treatment.

Since the first report of linkage between chromosome 11q13 and atopy in 1989,[1] there have been thousands of published studies of the genetics of asthma and other allergic diseases. Their aim is to identify the genetic factors that modify susceptibility to allergic diseases, determine severity of disease in affected individuals and affect the response to treatment. This recent expansion in our knowledge has provided intriguing insights into the pathophysiology of these complex disorders. In this chapter, we outline the approaches used to undertake genetic studies of common diseases such as atopic dermatitis and asthma and provide examples of how these approaches are beginning to reveal new insights into the pathophysiology of allergic diseases.

Why Undertake Genetic Studies of Allergic Disease?

Susceptibility to allergic disease is likely to result from the inheritance of many gene variants but the underlying cellular defects are unknown. By undertaking research into the genetic basis of these conditions, these gene variants and their gene products can be identified solely by the anomalous phenotypes they produce. Identifying the genes that produce these disease phenotypes provides a greater understanding of the fundamental mechanisms of these disorders, stimulating the development of specific new drugs or biologics to both relieve and prevent symptoms. In addition, genetic variants may also influence the response to therapy and the identification of individuals with altered response to current drug therapies will allow optimization of current therapeutic measures (i.e. disease stratification and pharmacogenetics). The study of genetic factors in large longitudinal cohorts with extensive phenotype and environmental information allows the identification of external factors that initiate and sustain allergic diseases in susceptible individuals and the periods of life in which this occurs, with a view to identifying those environmental factors that could be modified for disease prevention or for changing the natural history of the disorder. For example, early identification of vulnerable children would allow targeting of preventative therapy or environmental intervention, such as avoidance of allergen exposure. Genetic screening in early life may eventually become a practical and cost-effective option for allergic disease prevention.

Approaches to Genetic Studies of Complex Genetic Diseases

WHAT IS A COMPLEX GENETIC DISEASE?

The use of genetic analysis to identify genes responsible for simple Mendelian traits such as cystic fibrosis[2] has become almost routine in the 30 years since it was recognized that genetic inheritance can be traced with naturally occurring DNA sequence variation.[3] However, many of the most common medical conditions known to have a genetic component to their etiology, including diabetes, hypertension, heart disease, schizophrenia and asthma, have much more complex inheritance patterns.

Complex disorders show a clear hereditary component, however the mode of inheritance does not follow any simple Mendelian pattern. Furthermore, unlike single-gene disorders, they tend to have an extremely high prevalence. Asthma occurs in at least 10% of children in the UK, and atopy is as high as 40% in some population groups[4] as compared to cystic fibrosis at 1 in 2,000 live white births. Characteristic features of Mendelian diseases are that they are rare and involve mutations in a single gene that are 'severe', resulting in large phenotypic effects that may be independent of environmental influences. In contrast, complex disease traits are common and involve many genes, with 'mild' mutations leading to small phenotypic effects with strong environmental interactions.

HOW TO IDENTIFY GENES UNDERLYING COMPLEX DISEASE

Before any genetic study of a complex disease can be initiated, there are a number of different factors that need to be

https://CafePezeshki.IR

considered. These include: (1) assessing the heritability of a disease of interest to establish whether there is indeed a genetic component to the disease in question; (2) defining the phenotype (or physical characteristics) to be measured in a population; (3) the size and nature of the population to be studied; (4) determining which genetic markers are going to be typed in the DNA samples obtained from the population; (5) how the relationships between the genetic data and the phenotype measures in individuals are to be analyzed and (6) how the resulting data can be used to identify the genes underlying the disease.

One of the most important considerations in genetic studies of complex disease susceptibility is the choice of the methods of genetic analysis to be used. This choice will both reflect and be reflected in the design of the study. Will the study be a population study or a family-based study? What numbers of subjects will be needed?

Inheritance

The first step in any genetic analysis of a complex disease is to determine whether genetic factors contribute at all to an individual's susceptibility to disease. The fact that a disease has been observed to 'run in families' may reflect common environmental exposures and biased ascertainment, as well as a potential true genetic component. There are a number of approaches that can be taken to determine if genetics contributes to a disease or disease phenotype of interest including family studies, segregation analysis, twin and adoption studies, heritability studies and population-based relative risk to relatives of probands.

There are three main steps involved in the identification of genetic mechanisms for a disease.[5,6]

1. Determine whether there is familial aggregation of the disease – does the disease occur more frequently in relatives of cases than of controls?
2. If there is evidence for familial aggregation, is this because of genetic effects or other factors such as environmental or cultural effects?
3. If there are genetic factors, which specific genetic mechanisms are operating?

The exact methods used in this process will vary depending on a number of disease-specific factors. For example, is the disease of early or late onset, and is the phenotype in question discrete or continuous (e.g. insulin resistance or blood pressure)?

Family studies involve the estimation of the frequency of the disease in relatives of affected, compared with unaffected, individuals. The strength of the genetic effect can be measured as λ_R, where λ_R is the ratio of risk to relatives of type R (sibs, parents, offspring, etc.) compared with the population risk ($\lambda_R = \kappa_R/\kappa$, where κ_R is the risk to relatives of type R and κ is the population risk). The stronger the genetic effect, the higher the value of λ. For example, for a recessive single-gene Mendelian disorder such as cystic fibrosis, the value of λ is about 500; for a dominant disorder such as Huntington's disease, it is about 5,000. For complex disorders the values of λ are much lower, e.g. 20–30 for multiple sclerosis, 15 for insulin-dependent diabetes mellitus (IDDM), and 4 to 5 for Alzheimer's disease. It is important to note, though, that λ is a function of both the strength of the genetic effect and the frequency of the disease in the population. Therefore, if a disease has a λ value of 3 to 4 it does not mean that genes are less important in that trait than in a trait with a λ of 30 to 40. A strong effect in a very common disease will have a smaller λ than the same strength of effect in a rare disease.

Determining the relative contribution of common genes versus common environment to clustering of disease within families can be undertaken using twin studies where the concordance of a trait in monozygotic and dizygotic twins is assessed. Monozygotic twins have identical genotypes, whereas dizygotic twins share, on average, only one half of their genes. In both cases, they share the same childhood environment. Therefore, a disease that has a genetic component is expected to show a higher rate of concordance in monozygotic than in dizygotic twins. Another approach used to disentangle the effects of nature versus nurture in a disease is in adoption studies, where, if the disease has a genetic basis, the frequency of the disease should be higher in biologic relatives of probands than in their adopted family.

Once familial aggregation with a probable genetic etiology for a disease has been established, the mode of inheritance can be determined by observing the pattern of inheritance of a disease or trait and how it is distributed within families. For example, is there evidence of a single major gene and is it dominantly or recessively inherited? Segregation analysis is the most established method for this purpose. The observed frequency of a trait in offspring and siblings is compared with the distribution expected with various modes of inheritance. If the distribution is significantly different than predicted, that model is rejected. The model that cannot be rejected is therefore considered the most likely. However, for complex disease, it is often difficult to undertake segregation analysis, because of the multiple genetic and environmental effects making any one model hard to determine. This has implications for the methods of analysis of genetic data in studies, because some methods, such as the parametric logarithm (base 10) of odds (LOD) score approach, require a model to be defined to obtain estimates of parameters such as gene frequency and penetrance (see Approaches to analysis).

Phenotype

Studies of a genetic disorder require that a phenotype be defined, to which genetic data are compared. Phenotypes can be classified in two ways. They may be complex, such as asthma or atopy, and are likely to involve the interaction of a number of genes. Alternatively, intermediate phenotypes may be used, such as bronchial hyperresponsiveness (BHR) and eosinophilia for asthma and serum immunoglobulin E (IgE) levels and specific IgE responsiveness or positive skin prick tests to particular allergens for atopy. Together, these phenotypes contribute to an individual's expression of the overall complex disease phenotype but are likely to involve the interaction of fewer genetic influences, thus increasing the chances of identifying specific genetic factors predisposing toward the disease. Phenotypes may also be discrete or qualitative, such as the presence or absence of wheeze, atopy and asthma, or quantitative. Quantitative phenotypes, such as blood pressure (mm Hg), lung function measures (e.g. FEV_1) and serum IgE levels, are phenotypes that can be measured as a continuous variable. With quantitative traits, no arbitrary cut-off point has to be assigned (making quantitative trait analysis important), because clinical criteria used to define an affected or an unaffected phenotype may not reflect whether an individual is a gene carrier or not. In addition, the use of quantitative phenotypes allows the use of alternative methods of genetic analysis that, in some situations, can be more powerful. Cluster analysis has been used to identify individual phenotypic expressions of asthma in a population sample.[7,8]

https://CafePezeshki.IR

Population

Having established that the disease or phenotype of interest does have a genetic component to its etiology, the next step is to recruit a study population in which to undertake genetic analyses to identify the gene(s) responsible. The type and size of study population recruited depend heavily on a number of interrelated factors, including the epidemiology of the disease, the method of genetic epidemiologic analysis being used, and the class of genetic markers genotyped. For example, the recruitment of families is necessary to undertake linkage analysis, whereas association studies are better suited to either a randomly selected or case-control cohort. In family-based linkage studies, the age of onset of a disease will determine whether it is practical to collect multigenerational families or affected sib pairs for analysis. Equally, if a disease is rare, then actively recruiting cases and matched controls will be a more practical approach compared to recruiting a random population that would need to be very large to have sufficient power.

Genetic Markers

Genetic markers used can be any identifiable site within the genome (locus), where the DNA sequence is variable (polymorphic between individuals). The most common genetic markers used for linkage analysis are microsatellite markers comprising short lengths of DNA consisting of repeats of a specific sequence (e.g. CA_n). The number of repeats varies between individuals, thus providing polymorphic markers that can be used in genetic analysis to follow the transmission of a chromosomal region from one generation to the next. Single-nucleotide polymorphisms (SNPs) are the simplest class of polymorphism in the genome resulting from a single base substitution: for example cytosine substituted for thymidine. SNPs are much more frequent than microsatellites in the human genome, occurring in introns, exons, promoters and intergenic regions, with several million SNPs now having been identified and mapped.[9] Another source of variation in the human genome that has recently been recognized to be present to a much greater extent than was previously thought is copy number variations (CNVs). CNVs are either a deletion or insertion of a large piece of DNA sequence; CNVs can contain whole genes and therefore are correlated with gene expression in a dose-dependent manner.[10] Sequencing of an individual human genome revealed that non-SNP variation (which includes CNVs) made up 22% of all variation in that individual but involved 74% of all variant DNA bases in that genome.[11]

Approaches to Analysis

Linkage analysis involves proposing a model to explain the inheritance pattern of phenotypes and genotypes observed in a pedigree.[12] Linkage is evident when a gene that produces a phenotypic trait and its surrounding markers are co-inherited. In contrast, those markers not associated with the anomalous phenotype of interest will be randomly distributed among affected family members as a result of the independent assortment of chromosomes and crossing over during meiosis. In complex disease, non-parametric linkage approaches, such as allele sharing, are usually used. Allele-sharing methods test whether the inheritance pattern of a particular chromosomal region is not consistent with random Mendelian segregation by showing that pairs of affected relatives inherit identical copies of the region more often than would be expected by chance.[13] While family-based analysis utilizing linkage analysis or allele-sharing methods was the mainstay of gene identification for monogenic diseases in the past, it has been largely superseded for analysis of common disease by the use of genome-wide association studies (for common variants) and next-generation sequencing of whole or partial (e.g. protein-coding fraction or exome) individual genomes.

Association studies do not examine inheritance patterns of alleles; rather, they are case-control studies based on a comparison of allele frequencies between groups of affected and unaffected individuals from a population. The odds ratio of the trait in individuals is then assessed as the ratio of the frequency of the allele in the affected population compared with the unaffected population. The greatest problem in association studies is the selection of a suitable control group to compare with the affected population group. Although association studies can be performed with any random DNA polymorphism, they have the most significance when applied to polymorphisms that have functional consequences in genes relevant to the trait (candidate genes).

It is important to remember with association studies that there are a number of reasons leading to an association between a phenotype and a particular allele:

- A positive association between the phenotype and the allele will occur if the allele is the cause of, or contributes to, the phenotype. This association would be expected to be replicated in other populations with the same phenotype, unless there are several different alleles at the same locus contributing to the same phenotype, in which case association would be difficult to detect, or if the trait was predominantly the result of different genes in the other population (genetic heterogeneity).
- Positive associations may also occur between an allele and a phenotype if that particular allele is in linkage disequilibrium (LD) with the phenotype-causing allele. That is, the allele tends to occur on the same parental chromosome that also carries the trait-causing mutation more often than would be expected by chance. Linkage disequilibrium will occur when most causes of the trait are the result of relatively few ancestral mutations at a trait-causing locus and the allele is present on one of those ancestral chromosomes and lies close enough to the trait-causing locus that the association between them has not been eroded away through recombination between chromosomes during meiosis. LD is the non-random association of adjacent polymorphisms on a single strand of DNA in a population; the allele of one polymorphism in an LD block (haplotype) can predict the allele of adjacent polymorphisms (one of which could be the causal variant).
- Positive association between an allele and a trait can also be artefactual as a result of recent population admixture. In a mixed population, any trait present in a higher frequency in a subgroup of the population (e.g. an ethnic group) will show positive association with an allele that also happens to be more common in that population subgroup.[14] Thus, to avoid spurious association arising through admixture, studies should be performed in large, relatively homogeneous populations. An alternative method to test for association in the presence of linkage is the 'transmission test for linkage disequilibrium'

https://CafePezeshki.IR

(transmission/disequilibrium test [TDT]).[15,16] The TDT uses families with at least one affected child, and the transmission of the associated marker allele from a heterozygous parent to an affected offspring is evaluated. If a parent is heterozygous for an associated allele *A1* and a non-associated allele *A2,* then *A1* should be passed on to the affected child more often than *A2*.

Historically, association studies were not well suited to whole genome searches in large mixed populations. Because linkage disequilibrium extends over very short genetic distances in an old population, many more markers would need to be typed to 'cover' the whole genome. Therefore, genome-wide searches for association were more favorable in young, genetically isolated populations, because linkage disequilibrium extends over greater distances and the number of disease-causing alleles is likely to be fewer.

However, advances in array-based SNP genotyping technologies and haplotype mapping of the human genome[17] mean genome-wide association studies (GWAS) have revolutionized the study of genetic factors in complex common disease over the last decade.[18,19] For more than 150 phenotypes – from common diseases to physiological measurements such as height and BMI and biological measurements such as circulating lipid levels and blood eosinophil levels – GWAS have provided compelling statistical associations for thousands of different loci in the human genome[20] and are now the method of choice for identification of genetic variants influencing physiological or disease phenotypes.

Identify Gene

If, as in most complex disorders, the exact biochemical or physiologic basis of the disease is unknown, there are three main approaches to finding the disease gene(s). One method is to test markers randomly spaced throughout the entire genome for linkage with the disease phenotype. If linkage is found between a particular marker and the phenotype, then further typing of genetic markers including SNPs and association analysis will enable the critical region to be further narrowed. The genes positioned in this region can be examined for possible involvement in the disease process and the presence of disease-causing mutations in affected individuals. This approach is often termed *positional cloning,* or *genome scanning* if the whole genome is examined in this manner. Although this approach requires no assumptions to be made as to the particular gene involved in genetic susceptibility to the disease in question, it does require considerable molecular genetic analysis to be undertaken in large family cohorts, involving considerable time, resource and expense.

As noted above, this approach has now been superseded by genome-wide association studies using SNPs evenly spaced throughout the genome as an assumption-free approach to locate disease-associated genes involved in disease pathogenesis. As GWAS utilize large data sets, up to one million SNPs to test for association, stringent genotype calling, quality control, population stratification (genomic controls) and statistical techniques have been developed to handle the analysis of such data.[21] Studies start by reporting single marker analyses of primary outcome; SNPs are considered to be strongly associated if the P-values are below the 1% false discovery rate (FDR) or showing weak association above 1% but below the 5% FDR. A cluster of P-values below the 1% FDR from SNPs in one chromosomal location is defined as the region of 'maximal association' and is the first candidate gene region to examine further, with analysis of secondary outcome measures, gene database searches, fine mapping to find the causal locus and replication in other cohorts/populations. It is unlikely that the SNP showing the strongest association will be the causal locus, as SNPs are chosen to provide maximal coverage of variation in that region of the genome and not on biological function. Therefore, GWAS will often include fine mapping/haplotype analysis of the region with the aim of identifying the causal locus. If linkage disequilibrium prevents the identification of a specific gene in a haplotype block, then it may be necessary to utilize different racial and ethnic populations to hone in on the causative candidate gene that accounts for the genetic signal in GWAS.[22]

Finally, candidate genes can be selected for analysis because of a known role for the encoded product of the gene in the disease process. The gene is then screened for polymorphisms, which are tested for association with the disease or phenotype in question. A hybrid approach is the selection of candidate genes based not only on their function but also on their position within a genetic region previously linked to the disease (positional candidate). This approach may help to reduce the considerable work required to narrow a large genetic region of several megabases of DNA identified through linkage containing tens to hundreds of genes to one single gene to test for association with the disease.

Once a gene has been identified, further work is required to understand its role in the disease pathogenesis. Further molecular genetic studies may help to identify the precise genetic polymorphism that is having functional consequences for the gene's expression or function as opposed to those that are merely in linkage disequilibrium with the causal SNP. Often the gene identified may be completely novel and cell and molecular biology studies will be needed to understand the gene product's role in the disease and to define genotype/phenotype correlations. Furthermore, by using cohorts with information available on environmental exposures, it may be possible to define how the gene product may interact with the environment to cause disease. Ultimately, knowledge of the gene's role in disease pathogenesis may lead to the development of novel therapeutics.

ALLERGY AND ASTHMA AS COMPLEX GENETIC DISEASES

From studies of the epidemiology and heritability of allergic diseases, it is clear that these are complex diseases in which the interaction between genetic and environmental factors plays a fundamental role in the development of IgE-mediated sensitivity and the subsequent development of clinical symptoms. The development of IgE responses by an individual, and therefore allergies, is the function of several genetic factors. These include the regulation of basal serum immunoglobulin production, the regulation of the switching of Ig-producing B cells to IgE, and the control of the specificity of responses to antigens. Furthermore, the genetic influences on allergic diseases such as asthma are more complex than those on atopy alone, involving not only genes controlling the induction and level of an IgE-mediated response to allergen but also 'lung-' or 'asthma'-specific genetic factors that result in the development of asthma. This also applies equally to other clinical manifestations of atopy such as rhinitis and atopic dermatitis.

Phenotypes for Allergy and Allergic Disease: What Should We Measure?

The term *atopy* (from the Greek word for 'strangeness') was originally used by Coca and Cooke[23] in 1923 to describe a particular predisposition to develop hypersensitivity to common allergens associated with an increase of circulating reaginic antibody, now defined as IgE, and with clinical manifestations such as whealing-type reactions, asthma and hay fever. Today, even if the definition of *atopy* is not yet precise, the term is commonly used to define a disorder involving IgE antibody responses to ubiquitous allergens that is associated with a number of clinical disorders such as asthma, allergic dermatitis, allergic conjunctivitis and allergic rhinitis.

Atopy can be defined in several ways, including raised total serum IgE levels, the presence of antigen-specific IgE antibodies, and/or a positive skin test to common allergens. Furthermore, because of their complex clinical phenotype, atopic diseases can be studied using intermediate or surrogate disease-specific measurements such as BHR or lung function for asthma. As discussed earlier, phenotypes can be defined in several ways: subjective measures (e.g. symptoms), objective measures (e.g. BHR, blood eosinophils or serum IgE levels), or both. In addition, some studies have used quantitative scores that are derived from both physical measures such as serum IgE and BHR and questionnaire data.[24,25] It is a lack of a clear definition of atopic phenotypes that presents the greatest problem when reviewing studies of the genetic basis of atopy, with multiple definitions of the same intermediate phenotype often being used in different studies. Likewise, the definition of asthma can be problematic as this can be clinical (symptoms, parental reports), pharmacological (bronchodilator reversibility, steroid responsiveness) or derived from intermediate measures (BHR, lung function).

The Heritability of Atopic Disease: Are Atopy and Atopic Disease Heritable Conditions?

In 1916, the first comprehensive study of the heritability of atopy was undertaken by Robert Cooke and Albert Vander Veer[26] at the Department of Medicine of the Postgraduate Hospital and Medical School of New York. Although the atopic conditions they included, as well as those excluded (e.g. eczema), may be open for debate today, the conclusions nonetheless remain the same: that there is a high heritable component to the development of atopy and atopic disease, and as is now more clearly understood biologically, this is owing to the inheritance of a tendency to generate specific IgE responses to common proteins.

Subsequent to the work of Cooke and Vander Veer, the results of many studies have established that atopy and atopic disease such as asthma, rhinitis and eczema have strong genetic components. Family studies have shown an increased prevalence of atopy, and phenotypes associated with atopy, among the relatives of atopic compared with non-atopic subjects.[27–29] In a study of 176 normal families, Gerrard and colleagues[30] found a striking association between asthma in the parent and asthma in the child, between hay fever in the parent and hay fever in the child, and between eczema in the parent and eczema in the child. These studies suggest that 'end-organ sensitivity', or which allergic disease an allergic individual will develop, is controlled by specific genetic factors, differing from those that determine susceptibility to atopy per se. This hypothesis is borne out by a questionnaire study involving 6,665 families in southern Bavaria. Children with atopic diseases had a positive family history in 55% of cases compared with 35% in children without atopic disease ($P < .001$).[31] Subsequent researchers used the same population to investigate familial influences unique to the expression of asthma and found that the prevalence of asthma alone (i.e. without hay fever or eczema) increased significantly if the nearest of kin had asthma alone (11.7% vs 4.7%, $P < .0001$). A family history of eczema or hay fever (without asthma) was unrelated to asthma in the offspring.[32]

Numerous twin studies[33–39] have shown a significant increase in concordance for atopy among monozygotic twins compared with dizygotic twins, and both twin and family studies have shown a strong heritable component to atopic asthma.[37,38,40–42] Using a twin-family model, Laitinen and colleagues[43] reported that in families with asthma in successive generations, genetic factors alone accounted for as much as 87% of the development of asthma in offspring, and the incidence of the disease in twins with affected parents is 4-fold compared with the incidence in twins without affected parents. This indicates that asthma is recurring in families as a result of shared genes rather than shared environmental risk factors. This has been further substantiated in a study of 11,688 Danish twin pairs suggesting that 73% of susceptibility to asthma was the result of the genetic component. However, a substantial part of the variation in liability of asthma was the result of environmental factors; there also was no evidence for genetic dominance or shared environmental effects.[44]

Molecular Regulation of Atopy and Atopic Disease, I: Susceptibility Genes

POSITIONAL CLONING BY GENOME-WIDE SCREENS

Many genome-wide screens for atopy and atopic disorder susceptibility genes have been undertaken.[45,46] Multiple regions of the genome have been observed to be linked to varying phenotypes with differences between cohorts recruited from both similar and different populations. This illustrates the difficulty of identifying susceptibility genes for complex genetic diseases. Different genetic loci will show linkage in populations of different ethnicities and different environmental exposures. As mentioned earlier, in studies of complex disease, the real challenge has not been identification of regions of linkage, but rather identification of the precise gene and genetic variant underlying the observed linkage. To date, several genes have been identified as the result of positional cloning using a genome-wide scan for allergic disease phenotypes, including for example *ADAM33, GPRA, DPP10, PHF11* and *UPAR* for asthma, *COL29A1* for atopic dermatitis and *PCDH1* for bronchial hyperresponsiveness.

GENES IDENTIFIED BY GENOME-WIDE ASSOCIATION STUDIES

Subsequent to positional cloning studies, improvements in technology have now enabled genome-wide association studies

https://CafePezeshki.IR

to be performed with great success in allergic diseases such as asthma, eczema and allergic sensitization. Figure 3-1 illustrates allergy-associated genes reported in GWAS for asthma, rhinitis, serum IgE, atopy and atopic dermatitis, and the overlap between genes associated with different allergic diseases.

The first novel asthma susceptibility locus to be identified by a GWAS approach contains the *ORMDL3* and *GSDML* genes on chromosome 17q12-21.1.[47] 317,000 SNPs (in genes or surrounding sequences) were characterized in 994 subjects with childhood-onset asthma and 1,243 non-asthmatics followed by replication in a further 2,320 subjects that revealed five significantly associated SNPs. Following gene expression studies, *ORMDL3* was found to be strongly associated with disease-associated markers ($P < 10^{-22}$ for rs7216389) identified by the GWAS.

Importantly, a number of subsequent studies have replicated the association between variation in the chromosome 17q21 region (mainly rs7216389) and childhood asthma in ethnically diverse populations.[48–51] A GWAS by the GABRIEL consortium[52] of 26,475 people confirmed the association between

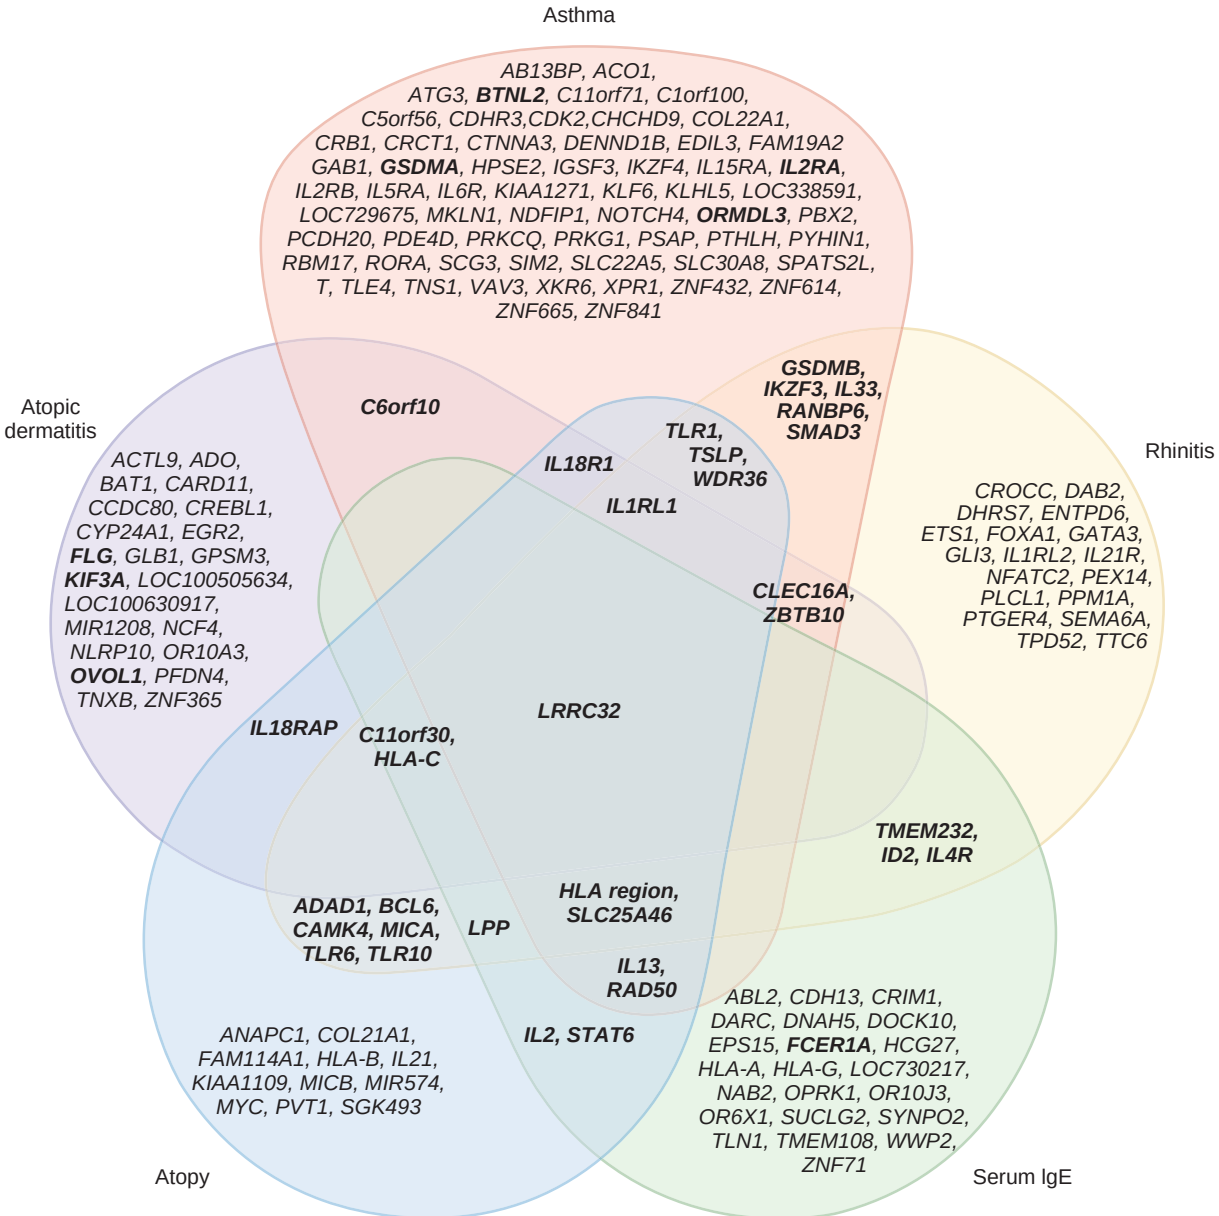

Figure 3-1 Overlapping sets of genes have been reported in genome-wide association studies for asthma, rhinitis, serum IgE levels, atopy and atopic dermatitis, supporting a common genetic element within the mechanisms predisposing individuals toward different allergic disease phenotypes. GWAS have also identified many genes in association with only one allergic disease phenotype – these most likely represent the tissue-specific component of each allergic disease (e.g. *FLG* in the epidermal barrier in atopic dermatitis). To date, more GWAS have been conducted analyzing genetic variants associated with asthma than with other allergic diseases. In the future it is likely that more risk variants for other allergic diseases will be identified.

Genes reported in more than one GWAS are shown in bold font. The gene/s reported for SNPs detected to be significantly associated ($P \leq 1 \times 10^{-5}$) with each allergic disease phenotype were obtained by searching the NHGRI GWAS catalog (http://www.genome.gov/gwastudies, accessed 4 August 2014).

https://CafePezeshki.IR

GSDML-ORMDL3 and childhood-onset asthma as well as implicating a number of genes involved in Th2 activation including *IL33*, *IL1RL1* and *SMAD*. The loci associated with asthma were not associated with serum IgE levels.

However, a study of association between SNPs and gene expression levels found that a distant SNP rs1051740 (greater than 4 megabases away and on a different chromosome) in the *EPHX1* gene associates with *ORMDL3* gene expression at a more significant level than rs7216389.[53] Long-distance genomic interactions can mean that the gene within which the SNP is located is not necessarily the causal gene.[54,55] Therefore, it is important to remember that considerable work is still required to fully characterize this region of the genome before accepting *ORMDL3* as the causal gene through 'guilt by association' because many genes in a region of linkage disequilibrium will be associated with disease in a GWAS without, necessarily, being the causative gene. GWAS have also identified novel genes underlying blood eosinophil levels (and also associated with asthma),[56] occupational asthma,[57] total serum IgE levels[58] and eczema.[59]

Studies of other atopic diseases have focussed on serum IgE levels and/or allergic sensitization. Weidinger et al identified a locus associated with the high-affinity IgE receptor (*FCER1A*) as strongly associated with both serum IgE and sensitization as well as confirming candidate gene findings of *STAT6* and the 5q31 region related to Th2 cytokines.[58] An Icelandic study showed an association between *IL1RL1* (the IL-33 receptor coding gene) and blood IgE levels.[56] This region was also identified in the asthma GWAS by Moffatt et al[52]; however that study did not find an association between asthma and loci associated with serum IgE levels. A meta-analysis of GWAS studies into allergic sensitization that included a total of 16,170 sensitized individuals, identified a total of 10 loci that are estimated to account for 25% of allergic sensitization and allergic rhinitis. Nine of the 10 SNPs identified also showed a directionally consistent association with asthma. Associations were also identified with atopic dermatitis, albeit weaker than with asthma. The authors also investigated known susceptibility loci and found only weak associations with total IgE levels (*FCER1A* and *HLA-A*) and asthma (17q12-21 and *IL33*). This suggests that these loci do not increase asthma risk through allergic sensitization.[60]

Until recently, very little was known of the genetic causes of atopic dermatitis (AD), aside from *filaggrin*, which is described in more detail below. However, recent studies have expanded this knowledge: a recent meta-analysis of atopic dermatitis studies by Paternoster et al on 11,025 cases and 40,398 controls revealed loci at *OVOL1* and *ACTL9* associated with epidermal proliferation and *KIF3A* in the 5q31 Th2 cytokine cluster. The study also confirmed the *filaggrin* (*FLG*) locus association.[61] Meanwhile, Weidinger et al studied childhood-onset AD and again identified the *FLG* association as well as the *KIF3A* locus mentioned above and the previously identified 11q13.5 and 5q31 regions. They also noted some overlap with asthma and psoriasis, strengthening the view that AD arises from both epithelial and immune dysfunction.[62] This theory is backed up by the discovery of an AD-associated SNP adjacent to *C11orf30*, which was previously identified as a Crohn's disease susceptibility locus, another disease of immune and epithelial dysfunction.[59] Sun et al identified *TMEM232* and *SLC25A46* at 5q22 and *TNFRSF6B* and *ZGPAT* at 20q13 in association with AD in Chinese populations.[63]

Atopic rhinitis is poorly understood but GWAS have identified loci in *C11orf30*,[64] mentioned above, as well as the HLA region, *MRPL4* and *BCAP*.[65] Candidate gene studies found an association with *IL13* loci,[66] and GWAS have identified several rhinitis-associated loci[64] and loci associated with the phenotype 'asthma and hay fever'.[67] Likewise, there is much overlap between food allergy and atopy with candidate gene studies showing associations with *CD14*, *STAT6*, *SPINK5* and *IL10*[68] but, to date, there have been no GWAS in food allergy.

These studies show the power of the GWAS approach for identifying complex disease susceptibility variants and current research is both expanding these known variants and confirming their associations with clinical phenotypes.[69] GWAS has now moved on from simple loci of association with a broad disease definition, such as asthma, and studies are now identifying particular regions associated with phenotypes of disease or subgroups. For example, Du et al identified *CRTAM* as associated only with asthma exacerbations in those with low vitamin D, and another recent GWAS has identified *CDHR3* as being associated with severe asthma.[70] We are also gaining a better understanding of how atopic and non-atopic asthma overlap with other atopic diseases such as atopic dermatitis[61] and rhinitis.[71] We may also be able to integrate epigenetic information into the expression patterns of known and novel SNPs, for example, asthma risk resulting from the *IL4R* polymorphism rs3024685 is dramatically increased by higher levels of *IL4R* DNA methylation.[72] Although GWAS has not fully explained the heritability of asthma and atopic disease, geneticists remain optimistic, as it is believed that this 'missing heritability' can be accounted for.[73] It is thought that the inability to find genes could be explained by limitations of GWAS, such as other variants not screened for, analyses not adjusted for gene-environment and gene-gene interactions or epigenetic changes in gene expression. One explanation for missing heritability, after assessing common genetic variation in the genome, is that rare variants (below the frequency of SNPs included in GWAS studies) of high genetic effect, or common copy number variants may be responsible for some of the genetic heritability of common complex diseases.[9]

CANDIDATE GENE/GENE REGION STUDIES

A large number of candidate regions have been studied for both linkage to and association with a range of atopy-related phenotypes. In addition, SNPs in the promoter and coding regions of a wide range of candidate genes have been examined. Candidate genes are selected for analysis based on a wide range of evidence, for example biological function, differential expression in disease, involvement in other diseases with phenotypic overlap, affected tissues, cell type(s) involved and findings from animal models. There are now more than 500 studies that have examined polymorphism in more than 200 genes for association with asthma and allergy phenotypes.[45,74] When assessing the significance of association studies, it is important to consider several things. For example, was the size of the study adequately powered if negative results are reported? Were the cases and controls appropriately matched? Could population stratification account for the associations observed? In the definitions of the phenotypes, which phenotypes have been measured (and which have not)? How were they measured? Regarding correction for multiple testing, have the authors taken multiple testing into account when assessing the

https://CafePezeshki.IR

significance of association? Publications by Weiss,[75] Hall,[76] and Tabor and colleagues[77] review these issues in depth.

Genetic variants showing association with a disease are not necessarily causal, because of the phenomenon of linkage disequilibrium (LD), whereby polymorphism A is not affecting gene function but rather it is merely in LD with polymorphism B that is exerting an effect on gene function or expression. Positive association may also represent a Type I error; candidate gene studies have suffered from non-replication of findings between studies, which may be due to poor study design, population stratification, different LD patterns between individuals of different ethnicity and differing environmental exposures between study cohorts. The genetic association approach can also be limited by under-powered studies and loose phenotype definitions.[78]

An Example of a Candidate Gene: Interleukin-13

Given the importance of Th2-mediated inflammation in allergic disease, and the biological roles of *IL13*, including switching B cells to produce IgE, wide-ranging effects on epithelial cells, fibroblasts, and smooth muscle promoting airway remodeling and mucus production, *IL13* is a strong biological candidate gene. Furthermore, *IL13* is also a strong positional candidate. The gene encoding *IL13*, like *IL4*, is located in the Th2 cytokine gene cluster on chromosome 5q31 within 12 kb of *IL4*,[79] with which it shares 40% homology. This genomic location has been extensively linked with a number of phenotypes relevant to allergic disease including asthma, atopy, specific and total IgE responses, blood eosinophils and BHR.[80]

Asthma-associated polymorphisms have been identified in the *IL13* gene, including a single-base pair substitution in the promoter of *IL13* adjacent to a consensus nuclear factor of activated T cell binding sites. Asthmatics are significantly more likely to be homozygous for this polymorphism ($P = .002$, odds ratio = 8.3)[81] and the polymorphism is associated, in vitro, with reduced inhibition of *IL13* production by cyclosporine and increased transcription factor binding. Hypotheses proposed to explain the association of this *IL13* polymorphism and development of atopic disease include decreased affinity for the decoy receptor IL13Rα2, increased functional activity through IL13Rα1 and enhanced stability of the molecule in plasma (reviewed in Kasaian and Miller[82]).

An amino acid polymorphism of *IL13* has also been described: R110Q (rs20541).[83–85] The 110Q variant enhances allergic inflammation compared to the 110R wild-type IL-13[86] by inducing STAT6 phosphorylation, CD23 expression in monocytes and hydrocortisone-dependent IgE switching in B cells. It also has a lower affinity for the IL-13Rα2 decoy receptor and produced a more sustained eotaxin response in primary human fibroblasts expressing low levels of IL-13Rα2.[87]

IL-13 polymorphism associations have been inconsistent with some studies showing association with atopy in children[85,88] while others show associations with asthma and not atopy.[86] Howard and colleagues[89] also showed that the −1112 C/T variant of *IL13* contributes significantly to BHR susceptibility ($P = .003$) but not to total serum IgE levels. Thus, it is possible that polymorphisms in *IL13* may confer susceptibility to airway remodeling in persistent asthma, as well as to allergic inflammation in early life.

As discussed previously, positive association observed between an SNP and a phenotype does not imply that the SNP is casual. *IL13* lies adjacent to *IL4*, an equally strong biological candidate in which SNPs have shown association with relevant phenotypes,[90] and within the chromosome 5q31 gene cluster that is known to contain an asthma susceptibility gene. Therefore association observed with *IL13* SNPs may simply represent a proxy measure of the effect of polymorphisms in *IL4* or another gene in the region. For example, a recent genome-wide association study of total IgE levels reported significant associations between polymorphisms in an adjacent gene, *RAD50,* and total serum IgE levels,[62] in a region containing a number of evolutionary conserved non-coding sequences that may play a role in regulating *IL4* and *IL13* transcription.[91] However, given the extensive biologic evidence for functionality and recent studies examining polymorphisms across the gene region showing independent effects of the *IL13* R110Q SNP, it is likely that the reported *IL13* associations are real.

Many studies have observed positive associations of specific genetic polymorphisms with differential response to environmental factors in asthma and other respiratory phenotypes.[92,93] *IL13* levels have been shown to be increased in children whose parents smoke[94] and interaction between *IL13* −1112 C/T and smoking with childhood asthma as an outcome has been reported,[95] as well as evidence for this same SNP modulating the adverse effect of smoking on lung function in adults.[96] Thus, differences in smoking exposure between studies may account for some of the differences in findings between studies. DNA methylation is affected by both genetic variants and environment, which may later determine disease risk. For example, Patil et al demonstrated that while rs20541 polymorphisms interacted with maternal smoking to determine methylation at the cg13566430 *IL13* promoter region methylation site, a relationship between the rs1800925 SNP in the *IL13* locus and the same cg13566430 methylation site affected lung function. This demonstrates the 'two-step' model of environment and genetic variance affecting disease state, as shown in Figure 3-2.[97]

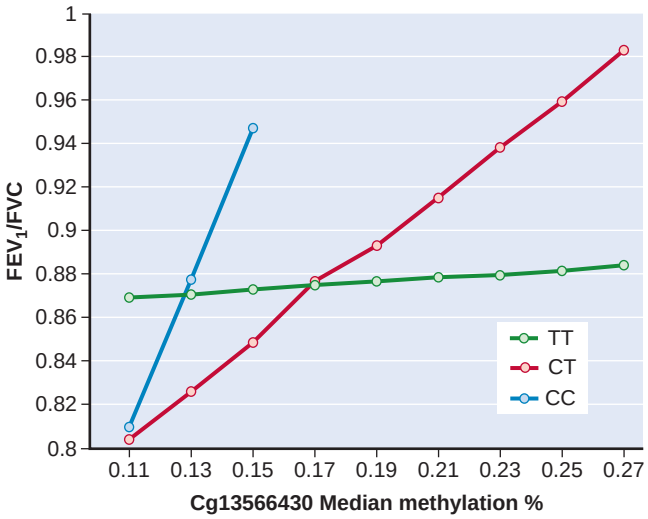

Figure 3-2 Graph showing effect of interaction between single nucleotide polymorphism (SNP) at rs1800925 (red, blue and green lines show different genotypes) and percentage methylation at cg13566430 on lung function (FEV_1/FVC). The modifying effect of genotype on the relationship between methylation and lung function demonstrates the interaction of early environment (methylation) and genetics (SNP).[98] FEV_1 – forced expiratory volume in 1 second, FVC – forced vital capacity.

https://CafePezeshki.IR

An Example of a Candidate Gene: Interleukin-33

Since its identification in 2005, *IL-33* has emerged as one of the most important cytokines in Th2 differentiation, and its receptor, ST2, is an excellent marker of Th2 cells.[99] IL-33 is a member of the IL-1 family and is located on chromosome 9, therefore separate from the chromosome 5q31 cluster of *IL13* and *IL4*, and not in LD with these genes. Its receptor is encoded by *IL1RL1* on chromosome 2, associated with the *IL1* cluster. *IL33* polymorphisms within two LD blocks have been identified in GWAS as associated with asthma,[56,98,100,101] but these findings have not always been replicated.[70] A number of polymorphisms have also been identified by candidate gene approaches and by both candidate gene and GWAS in the *IL1RL1* gene (IL-33 receptor).[102] The IL-33/IL1RL1 pathway has been implicated in the stimulation of type 2 innate lymphoid cells (ILC2s) that produce IL-4, IL-5 and IL-13[103] and thus may have a pivotal role in initiating the Th2 phenotype in atopy/asthma. Indeed *IL1RL1* polymorphisms have been shown to be associated with lower levels of *IL1RL1* transcription.[104]

Any observed association of *IL13* or *IL33/IL1RL1* polymorphisms should have its effect reported in context by considering other variation in other relevant genes, whose products may modulate its effects. For example, there are a number of other functional polymorphisms in genes encoding other components of the *IL4/IL13* signaling pathway (*IL4, IL13, IL4RA, IL13Rα1, IL13Rα2* and *STAT6*) with synergistic effects.[105] Likewise, the *IL1RL1* locus is closely related to the IL-18 receptor gene (*IL18R1*), which has a complex LD structure. IL-18 is associated with Th1 responses and cell adhesion. This difficulty has been reviewed by Grotenboer et al who describe the multiple genetic signals in the *IL33* and *IL1RL1* loci that contribute to asthma pathogenesis. Their suggestion is that the complex LD may be overcome by performing further association studies in other populations with less LD or using meta-analysis with a number of conditional sub-analyses. Further functional and mechanistic studies are also needed.[102]

The *IL13/IL33* polymorphism studies illustrate many of the difficulties of genetic analysis in complex disease. Replication is often not found between studies and this may be accounted for by the lack of power to detect the small increases in disease risk that are typical for susceptibility variants in complex disease. Differences in genetic make-up,[106,107] in environmental exposure between study populations, and failure to 'strictly replicate'[77] in either phenotype (IgE and atopy vs asthma and BHR) or genotype (different polymorphisms in the same gene) can all contribute to the lack of replication between studies. Furthermore, studies of a single polymorphism, or even a single gene in isolation can over-simplify the complex genetic variants in asthma pathogenesis and the cross-talk between implicated cytokines, as shown by the roles of IL-13, IL-33, IL1RL1 and Th2/ILC2 cells in asthma pathogenesis.

ANALYSIS OF CLINICALLY DEFINED SUBGROUPS

One approach is to identify genes in a rare, severely affected subgroup of patients, in whom disease appears to follow a pattern of inheritance that indicates the effect of a single major gene. The assumption is that mutations (polymorphisms) of milder functional effect in the same gene in the general population may play a role in susceptibility to the complex genetic disorder. One example of this has been the identification of the gene encoding the protein filaggrin as a susceptibility gene for atopic dermatitis.

Filaggrin

Filaggrin (filament-aggregating protein) has a key role in epidermal barrier function. The protein is a major component of the protein-lipid cornified envelope of the epidermis important for water permeability and blocking the entry of microbes and allergens.[108] In 2002, the condition ichthyosis vulgaris, a severe skin disorder characterized by dry flaky skin and a predisposition to atopic dermatitis and associated asthma, was mapped to the epidermal differentiation complex on chromosome 1q21; this gene complex includes the *filaggrin* gene (*FLG*).[109] In 2006, Smith and colleagues[110] reported that loss of function mutations in the *filaggrin* gene caused ichthyosis vulgaris.

Noting the common occurrence of atopic dermatitis in individuals with ichthyosis vulgaris, these researchers subsequently showed that common loss of function variants (combined carrier frequencies of 9% in the European population[111]) were associated with atopic dermatitis in the general population.[112] Subsequent studies have confirmed an association with atopic dermatitis,[113–115] and also with asthma[116] and allergy[117] but only in the presence of atopic dermatitis. Atopic dermatitis in children is often the first sign of atopic disease and these studies of *filaggrin* mutation have provided a molecular mechanism for the co-existence of asthma and dermatitis. It is thought that deficits in epidermal barrier function could initiate systemic allergy by allergen exposure through the skin and start the 'atopic march' in susceptible individuals.[118,119]

Molecular Regulation of Atopy and Atopic Disease, II: Disease-Modifying Genes

The concept of genes interacting to alter the effects of mutations in susceptibility genes is not unknown. A proportion of inter-familial variability can be explained by differences in environmental factors and differences in the effect of different mutations in the same gene. Intra-familial variability, especially in siblings, cannot be so readily accredited to these types of mechanisms. Many genetic disorders are influenced by 'modifier' genes that are distinct from the disease susceptibility loci.

GENETIC INFLUENCES ON DISEASE SEVERITY

Very few studies of the heritability of IgE-mediated disease have examined phenotypes relating to severity. Sarafino and Goldfedder[35] studied 39 monozygotic twin pairs and 55 same-sex dizygotic twin pairs for the heritability of asthma and asthma severity. Asthma severity (as measured by frequency and intensity of asthmatic episodes) was examined in twin pairs concordant for asthma. Severity was significantly correlated for monozygotic pairs but not for dizygotic pairs, suggesting there are distinct genetic factors that determine asthma severity as opposed to susceptibility.

A number of studies have examined associations between asthma severity and polymorphisms in candidate genes but were initially hampered by the lack of clear, easily applied, accurate phenotype definitions for asthma severity that distinguish between the underlying severity and level of therapeutic control. For example, it has been suggested that

https://CafePezeshki.IR

β_2-adrenergic receptor polymorphisms could influence asthma severity, and the Arg16Gly polymorphism has been associated with measures of asthma severity.[120] However, it is not clear whether β_2-adrenergic receptor polymorphisms affect patients' responses to β_2 agonists or, regardless of their effects on treatment, these polymorphisms lead to more severe chronic asthma.[121] GWAS has identified *CDHR3* as being associated with severe asthma[122] and a retrospective study of the Childhood Asthma Management Program (CAMP) cohort showed that variation in the gene encoding the low-affinity IgE receptor, *FCER2*, is associated with high IgE levels and increased frequency of severe exacerbations despite inhaled corticosteroid treatment.[123]

GENETIC REGULATION OF RESPONSE TO THERAPY: PHARMACOGENETICS

Genetic variability may not only play a role in influencing susceptibility to allergy but may also modify its severity or influence the effectiveness of therapy.[70] In asthma, patient response to drugs such as bronchodilators, corticosteroids and anti-leukotrienes is heterogeneous.[124,125] In the future, identification of such pharmacogenetic factors has the potential to allow individualized treatment plans based on an individual's genetic background.[126] One of the most investigated pharmacogenetic effects has been the effect of polymorphisms at the gene encoding the β_2-adrenergic receptor, *ADRB2*, on the bronchodilator response to inhaled short- and long-acting β agonists.

Clinical studies have shown that β_2-adrenergic receptor polymorphisms may influence the response to bronchodilator treatment. The two most common polymorphisms of the receptor are at amino acid 16 (Arg16Gly) and at amino acid 27 (Gln27Glu).[127] Asthmatic patients carrying the Gly16 polymorphism have been shown to be more prone to develop bronchodilator desensitization,[128] whereas children who are homozygous or heterozygous for Arg16 are more likely to show positive responses to bronchodilators.[129] Studies in vitro have shown that the Gly16 polymorphism increases down-regulation of the β_2-adrenergic receptor after exposure to a β_2 agonist. In contrast, the Glu27 polymorphism appears to protect against agonist-induced down-regulation and desensitization of the β_2-adrenergic receptor.[130,131]

However, a study of 190 asthmatics examined whether β_2-adrenergic receptor genotype affects the response to regular versus as-needed albuterol use.[132] During a 16-week treatment period, there was a small but significant decline in morning peak flow in patients homozygous for the Arg16 polymorphism who used albuterol regularly. The effect was magnified during the 4-week run-out period when all patients returned to albuterol as needed. However, other studies have suggested that response to bronchodilator treatment is genotype independent.[133,134]

In contrast to the possible effects on short-acting bronchodilators, pharmacogenetic analysis of β_2-adrenergic receptor polymorphisms has found no effect on response to long-acting β_2 agonist therapy in combination with corticosteroids.[135,136] These findings are difficult to explain in the light of the studies discussed linking the Gly16 allele with BHR, β_2 agonist effectiveness, and asthma severity but may indicate that the co-administration of corticosteroids abrogates the effect of variation of *ADRB2*. The complexity of the genotype by response effects observed for variation in *ADRB2* makes clinical application limited at this time and may require the use of detailed haplotypic variation to fully understand the role that variation at this locus plays in regulating β_2 agonist response.[137] *ARG1* encoding for arginase 1 is also associated with response to albuterol.[138]

While glucocorticoid therapy is a potent anti-inflammatory treatment for asthma, there is a subset of asthmatics who are poor responders and clinical studies have shown that those with severe disease are more likely to have glucocorticoid resistance.[139] Numerous mutations in the glucocorticoid receptor gene that alter expression, ligand binding and signal transactivation have been identified; however, these are rare and studies in asthma have not revealed an obvious correlation between any specific polymorphism in the glucocorticoid receptor gene and a response to corticosteroid treatment. However, a number of studies have examined variations in components of downstream signaling pathways or other related genes. For example, Tantisira and colleagues[140] have shown that variation in the *Adenylcyclase 9* gene predicts improved bronchodilator response following corticosteroid treatment, and also identified variation in the *CRHR1* locus[141,142] and the gene encoding *TBX21*[143] as potential markers for steroid responsiveness. Other genes implicated in steroid responsiveness are *STIP*,[144] *GLCCI1*[145] and *T*.[146] These discoveries have contributed to the growing recognition of steroid-resistant asthma as a separate phenotype that may be neutrophil-driven rather than eosinophilic.[147]

Genetic polymorphism may also play a role in regulating responses to anti-leukotrienes.[148] In part, this is mediated by polymorphism in both *ALOX5* and other components of the leukotriene biosynthetic pathway such as *GPR99*.[149–151] There is also a substantial overlap in the genetic modulation of response to the two classes of leukotriene modifier drugs (5-LO inhibitor and Cysteinyl LT1 receptor antagonists).[152] Genetic variation in the leukotriene biosynthetic pathway has also been shown to be associated with increased susceptibility to several chronic disease phenotypes including myocardial infarction,[153,154] stroke,[154,155] atherosclerosis[156] and asthma,[157] suggesting variation in leukotriene production increases risk and severity of inflammation in many conditions. *ALOX5* polymorphisms have also been linked to asthma severity.[158]

Increasingly, there is a focus on developing immune response modifier biologicals of asthma cytokines such as IL-4, IL-13, IL-5 and IL-33. Pikantra is a biological developed as an IL-4 variant that inhibits the IL-4/13 pathway, but response is dependent on *IL4R* genotype.[159]

The aim of pharmacogenetic approaches is to maximize the therapeutic response and minimize any side-effects and although there is no direct pharmacogenetic test for asthma treatment, there is a growing body of research suggesting that development of these tests would be of great benefit to develop new drugs, tailor treatment to those who will most benefit (improving cost-effectiveness) and provide better control of asthma.

Epigenetics and Allergic Disease

The important role of epigenetics as a mechanism by which the environment can alter disease risk in an individual is being increasingly recognized. The term *epigenetics* refers to biological processes that regulate gene activity but do not involve changes in the DNA sequence. Epigenetic processes include post-translational modification of histones by acetylation and methylation, and DNA methylation. Modification of histones,

https://CafePezeshki.IR

around which the DNA is coiled, alters the tightness with which the chromatin fiber is packed and affects rate of transcription. DNA methylation involves the addition of a methyl group to specific cytosine bases, altering gene expression. Increased DNA methylation in the promoter is typically associated with decreased gene expression, whereas within the body of the gene it is associated with increased gene expression, and around exon boundaries it can affect alternative splicing. DNA methylation patterns can be heritable across both cellular divisions and organismal generations. Epigenetic marks are altered by environmental exposures experienced by the individual, and these changes can last decades.

There is evidence that epigenetic factors are important in allergic disease. Epigenetic profiles differ between individuals with and without allergic disease,[160,161] though it is important to note that in most cases these epigenetic changes can be both causes and consequences of allergic disease. Importantly, changes to histone modifications and DNA methylation can be induced by risk factors for allergy such as tobacco smoke, caesarean birth and maternal nutrition in early life.[162] This evidence strongly supports epigenetics as a mechanism by which the environment affects allergic disease risk and a mechanism by which gene-environment interaction can occur. Indeed, interactions between genetic variants and DNA methylation have been observed in asthma,[72] lung function[97] (Figure 3-2) and eczema.[163]

However, in itself, environmentally induced epigenetic change to an individual's epigenome cannot explain the observed heritability of allergic disease – this would require the epigenetic change to be inherited through meiosis and the effect of exposure in one generation to lead to increased risk in subsequent generations. In humans, trans-generational effects have been observed where the initial environmental exposure occurred in F0 generation and changes in disease susceptibility were still evident in F2 (grandchildren). Pembrey and colleagues[164] showed that exposures such as poor nutrition or smoking during the slow growth period of the F0 generation resulted in effects on life expectancy and growth through the male line and female line in the F2 generation, although there had been no further exposure. In mouse models, ancestral folate deprivation causes congenital malformations that persist for five generations, most likely via epigenetics.[165] Observations such as grandmaternal smoking increasing the risk of childhood asthma in their grandchildren[166] support the concept that trans-generational epigenetic effects may be operating in allergic disease. This is further supported by the study of animal models, for example in one model where mice were exposed to in utero supplementation with methyl donors and exhibited enhanced airway inflammation following allergen challenge.[167] It is probable in the near future that the study of large prospective birth cohorts with information on maternal environmental exposures during pregnancy will provide important insights into the role of epigenetic factors in the heritability of allergic disease.[168]

Conclusions

The varying and sometimes conflicting results of studies to identify allergic disease susceptibility genes reflect the genetic and environmental heterogeneity seen in allergic disorders and illustrate the difficulty of identifying susceptibility genes for complex genetic diseases. This is the result of a number of factors, including difficulties in defining phenotypes and population heterogeneity with different genetic loci showing association in populations of differing ethnicity and differing environmental exposure. However, despite this, there is now a rapidly expanding list of genes robustly associated with a wide range of allergic disease phenotypes.

This leads to the question, is it possible to predict the likelihood that an individual will develop allergic disease? To an extent, clinicians already make some predictions of the risk of developing allergic disease through the use of family history and this has been shown to have some validity.[169] However, at present, we are not in a position to utilize the rapidly accumulating knowledge of genetic variants that influence allergic disease progression in clinical practice. This simply reflects the complex interactions between different genetic and environmental factors required both to initiate disease and determine progression to a more severe phenotype in an individual, meaning that the predictive value of variation in any one gene is low, with a typical genotype relative risk of 1.1–1.5.[170]

However, it is possible that, as our knowledge of the genetic factors underlying disease increases, the predictive power of genetic testing will increase sufficiently to enable its use in clinical decision making (Box 3-1). For example, simulation studies based on the use of 50 genes relevant for disease development demonstrated that an area under a curve (AUC) of 0.8 can be reached if the genotype relative risk is 1.5 and the risk allele frequency is 10%.[170,171] Whether this is likely to improve on diagnostics using traditional risk factor assessment is a separate issue. Analyses of the power of genetic testing to predict risk of non-insulin-dependent diabetes (for which many more genetic risk factors have been identified through genome-wide approaches than for allergic disease at this stage) demonstrate that, currently, the inclusion of common genetic variants has only a small effect on the ability to predict the future development of the condition.[172,173] This has led some to question the 'disproportionate attention and resources' given to genetic studies in the prevention of common disease.[174] However, the identification of further risk factors and the development of better methods for incorporating genetic factors into risk models are likely to substantially increase the value of genotypic risk factors and may also provide a means for predicting progression to severe disease and targeting of preventative treatment in the future.[175]

BOX 3-1 KEY CONCEPTS

What Can Genetics Studies of Allergic Disease Tell Us?

Greater Understanding of Disease Pathogenesis

- Identification of novel genes and pathways leading to new pharmacologic targets for developing therapeutics

Identification of Environmental Factors that Interact with an Individual's Genetic Make-up to Initiate Disease

- Prevention of disease by environmental modification

Identification of Susceptible Individuals

- Early-in-life screening and targeting of preventative therapies to at-risk individuals to prevent disease

Targeting of Therapies

- Subclassification of disease on the basis of genetics and targeting of specific therapies based on this classification
- Determination of the likelihood of an individual responding to a particular therapy (pharmacogenetics) and individualized treatment plans

https://CafePezeshki.IR

Whatever the future value of genetic studies of allergic disease in predicting risk, it is unlikely that this will be the area of largest impact of genetics studies on the treatment and prevention of these conditions. Rather, it is the insight the genetic studies have provided, and undoubtedly will continue to provide, into disease pathogenesis. It is clear from genetic studies of allergic disease that the propensity to develop atopy is influenced by factors different than those that influence atopic disease. However, these disease factors require interaction with atopy (or something else) to trigger disease. For example, in asthma, bronchoconstriction is triggered mostly by an allergic response to inhaled allergen accompanied by eosinophilic inflammation in the lungs, but in some people who may have 'asthma susceptibility genes' but not atopy, asthma is triggered by other exposures, such as toluene di-isocyanate.[57] It is possible to group the genes identified into four broad groups (Figure 3-3). Firstly, there is a group of genes that are involved in directly modulating response to environmental exposures. These include genes encoding components of the innate immune system that interact with levels of microbial exposure

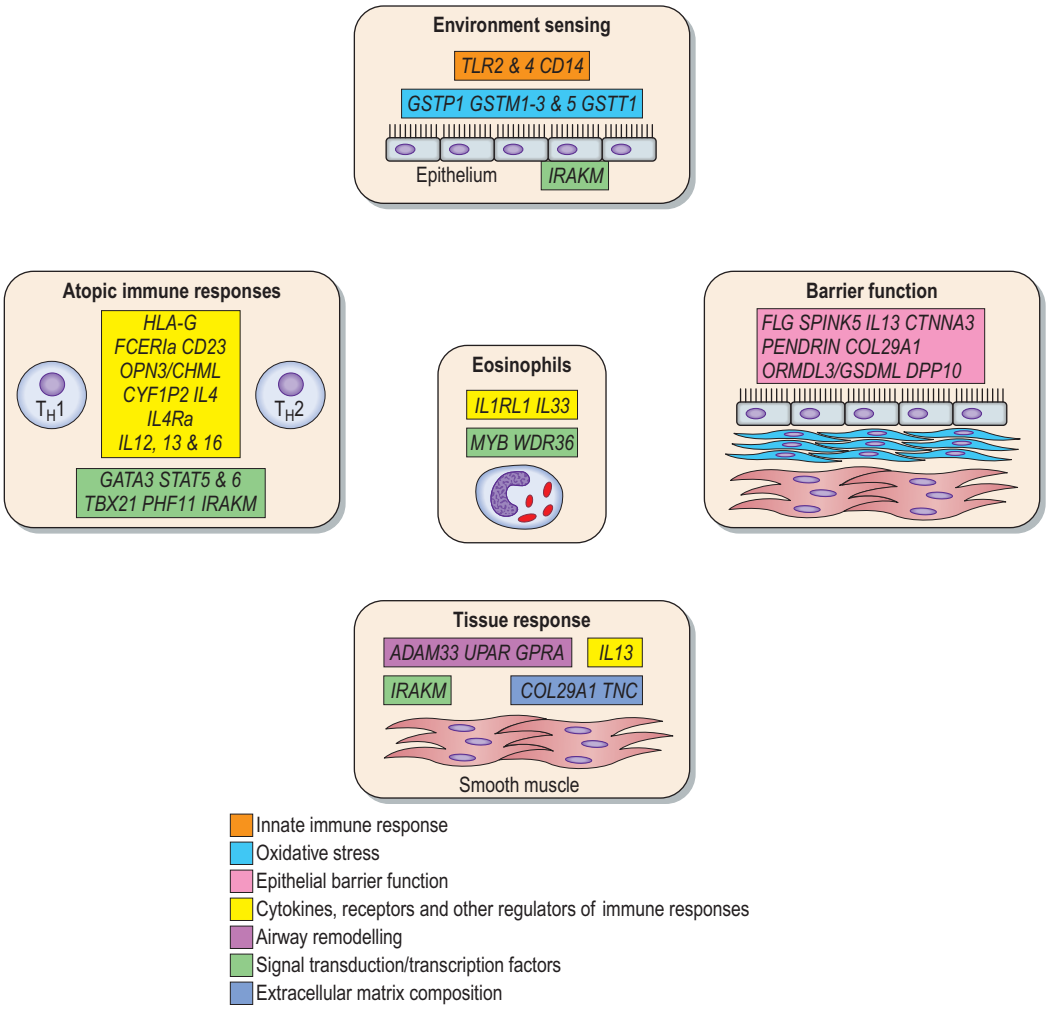

Figure 3-3 Susceptibility genes for allergic disease: a large number of robustly associated genes have been identified that predispose to allergic disease. These can be broadly divided into four main groups. **Group 1 – sensing the environment.** This group of genes encodes molecules that directly modulate the effect of environmental risk factors for allergic disease. For example, genes such as *TLR2, TLR4* and *CD14* encoding components of the innate immune system interact with levels of microbial exposure to alter risk of developing allergic immune responses. Polymorphism of glutathione-S-transferase genes (*GSTM1, -2, -3,* and *-5, GSTT1* and *GSTP1*) has been shown to modulate the effect of exposures involving oxidant stress such as tobacco smoke and air pollution on asthma susceptibility. **Group 2 – barrier function.** The body is also protected from environmental exposure through the direct action of the epithelial barrier both in the airways and in the dermal barrier of the skin. A high proportion of the novel genes identified for susceptibility to allergic disease through genome-wide linkage and association approaches has been shown to be expressed in the epithelium. This includes genes such as *FLG* that directly affect dermal barrier function and are associated not only with increased risk of atopic dermatitis but also with increased atopic sensitization and inflammatory products produced directly by the epithelium such as chemokines and defensins. Other novel genes such as *ORMDL3/GSDML* are also expressed in the epithelium and may have a role in possibly regulating epithelial barrier function. **Group 3 – regulation of (atopic) inflammation**. This group of genes includes genes that regulate Th1/Th2 differentiation and effector function such as *IL13, IL4RA, STAT6, TBX21* (encoding T-bet) and *GATA3*, as well as genes such as *IRAKM* and *PHF11* that potentially regulate both atopic sensitization and the level of inflammation that occurs at the end organ location for allergic disease (airway, skin, nose, etc.). This also includes the genes recently identified as regulating the level of blood eosinophilia using a GWAS approach (*IL1RL1, IL33, MYB* and *WDR36*). **Group 4 – tissue response genes**. This group of genes appears to modulate the consequences of chronic inflammation such as airway remodeling. They include genes such as *ADAM33* expressed in fibroblasts and smooth muscle and *COL29A1*, encoding a novel collagen expressed in the skin and linked to atopic dermatitis. It is important to recognize that some genes may affect more than one component, for example *IL13* may regulate atopic sensitization through switching B cells to produce IgE but also has direct effects on the airway epithelium and mesenchyme promoting goblet cell metaplasia and fibroblast proliferation.

https://CafePezeshki.IR

to alter risk of developing allergic immune responses as well as detoxifying enzymes such as the Glutathione S-transferase genes that modulate the effect of exposures involving oxidant stress, such as tobacco smoke and air pollution. The second major group that includes many of the genes identified through hypothesis independent genome-wide approaches is a group of genes involved in maintaining the integrity of the epithelial barrier at the mucosal surface and signaling of the epithelium to the immune system following environmental exposure. For example, polymorphisms in *FLG* that directly affect dermal barrier function are associated, not only with increased risk of atopic dermatitis, but also with increased atopic sensitization. The third group of genes are those that regulate the immune response, including those such as *IL13, RAD50 IL4RA, STAT6, TBX21* (encoding Tbet), *FCER1A*, *HLAG* and *GATA3* that regulate Th1/Th2 differentiation and effector function, but also others such as *IRAKM* and *PHF11* that may regulate the level of inflammation that occurs at the end organ for allergic disease (i.e. airway, skin, nose, etc.). Finally, but not least, a number of genes appear to be involved in determining the tissue response to chronic inflammation, such as airway remodeling. They include genes such as *ADAM33* expressed in fibroblasts and smooth muscle and *COL29A1* encoding a novel collagen expressed in the skin and linked to atopic dermatitis.

Thus, the insights provided by the realization that genetic variation in genes regulating atopic immune responses is not the only, or even the major, factor in determining susceptibility to allergic disease, have highlighted the importance of local tissue response factors and epithelial susceptibility factors in the pathogenesis of allergic disease.[176] This is possibly the greatest contribution that genetic studies have made to the study of allergic disease and where the most impact in the form of new therapeutics targeting novel pathways of disease pathogenesis is likely to occur.

In conclusion, over the past 15 years, there have been many linkage and association studies examining genetic susceptibility to atopy and allergic disease resulting in the unequivocal identification of a number of loci that alter the susceptibility of an individual to allergic disease. While further research is needed to confirm previous studies and to understand how these genetic variants alter gene expression and/or protein function, and therefore contribute to the pathogenesis of disease, genetic studies have already helped to change our understanding of these conditions. In the future, the study of larger cohorts and the pooling of data across studies will be needed to allow the determination of the contribution of identified polymorphisms to susceptibility and how these polymorphisms interact with each other and the environment to initiate allergic disease. Furthermore it is now apparent that the added complexity of epigenetic influences on allergic disease needs to be considered. Despite these challenges for the future, genetic approaches to the study of allergic disease have clearly shown that they can lead to identification of new biologic pathways involved in the pathogenesis of allergic disease, the development of new therapeutic approaches and the identification of at-risk individuals (Box 3-2).

BOX 3-2 KEY CONCEPTS

GENETIC EFFECTS ON ALLERGY AND ALLERGIC DISEASE

Determine Susceptibility Atopy

- *'Th2' or 'IgE switch' genes*
  Determine specific target-organ disease in atopic individuals
- *Asthma susceptibility genes*
  'Lung-specific factors' that regulate susceptibility of lung epithelium/fibroblasts to remodeling in response to allergic inflammation, such as *ADAM33*
- *Atopic dermatitis susceptibility genes*
  Genes that regulate dermal barrier function, such as *FLG*

Influence the Interaction of Environmental Factors with Atopy and Allergic Disease

- Determining immune responses to factors that drive Th1/Th2 skewing of the immune response, such as *CD14* and *TLR4* polymorphism and early childhood infection
- Modulating the effect of exposures involving oxidant stress such as tobacco smoke and air pollution on asthma susceptibility
- Altering interaction between environmental factors and established disease, such as genetic polymorphism regulating responses to respiratory syncytial virus infection and asthma symptoms

Modify Severity of Disease

- Examples are tumor necrosis factor α and CDHR3 polymorphisms

Regulate Response to Therapy

- Pharmacogenetics
- Examples are β_2-adrenergic receptor polymorphism and response to β_2 agonists

Regulation and Biology of Immunoglobulin E

HANS C. OETTGEN

KEY POINTS

- IgE-producing B cells arise from IgM^+ or IgG^+ B cells via the process of class switch recombination (CSR). B cells undergoing CSR undergo somatic gene rearrangements in the immunoglobulin heavy chain locus leading to the assembly of a gene encoding the ε-heavy chain retaining the original antigenic specificity of the B cell clone.
- IgE antibody production is regulated by Th2 cells. These provide a combination of signals including secreted cytokine (IL-4 or IL-13) and cell surface molecules (CD40L).
- IgE signaling via FcεRI, its high-affinity receptor, on mast cells and basophils by polyvalent antigen leads to the activation of a complex array of signaling pathways resulting in the release of preformed and newly synthesized mediators of immediate hypersensitivity.
- The low-affinity IgE receptor, CD23, mediates IgE-facilitated antigen uptake by antigen-presenting cells, transcellular allergen transport in gastrointestinal and airway epithelium and regulation of IgE production.
- IgE antibodies regulate numerous aspects of hypersensitivity including IgE-receptor density on mast cells and basophils and mast cell homeostasis.

Normally present at very low levels in plasma, antibodies of the immunoglobulin E (IgE) isotype were first discovered in 1967, decades after the description of IgG, IgA and IgM. IgE antibodies are produced primarily by plasma cells in mucosal-associated lymphoid tissue and their levels are uniformly elevated in patients suffering from atopic conditions like asthma, allergic rhinitis and atopic dermatitis. Production of allergen-specific IgE in atopic individuals is driven both by a genetic predisposition to the synthesis of this isotype as well as by environmental factors, including chronic allergen exposure. The lineage commitment by B cells to produce IgE involves irreversible genetic changes at the immunoglobulin heavy chain gene locus and is very tightly regulated. It requires both cytokine signals (interleukin [IL]-4 and IL-13) and interaction of TNF receptor family members on the B cell surface with their ligands.

IgE antibodies exert their biologic functions via the high-affinity IgE receptor, FcεRI, and the low-affinity receptor, CD23. In the classic immediate hypersensitivity reaction, the interaction of polyvalent allergens with IgE bound to mast cells via FcεRI triggers receptor aggregation, which initiates a series of signals that result in the release of vasoactive and chemotactic mediators of acute tissue inflammation. Clinical manifestations of IgE-induced immediate hypersensitivity include systemic anaphylaxis (triggered by foods, drugs and insect stings), bronchial edema with smooth muscle constriction and acute airflow obstruction in asthmatic patients (following allergen inhalation), angioedema and urticaria. Although best known for their critical function in mediating antigen-specific immediate hypersensitivity reactions, IgE antibodies also exert potent immunoregulatory effects including regulation of mast cell homeostasis, stabilization of IgE receptor expression and enhancement of mast cell-mediated expansion of Th2 responses and suppression of T_{REG} responses to allergens.

Components of the Immune Response

IMMUNOGLOBULIN E PROTEIN STRUCTURE AND GENE ORGANIZATION

Immunoglobulin E (IgE) antibodies are tetramers consisting of two light chains (κ or λ) and two ε-heavy chains (Figure 4-1 and Box 4-1). The heavy chains each contain a variable (V_H) region and four constant region domains. The V_H domain, together with the V-regions of the light chains (V_L), confers antibody specificity and the Cε domains confer isotype-specific functions, including interaction with FcεRI and CD23. IgE antibodies are heavily glycosylated and contain numerous intrachain and interchain disulfide bonds. The exons encoding the ε-heavy chain domains are located in the Cε locus near the 3′ end of the immunoglobulin heavy chain locus (IgH) (Figure 4-2).[1] Additional exons, M1 and M2, encode hydrophobic sequences present in the ε-heavy chain mRNA splice isoforms encoding transmembrane IgE in IgE^+ B cells. In contrast to IgG antibodies, which have a half-life of about 3 weeks, IgE antibodies are very short-lived in plasma ($T_{1/2}$ 1ess than 1 day), but they can remain fixed to mast cells in tissues for weeks or months.

The assembly of a functional IgE gene requires two sequential processes of DNA excision and ligation.[2,3] In the first, which occurs in pre-B cells, individual V_H, D, and J_H exons randomly combine to generate a V_HDJ_H cassette encoding an antigen-specific V_H domain. In B cells that have undergone 'productive' V_HDJ_H rearrangements (e.g. no stop codons have been introduced during assembly), this V_HDJ_H cassette is situated just upstream of the Cμ and Cδ exons so that functional μ- and δ-heavy chain transcripts can be produced.

A second DNA excision and ligation process, called *class switch recombination* (CSR), must occur before B cells can produce antibodies of other isotypes, including IgE. These antibodies retain their original V_HDJ_H cassette and antigenic specificity but exchange C_H cassettes of various isotypes to construct

https://CafePezeshki.IR

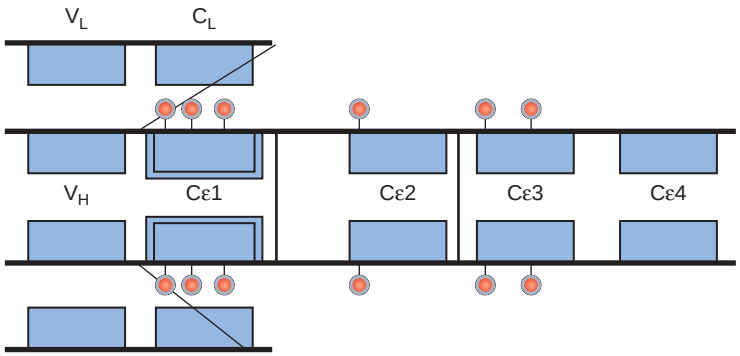

Figure 4-1 IgE antibody structure. IgE antibodies are tetramers containing two immunoglobulin light chains and two immunoglobulin ε-heavy chains connected by interchain disulfide bonds as indicated. Each light chain contains one V_L and one C_L immunoglobulin domain and each ε-heavy chain contains an N-terminal V_H domain and four Cε domains. Intrachain disulfide bonds are contained within each of these immunoglobulin domains. The Cε domains contain IgE isotype-specific sequences important for interactions with IgE receptors FcεRI and CD23. IgE antibodies are relatively heavily glycosylated; glycosylation sites are indicated with circles.

different heavy chains that exert distinct biologic functions. In this tightly regulated and irreversible process, sometimes referred to as deletional switch recombination, a long stretch of genomic DNA spanning from the Sμ region between V_HDJ_H and Cμ to Sε upstream of the Cε locus is excised (see Figure 4-2). The DNA products of this reaction include an extrachromosomal circle of intervening DNA and the contiguous V_HDJ_H and Cε sequences, joined by Sμ-Sε ligation, to generate a functional IgE gene. A complex series of cytokine signals and cell surface interactions collaborate to trigger deletional switch recombination in B cells destined for IgE production.

REGULATION OF IgE ISOTYPE SWITCHING

ε-Germline Transcription Precedes Isotype Switch Recombination

Before deletional isotype switch recombination is initiated, cytokine signals provided by IL-4 and/or IL-13 induce RNA transcription in the IgH locus of B cells. This occurs at the unrearranged or 'germline' ε-heavy chain locus driven from a promoter 5′ of the Iε exon, located just upstream of the Sε switch recombination region and the four Cε exons (Figure 4-3). This is referred to as ε-germline RNA and the transcripts include a 140-bp Iε exon as well as exons Cε1-Cε4.[4,5] As Iε contains several stop codons, germline transcripts do not encode functional proteins and have been referred to as 'sterile'.[6]

Regulation of Germline Transcription, The Iε Promoter

Initiation of germline transcription is regulated by the Iε promoter that contains binding sites for several known transcription factors including STAT-6, NF-κB, BSAP (Pax5), C/EBP and PU.1 (see Figure 4-3). Accessibility of the promoter is regulated by the non-histone chromosomal protein, HMG-I(Y).[7] This repression is released upon IL-4-driven phosphorylation of the protein.[8,9] Translocation of activated STAT-6 to the nucleus is triggered by IL-4 and IL-13 signaling. STAT-6 activation appears to be the key inducible regulator of ε-germline transcription; neither BSAP nor NF-κB nuclear-binding activities are altered by cytokine signaling, but these promoter elements must be present for normal Iε promoter function.[10,11] CD40 signaling also enhances cytokine-driven germline transcription by activating the NF-κB promoter elements.

BCL-6, a POZ/zinc-finger transcription factor expressed in B cells, is an important negative regulator of the Iε promoter. BCL-6 binds to STAT-6 sites and can repress the induction of ε-germline transcripts by IL-4.[12,13] BCL-6 is induced by the cytokine, IL-21, which is known to suppress IgE production in B cells and which has been reported to induce apoptosis of IgE^+ B cells.[14] IL-21 is important in germinal center formation and germinal centers have relatively low levels of IgE production.[14,15]

Cytokines IL-4 and IL-13 Activate STAT-6

The cytokines IL-4 and IL-13 are potent inducers of ε-germline transcription in B cells.[5,16,17] The multimeric receptors for these two cytokines share the IL-4R-αchain. The type I IL-4 receptor, which binds IL-4, is composed of the ligand-binding IL-4Rα and the signal-transducing common cytokine receptor γ-chain γc. The type II receptor, which can bind either IL-4 or IL-13, contains the IL-4R-α chain along with an IL-13 binding chain, IL-13Rα1. IL-4 receptor signaling triggers the activation of Janus family tyrosine kinases Jak-1 (via IL-4Rα), Jak-3 (via γc) and TYK2 (via IL-13Rα).[18–21] These activated Jaks then phosphorylate tyrosine residues in the intracellular domains of the receptor chain. These phosphotyrosines serve as binding sites

https://CafePezeshki.IR

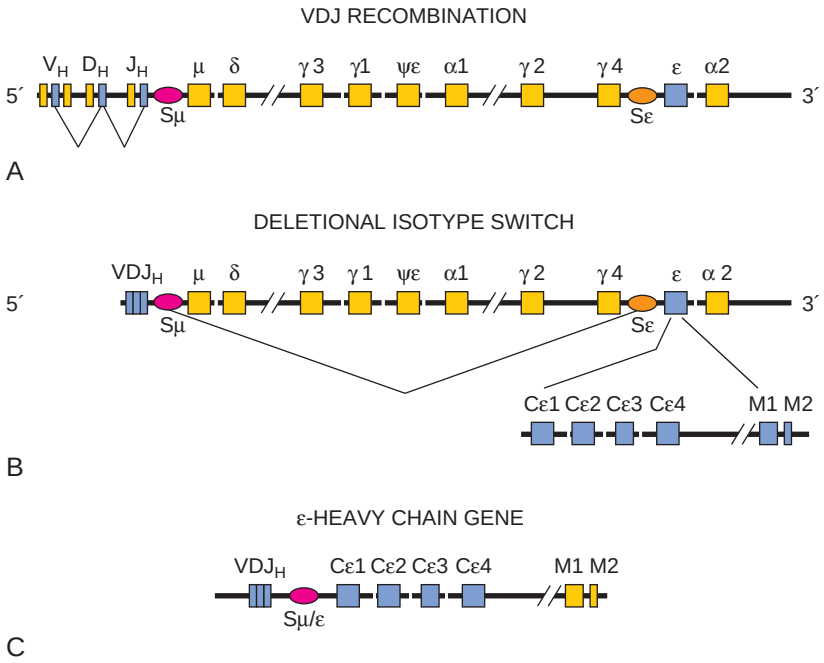

Figure 4-2 The human immunoglobulin heavy chain gene locus; deletional class-switch recombination. **(A)** The human immunoglobulin heavy chain locus contains clusters of V_H, D_H and J_H cassettes that are stochastically rearranged during B cell ontogeny. This process, which involves DNA excision and repair, results in the assembly of a complete VDJ exon encoding an antigen-binding V_H domain. Pre-B cells that have completed this rearrangement are capable of producing intact μ-heavy chains and, following an analogous process of light chain rearrangements, can produce intact IgM antibodies. **(B)** Production of other antibody isotypes, bearing the original antigenic specificity, requires an additional excision and repair process, deletional 'class-switch recombination' (CSR). For IgE isotype switching, this process involves the excision of a large piece of genomic DNA spanning from Sμ switch sequences just upstream of the μ-heavy chain exons to the Sε sequence 5′ of the Cε exons. **(C)** Ligation of the VDJ sequences to the Cε locus then gives rise to an intact ε-heavy chain gene containing a V_H-encoding VDJ exon and exons Cε1-4 encoding the constant region domains of ε-heavy chain. The M1 and M2 exons encode trans-membrane sequences that are present in RNA splice isoforms encoding the membrane IgE of IgE^+ B cells.

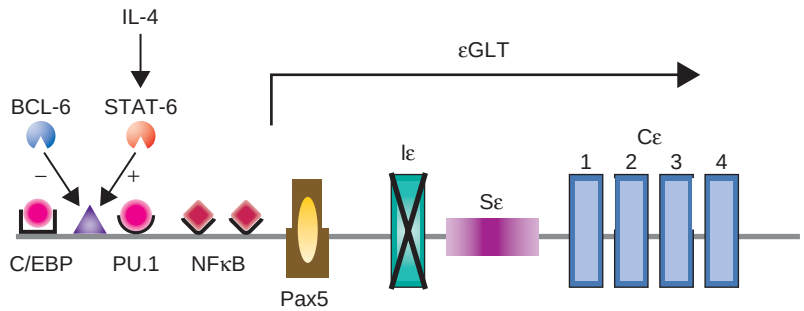

Figure 4-3 ε-Germline transcription *(εGLT)*. Class switch recombination is invariably preceded by a process of RNA transcription at the C_H locus being targeted by specific cytokine signals. ε-Germline transcripts originate at a promoter upstream of the Iε exon. This promoter contains binding sites for transcription factors C/EBP, PU.1, STAT-6, NF-κB (two sites), and Pax5. STAT-6 activation is triggered by IL-4 and IL-13 receptor signaling and is the critical regulatory factor in ε-germline transcription. BCL-6 is a transcriptional repressor that binds to the STAT-6 target site and inhibits εGLT. Germline transcripts contain Iε and Cε1-4 exons but, because the Iε exon contains stop codons ('X'), these RNAs do not encode a functional protein.

for STAT-6, which is, in turn, phosphorylated and then dimerizes and translocates to the nucleus.[22,23]

CD40/CD154 Provides Second Signal for Isotype Switch Recombination

The cytokines IL-4 and IL-13 are very efficient inducers of ε-germline transcription, and this transcription is an absolute prerequisite for isotype switching. However, cytokine-induced germline transcription alone is not sufficient to drive B cells to complete the genomic deletional switch recombination reaction that gives rise to a functional IgE gene. A second signal, provided by the interaction of the TNF receptor family member CD40 on B cells with its ligand, CD154, on activated T cells, is required to bring the process to completion.

CD154 is transiently expressed on antigen/MCH-stimulated T cells.[24] T cell CD154 induces CD40 aggregation on B cells, triggering signal transduction via four intracellular proteins belonging to the TRAF family of TNF-receptor associated factors.[25,26] TRAF-2, -5, and -6 promote the dissociation of NF-κB from its inhibitor, IκB, allowing NF–κB to translocate to the nucleus and synergize with STAT-6 to activate the Iε promoter as described above.[27,28] In addition to inducing TRAF association and signaling, aggregation of CD40 activates protein tyrosine kinases (PTKs) including Jak-3, which play an

https://CafePezeshki.IR

important role in immunoglobulin class switching.[29,30] CD154 is encoded on the X chromosome. Boys with X-linked immunodeficiency with hyper-IgM (XHIM) are deficient in CD154. Consequently, their B cells are unable to produce IgG, IgA or IgE.[31–35]

Alternative Second Signals for Isotype Switch Recombination

Recently, alternative switching pathways have been defined in which the second 'switch' signal is provided not by CD40/CD154 ligation but rather by interaction of other TNF-like molecules with their receptors. One such TNF family member, BAFF, binds to its receptor TACI on cytokine-stimulated B cells, inducing isotype switching even in the absence of CD40.[36,37] BAFF/TACI-driven switching may be of particular importance at mucosal sites, especially IgA production in the gastrointestinal tract. Defects in this pathway underlie some cases of IgA deficiency.[38,39] Although BAFF can drive IgE switching, its physiologic relevance in IgE regulation remains to be clarified. It has been reported that respiratory epithelium produces BAFF, with elevations of the factor in bronchoalveolar lavage fluid (BAL) of segmental allergen-challenged subjects.[40,41] In addition, it has been demonstrated that IgE class switch recombination occurs not only in central lymphoid organs but also in the respiratory mucosa of patients with allergic rhinitis and asthma.[42]

Cytokine-Stimulated Germline Transcripts and CD40-Induced AID Collaborate to Execute Switch Recombination

Deletional class switch recombination stimulated by cytokines and CD40/CD154 requires the synthesis of a new intracellular protein, activation-induced cytidine deaminase (AID), which is expressed in activated splenic B cells and in the germinal centers of lymph nodes.[43,44] AID-deficient mice have elevated IgM levels and a major defect in isotype switching with absent IgG, IgE and IgA. A rare autosomal form of hyper-IgM syndrome (HIGM2), which is associated with striking lymphoid hypertrophy, has now been attributed to mutations in the AID gene.[45]

AID is recruited to sites of active germline transcription where it deaminates deoxy-cytidine residues within the C-rich Sε and Sμ sequences, generating uracils and consequent U:G mismatches (see Figure 4-4).[46,47] Subsequent removal of these uracils by the enzyme uracil glycocylase (UNG) results in the introduction of abasic sites. The enzyme apurinic/apyrimidinic

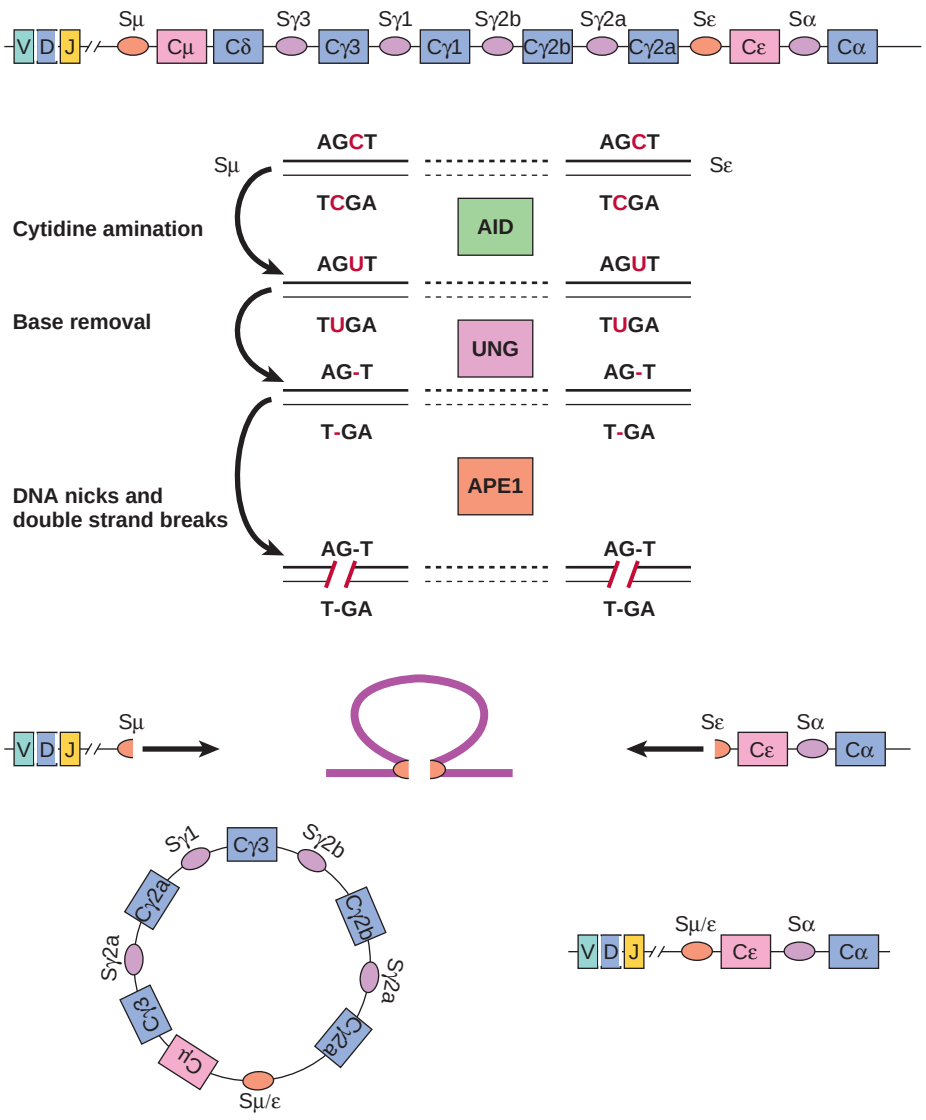

Figure 4-4 Activation-induced cytidine deaminase *(AID)* is recruited to sites of cytokine-driven germline transcription (Sμ and Sε) in the IgH locus where it catalyzes cytidine deamination to uracil. Uracil glyosylase *(UNG)* introduces abasic sites which are then converted to nicks by apurinic/apyridinimic endonuclease 1 *(APE1)*. Subsequent double strand DNA breaks followed by end joining of the Sμ and Sε sequences leads to the generation of an intact VDJ-Cε$_{1\text{-}4}$ ε-heavy chain gene along with an excised episomal DNA circle containing the intervening sequences.

https://CafePezeshki.IR

endonuclease 1, APE1, generates nicks at these sites which ultimately lead to double-stranded DNA breaks. In subsequent steps of the process, analogous breaks, located at Sμ between V_HDJ_H and the Cμ exons, are annealed to generate a functional IgE gene. The heterogeneous nature of the Sμ-Sε junctions suggests a nonhomologous end-joining mechanism such as would be generated by the DNA repair enzymes, Ku70, Ku80 and DNA-PKcs. Consistent with this possibility, B cells lacking Ku70, Ku80 and DNA-PKcs, all of which are involved in nonhomologous end joining, cannot execute isotype switching normally.[48,49]

REGULATION OF ALLERGEN-SPECIFIC T CELL RESPONSES

The execution of IgE isotype switch recombination in B cells, as detailed previously, requires that cytokine (IL-4 and IL-13) signals and the CD40 ligand, CD154 signal, be delivered in a coordinated fashion. Both these stimuli are provided by Th2-type allergen-specific T-helper cells. Thus, the mechanisms that regulate expansion and survival of Th2 cells are crucial in regulating IgE responses.

Th2 Helper T Cell Development

Naïve $CD4^+$ Th cells have the capacity to differentiate into a number of distinct types of effector helper, each with distinct capacities for induction of cellular immune responses (Th1), antibody production and allergic responses (Th2), inflammatory responses (Th17) and regulation (T_{REG}, see Figure 4-5). These Th types are further characterized by the expression of specific transcription factors that maintain their specific lineage commitments and direct their respective cytokine transcription profiles (Chapter 5). Some of the Th lineages can be identified by specific cell surface markers. Th1 cells, which arise under the direction of IL-12 or IL-18, express abundant IFN-γ and IL-2 and are important in immunity to intracellular pathogens. Th1 cells are further characterized by the presence of the transcription factor, T-bet. The Th17 subset is induced in the presence of TGF-β and IL-6 and produces IL-17, TNF-α and IL-1. Th17 cells harbor the transcription factors RORγt and STAT3 and are important in driving neutrophil recruitment and inflammatory responses. As their name implies, T_{REG}, which are generated in the presence of TGF-β and IL-2 (absent IL-6), are important in controlling immune responses via immunosuppressive cytokines including TGF-β and IL-10. The transcription factor associated with this lineage is FoxP3.

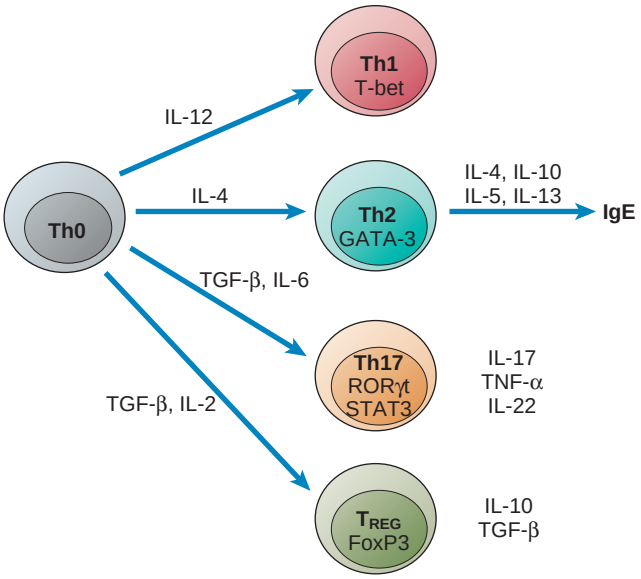

Figure 4-5 $CD4^+$ T-helper cell differentiation. $CD4^+$ T-helper cells undergo a process of differentiation to Th1 (producing IL-2, IFN-γ and TNF-α), Th2 (producing IL-4, IL-5, IL-6, IL-9, IL-10, IL-13 and GM-CSF), Th17 (producing IL-17, TNF-α and IL-22) and T_{REG} (producing IL-10 and TGF-β) phenotypes. Each lineage is further characterized by the presence of specific transcription factors (as indicated in the nuclei). The critical regulator of IgE production is the Th2 lineage which uniquely produces IL-4.

The critical Th cells promoting IgE production are Th2, which are induced by IL-4, express the transcription factor GATA-3 and produce IL-4, IL-5, IL-6, IL-9, IL-10, IL-13 and GM-CSF. Th2 cells express cell surface receptors, which target their trafficking to allergic sites and trigger activation in settings of allergic inflammation, including the chemokine receptors CCR3, CCR4, CRTh2 and CCR8 and the IL-33 receptor, T1/ST2.[50–53]

Genetic Influences on Th2 Development

Both host and environmental factors promote the Th2 shift observed in allergic individuals. Genetic predispositions toward Th1 or Th2 are partly accounted for by T cell autonomous tendencies to transcribe Th1 versus Th2 cytokines, but are also the result of a wide range of influences external to T cells.[54] Perhaps the most potent Th1/Th2-polarizing effect is exerted by the cytokine milieu, particularly tissue levels of IL-4, IL-12 and IFN-γ. IL-4 promotes Th2 responses and suppresses Th1 development. IL-12 drives Th1 differentiation (an effect that is greatly potentiated by the presence of IFN-γ) and can inhibit and even reverse Th2 development. In ongoing immune responses these cytokines can be provided by existing T cells already committed to a particular Th phenotype. In de novo allergen encounters, cytokines produced by cells of the 'innate' immune response may tip the balance.

Antigen-Presenting Cell Function in Th Differentiation

Naïve T cells initially encounter antigens as MHC-bound processed peptides on the surface of antigen-presenting cells (APCs). The most potent APCs are dendritic cells (DCs), which reside in tissues as immature sentinels and sample antigens in their milieu. Upon activation, these cells acquire mature APC function and migrate to regional lymphoid tissues, where they efficiently activate antigen-specific T helper cells via MHC-peptide complexes. Dendritic cells obtained from various lymphoid tissues in vivo or cultured ex vivo under a range of conditions all express MHC II and, following activation, express costimulatory molecules, including CD80/86. However, there is some functional heterogeneity among DCs, especially with respect to the ability to induce Th1 versus Th2 T helper responses.[55] DC-derived IL-12 drives Th1 responses; IL-23, TGF-β and IL-6 support Th17 induction; and IL-10 drives both T_{REG} and Th2.[56]

Microbial Products and Dendritic Cell Phenotype

The recent understanding that Th polarity may be determined by DC polarity obviously begs the following question: what

https://CafePezeshki.IR

determines DC polarity? IFN-γ favors DC1 development, whereas histamine and PGE_2 promote the development of DC2.[57–59] IL-10 may negatively regulate DC production of IL-12.[60] Conserved microbial structures, which signal via the Toll-like receptor (TLR) family of receptors, can shift DC polarity. Dendritic cells express a range of TLR and the specific effects of ligand binding by each of these receptors on DC phenotype remain to be fully elucidated. The default state of mucosal DC appears to be skewed toward Th2 induction with relatively low basal IL-12 and constitutive production of IL-10.[61]

Non-T Cell Sources of IL-4: Mast Cells, Basophils, NKT Cells and NK Cells

Although allergen-specific T-helper cells committed to the Th2 lineage are a major source of IL-4 in allergic tissues and may predominate during chronic or memory responses to allergen, several other cell types can provide IL-4 and IL-13 and may be more important in initial allergen encounters. Mast cells, which are abundant in the respiratory and gastrointestinal mucosa, are excellent producers of both IL-4 and IL-13 following activation via IgE/FcεRI.[62,63] IgE-stimulated mast cells appear to be a key early source of IL-4 in Th2-dominant immune responses to food allergens.[64] Basophils are rapidly induced in response to allergens or parasites and constitutively produce large quantities of IL-4. $NK1.1^+$ $CD4^+$ T (NKT) cells are another source of IL-4. These cells express a very restricted repertoire of αβ T cell receptors and interact with the non-classical MHC class I molecule, CD1.[65] The intravenous injection of anti-CD3 in mice induces large amounts of IL-4, derived primarily from these NKT cells. Another recently identified cytokine-producing cell of the innate immune system, the innate lymphoid cell type-2 (ILC2), is commonly found at mucosal sites where its expansion is stimulated by the epithelial cell cytokines, IL-25 and IL-33.[66] The ILC2 lineage is stabilized by the transcription factor RORα, and secretes IL-4, IL-13 and IL-5.

Sites of IgE Class Switch Recombination and Mechanisms of IgE Memory

Studies of IgG production in mice have revealed that high-affinity antibody responses arise in germinal centers of secondary lymphoid tissues in which IgM^+ B cells are driven by cytokine signals and costimulatory molecules from T follicular helper cells (T_{FH}) to switch to IgG (μ-γ switch), followed by affinity maturation and generation of long-lived memory B cells. IgE responses may also be induced in germinal centers via direct IgM-IgE switching (μ-ε), but several lines of evidence suggest that affinity maturation is optimized in B cells that have sequentially undergone μ-γ, and then γ-ε switches and that memory resides in the intermediate IgG^+ B cell compartment. IgE^+ B cells are short-lived in germinal centers, possibly because of rapid transition to plasma cells. Early, low-affinity IgE responses may arise at extrafollicular sites including in the respiratory and gastrointestinal mucosa where the presence of ε germline transcripts and switch excision circles (Figure 4-4) is readily detected, especially following allergen exposure. Mice unable to generate germinal centers (including $BCL\text{-}6^{-/-}$ and MHC II-deficient mice) are capable of producing abundant IgE. The current understanding of IgE synthesis gleaned from these observations is that early low-affinity IgE responses arise in mucosal sites, but that affinity maturation and memory are optimized in germinal centers.[67,68]

IgE RECEPTORS

FcεRI Structure

The high-affinity IgE receptor FcεRI is a multimeric complex expressed in two isoforms, a tetrameric αβγ2 receptor present on mast cells and basophils and a trimeric αγ2 receptor expressed, albeit at levels 10-fold to 100-fold lower, by several cell lineages including eosinophils, platelets, monocytes, dendritic cells and cutaneous Langerhans cells[69] (Figure 4-6). The α chain contains two extracellular immunoglobulin-related domains and is responsible for binding IgE. The β subunit of the receptor contains four transmembrane-spanning domains with both N- and C-terminal ends on the cytosolic side of the plasma membrane. FcεRI-β appears to have two functions that result in enhanced receptor activity. β-chain expression both enhances cell surface density of FcεRI and amplifies the signal transduced following activation of the receptor by IgE aggregation.[69–72] The γ chains (which have homology to the ζ and η chains important in T cell receptor signaling) exist as disulfide-linked dimers with trans-membrane domains and cytoplasmic tails. The β and γ chains perform critical signal transduction functions and their intracellular domains contain immunoreceptor tyrosine-based activation motifs (ITAMs), 18 amino acid long tyrosine-containing sequences that constitute docking sites for SH2 domain-containing signaling proteins.

CD23 Expression and Structure

Although its common designation as the 'low-affinity' IgE receptor implies differently, CD23 actually has a fairly high affinity for IgE with a K_A of about 10^8.[73,74] A wide variety of cell types express CD23 in humans, including B cells, Langerhans cells, follicular dendritic cells, T cells and eosinophils.[75] It is a type II transmembrane protein with a C-type lectin domain, making it the only immunoglobulin receptor that is not in the Ig superfamily.[76–78] Adjacent to its lectin domain, CD23 has sequences that are predicted to give rise to α-helical coiled-coil stalks (Figure 4-7). As a result, CD23 is known to have a tendency to multimerize and only oligomeric CD23 will bind IgE.[79] CD23 has homology to the asialoglycoprotein receptor, suggesting a role for CD23 in endocytosis. In addition to binding IgE, CD23 binds to a second ligand, the B cell surface molecule, CD21.[80,81]

Principles of IgE-Mediated Disease Mechanisms

Once produced, allergen-specific IgE antibodies engage their receptors and trigger a wide variety of tissue-specific responses. The cellular and molecular mechanisms of pathogenesis giving rise to specific allergic disorders are presented in great detail in Chapters 24–58. This section will provide a general overview of the consequences of IgE interaction with its receptors, including immediate hypersensitivity, late-phase reactions, regulation of IgE receptor expression and immune modulation (Box 4-2).

MAST CELL ACTIVATION AND HOMEOSTASIS

FcεRI Signaling

FcεRI has high affinity for IgE (Kd 10^{-8} M) and under physiologic conditions mast cell and basophil FcεRI is fully occupied by IgE antibodies. Aggregation of this receptor-bound IgE by

https://CafePezeshki.IR

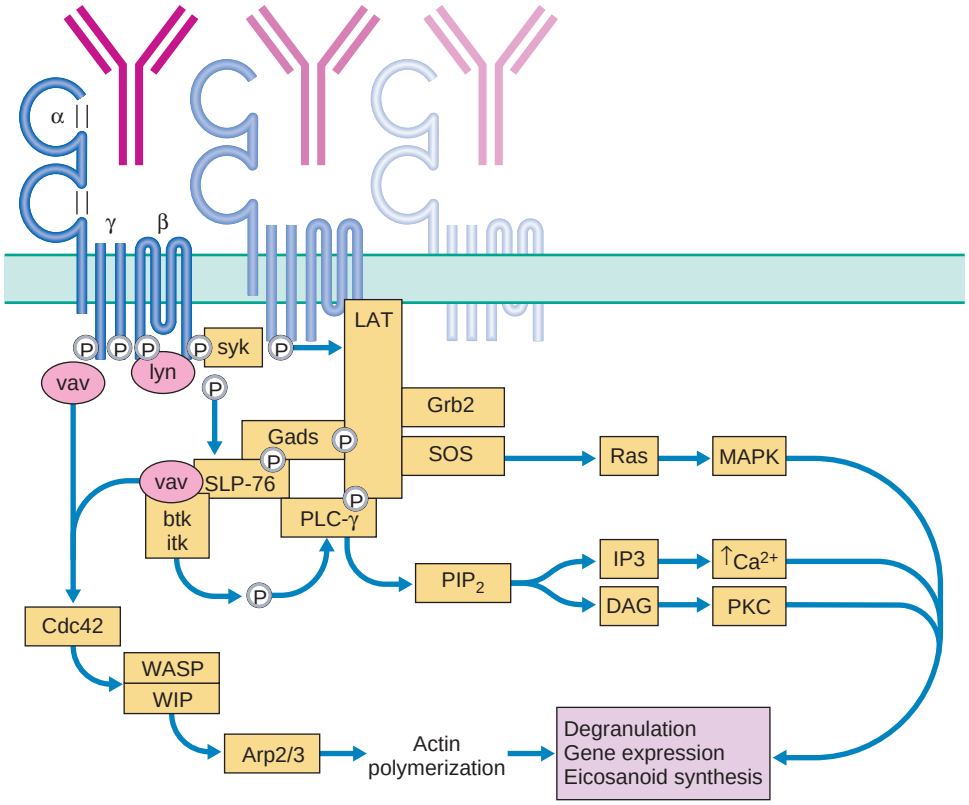

Figure 4-6 FcεRI structure and signal transduction. FcεRI is a tetramer containing an IgE-binding α-chain (with two extracellular immunoglobulin-type domains), a disulfide-linked, signal-transducing dimer of γ-chains, each of which contains an intracellular immunoreceptor tyrosine-based activation motif (ITAM) and a tetramembrane spanner β-chain that also contains a cytosolic ITAM and serves to augment FcεRI surface expression and signal transduction intensity. Trimeric forms of the receptor, lacking the β-chain, can be expressed on some cell types.

Aggregation of the receptor by the interaction of its ligand, IgE, with polymeric antigens induces signal transduction. The β-chain associated protein tyrosine kinase, lyn, in aggregated receptor complexes phosphorylates *(P)* the β- and γ-chain ITAMs, generating docking sites for the SH2-domain containing kinase, syk. Activated syk phosphorylates the membrane-associated scaffolding protein LAT as well as the adapter, SLP-76 (which is also bound to LAT via the Grb-2 homolog, Gads). These proteins have no inherent enzymatic activity but serve to assemble a membrane-associated supramolecular complex of proteins that brings together a number of signaling molecules. LAT and SLP-76 both recruit PLC-γ, whose activity is enhanced by the SLP-76 associated kinases btk and itk. PLC-γ activation results in the conversion of PIP_2 (phosphatidylinositol 4,5-bisphosphate) into inositol trisphosphate *(IP3)* and diacyl glycerol *(DAG)* with resultant increases in intracellular Ca^{2+} and activation of protein kinase C *(PKC)*.

Alongside this protein tyrosine kinase pathway, FcεRI aggregation triggers a vav/cytoskeletal signaling cascade. The guanine nucleotide exchange factor, vav, which is directly associated with FcεRI-γ as well as with SLP-76, activates the GTPase Cdc42 which, in turn, induces a conformational change in a complex of proteins, WASP and WIP, associated with the cytoskeleton. This exposes binding sites for Arp2/3, a complex of proteins that mediates actin polymerization. Vav activation also drives the stress- activated protein kinase (SAPK) pathway. Vav and Sos, another guanine nucleotide exchange factor, also result in the activation of the Ras/MAPK pathway. The combined effects of elevated Ca^{2+}, PKC activation, actin polymerization and SAPK activation drive mast cell degranulation, eicosanoid formation and induction of gene expression.

BOX 4-2 KEY CONCEPTS

Principles of Disease Mechanism

EFFECTOR FUNCTIONS OF IgE

• Mast cell activation/ FcεRI	FcεRI signaling – antigen dependent Immediate hypersensitivity reactions Late-phase reactions FcεRI signaling – antigen independent
• IgE regulation of IgE receptors	FcεRI CD23
• IgE regulation of mast cell homeostasis	Enhanced mast cell survival
• CD23 functions	IgE antigen capture Regulation of IgE synthesis by CD23 and sCD23

an encounter with polyvalent allergen triggers a cascade of signaling events[82,83] (see Figure 4-6). Receptor aggregation induces transphosphorylation of intracellular ITAMs on FcεRI-β and FcεRI-γ by receptor-associated lyn tyrosine kinase, providing docking sites to recruit the SH2-containing syk protein tyrosine kinase. Syk levels are decreased during chronic IgE-mediated stimulation of FcεRI, suggesting a possible mechanism whereby drug desensitization might attenuate mast cell activation at this early step in the signaling cascade.[84] Receptor-associated syk phosphorylates a series of scaffolding and adapter molecules leading to the assembly of a supramolecular plasma membrane-localized signaling complex, focused around the scaffolding molecules LAT1/2, SLP-76 and Grb2. This complex recruits and activates PLCγ with resultant changes in cytosolic calcium, degranulation, activation of gene transcription and induction of PLA2 activity with eicosanoid formation. Mast cells from animals with mutations in several key components of this

https://CafePezeshki.IR

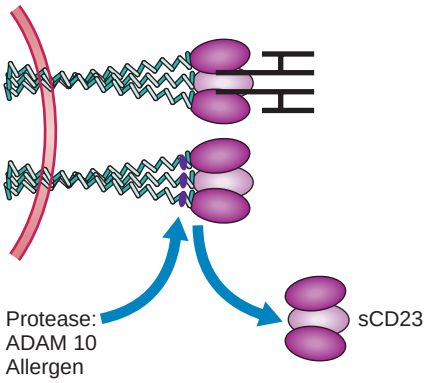

Figure 4-7 CD23 structure. CD23 is a type II transmembrane protein (with intracellular N-terminus) that contains α-helical coiled stalks and oligomerizes at the cell surface. Occupancy of the receptor by IgE stabilizes the receptor. In the absence of the IgE ligand, protease-sensitive sites appear *(ovals)* and endogenous proteases (ADAM10) as well as proteases present in allergens such as Der p 1 cleave CD23, shedding soluble sCD23 into the milieu.

signaling complex, including LAT and SLP-76, have markedly inhibited FcεRI-mediated mast cell activation following receptor cross-linking.[85,86] Cytoskeletal reorganization provides a critical parallel signaling pathway driven by FcεRI aggregation in mast cells and basophils. This cytoskeletal signaling is driven by the guanine nucleoside exchange factor 'vav'.[87] Vav is encoded a proto-oncogene, important in hematopoiesis, playing a role in T cell and B cell development and activation. Vav associates both with the SLP-76/LAT complex and directly with FcεRI.[88] Vav activates Cdc42, a GTPase, which binds to Wiskott-Aldrich syndrome protein (WASP) and induces a conformational change in the cytoskeletal WASP/WASP-interacting protein (WIP) protein complex, allowing interaction with the actin-polymerizing Arp2/3 complex.[89] Vav (as well as Sos, another GTP exchanger) also activates the Ras pathway with resultant transcriptional activation. It has recently been shown that the affinity of antigen:IgE interaction can affect which signaling pathways are preferentially activated, with low-affinity binding favoring Syk phosphorylation of LAT1 and cytokine production and high-affinity binding leading to LAT2 phosphorylation and chemokine production.[90] The activating signaling pathways initiated in mast cells by FcεRI cross-linking can be countered by IgG antibodies interacting with the inhibitory receptor, FcγRIIb. This mechanism may account in part for the ability of patients undergoing allergen immunotherapy, who generate strong IgG responses, to tolerate allergen challenge despite persistently elevated specific IgE.[91,92]

In the classic immediate hypersensitivity reaction, cross-linking of IgE induces the complex signaling cascade described above, resulting in the release of preformed mediators including histamine, proteoglycans and proteases; transcription of cytokines (IL-4, TNF, IL-6); and de novo synthesis of prostaglandins (PGD_2) and leukotrienes (LTD_4). In the airways of asthmatic patients, these mediators rapidly elicit bronchial mucosal edema, mucus production and smooth muscle constriction and, eventually, recruit an inflammatory infiltrate. In asthmatic patients subjected to allergen inhalation, these cellular and molecular events result in an acute obstruction of airflow with a drop in FEV_1, an effect that can be blocked by inhibition of IgE with a monoclonal anti-IgE antibody.[93–95]

In many subjects exposed to allergens by inhalation, ingestion, cutaneous exposure or injection, immediate responses are followed 8 to 24 hours later by a second, delayed-phase reaction, designated the late-phase response (LPR). LPR can manifest as delayed or repeated onset of airflow obstruction, gastrointestinal symptoms, skin inflammation or anaphylaxis hours after initial allergen exposure and after the acute response has completely subsided. In animal models, IgE antibodies can transfer both acute and LPR sensitivity to allergen challenge.[96] Interference with mast cell activation or inhibition of mast cell mediators blocks the onset of both acute-phase and late-phase responses.[97] It has been proposed that chronic obstructive symptoms in asthma patients subjected to recurrent environmental allergen exposure result from persistent late-phase responses.[98,99]

Antigen-Independent IgE Signaling via FcεRI and IgE Effects on Mast Cell Homeostasis

Although IgE-mediated signaling via FcεRI has long been believed to be dependent on antigen-mediated receptor aggregation, some recent evidence suggests that the binding of IgE per se, in the absence of antigen, provides a signal to mast cells and basophils. Experiments using cultured bone marrow mast cells have revealed that monomeric IgE has an FcεRI-mediated survival-enhancing effect, protecting these cells from apoptosis following the withdrawal of growth factor.[100,101] A number of other mast cell functions have been reported to be induced by IgE alone, in the absence of antigen, including cytokine production, histamine release, leukotriene synthesis and calcium flux.[102–105]

The observation that IgE antibodies promote the viability of cultured mast cells suggests that IgE might similarly regulate mast cell survival in vivo. Indeed, there is evidence that mast cell induction in parasitized mice or animals exposed to allergens depends upon the presence of IgE antibodies.[106,107] Thus, in addition to their role in allergen-triggered mast cell activation, IgE antibodies are key regulators of mast cell homeostasis.

Regulation of IgE Receptors by IgE

The expression of both FcεRI and CD23 is positively regulated by their mutual ligand, IgE. FcεRI expression is markedly diminished on peritoneal mast cells from IgE-deficient mice and this defect can be reversed in vivo by injection of IgE antibodies.[108–110] Low FcεRI expression in $IgE^{-/-}$ mice is associated with diminished mast cell activation following IgE sensitization and allergen exposure. Treatment of allergic subjects with anti-IgE has been shown to induce a decrease in IgE receptor expression on mast cells, basophils and dendritic cells.[88,111,112]

CD23 expression on cultured B cells is enhanced in the presence of IgE, which, by occupancy of its receptor, prevents proteolytic degradation of CD23 and shedding into the medium.[73,113] This shedding is mediated by the endogenous protease, ADAM10, but can also be triggered by allergens with protease activity, including Der p 1.[114,115] This regulatory interaction between IgE and CD23 is operative in vivo as well: B cells from $IgE^{-/-}$ animals have markedly diminished CD23 levels and intravenous injection of IgE induces normal CD23 expression.[116] Restoration of CD23 expression can be induced using

https://CafePezeshki.IR

monomeric IgE and is antigen independent. Exposure to IgE does not alter transcription of mRNA encoding CD23 or the FcεRI subunits but rather modulates receptor turnover and proteolytic shedding.[117] The positive feedback interaction between IgE and its receptors may have implications in terms of augmenting allergic responses in atopic individuals with high IgE levels.

CD23 Function: Antigen Capture

Several investigators have now shown that the binding of allergen by specific IgE facilitates allergen uptake by CD23-bearing cells for processing and presentation to T cells.[118–120] Mice immunized intravenously with antigen produce stronger IgG responses when antigen-specific IgE is provided at the time of immunization.[121,122] As expected, $CD23^{-/-}$ mice cannot display augmentation of immune responses by IgE but acquire responsiveness to IgE following reconstitution with cells from $CD23^{+}$ donors.[123,124] These findings suggest a scenario in which preformed allergen-specific IgE present in the bronchial and gut mucosa of patients with recurrent allergen exposure would enhance immune responses upon repeated allergen inhalation or ingestion.

CD23 Function: IgE Regulation

In addition to its role in allergen uptake, CD23 appears to have regulatory influences on IgE synthesis and allergic inflammation. Although the data in this area have seemed to be conflicting at times, the emerging consensus from human and animal studies is that ligation of membrane-bound CD23 on B cells suppresses IgE production. Ligation of CD23 on human B cells by activating antibodies inhibits IgE synthesis[125] and transgenic mice overexpressing CD23 have suppressed IgE responses.[126,127] Conversely, mice rendered CD23-deficient by targeted gene disruption have increased and sustained specific IgE titers following immunization, also consistent with a suppressive effect of membrane-bound CD23.[128] This enhanced tendency toward IgE synthesis in $CD23^{-/-}$ mice is also observed following allergen inhalation and is accompanied by increased eosinophilic inflammation of the airways.[129–132]

In contrast, there have been reports that soluble CD23 (sCD23) fragments, which are generated by proteolytic cleavage, may enhance IgE production, either by direct interaction with B cells (via CD21) or by binding to IgE, thereby blocking its interaction with membrane-bound CD23.[133] The IgE-enhancing effects of crude sCD23 have not yet been reproduced with recombinant sCD23[134] and it is unclear whether this discrepancy arises from IgE-inducing activity attributable to other components of sCD23-containing culture supernatants or whether the lack of activity of recombinant sCD23 is the consequence of a nonphysiologic structure. Recent data implicate a role for allergens, some of which are proteases, as effectors of CD23 cleavage and for IgE itself as a stabilizer of membrane CD23 and inhibitor of proteolytic shedding.[135] Two possible consequences of such allergen-mediated cleavage would be decreased suppressive signaling to the B cell via CD23, along with increased production of activating sCD23 fragments, both promoting IgE production. Inhibition of proteolytic activity of Der p 1 blocks its ability to induce IgE responses in vivo both in normal and humanized scid mice.[136,137] Similar effects are observed in culture systems. Metalloproteinase inhibitors block sCD23 shedding in cultures of tonsillar B cells or peripheral blood mononuclear cells, and this is accompanied by decreased IgE production following stimulation with IL-4.[138]

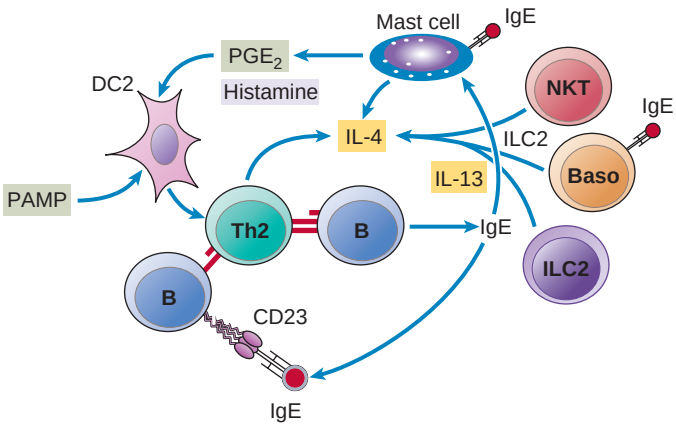

Figure 4-8 The IgE network: cellular and cytokine control of IgE production in allergic tissues and amplification of allergic responses by preformed IgE. A confluence of cellular and molecular stimuli supports IgE synthesis in the tissues of asthmatic patients. Tissue DCs are driven toward a Th2-promoting DC2 phenotype by a variety of environmental influences, including exposure to microbial 'pathogen-associated molecular patterns' *(PAMPs)* and histamine and PGE_2 (both of which can be provided by mast cells). Activated DC2s translocate to mucosal- or skin-associated lymphoid tissues where they attain competence as antigen-presenting cells (APCs) and drive the generation of Th2 cells. B cells also serve as APCs, a function that is augmented when preformed IgE (generated during previous allergen encounter) is present and can facilitate B cell antigen uptake via CD23.

IL-4 and IL-13 are derived from numerous cellular sources. In the setting of recurrent allergen challenge, preexisting, allergen-specific Th2 T cells are likely to provide a major source of IL-4. Additional producers of IL-4 include NKT cells and mast cells. Mast cell IL-4 synthesis can be triggered via FcεRI in the presence of preformed IgE. IL-4 and IL-13 along with cognate T-B interactions involving antigen presentation and CD40 signaling then support IgE isotype switching in B cells.

Conclusions

To summarize, IgE antibodies are typically elevated in individuals affected by the atopic conditions of asthma, allergic rhinitis and atopic dermatitis. The production of IgE follows a series of complex genomic rearrangements in B cells, called deletional class switch recombination, a process that is tightly regulated by the cytokines IL-4 and IL-13 along with T-B cell interaction and CD40/CD154 signaling. IgE antibodies exert their biologic effects via receptors FcεRI and CD23. It is now clear that, in addition to mediating the classic immediate hypersensitivity reactions by inducing acute mediator release by mast cells, IgE antibodies have a number of immunomodulatory functions (Figure 4-8). These include up-regulation of IgE receptors, promotion of mast cell survival, enhancement of allergen uptake by B cells for antigen presentation, and induction of Th2 cytokine expression by mast cells and may all collaborate to amplify and perpetuate allergic responses in susceptible individuals. Thus, blockade of IgE effects, using novel anti-IgE therapies, may ultimately prove to have a broad benefit.

5 Inflammatory and Effector Cells/Cell Migration

BENJAMIN P. DAVIS | MARC E. ROTHENBERG

KEY POINTS

- A hallmark of allergic inflammation is the accumulation of a large number of leukocytes, including eosinophils, neutrophils, lymphocytes, basophils and macrophages, in the inflammatory tissues.
- Leukocyte migration into tissues is regulated by chemokines, chemoattractive cytokines.
- Th2 cytokines (e.g. interleukin [IL]-4 and IL-13) are potent inducers of allergy-associated chemokines (e.g. eotaxin).
- Chemokines are potent cellular activating factors.
- Leukocytes bind to the endothelium via low-affinity reversible interactions mediated by selectins, and tight adhesion of leukocytes to endothelium is mediated by specific adhesion molecules such as integrins.
- Animal and human experimental systems have demonstrated that allergic inflammatory responses are often biphasic.

Introduction

One of the hallmarks of allergic inflammation is the accumulation of an abnormally large number of leukocytes, including eosinophils, neutrophils, lymphocytes, basophils and macrophages, in the inflammatory tissue. There is substantial evidence that inflammatory cells are major effector cells in the pathogenesis of allergic disorders. Therefore, understanding the mechanisms by which leukocytes accumulate and are activated in tissues is very relevant to allergic diseases. Substantial progress has been made in understanding the specific molecules involved in leukocyte migration and the specific mechanisms by which effector cells participate in disease pathogenesis. In particular, cellular adhesion proteins, integrins and chemoattractant cytokines (chemokines) have emerged as critical molecules in these processes. Chemokines are potent leukocyte chemoattractants and cellular activating factors, making them attractive new therapeutic targets for the treatment of allergic disease. This chapter focusses on recently emerging data on the mechanisms by which specific leukocyte subsets are recruited into allergic tissues and how leukocytes participate in disease pathogenesis.

Animal and human experimental systems have demonstrated that allergic inflammatory responses are often biphasic. For example, asthma is characterized by a biphasic bronchospasm response, consisting of an early-phase asthmatic response (EAR) and a late-phase asthmatic response (LAR)[1] (Figure 5-1). The EAR is characterized by immediate bronchoconstriction in the absence of pronounced airway inflammation or morphologic changes in the airway tissue.[1,2] The EAR has been shown to directly involve immunoglobulin(Ig) E/mast cell-mediated release of histamine, prostaglandin D_2 and cysteinyl-peptide leukotrienes (CysLTs), which are potent mediators of bronchoconstriction. After the immediate response, individuals with asthma often experience an LAR, which is characterized by persistent bronchoconstriction associated with extensive airway inflammation and morphologic changes to the airways.[1,3–5] Clinical investigations have demonstrated that the LAR is associated with increased levels of inflammatory cells, in particular activated T lymphocytes and eosinophils (Figure 5-1). The elevated levels of T lymphocytes and eosinophils correlate with increased levels of eosinophilic constituents in the bronchoalveolar lavage fluid (BALF), the degree of airway epithelial cell damage, enhanced bronchial responsiveness to inhaled spasmogens and disease severity[1,4–8] In this chapter, we concentrate on understanding the inflammatory cells that participate in allergic responses, the mechanisms involved in their accumulation in natural human allergic responses and in experimental models, such as the biphasic response described above (Figure 5-1), and the complex interplay of these diverse cells with resident cells including endothelial, epithelial, smooth muscle cells and fibroblasts.[9–11]

Myelocytes

EOSINOPHILS

Eosinophils are multifunctional leukocytes implicated in the pathogenesis of numerous inflammatory processes, especially allergic disorders.[12] In addition, eosinophils play a role in homeostasis and may have a physiologic role in organ morphogenesis (e.g. postgestational mammary gland development) and the development of immune architecture, particularly the formation and function of IgA-secreting B cells.[13,14] The gastrointestinal (GI) tract, spleen, lymph nodes, thymus, mammary glands and uterus are rich in eosinophils.[15,16] In adipose tissue, eosinophils are important for the maintenance of glucose metabolic homeostasis.[17] Additionally, experimental eosinophil accumulation in the GI tract is associated with the development of weight loss, which is attenuated in eotaxin-deficient mice that have a deficiency in GI eosinophils.[18] It is important to note that recent attention has focussed on the key role of innate helper lymphoid cells (ILC), particularly ILC2, in regulating eosinophils via production of interleukin (IL)-5 and IL-13, and this regulation is related to nutritional intake in the GI tract.[19]

Eosinophils express numerous receptors for chemokines (e.g. eotaxin, an eosinophil-selective chemoattractant) that,

https://CafePezeshki.IR

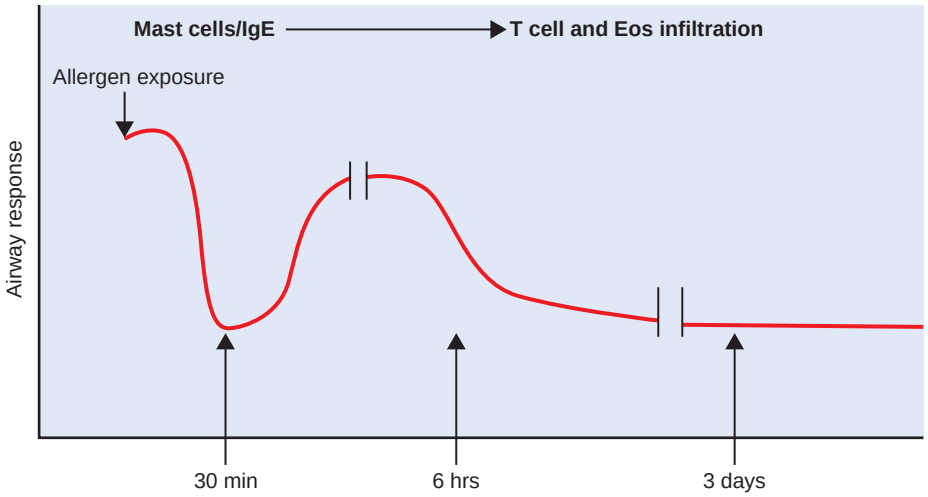

Figure 5-1 Early-phase and late-phase allergic responses. The airway response (e.g. forced expiratory volume in the first second [FEV_1]) is illustrated for when an allergen-sensitized individual is experimentally exposed to an allergen. A biphasic bronchospasm response, consisting of an early-phase asthmatic response (EAR) and a late-phase asthmatic response (LAR), is shown. The EAR phase is characterized by immediate bronchoconstriction in the absence of pronounced airway inflammation or morphologic changes in the airways tissue. The EAR phase has been shown to directly involve IgE/mast cell-mediated release of histamine, prostaglandin D_2 and cysteinyl-peptide leukotrienes, which are potent mediators of bronchoconstriction. After the immediate response, the airway recovers but later undergoes marked decline in function, which is characterized by more persistent bronchoconstriction associated with extensive airway inflammation (involving T cells and eosinophils [*Eos*]).

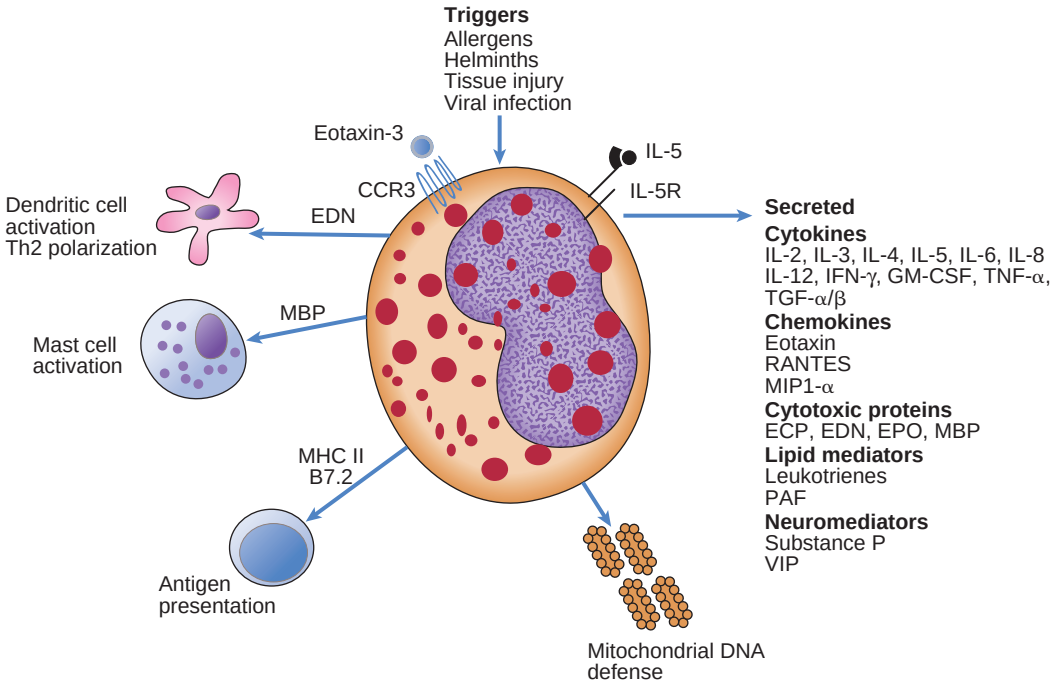

Figure 5-2 Schematic diagram of an eosinophil and its diverse properties. Eosinophils are bilobed granulocytes that respond to diverse stimuli including allergens, helminths, viral infections, allografts and nonspecific tissue injury. Eosinophils express the receptor for IL-5, a critical eosinophil growth and differentiation factor, as well as the receptor for eotaxin and related chemokines *(CCR3)*. The secondary granules contain four primary cationic proteins designated eosinophil peroxidase *(EPO)*, major basic protein *(MBP)*, eosinophil cationic protein *(ECP)* and eosinophil-derived neurotoxin *(EDN)*. All four proteins are cytotoxic molecules; also, ECP and EDN are ribonucleases. In addition to releasing their preformed cationic proteins, eosinophils can release a variety of cytokines, chemokines and neuromediators and generate large amounts of LTC_4. Lastly, eosinophils can be induced to express MHC class II and costimulatory molecules and may be involved in propagating immune responses by presenting antigen to T cells.

when engaged, lead to eosinophil activation, resulting in several processes, including the release of toxic secondary granule proteins[20] (Figure 5-2). The secondary granule contains a crystalloid core composed of major basic protein (MBP) and a granule matrix that is mainly composed of eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN) and eosinophil peroxidase (EPO). These granule proteins have been shown to be cytotoxic, helminthotoxic and virotoxic.[15,16,21] Importantly, an anti-eotaxin antibody (bertilimumab) has been shown to decrease nasal congestion with a trend of decreased eosinophils in allergic rhinitis and is being studied currently for another eosinophil-related condition, ulcerative colitis.[22]

https://CafePezeshki.IR

Activation of eosinophils also leads to the generation of large amounts of LTC_4, which induces increased vascular permeability, mucus secretion and smooth muscle constriction.[23] Also, activated eosinophils generate a wide range of cytokines including IL-1, IL-3, IL-4, IL-5 and IL-13; GM-CSF; transforming growth factor (TGF)-α/β; tumor necrosis factor (TNF)-α; RANTES (regulated on activation, normal T cells expressed and secreted); macrophage inflammatory protein (MIP)-1α; and eotaxin. This indicates that they have the potential to sustain or augment multiple aspects of the immune response, inflammatory reaction and tissue repair processes.[24] Eosinophils also have the capacity to initiate antigen-specific immune responses by acting as antigen-presenting cells. Consistent with this role, eosinophils express relevant costimulatory molecules (CD40, CD28, CD86, B7),[25,26] secrete cytokines capable of inducing T cell proliferation and maturation (IL-2, IL-4, IL-6, IL-10, IL-12)[24,27,28] and can be induced to express MHC class II molecules.[27] Interestingly, experimental adoptive transfer of antigen-pulsed eosinophils induces antigen-specific T cell responses in vivo[29] (Box 5-1). Finally, it has been shown that the GI eosinophils have a unique and fascinating innate effector response. It appears that eosinophils may eliminate invading bacteria by ejecting their mitochondrial DNA, which is encased in highly cationic proteins.[30] Evidence continues to emerge suggesting that eosinophils have an important role in innate immune responses, in addition to their well-established role in allergic disease.

Eosinophils are important for the development of asthma-associated airway hyperresponsiveness (AHR).[15,16,31] Eosinophils are the principal source of CysLTs and have been identified as the dominant source of leukotriene LTC_4 in asthmatic bronchial airway.[32] These leukotrienes can initiate mucus hypersecretion, AHR and edema. MBP is cytotoxic to airway epithelial cells and may be at least partly responsible for the tissue damage that is associated with eosinophil infiltration in bronchial mucosa in asthma and has been associated with fatal asthma.[33] Importantly, eosinophils have been implicated in the regulation of pulmonary T cell responses[34] and appear to be required for complete Type 2 T helper cell (Th2) cytokine production and allergen-induced mucus production in the lung.[35] Within the last few years, attempts have been made to further classify asthma phenotypes; one subtype is eosinophilic asthma, which is often a severe, steroid-refractory disease.[36] Eosinophils selectively express the receptor for IL-5, a cytokine that regulates eosinophil expansion and eosinophil survival and primes eosinophils to respond to appropriate activating signals. Multiple studies have supported the beneficial usage of anti-IL-5 therapy for patients with asthma[16,37,38] and nasal polyposis.[39] Moreover, peripheral blood eosinophils and eosinophil granule protein levels are increased and correspond with disease activity in most patients with atopic dermatitis, and eosinophil granule proteins have been shown to be deposited in lesional skin.[40] Eosinophil accumulation in the GI tract is a common characteristic of numerous disorders, including gastroesophageal reflux disease (GERD), inflammatory bowel disease (IBD), drug reactions, helminthic infections, hypereosinophilic syndrome (HES), eosinophilic GI disorders (EGIDs) and allergic colitis.[15,16,38] EGIDs, including eosinophilic esophagitis (EoE), eosinophilic gastritis (EG) and eosinophilic gastroenteritis (EGE), often occur without peripheral blood eosinophilia, indicating the significance of GI-specific mechanisms for regulating local eosinophil levels. Although absent in the normal esophagus, eosinophils markedly accumulate in the esophagus of patients with EoE. A number of experimental models have provided evidence that eosinophils are key effector cells in EGIDs and contribute to the disease pathology.[41] In allergic rhinitis during allergy season, there is an increase in eosinophils and their granule proteins.[42] The above data collectively demonstrate the importance of eosinophils in allergic disease.

BOX 5-1 KEY CONCEPTS

Eosinophils

- Eosinophils are multifunctional leukocytes that normally account for 1% to 3% of circulating leukocytes.
- Eosinophils normally reside in mucosal tissues such as the gastrointestinal tract.
- Eosinophil granules contain cationic (basic) proteins that are cytotoxic to a variety of host tissues (e.g. respiratory epithelium).
- Eosinophil expansion is regulated by the growth factor IL-5.
- Eosinophil tissue mobilization is regulated by the eotaxin subfamily of chemokines.

MAST CELLS

Mast cells are normally present particularly in tissues in contact with the external environment (i.e. skin, respiratory mucosa, conjunctiva and GI mucosa). Mast cells contribute to immune responses to bacteria[43] and venom[44] and are important in homeostasis and wound repair.[45] Mast cells are major effector cells involved in allergic responses; in addition, they are important cytokine-producing cells that are involved in nonallergic processes such as the innate immune response (Figure 5-3). In contrast to other hematopoietic cells that complete their differentiation in the bone marrow, mast cell progenitors leave the bone marrow and complete their differentiation in tissues. Elegant studies in mice have demonstrated that development of mast cells from bone marrow cells is dependent on IL-3 and that their tissue differentiation is primarily dependent on stem cell factor (SCF).[46–48] In contrast to the mast cell culture

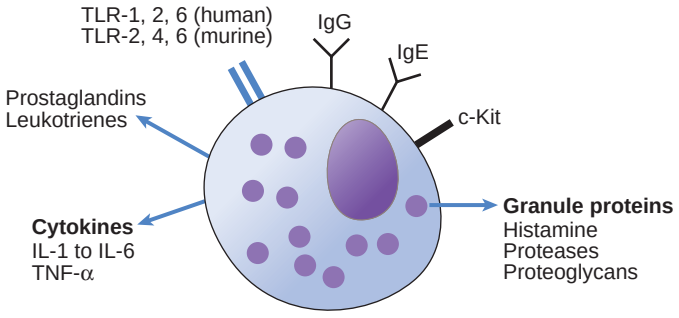

Figure 5-3 Schematic diagram of a mast cell and its products. Mast cells are mononuclear cells that express high-affinity IgE receptors and contain a large number of metachromatic granules. Mast cells express c-Kit, the receptor for stem cell factor (SCF), a critical mast cell growth and differentiation factor. The secondary granule of a mast cell also contains abundant levels of proteases, proteoglycans and histamine. In addition to releasing their preformed proteins, mast cells can also release a variety of cytokines and generate large amounts of prostaglandins (PGD_2) and leukotrienes (LTC_4). Mast cells also express Toll-like receptors (TLR), indicating that mast cells participate during innate immune responses.

https://CafePezeshki.IR

conditions in the murine system (which depend on IL-3), mature human mast cells are obtained by culturing progenitor cells with SCF, IL-6 and IL-10. Furthermore, treatment of mature human mast cells with IL-4 induces further maturation, including enhancing their capacity for IgE-dependent activation and their enzymatic machinery for synthesizing PGD_2 and CysLTs.[49]

Mast cells exist as heterogeneous populations depending on the tissue microenvironment in which they reside and on the immunologic status of the individual. In work with rodents, the terms *mucosal mast cell* (MMC) and *connective tissue mast cell* (CTMC) have emerged, but designating these two populations of mast cells by tissue location alone is an oversimplification. In general, MMCs express less sulfated proteoglycans (chondroitin sulfate) in their granules than CTMCs and hence have different staining characteristics with metachromatic stains. In addition, mast cell populations express distinct granule proteases; in humans, the mast cell nomenclature is based on neutral protease expression. Human cells that express only tryptase (MC_T) are distinguished from mast cells that express tryptase, chymase, carboxypeptidase and cathepsin G (MC_{TC}). In normal tissues, MC_T cells are the predominant cells in the lung and small intestinal mucosa, whereas MC_{TC} cells are the predominant types found in the skin and GI submucosa.

Mast cell activation occurs through several pathways. Classically, a multivalent allergen cross-links IgE molecules bound to the high-affinity IgE receptor (FcεRI). Mast cells undergo regulated exocytosis of their granules, resulting in the release of preformed mediators; in addition, activated mast cells undergo de novo synthesis and release of a variety of potent mediators (such as prostaglandin D_2 and LTC_4). Preformed mediators in mast cells include biogenic amines such as histamine (a vasodilator), various neutral proteases, a variety of cytokines, acid hydrolases (e.g. β-hexosaminidase) and proteoglycans. Notably, nearly 20% of the protein of human mast cells is composed of tryptase, a proinflammatory protease with a wide range of activities (e.g. cleavage of complement proteins).[50] Mast cells store a variety of cytokines in their granules (e.g. TNF-α, IL-1, IL-4, IL-5 and IL-6 and chemokines including IL-8) and, after activation with allergens or cytokines, mast cells can increase their synthesis and secretion of these cytokines.[51]

It is well established that mast cell products contribute to the immediate allergic responses in asthma,[52] anaphylaxis,[52] allergic rhinoconjunctivitis[53] and urticaria.[54] There is also evidence that mast cells can contribute to allergic sensitization via IL-4-mediated skewing of T cells toward the Th2 phenotype[55] via a mechanism involving dendritic cell activation of T cells.[56–59]

The contribution of mast cell products such as cytokines has been less clear, though mast cells appear to be a chief source of TNF-α in asthmatic lung (Box 5-2). In addition, mast cells have been shown to contribute to the chronic inflammation associated with the LAR in experimental asthma.[52] The LAR also responds dramatically to omalizumab therapy,[60] suggesting that LAR is initiated by mast cell activation during the EAR. Additionally, mast cells have been linked to more chronic, T cell-mediated allergic diseases such as atopic dermatitis[61] and EoE.[62]

BASOPHILS

Basophils are hematopoietic cells that arise from a granulocyte-monocyte progenitor (GMP) that shares its lineage with mast cells and eosinophils.[63] Basophils complete their development in the bone marrow and circulate as mature cells, representing less than 2% of blood leukocytes (Box 5-3). Similar to mast cells, basophils express substantial levels of FcεRI and store histamine in their granules. They are distinguished from mast cells by their segmented nuclei, ultrastructural features, growth factor requirements, granule constituents and surface marker expression ($c\text{-}Kit^-$, $Fc\varepsilon RI^+$).[64] Basophils are more readily distinguished from eosinophils microscopically due to differences in their nuclei, cytoplasmic granules and appearance on hematoxylin- and eosin-stained tissues. In the human system, they develop largely in response to IL-3 in a process augmented by TGF-β. Mature basophils maintain expression of the IL-3 receptor, and IL-3 is a potent basophil-priming and -activating cytokine.[65]

Several processes activate basophils; upon cross-linking of their surface-bound IgE, basophils release preformed mediators including histamine and proteases and synthesize LTC_4. In addition, they secrete cytokines such as IL-4 and IL-13; notably, the amount of IL-4 secreted by basophils compared with that by Th2 cells appears to be substantial.[66] Similar to eosinophils, basophils are also activated by IgA (via FcαR) and by CCR3 ligands. Basophils also express several other chemokine receptors, including CCR2, whose ligands are potent histamine-releasing factors. Basophils also express major histocompatibility complex (MHC) class II and costimulatory molecules CD80 and CD86 and may be an antigen-presenting cell that can induce Th2 cell differentiation in the lymph node via IL-4.[67–69]

Recent murine studies suggest that basophils help to expel helminths.[70] Additionally, other animal models have suggested that basophils participate in the resistance of ectoparasitic ticks.[71] Studies have linked basophils to the sensitization phase in EoE[72] and the late-phase response in allergic rhinitis, asthma and allergic contact dermatitis.[73–76] Basophils have also been implicated in a unique IgG-mediated mechanism of anaphylaxis in mice. It appears that this mechanism of anaphylaxis is dependent upon IgG, macrophages and platelet-activating factor (PAF). Elegant mouse studies have demonstrated that

BOX 5-2 KEY CONCEPTS

Mast Cells

- Mast cells are bone marrow-derived, tissue-dwelling cells.
- Mast cells do not normally exist in the circulation.
- Mast cell development is critically dependent on the cytokine stem cell factor and its receptor c-Kit.
- Mast cells express a high-affinity IgE receptor (FcεR) that is normally occupied with IgE.
- Mast cell activation results in the release of preformed mediators (e.g. histamine and proteases) and newly synthesized mediators such as prostaglandins and leukotrienes.
- Mast cells also produce cytokines such as tumor necrosis factor (TNF)-α and have an important role in innate immune responses (e.g. by attracting neutrophils).

BOX 5-3 KEY CONCEPTS

Basophils

- Basophils are bone marrow leukocytes that normally account for less than 2% of circulating leukocytes.
- Basophils express the high-affinity IgE receptor FcεR.
- Basophils are distinguished from mast cells by their separate lineage, bilobed nuclei and distinct granule proteins.
- Basophils accumulate in tissues during late-phase responses.

https://CafePezeshki.IR

mice deficient in IgE, FcεRI and mast cells still experience anaphylaxis via an IgG-mediated process.[77] However, IgG-mediated anaphylaxis is abolished in basophil-deficient mice.[78] Further investigations are needed to define the role of basophils in this newly described anaphylactic pathway.

MACROPHAGES

Macrophages are tissue-dwelling cells that originate from hematopoietic stem cells in the bone marrow and are subsequently derived from circulating blood monocytes.[79] Under healthy conditions, bone marrow colony-forming cells rapidly progress through monoblast and promonocyte stages to monocytes, which subsequently enter the bloodstream for about 3 days, where they account for about 5% of circulating leukocytes in most species. On entering various tissues, monocytes terminally differentiate into morphologically, histochemically and functionally distinct tissue macrophage populations that have the capacity to survive for several months.[80] Tissue-specific populations of macrophages include dendritic cells (skin, gut), Kupffer cells (liver) and alveolar macrophages (lung). Macrophage colony-stimulating factor (M-CSF) 1 promotes monocyte differentiation into macrophages, and mice with a genetic mutation in *Csf1* have a deficiency of tissue macrophages.[81] In addition, GM-CSF promotes the survival, differentiation, proliferation and function of myeloid progenitors, as well as the proliferation and function of macrophages.[82]

Tissue macrophages contribute to innate immunity by virtue of their ability to migrate, phagocytose and kill microorganisms and to recruit and activate other inflammatory cells. By expressing Toll-like receptor mediated pathogen-recognition molecules that induce the release of cytokines capable of programming adaptive immune responses, macrophages provide important links between innate and adaptive immunity.[83] Macrophages also express high- and low-affinity receptors for IgG (FcγRI/II) and complement receptors (CR1) that promote their activation. Activated macrophages produce a variety of pleiotropic proinflammatory cytokines such as IL-1, TNF-α and IL-8, as well as lipid mediators (e.g. leukotrienes and prostaglandins). Notably, macrophages express costimulatory molecules (e.g. CD86) and are potent antigen-presenting cells capable of efficiently activating antigen-specific T cells.

A substantial body of evidence has revealed that macrophages are critical effector cells in allergic responses. For example, peripheral blood monocytes from asthmatic individuals secrete elevated levels of superoxide anion and GM-CSF.[84] In addition, the lung tissue and BALF from asthmatic individuals have elevated levels of macrophages.[85] Consistent with this finding, the asthmatic lung overexpresses macrophage-attracting chemokines (e.g. mast cell protease [MCP]-1).[86] Additionally, there appear to be different types of lung macrophages based on tissue location. Alveolar macrophages promote an inflammatory response, whereas interstitial macrophages have decreased phagocytosis and increased antiinflammatory effect.[87] Alveolar macrophages have no antiinflammatory effect during the sensitization phase of lung immune responses,[88] whereas interstitial macrophages suppress responses against inhaled allergens.[89] Interstitial macrophages prevent Th2 polarization in response to inhaled antigens via an IL-10/dendritic cell mechanism.

We now recognize that there are at least two distinct subsets of macrophages, classically and alternatively activated macrophages. Classically activated macrophages (M1) are associated with a proinflammatory response and are activated by Th1 cytokines, whereas alternatively activated macrophages, so named because they are activated in the presence of Th2 cytokines, are associated with the resolution of inflammation and tissue repair. Alternatively activated macrophages (M2) may serve as a link between the innate and adaptive immune system, and further investigation into their function in allergic disorders is needed. A central mechanism for the differentiation of these macrophage subsets is the metabolism of arginine via two competing pathways, depending on their cytokine polarization.[90] For example, interferon (IFN)-γ and lipopolysaccharide (LPS) augment the expression of inducible nitric oxide synthase (iNOS), which results in the production of NO as a product of arginine metabolism. NO is a potent smooth muscle relaxer and endothelial cell regulator. Alternatively, the treatment of macrophages with IL-4 or IL-13 induces the expression of arginase, which preferentially shunts arginine away from NO and thus promotes bronchoconstriction. Arginase metabolizes arginine into ornithine, a precursor for polyamines and proline, critical regulators of cell growth and collagen deposition, respectively. Both M1 and M2 macrophages have been reported in asthmatics.[91–93]

NEUTROPHILS

Neutrophils are bone marrow-derived granulocytes and account for the largest proportion of cells in most inflammatory sites. Neutrophils develop in the bone marrow by the sequential differentiation of progenitor cells into myeloblasts, promyelocytes and then myelocytes, an ordered process regulated by growth factors such as GM-CSF. Granulocyte-CSF promotes the terminal differentiation of neutrophils, which normally reside in the bloodstream for only 6 to 8 hours. A significant pool of marginated neutrophils exists in select tissues,[94] allowing rapid mobilization of neutrophils in response to a variety of triggers (e.g. IL-8, LTB_4, PAF).

Activated neutrophils have the capacity to release a variety of products at inflammatory sites, which may induce tissue damage. These products include those of primary (azurophilic), secondary (or specific) and tertiary granules, including proteolytic enzymes, oxygen radicals and lipid mediators (LTB_4, PAF and thromboxane A_2). Neutrophil granules contain more than 20 enzymes; of these, elastase, collagenase and gelatinase have the greatest potential for inducing tissue damage. Neutrophil-derived defensins, lysozyme and cathepsin G have well-defined roles in antibacterial defense. In fact, studies have suggested that the major function of superoxide release into the phagocytic vesicle is increasing the intravesicular concentration of H^+ and K^+, permitting conditions for optimal protease-mediated bacterial killing.[95]

Although neutrophils are not the predominant cell type associated with allergic disorders, several studies have demonstrated a correlation and possible role for neutrophils in the pathogenesis of allergic disease.[96] Individuals who die within 1 hour of the onset of an acute asthma attack have neutrophil-dominant airway inflammation,[97] suggesting that neutrophils may have a pathogenic role in some clinical situations. Neutrophils in bronchial biopsy and induced sputum are more likely seen with severe asthma.

Patients with neutrophilic asthma appear to be less responsive to corticosteroids, and high doses of corticosteroids may

https://CafePezeshki.IR

increase neutrophils by reducing apoptosis.[98] Another lung disease associated with asthma, allergic bronchopulmonary aspergillosis (ABPA), features neutrophilic inflammation and activation.[99] Numerous risk exposures are linked to neutrophilic inflammation, including environmental exposures such as air pollution, smoking, infection and endotoxin, and health-related exposures such as high-fat, low-antioxidant diets, obesity and inflammatory states. Two fairly specific neutrophil therapies (anti-CXCL8 and anti-CXCR2) have begun to show promise in treating neutrophilic airway inflammation.[100,101] Collectively, these data suggest an important role for neutrophils in the acute and chronic manifestations of allergen-induced asthma.

DENDRITIC CELLS

Dendritic cells are unique antigen-presenting cells that have a pivotal role in innate and acquired immune responses. They are considered the quintessential antigen-presenting cells and are known for their ability to effect a primary immune response including allergen sensitization. These cells are also important in maintenance of allergic inflammation via propagation of effector responses. Dendritic cells originate in the bone marrow and subsequently migrate into the circulation before they assume tissue locations as immature dendritic cells, incidentally at locations where maximum allergen encounter occurs (e.g. skin, GI tract and airways). Immature dendritic cells are potent in antigen uptake, efficient in capturing pathogens and producers of potent cytokines (e.g. IFN-α and IL-12). By expressing pattern-recognition receptors, dendritic cells directly recognize a variety of pathogens. Immature dendritic cells express the CC chemokine receptor (CCR) 6 that binds to MIP-3α and β-defensin, which are produced locally in tissues such as those in the lung.[102] After antigen uptake, dendritic cells rapidly cross into the lymphatic vessels and migrate into draining secondary lymphoid tissue. During this migration, the dendritic cells undergo maturation, which is characterized by down-regulation of their antigen-capturing capacity, up-regulation of their antigen-processing and -presenting capabilities, and up-regulation of CCR7, which likely promotes dendritic cell recruitment to secondary lymphoid organs (which express CCR7 ligands).[103] After presentation of antigen to antigen-specific T cells in the T cell-rich areas of secondary lymphoid organs, dendritic cells mainly undergo apoptosis.

Dendritic cells are composed of heterogeneous populations based on ultrastructural features, surface molecule expression and function. In human blood, dendritic cells are divided into three types comprising two myeloid-derived subpopulations and one lymphoid-derived population (plasmacytoid dendritic cells).[104] The myeloid populations can be divided into $CD1^+$ and $CD1^-$. CD1 is a molecule involved in the presentation of glycolipids to T cells. $CD1c^+$ myeloid dendritic cells also express high levels of CD11c (complement receptor 4 [iC3b receptor]) and include interstitial and Langerhans dendritic cells; a skin-specific, self-renewing specialized dendritic cell; and inflammatory dendritic cells. $CD1^-$ myeloid dendritic cells are identified by CD141 expression and are cross-presenting dendritic cells.[105] The plasmacytoid dendritic cell population is $CD1c^-/CD11c^-$ but is distinguished by its high levels of IL-3 receptor expression. This population of dendritic cells appears to be a primary source of IFN-α. Dendritic cells can be cultured from freshly isolated human cord or peripheral blood; myeloid dendritic cells are primarily derived in response to stimulation with GM-CSF, TNF-α and IL-4; plasmacytoid dendritic cells develop in culture with IL-3. Monocyte-derived dendritic cells give rise to inflammatory dendritic cells that have a potent stimulatory capacity toward naïve $CD4^+$ T cells and the ability to cross-present antigen to $CD8^+$ T cells and to produce key inflammatory cytokines including IL-1, IL-6, TNF-α, IL-12 and IL-23.[105]

Dendritic cells can influence Th cell differentiation (Figure 5-4). There is evidence that the same population of dendritic cells can influence Th1 and Th2 differentiation depending on several factors. For example, the ratio between dendritic cells and T cells has profound effects on influencing Th1 and Th2 differentiation.[106] In addition, Th1-polarized effector dendritic cells induce Th1 responses, whereas Th2-polarized dendritic cells induce Th2 responses.[104] Also, plasmacytoid dendritic cells stimulated first with IL-3 and then with CD40 ligand (before adding naïve T cells) induce strong Th1 responses but no Th2 cytokine production. MicroRNA (miR)-21 expression in dendritic cells targets IL-12p23; hence, up-regulation of miR-21 by Th2 cytokines introduces a Th2-generating propagation loop. Finally, dendritic cells that express specific costimulatory molecules may promote distinct Th differentiation; for example, expression of B7-related protein (ICOS ligand) promotes Th2 development.[107]

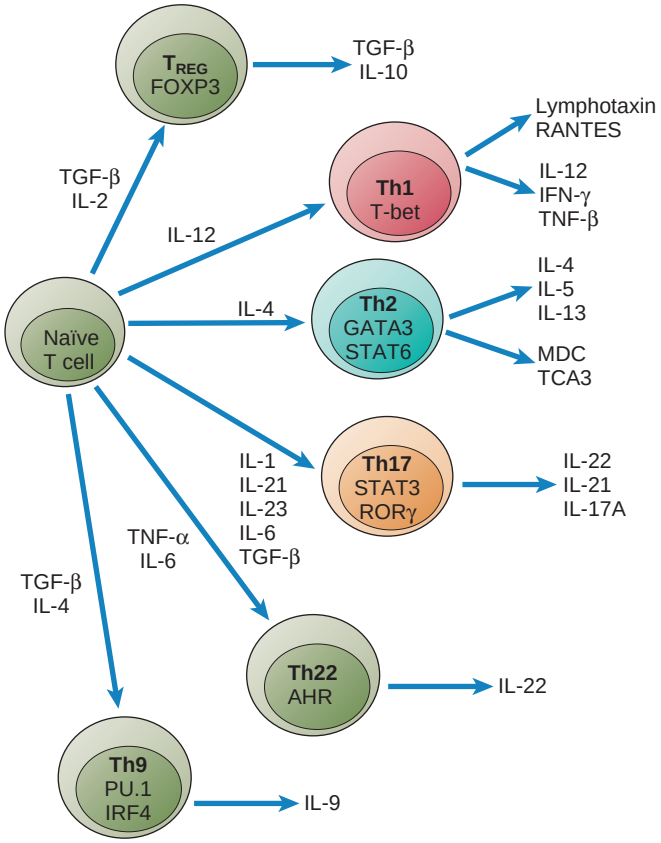

Figure 5-4 T helper subsets. All currently recognized T helper subsets have been implicated in allergic disease. Th0 cells differentiate into T regulatory (T_{REG}), Th1, Th2, Th9, Th17 or Th22 cells after their activation by antigen-presenting cells in the context of their respective promoting cytokines as noted. The unique transcription factors responsible for driving cytokine development are identified. AHR – Aryl hydrocarbon receptor.

https://CafePezeshki.IR

BOX 5-4 KEY CONCEPTS

Dendritic Cells

- Dendritic cells normally exist as tissue surveillance cells.
- On contact with antigen (e.g. invading pathogen), dendritic cells migrate via lymphatics to secondary lymphoid organs.
- Immature dendritic cells are chief sources of innate cytokines (e.g. interferon [IFN]-α).
- Mature dendritic cells are potent antigen-presenting cells.
- Dendritic cells can preferentially activate T subset responses.

Dendritic cells likely have critical roles in the development of allergic responses. Current evidence and theory suggest that allergen can induce a Th2-mediated response, either alone (with a self-adjuvant effect) or in combination with other environmental adjuvants (viral or bacterial infections or air pollution),[108] and that this effect likely occurs via communication of resident stromal cells and dendritic cells.[109,110] Pollen allergens in vitro have been shown to induce a Th2-polarizing dendritic cell,[111] whereas house dust mite-mediated dendritic cell polarization is dependent on the allergy background of the patient.[112,113] Dendritic cells are required for the development of eosinophilic airway inflammation in response to inhaled antigen.[114] Importantly, adoptive transfer of antigen-pulsed dendritic cells has been shown to be sufficient for the induction of Th2 responses and eosinophilic airway inflammation to inhaled antigen.[103,115] Elevated levels of $CD1a^+$/MHC class II^+ dendritic cells are found in the lung of atopic asthmatics compared with of nonasthmatics[103] (Box 5-4).

In addition to the importance of dendritic cells in sensitization, selective depletion of dendritic cells during allergen challenge in both asthma and allergic rhinitis murine models has demonstrated the importance of dendritic cells in the effector phase of these diseases.[116,117] FcεRI expression on dendritic cells in humans and mice in asthma and atopic dermatitis is correlated with increased Th2 effector response.[118–120]

LYMPHOCYTES

Lymphocytes are integral to the development of a complete innate and adaptive immune response. One important function of lymphocytes is to generate adaptive immune responses and to develop a memory compartment for future responses. Innate lymphocytes serve as sentinel cells in epithelial-associated tissues, providing prompt release of cytokines that help to form the adaptive response. Lymphocytes both aid in pathogen defense and facilitate allergic disease. In addition to Th2 cells, many lymphocytes can participate in allergic inflammation including Th1 cells, Th17 cells, $CD8^+$ T cells, B cells, γ/δ T cells, natural killer (NK) cells and natural killer T (NKT) cells.

T CELLS

T cells are specialized leukocytes distinguished by their expression of antigen-specific receptors that arise from somatic gene rearrangement. Two major subpopulations were originally defined on the basis of the expression of the CD4 and CD8 antigens and their associated function. $CD4^+$ T cells recognize antigen in association with MHC class II molecules on antigen-presenting cells, including dendritic cells, B cells and macrophages, and are primarily involved in orchestrating immune responses, whereas $CD8^+$ T cells recognize antigen in association with MHC class I molecules and are primarily involved in cytotoxicity. Class I MHC molecules are present on the surface of all nucleated cells, and their antigens are typically intracellularly derived. More recently, populations of regulatory T cells have been characterized. Regulatory T cells are commonly identified as $CD4^+/CD25^+/FOXP3^+$ T cells; these cells are chief sources of regulatory cytokines, including IL-4 and IL-10, and are thought to participate in tolerance induction after allergen immunotherapy.[121] The absence of or decrease in the function of T regulatory cells leads to an increase in activity of effector T lymphocytes and is associated with the development of autoimmunity.[122] $CD4^+$ T lymphocytes have central roles in allergic responses by regulating the production of IgE and the effector function of mast cells and eosinophils.[123]

$CD4^+$ Th1-type T lymphocytes produce IL-2, TNF-β (lymphotoxin) and IFN-γ and are involved in delayed-type hypersensitivity responses. Th2 lymphocytes secrete IL-4, IL-5, IL-9, IL-10 and IL-13 and promote antibody responses and allergic inflammation (Figure 5-4). Notably, there is a strong correlation between the presence of $CD4^+$ Th2 lymphocytes and disease severity, suggesting an integral role for these cells in the pathophysiology of allergic diseases.[124,125] Th2 cells are thought to induce asthma through the secretion of cytokines that activate inflammatory and residential effector pathways both directly and indirectly.[126] The major T cell subset in allergic disease is Th2, but other subsets, such as Th1, $CD8^+$, Th9, Th17 and Th22, also participate, especially in severe disease.[127–129] In fact, Th17 cells appear to be a critical component of the neutrophilic inflammation associated with severe asthma.[130]

Th2-associated cytokines, IL-4 and IL-13, are produced at elevated levels in the allergic tissue and are thought to be central regulators of many of the hallmark features of the disease.[131] However, in addition to Th2 cells, inflammatory cells within the allergic tissue also produce IL-4, IL-13 and a variety of other cytokines.[20,24] IL-4 promotes Th2 cell differentiation, IgE production, tissue eosinophilia and, in the case of asthma, morphologic changes to the respiratory epithelium and AHR.[132] IL-13 induces IgE production, mucus hypersecretion, eosinophil recruitment and survival, AHR and the expression of CD23, adhesion systems and chemokines.[131,133,134] A critical role for IL-13 in orchestrating experimental asthma has been suggested by the finding that a soluble IL-13 receptor homolog blocks many of the essential features of experimental asthma.[135,136] Furthermore, mice deficient in the IL-4Rα chain have impaired eosinophil recruitment and mucus production but still develop AHR.[137]

Collectively, these studies have provided the rationale for the development of multiple therapeutic agents that interfere with specific inflammatory pathways. Additionally, as noted above, another important Th2-produced cytokine, IL-5, is important for eosinophil proliferation, survival and activation, and its inhibition has been linked to improved asthma and nasal polyposis (Box 5-5).

B CELLS

B cells play a key role in humoral allergic response through IgE production. Lymph nodes are the major anatomic structure of antigenic B cell education or affinity maturation. After these processes, B cells then become either memory B cells or antibody-producing plasma cells. IgE synthesis is regulated by

https://CafePezeshki.IR

BOX 5-5 KEY CONCEPTS

T Cells

- Mature T cells are primarily divided into $CD4^+$ and $CD8^+$ cells.
- T cells express antigen-specific T cell receptors (TCR) that recognize antigen in the context of major histocompatibility molecules (MHC).
- $CD4^+$ T cells are engaged by antigen in the context of class II molecules.
- $CD4^+$ T cells subsets include Th1, Th2, Th9, Th17, Th22 and T_{REG} cells.
- Th1 cells are major producers of Th1 cytokines (e.g. interferon [IFN]-γ), and Th2 cells are major producers of Th2 cytokines (e.g. IL-4, IL-5, IL-13). Newly discovered subsets include Th9, Th17 and Th22, which are major producers of IL-9, IL-17A and IL-22, respectively.

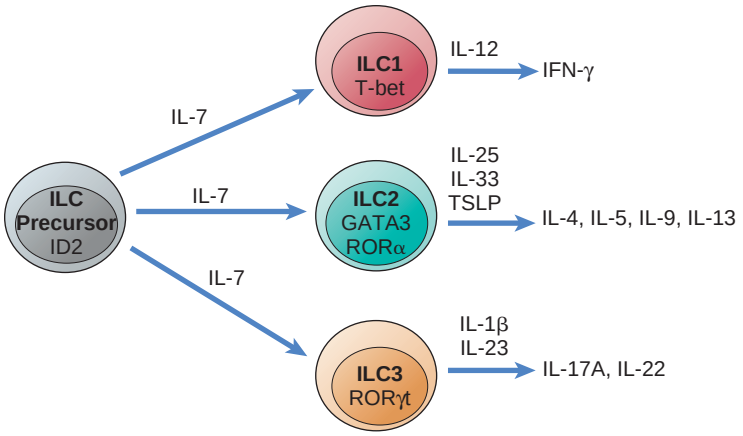

Figure 5-5 Innate lymphoid cell subsets. Three main subtypes of innate lymphoid cells have been identified: ILC1, ILC2 and ILC3. They arise from a common precursor cell that expresses a transcription factor called inhibitor of DNA binding-2 (ID2). The unique cytokine profile and transcription factors responsible for driving cytokine development for the respective subsets are identified.

IL-4 and IL-13 and may be augmented by IL-9. B cells also are found in gut lymphoid tissue and localized in diseased epithelial tissue.[138] In allergic rhinitis, asthma and EoE, localized epithelial B cells produce Cε germ-line transcripts, as well as IL-4 and IL-13.[139,140] Additionally, MHC class II-expressing B cells can function as antigen-presenting cells and drive Th2 cells.[141]

NATURAL KILLER CELLS

NK cells lack rearranged antigen receptors and are considered part of the innate immune system. They produce high levels of IFN-γ early during infection and directly kill virally infected cells by release of cytotoxic granules and Fas ligand-induced cell death. Additionally, NK cells suppress Th2 allergic airway inflammation post respiratory syncytial virus.[142] However, NK cells have also been shown to produce IL-5 and have been associated with eosinophilic inflammation.[143]

NATURAL KILLER T CELLS

NKT cells are a population of CD1d-restricted T cells that express α/β T cell receptor (TCR), have some NK cell receptors, and share similar cytotoxic mechanisms to NK cells. Invariant NKT (iNKT) cells have a narrow repertoire of TCRs and respond to glycolipid antigen. iNKT cells can promote IgE production and, via cytokine production, may impact Th2 differentiation in the respiratory tract; they accumulate in the airways of asthmatics and increase with antigen challenge or exacerbation.[144]

γ/δ T CELLS

The γ/δ T cells are a subset of T cells that have a TCR formed from γ and δ chains rather than α/β chains. The γ/δ T cells reside in intraepithelial regions in the skin and mucosa and in lymphoid tissue. Intraepithelial γ/δ T cells do not recognize antigen in the context of MHC but rather respond to nonprocessed antigens, including lipids and heat shock proteins.[145] They produce IFN-γ and IL-4 in vivo in response to Th1- or Th2-stimulating pathogens, respectively.[146] γ/δ T cells that produce IL-4, IL-5 and IL-13 have been isolated from asthmatic airways and increase in number after antigen challenge.[147] Interestingly, murine γ/δ T cells appear to be important both in the generation of Th2 immunity and protection from Th2-mediated disease.[147]

INNATE LYMPHOID CELLS

Populations of resident tissue lymphoid cells that lack B and T cell antigen receptors (BCR and TCR) and promote T helper cell development have been identified. These cells are lineage negative, meaning that they fail to express mature lymphocyte markers such as CD3, CD14, CD16, CD19, CD20 and CD56, but express high levels of stem cell markers such as CD117 (c-Kit). These cells are a small fraction of the total cell population in a given tissue but appear to be a major reservoir of T cell-skewing cytokines. Recently, it has been appreciated that these cells, like T helper cells, divide into subsets, and their nomenclature has been defined to reflect the cytokine and transcription factor similarity to their respective $CD4^+$ T cell subsets Th1, Th2 and Th17. The proposed subsets include ILC1, ILC2 and ILC3.[148]

ILC1s, like NK cells, are triggered by IL-12 to secrete high levels of IFN-γ and are dependent on T-bet,[149] but unlike NK cells, they lack perforin and granzyme expression.[150] ILC2 cells were identified in lung, intestine and blood. They produce IL-4, IL-5 and IL-13 in response to stimulation with IL-25, IL-33 and thymic stromal lymphopoietin (TSLP) and are dependent on GATA3.[151] They are the first producers of IL-13 in the gut after helminth infection.[152] ILC2s have been shown to be important in multiple Th2-mediated allergic diseases, including asthma and atopic dermatitis.[153,154] As mentioned above, ILC2s are also important regulators of eosinophil homeostasis in the gut in a nutritionally dependent fashion.[19] ILC3s secrete IL-17A and IL-22 upon IL-23 stimulation and are dependent on RORγt.[155] The role of these cells in relation to specific disease phenotypes is being actively investigated (Figure 5-5).

Leukocyte Recruitment

The trafficking of leukocytes into various tissues is regulated by a complex network of signaling events between leukocytes in the circulation and endothelial cells lining blood vessels. After injury or infection, resident cells at the site of injury or infection release chemokines, which interact via a gradient with the corresponding chemokine receptors on inflammatory cells. This

https://CafePezeshki.IR

chemokine : chemokine receptor interaction is critical for both leukocyte extravasation from the bloodstream into the tissue and leukocyte navigation within tissue to the site of injury or infection. Because each type of leukocyte expresses a different array of chemokine receptors, the type of inflammation that develops in a given situation is highly dependent on the chemokines secreted by resident cells. These interactions involve a multistep process: (1) leukocyte rolling (mediated by endothelial selectin and specific leukocyte carbohydrate ligands), which exposes chemokine receptors on leukocytes to chemokines displayed on endothelial cells; (2) rapid activation of leukocyte integrins, in which chemokine receptor signaling induces an *inside-out* signaling in the leukocyte leading to integrin clustering on the cell surface and an increase in the integrin's affinity for its ligand; (3) firm adhesion between endothelial molecules and counterligands on leukocytes (via integrins); and (4) transmigration of leukocytes through the endothelial layer via junctional adhesion molecules (JAMs), platelet endothelial cell adhesion molecule (PECAM), CD99 and endothelial cell-selective adhesion molecule (ESAM) (Figure 5-6). This multistep signaling cascade must occur rapidly to allow for the leukocytes to reduce rolling velocity, mediate adherence and extravasate into tissues in response to a chemokine gradient. In addition to mediating leukocyte movement from the bloodstream into tissues, chemokines use similar steps to mediate leukocyte-directed motion across other tissue barriers, such as respiratory epithelium and the extracellular matrix (Box 5-6). Leukocyte adhesion deficiency (LAD) is a human disease associated with recurrent bacterial infections. The defect is in CD18, or β2 integrin, and results in the inability of neutrophils to be recruited from the blood to the site of infection.

BOX 5-6 KEY CONCEPTS

Leukocyte Trafficking

- Leukocytes bind to the endothelium via low-affinity reversible interactions mediated by selectins.
- Tight adhesion of leukocytes to endothelium is mediated by specific adhesion molecules such as integrins (e.g. β2 integrins).
- Transmigration is mediated by PECAM, CD99, JAMs, and ESAM.
- Leukocyte migration into tissues is regulated by chemoattractants.

CHEMOKINE AND CHEMOKINE RECEPTOR FAMILIES

Chemokines are the guiding signals that direct leukocytes to the site of injury or infection. Chemokines represent a large family of chemotactic cytokines that have been divided into four groups, designated CXC, CC, C and CX3C, on the basis of the spacing of conserved cysteines (Figure 5-7). These four families of chemokines are grouped into distinct chromosomal loci (Figure 5-7). The CXC and CC groups, in contrast to the C and CX3C groups, contain many members and have been studied in great detail. The CXC chemokines mainly target neutrophils, whereas the CC chemokines target a variety of cell types including macrophages, eosinophils and basophils. The current chemokine receptor nomenclature uses CC, CXC, XC or CX3C (to designate chemokine group) followed by R (for receptor) and then a number. The new chemokine nomenclature substitutes the R for L (for ligand), and the number is derived from the one already assigned to the gene encoding the chemokine from the SCY (small secreted cytokine) nomenclature. Thus, a given gene has the same number as its protein ligand (e.g. the gene encoding eotaxin-1 is *SCYA11,* and the chemokine is referred to as CCL11). Table 5-1 summarizes the chemokine family using this nomenclature.[156,157] There have been seven CXC receptors identified, which are referred to as CXCR1 through CXCR7, and 11 human CC receptor genes cloned, which are known as CCR1 through CCR11 (Figure 5-8). The chemokine and leukocyte selectivities of chemokine receptors overlap extensively; a given leukocyte often expresses multiple chemokine receptors, and more than one chemokine typically binds to the same receptor (Figure 5-8), creating a scheme of redundancy and pleiotropy that ensures adequate leukocyte recruitment.

CHEMOKINE RECEPTOR SIGNAL TRANSDUCTION

With nearly 1,000 members, the seven-transmembrane, G protein-coupled receptors (GPCRs) are universally employed to sense small changes in concentrations of molecules. The chemokine receptors are a subfamily of this GPCR superfamily. Chemokines induce leukocyte migration and activation by binding to specific GPCRs.[156] Although chemokine receptors are similar to many GPCRs, they have unique structural motifs such as the amino acid sequence DRYLAIV in the second intracellular domain.

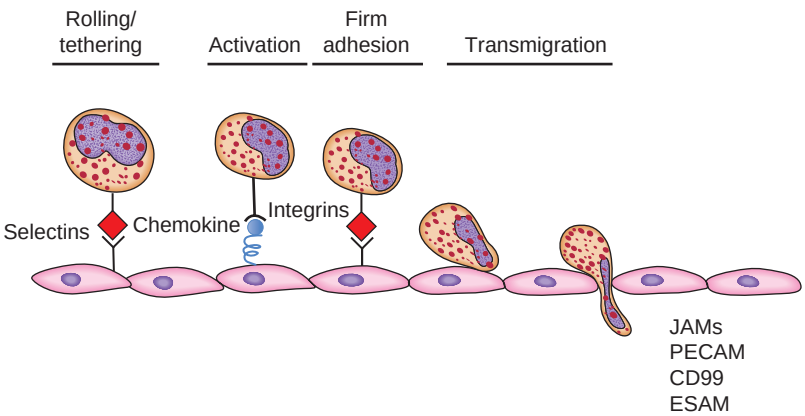

Figure 5-6 Overview of leukocyte migration. The trafficking of leukocytes into various tissues is regulated by a complex network of signaling events between leukocytes in the circulation and endothelial cells lining blood vessels. These interactions involve a multistep process including (1) leukocyte rolling (mediated by endothelial selectin and specific leukocyte ligands), (2) rapid activation of leukocyte integrins by chemokines, (3) firm adhesion between endothelial molecules and activated integrins on leukocytes, and (4) transmigration of leukocytes through the endothelial layer via junctional adhesion molecules *(JAMs)*, platelet endothelial cell adhesion molecule *(PECAM)*, CD99 and endothelial cell-selective adhesion molecule *(ESAM)*.

https://CafePezeshki.IR

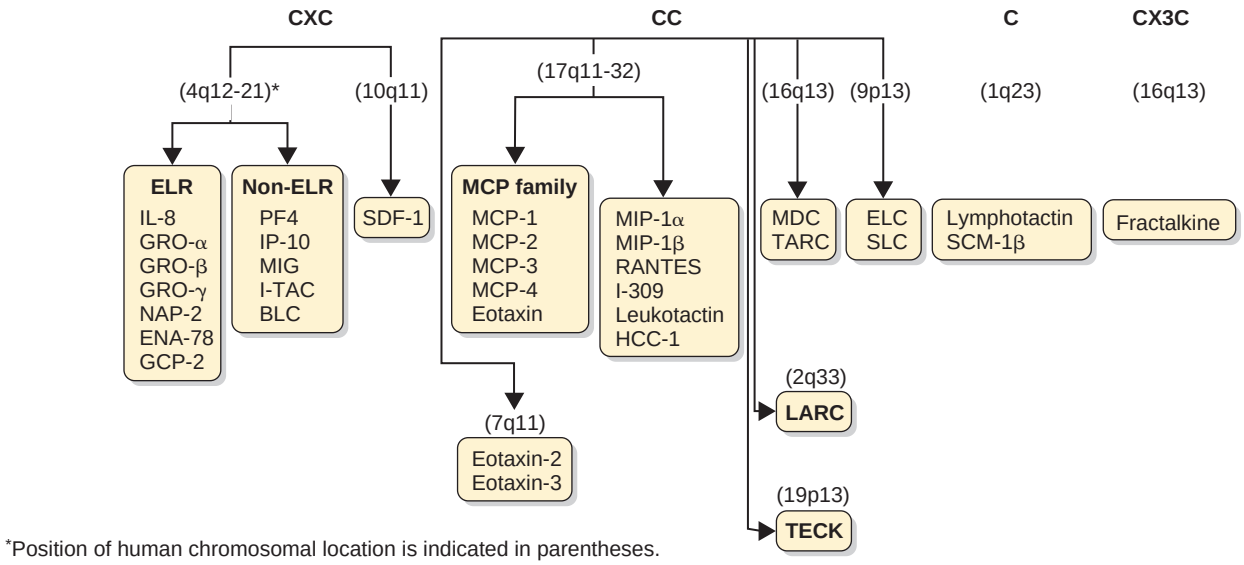

Figure 5-7 The human chemokine family.

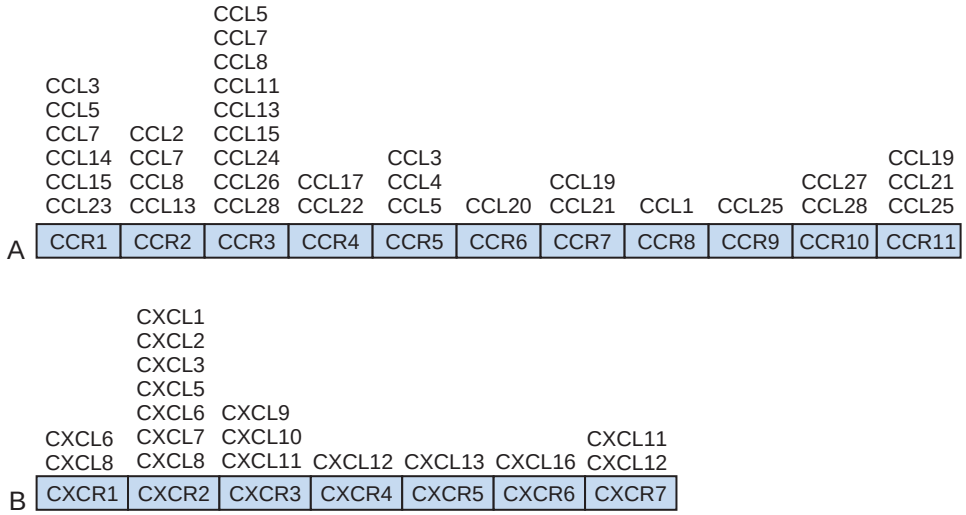

Figure 5-8 Ligands for CC (A) and CXC (B) receptor families.

Receptor activation leads to a cascade of intracellular signaling events. In addition to triggering intracellular events, engagement with ligand induces rapid chemokine receptor internalization. Ligand-induced internalization of most chemokine receptors occurs independent of calcium transients, G protein coupling and protein kinase C, indicating a mechanism different from the one induced by chemotaxis. Thus, chemokine receptor internalization may provide a mechanism for chemokines also to halt leukocyte trafficking in vivo. There are many signaling pathways downstream of chemokine receptor binding. This heterogeneity of signaling pathways allows for different chemokine receptors, expressed on the same cell, to signal through distinct pathways and for the same chemokine receptor to induce a variety of effects.

REGULATION OF CHEMOKINE AND CHEMOKINE RECEPTOR EXPRESSION

The main stimuli for the secretion of chemokines are the early proinflammatory cytokines such as IL-1 and TNF-α, bacterial products such as LPS and viral infection[158–160] (Figure 5-9). In addition, products of the adaptive arm of the immune system, including from both Th1 and Th2 cells, IFN-γ and IL-4, respectively, also induce the production of chemokines independently and in synergy with IL-1 and TNF-α. Recently, it has been demonstrated that miRs also regulate chemokines. miR-21 regulates polarization of the adaptive immune response in asthma and is one of the most up-regulated in EoE.[161] It has also been correlated with increased CCL26 (eotaxin-3) and tissue eosinophilia in EoE.[162] Additionally, miR-21 has been shown to regulate keratinocyte-derived chemokine (KC),[163] CXCL10[164] and CCL20.[165,166] miR-155 is the most up-regulated miR in atopic dermatitis and regulates MCP-1,[167] CXCL8[168] and CCL2.[169]

Although there are many similarities in the regulation of chemokines, important differences that may have implications for asthma are beginning to be appreciated. For example, in the healthy lung, epithelial cells are the primary source of chemokines; however, in the inflamed lung, infiltrating cells within the submucosa are a major cellular source of chemokines.[170]

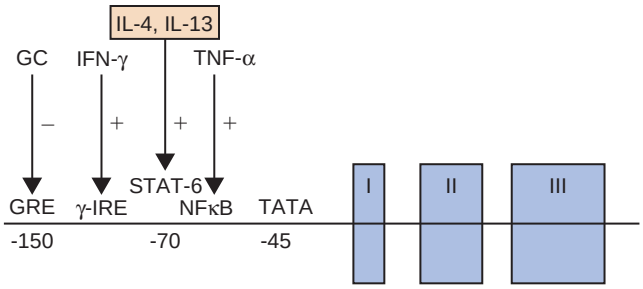

Figure 5-9 Regulatory elements in chemokine promoter. Depicted are the positions of the transcription factor motifs and the regulatory cytokines of the eotaxin-1 promoter. The three exons of the gene are depicted with rectangles. Positive signals are indicated with (+), whereas inhibitory signals are indicated with (–). Notably, IL-4/IL-13 via STAT-6 induces transcription; IFN-γ induces transcription through an IFN response element (γ-IRE); and TNF-α induces transcription through NFκB. Glucocorticoids (GC) inhibit transcription via the glucocorticoid response element (GRE).

BOX 5-7 KEY CONCEPTS

Chemokines

- Chemokines are chemoattractive cytokines.
- Chemokines are functionally divided into molecules that are constitutively expressed and those that are inducible.
- Chemokines are divided into several families depending on the spacing of the first two cysteines (e.g. CC and CXC families).
- Chemokines bind to seven-transmembrane, G protein-linked receptors.
- Chemokine receptors are genetically polymorphic.
- Chemokine receptors often bind to more than one chemokine ligand (i.e. they are promiscuous).

CELLULAR RECEPTOR EXPRESSION

Chemokine receptors are constitutively expressed on some cells, whereas they are inducible on others. For example, CCR1 and CCR2 are constitutively expressed on monocytes but are expressed on lymphocytes only after IL-2 stimulation.[171,172] Activated lymphocytes are then responsive to multiple CC chemokines that use these receptors, including the MCPs. In addition, some constitutive receptors can be down-modulated by biologic response modifiers. For example, IL-10 was shown to modify the activity of CCR1, CCR2 and CCR5 on dendritic cells and monocytes.[173] Normally, dendritic cells mature in response to inflammatory stimuli and shift from expressing CCR1, CCR2, CCR5 and CCR6 to expressing CCR7. However, IL-10 blocks the chemokine receptor switch. Importantly, although CCR1, CCR2 and CCR5 remain detectable on the cell surface and bind appropriate ligands, they do not signal in calcium mobilization or chemotaxis assays. Thus, IL-10 converts chemokine receptors to functional decoy receptors, thereby serving a down-regulatory function (Box 5-7).

Chemokine Regulation of Leukocyte Effector Function

CHEMOATTRACTION

Structural motifs in the primary amino acid sequence of chemokines have an important impact on their chemoattractive

https://CafePezeshki.IR

ability. For example, CXC chemokines are mainly chemoattractants for neutrophils and lymphocytes. Furthermore, ELR (Glu-Leu-Arg)-containing CXC chemokines (e.g. IL-8) are mainly chemoattractive on neutrophils, whereas non-ELR CXC chemokines (e.g. IP-10) chemoattract selected populations of lymphocytes (Figure 5-7). In contrast to cellular specificity of CXC chemokines, CC chemokines are active on a variety of leukocytes, including dendritic cells, monocytes, basophils, lymphocytes and eosinophils. For example, as their names imply, all MCPs have strong chemoattractive activity for monocytes. However, they display partially overlapping chemoattractant activity on basophils and eosinophils. In particular, MCP-2, MCP-3 and MCP-4 have basophil and eosinophil chemoattractive activity, but MCP-1 is only active on basophils. In contrast to the MCPs, the members of the eotaxin subfamily of chemokines (i.e. eotaxin-1, -2 and -3) have limited activity on macrophages but are potent eosinophil and basophil chemoattractants.[174,175] Chemokines also work in concert with other cytokines to promote leukocyte trafficking. IL-5 collaborates with eotaxin in promoting tissue eosinophilia by (1) increasing the pool of circulating eosinophils (by stimulating eosinophilopoiesis and bone marrow release) and (2) priming eosinophils to have enhanced responsiveness to eotaxin. The ability of two cytokines (IL-5 and eotaxin) that are relatively eosinophil selective to cooperate in promoting tissue eosinophilia offers a molecular explanation for the occurrence of selective tissue eosinophilia in human allergic diseases (Box 5-8).

CELLULAR ACTIVATION

In addition to promoting leukocyte accumulation, chemokines are potent cell activators. After binding to the appropriate GPCR, chemokines elicit transient intracellular calcium flux, localized actin reorganization, oxidative burst with release of superoxide free radicals, the exocytosis of secondary granule constituents and increased avidity of integrins for their adhesion molecules. For example, in basophils, chemokine-induced cellular activation results in degranulation with the release of histamine and the de novo generation of LTC_4.[158,176,177] Basophil activation by chemokines requires cellular priming with IL-3, IL-5 or GM-CSF for the maximal effect of each chemokine, highlighting the capacity for cooperation between cytokines and chemokines.

HEMATOPOIESIS

In addition to being involved in leukocyte accumulation, chemokines also have a role in regulating hematopoiesis. These functions include (1) chemotaxis of hematopoietic progenitor cells (HPC), (2) suppressing or enhancing HPC proliferation and differentiation and (3) mobilizing HPCs to the peripheral blood.[178] For example, stromal cell-derived factor (SDF)-1, a CXC chemokine, is critical for B cell lymphopoiesis and bone marrow myelopoiesis as demonstrated by gene targeting.[179] Furthermore, eotaxin has been shown to directly stimulate the release of eosinophilic progenitor cells and mature eosinophils from the bone marrow.[180] Eotaxin synergizes with SCF in stimulating yolk sac development into mast cells in vitro[181] and has been shown to function as a GM-CSF after allergic challenge in the lungs.[182]

MODULATION OF T CELL IMMUNE RESPONSES

T lymphocytes have been shown to express receptors for most chemokines, thus making them potentially responsive to a large number of different chemokines. Characterization of chemokine receptor expression has shown that T lymphocytes display a dynamic expression pattern of chemokine receptors and that it is the differential expression of receptors during T lymphocyte maturation and differentiation that is thought to allow for individual chemokine-specific functionality on T lymphocytes.[183] As with dendritic cells, CCR7 also plays an important role in trafficking of naïve T cells into lymph nodes.[184] Upon activation, T cells may express an array of chemokine receptors. Thus, they become sensitive to inflammatory chemokines, including MIP-1α, MIP-1β, MCP-3 and RANTES, which are thought to mediate T cell trafficking to sites of inflammation.[185]

Chemokines have an important role in the induction of inflammatory responses and are central in selecting the type of T helper response. During bacterial or viral infections, IP-10, MIG, IL-8 and I-TAC production correlates with the presence of $CD4^+$ Th1-type T cells. In contrast, during allergic inflammatory responses, eotaxin, RANTES, MCP-2, MCP-3 and MCP-4 are induced, and the majority of the $CD4^+$ T lymphocytes are of the Th2-type phenotype. The characterization of chemokine receptor expression on T lymphocytes suggests that these findings may be explained by CXCR3 and CCR5 being predominantly expressed on Th1-type T cells, whereas CCR3, CCR4 and CCR8 have been associated with Th2-type T cells and CCR6 on Th17 cells (Figure 5-5). In addition, Th1 and Th2 cells secrete distinct chemokines[186] (Figure 5-5). In mice, Th1 cells preferentially secrete RANTES and lymphotactin, whereas Th2 cells secrete MDC and TCA3. Interestingly, supernatants from Th2 cells preferentially attract Th2 cells. Alternatively, chemokines may directly influence the differentiation of naïve T cells to the Th1 or Th2 phenotype. MIP-1α and MCP-1 have been described as capable of inducing the differentiation of Th1 and Th2 cells,[187] and MCP-1-deficient mice have defective Th2 responses.[188] Consistent with this possibility, BCL-6-deficient animals express high levels of chemokines, including MCP-1, and have systemic Th2-type inflammation.[189]

The interaction of tissue-specific dendritic cells with T cells triggers expression of tissue-specific homing molecules on T cells. For example, intestinal dendritic cells induce direct T cell expression of the intestinal homing molecules $\alpha_4\beta_7$ and CCR9,[190] which recognize intestinal vascular mucosal addressin cell adhesion molecule 1 (MAdCAM-1) and intestinal epithelial CCL25.[190]

BOX 5-8 KEY CONCEPTS

Chemokines in Allergic Responses

- Chemokines regulate leukocyte recruitment.
- Chemokines are potent cellular activating factors.
- Chemokines are potent histamine-releasing factors.
- Th2 cytokines (e.g. IL-4 and IL-13) are potent inducers of allergy-associated chemokines (e.g. eotaxin).
- In allergic tissue, chemokines are frequently produced by epithelial cells.

https://CafePezeshki.IR

Conclusion

Allergic disorders involve the complex interplay of a large number of leukocytes (especially mast cells, eosinophils, neutrophils, lymphocytes, basophils, dendritic cells, innate lymphocytes and lymphoid cells) and structural tissue cells (especially epithelial cells, smooth muscle cells and fibroblasts). A combination of murine and human studies has been used to define the specific mechanisms involved in leukocyte activation, migration and effector function. In particular, cellular adhesion proteins, integrins and chemokines have emerged as critical molecules involved in leukocyte accumulation and activation. Also, combinations of innate activation pathways (involving mast cells, dendritic cells, eosinophils and innate lymphocytes and lymphoid cells) that induce proinflammatory pathways and adaptive immune pathways have been elucidated. Although we are in the early phases of analysis of disease pathogenesis, we have already identified critical pathways that are currently being therapeutically targeted in patients. It is the authors' hope that this chapter has provided the appropriate framework for the reader to understand (and contribute to) the next generation of clinical intervention strategies for the treatment of allergic disorders.

6 The Developing Immune System and Allergy

ELYSIA M. HOLLAMS | PATRICK G. HOLT

KEY POINTS

- The fetal immune system develops at least partial functional competence prior to birth, but whether this includes capacity to prime for subsequent postnatal production of the allergen-specific IgE antibody associated with persistent atopy remains contentious.
- Production of Th1 cytokines such as IFN-γ is restricted during fetal development, presumably to prevent rejection of the fetus by the mother's immune system; relevant mechanisms include reversible promoter methylation.
- T cell populations in neonates are dominated by recent thymic emigrants, which respond to antigen with reduced specificity and have a reduced capacity to promote lasting T cell memory.
- Capacity for innate immune function in the neonatal period is a major determinant for risk of infection. Preterm babies, who are particularly susceptible to severe bacterial infections, have been shown to exhibit reduced Toll-like receptor function, a phenomenon also observed in infants with atopic mothers.
- Benign microbial stimulation, both postnatally and during intrauterine growth, promotes maturation of balanced innate and adaptive immune functions; delayed immune maturation in children is associated with heightened risk for allergy.

The prevalence of allergic diseases has risen markedly since the 1960s, particularly in the western world, and similar trends are emerging in developing countries transiting toward more affluent 'western' lifestyles. The diseases manifest initially during childhood, and have become more prevalent and persistent in successive birth cohorts, although there is evidence that prevalence may have peaked in several western countries. The importance of genetic susceptibility in the disease process is widely recognized, and it is further recognized that the ultimate expression of the disease is the result of complex interactions between genetic and environmental factors, neither of which have yet been comprehensively characterized. There is increasing evidence that the level of complexity inherent in the pathogenesis of allergic diseases may be even greater than is currently contemplated, as an additional set of crucial factors appear to be involved. Notably, it appears likely that the ultimate effect(s) of these 'gene × environment' interactions within individuals may also be related to the developmental status of the relevant target tissues at the time the interactions occur. Examples of the latter, discussed below, are elements of innate and adaptive immune function and aspects of airways function relevant to atopic asthma.

Immune Function during Fetal Life

The initial stage of hematopoiesis in the human fetus occurs in extraembryonic mesenchymal tissue and in the mesoderm of the yolk sac. Pluripotent erythroid and granulo-macrophage progenitors are detectable in the latter at around the fourth week of gestation (Box 6-1). These cells appear subsequently in the fetal circulation and by weeks 5 to 6 in the liver, which at that stage of development is the major site of hematopoiesis. Within the liver, the interactions between stromal cells and hematopoietic cells play an important role in regulation. Expression of fibronectin by stromal cells is increased during the second trimester and is believed to result in enhanced proliferation and differentiation of hematopoietic cells.[1] The spleen and thymus are seeded from the liver, and by the eighth week of development $CD7^+$ precursor cells are found in the thymus,[2–4] whereas stem cells do not appear in bone marrow until around the 12th week of gestation.[5] T cells recognizable by expression of characteristic TcR/CD3 are found in peripheral lymphoid organs from weeks 13 to 15 of gestation onwards,[6–8] despite the lack of well-defined thymic cortical and medullary regions and mature epithelial components.[3] These early T cells also express CD2 and CD5.[4] The maturation of nonlymphoid components within peripheral lymphoid tissues progresses even more slowly and takes up to 20 weeks.[8–11]

It is feasible that the fetal gastrointestinal tract may be an additional site for extrathymic T cell differentiation in the human fetus, as has been reported in the mouse.[12] T cells are detectable in the intestinal mucosa by 12 weeks of gestation,[13] and many of these express the CD8αα phenotype, in particular within Peyer's patches.[14] In the mouse, CD8αα cells appear to be thymus independent and are believed to develop in the gut. Although there is no direct evidence for this in humans, it is noteworthy that fetal gut lamina propria lymphocytes are initially an actively proliferating population as indicated by constitutive expression of Ki67, and there is little or no overlap between gut-derived and blood-derived TcRβ transcripts.[15]

The gut mucosa may also be a major site for differentiation of TcRγ/δ cells during fetal life. Rearranged TcRδ genes are first detectable in the gut at 6 to 9 weeks of gestation,[16] which is earlier than is observed in the thymus. The liver is another significant extrathymic site for TcRγ/δ differentiation in humans, including a unique subset expressing CD4.[17]

The capacity to respond to polyclonal stimuli such as phytohemagglutinin (PHA) is first seen at 15 to 16 weeks of gestation.[18] The degree to which the fetal immune system can respond

https://CafePezeshki.IR

BOX 6-1 KEY CONCEPTS

MATURATION OF THE IMMUNE SYSTEM

- Weeks 5–6 of gestation: pluripotent erythroid and granulomacrophage progenitors are detected in the liver
- Week 8 of gestation: $CD7^+$ precursor cells found in the thymus
- Week 12 of gestation: stem cells appear in bone marrow
- Weeks 13–15 of gestation: T cells found in peripheral lymphoid organs
- Weeks 15–16 of gestation: fetal T cells respond to mitogen
- IgM responses develop in fetus following maternal vaccination
- Infant T cells express CD1, PNA and CD38, indicative of mature thymocytes
- Proportion of $CD45RO^+$ $CD4^+$ T cells increases from <10% at birth to >65% in adulthood, reflecting progressive antigenic exposure
- Adult peripheral blood T cells express CCR-1, -2, -5, and -6 and CXCR-3 and CXCR-4, whereas cord blood expresses only CXCR-4, reflecting decreased capacity to respond to proinflammatory signals at birth
- At infancy, cytotoxic effector functions and capacity to drive B cell immunoglobulin production are attenuated

to foreign antigens has not been clearly established. On the one hand, the offspring of mothers infected during pregnancy with a range of pathogens including mumps,[19] ascaris,[20] malaria,[21] schistosomes[22] and helminths[23] display evidence of pathogen-specific T cell reactivity at birth, whereas infection with other organisms such as toxoplasma[24] may induce tolerance. However, more recent studies have detected significant populations of T cells in cord blood that express the effector memory phenotype, even in the absence of any evidence of previous maternal infection.[25] Additionally, vaccination of pregnant women with tetanus toxoid results in the appearance of IgM in the fetal circulation that is indicative of fetal T cell sensitization.[26] Similarly, vaccination of pregnant women against influenza results in the presence of influenza-specific IgM in cord blood, and virus-specific $CD8^+$ T cells detected by the use of MHC tetramers.[27] There is also a variety of evidence based on in vitro lymphoproliferation of cord blood mononuclear cells[28] and recently the presence of low levels of IgE in cord blood[29,30] which suggests that environmental antigens (including dietary and inhalant allergens) to which pregnant women are exposed may in some circumstances prime T cell responses transplacentally. However these conclusions have been challenged on the basis of a variety of evidence of low specificity of cord blood responses to allergen (further discussion below) and on the kinetics of postnatal development of allergen-specific Th memory,[31] and the issue remains contentious.[32] The recent discovery that the placenta is not sterile, but rather hosts a distinct microbiome in healthy pregnancy, is sure to stimulate much additional research into fetal immune function.[33]

Studies examining lymphocyte subsets in cord blood from babies born at gestational ages between 20 and 42 weeks found that the proportion of cord natural killer (NK) cells increased with gestational age, while the proportion of $CD4^+$ cells and the ratio of $CD4^+$: $CD8^+$ cells decreased.[34,35] Despite the lack of significant numbers of $CD4^+$ and $CD8^+$ $CD45RO^+$ T cells in cord blood, fetal spleen and cord blood samples from premature infants contain these cells in relatively high frequency.[36] These 'postactivated' or 'memory' T cells were unresponsive to recombinant IL-2, suggesting they may have been anergized by earlier contact with self or environmental antigens.[36] $CD4^+$ $CD25^+$ T regulatory cells are detected in fetal lymphoid tissue, and they have been shown to have a suppressive effect on fetal $CD4^+$ and $CD8^+$ T cells expressing the activation antigen CD69.[37] Fetal thymic exposure to high-avidity TcR ligand has been shown to promote development of T regulatory cells in mice, while exposure to low-affinity TcR ligand did not; it appears that T regulatory cells require a higher ligand avidity for positive selection than conventional T cells.[38] Interestingly, expression and function of T regulatory cells has been found to be impaired at birth in the offspring of atopic mothers.[39]

These findings collectively suggest that the fetal immune system develops at least partial functional competence before birth but lacks the full capacity to generate sustained immune responses; although IgM responses develop in the fetus following maternal tetanus vaccination, there is no evidence of class-switching in the offspring until they are actively vaccinated.[26] Given the fact that the fetal immune system can generate at least primary immune responses against external stimuli, the question arises as to how immune responses within or in close contact with the fetal compartment are regulated. The necessity for tight control of these responses becomes obvious in light of findings that a variety of T cell cytokines are exquisitely toxic to the placenta.[40] Part of this control may be at the level of transcription factor expression.

It is also pertinent to question how potential immunostimulatory interactions between cells derived from fetal and maternal bone marrow are regulated at the fetomaternal interface. It has been clearly demonstrated that fetal cells readily traffic into the maternal circulation,[41–45] potentially sensitizing the maternal immune system against paternal HLA antigens present on the fetal cells. However, it is clear that the maternal immune system in the vast majority of circumstances successfully eradicates fetal cells from the peripheral circulation while remaining functionally tolerant of the fetus.[46] This suggests that tolerance of the fetal allograft is a regionally controlled process that is localized to the fetomaternal interface.

The mechanisms that regulate the induction and expression of immune responses in this milieu are complex and multilayered. The first line of defense appears to involve tolerogenic HLA-G-expressing, IL-10-producing dendritic cells detectable in the maternal circulation and in the decidua,[47] and the activity of these is complemented by decidual macrophage populations.[48] The tolerogenic activity of these cell populations is supported via an immunosuppressive 'blanket' maintained through the local production within the placenta by trophoblasts and macrophages of metabolites of tryptophan generated via indolamine 2,3-dioxygenase, which are markedly inhibitory against T cell activation and proliferation.[49] Constitutive production of high levels of IL-10 by placental trophoblasts provides a second broad-spectrum immunosuppressive signal to dampen local T cell responses,[50] as well as the homeostatic function of alternatively activated macrophages.[51]

An additional line of defense involves mechanisms that operate to protect against T cell activation events, which evade suppression via these pathways. These include the expression of FasL on cells within the placenta providing a potential avenue for apoptosis-mediated elimination of locally activated T cells,[52,53] NK cells that selectively antagonize Th-17 cell activation,[54] and the presence of maternally derived $CD4^+$ $CD25^+$ T regulatory cells, which are recruited to the maternofetal interface where they act to dampen fetus-specific responses.[55] These

https://CafePezeshki.IR

mechanisms are complemented by a series of pathways that operate to selectively dampen production at the fetomaternal interface of Th1 cytokines, in particular interferon-gamma (IFN-γ). This cytokine plays an important role in implantation;[56] however, if it is produced in suprathreshold levels at later stages of pregnancy, triggered for example by local immune responses against microbial or allo-antigens, IFN-γ (and other Th1 cytokines) can potentially cause placental detachment and fetal resorption.[57,58] These Th2-trophic mechanisms involve local production of a range of immunomodulators including IL-10,[50] which programs antigen-presenting cells (APCs) for Th2 switching;[59] progesterone, which directly inhibits IFN-γ gene transcription;[60–62] progesterone and estradiol, which both inhibit the NF-κB pathway in monocytes;[63] and PGE_2, which promotes Th2 switching via effects upon APCs, in particular dendritic cells.[59] Circulating myeloid and plasmacytoid dendritic cells (mDC and pDC) in late pregnancy appear to be constrained with respect to the level of activation they can achieve, and it has been suggested that this mechanism may be mediated via the glycoprotein hormone activin-A.[64]

Resistance to Infection during Infancy

Infancy represents a period of high susceptibility to infection with a range of pathogens including bacteria and fungi[65] and, in particular, viruses.[66–68] The expression of cell-mediated immunity during active viral infection is attenuated in infants compared to older age groups,[69–71] and the subsequent generation of virus-specific immunologic memory is also inefficient.[72] These findings suggest that a range of developmentally related deficiencies in innate and adaptive immunologic mechanisms are operative in neonates.

Surface Phenotype of T Cells in Early Life

Total lymphocyte counts in peripheral blood are higher in infancy than in adulthood,[73] and at birth T cell levels are twice those of adults. Longitudinal studies on individual infants indicate a further rapid doubling in T cell numbers in the circulation during the first 6 weeks of life, which is maintained throughout infancy.[74] Surface marker expression on infant T cells differs markedly from that observed in adults. The most noteworthy characteristics are frequent expression of CD1,[75] PNA,[76] CD31[77] and CD38.[74,78,79] These four antigens are considered to mark mature thymocytes as opposed to circulating 'mature' naïve T cells.

Analyses performed on $CD38^+$ cord blood cells have reinforced this view. In particular, animal model studies on thymic output have led to the development of an accurate technique for phenotypic identification of recent thymic emigrants (RTE), which are newly produced peripheral naïve T cells that retain a distinct phenotypic signature of recent thymic maturation that distinguishes them from long-lived naïve T cells produced at remote sites. This approach involves the measurement of T cell receptor excision circles (TRECs), which are stable extrachromosomal products generated during the process of variable/diverse/joining (VDJ) TcR gene rearrangement. TRECs are not replicated during mitosis, becoming diluted with each round of cell division. Hassan and Reen[79] have demonstrated that the majority of circulating $CD4^+$ $CD45RA^+$ human T cells at birth are RTE, as reflected by their high level of TRECs. These researchers also demonstrated that, analogous to thymocytes, the RTE were highly susceptible to apoptosis,[79] and unlike mature adult-derived $CD4^+$ $CD45RA^+$ naïve T cells, they were uniquely responsive to common γ-chain cytokines, particularly IL-7.[79,80] Whereas IL-7 promotes their proliferation and survival, IL-7-exposed RTE could not reexpress recombination-activating gene-2 gene expression in vitro. These findings suggest that postthymic naïve peripheral T cells in early infancy are at a unique stage in ontogeny as RTE, during which they can undergo homeostatic regulation including survival and antigen-independent expansion, while maintaining their preselected TcR repertoire.[79]

Studies examining the patterns of postnatal change in T cell surface marker expression have identified relatively high numbers of T cells coexpressing both CD4 and CD8 during infancy, which is also a hallmark of immaturity.[74,81,82] In contrast, the expression of CD57 on T cells, which marks non-MHC-restricted cytotoxic cells, is infrequent, as are T cells coexpressing IL-2 and HLA-DR, which is indicative of recent activation.[82] The expression of other activation markers such as CD25, CD69 and CD154 is also low.[74]

Of particular interest in relation to the understanding of overall immune competence during postnatal life are changing patterns of surface CD45RA and CD45RO on T cells. T cells exported from the thymus express the CD45RA isoform of the leukocyte common antigen CD45, and after activation switch to CD45RO expression. Most postactivated neonatal $CD4^+$ $CD45RO^+$ T cells are short-lived and die within a matter of days, but a subset of these is believed to be programmed to enter the long-lived recirculating T cell compartment as T memory cells.[83] The proportion of $CD45RO^+$ cells within the $CD4^+$ T cell compartment progressively increases from a baseline of less than 10% at birth, up to 65% in adulthood, reflecting age-dependent accumulation of antigenic exposure.[74,82–88] The rate of increase within the TcRα/β and TcRγ/δ populations is approximately equivalent and is slightly more rapid for $CD4^+$ T cells relative to $CD8^+$ T cells.[86] The relative proportion of $CD45RO^+$ putative memory T cells attains adult-equivalent levels within the teen years,[82,86] although the population spread during the years of childhood is very wide.[86] This suggests substantial heterogeneity within the pediatric population in the efficiency of mechanisms regulating the generation of T helper memory.

Functional Phenotype of T Cells during Infancy and Early Childhood

T cell function during infancy exhibits a variety of qualitative and quantitative differences relative to that observed in adults. It has been demonstrated when employing a limiting dilution analytic system that at least 90% of peripheral blood $CD4^+$ T cells from adults can give rise to stable T cell clones, whereas the corresponding (mean) figure for immunocompetent T cell precursors in infants was less than 35%.[89] Moreover, the cytokine production profile of T cell clones from infants displayed a prominent Th2 bias,[89] which may be related to the recently described predilection of T cells from this age group for preferential expression of the master Th2 regulator GATA3.[77] Cloning frequencies within the infant population were bimodally distributed, with a significant subset of ostensibly normal

https://CafePezeshki.IR

healthy subjects displaying particularly low cloning frequencies of no more than 20%.[89]

In apparent contrast to these findings, the magnitude of initial T cell proliferation induced by polyclonal T cell mitogens such as PHA in short-term cultures is higher at birth than subsequently during infancy and adulthood.[90,91] However, proliferation is not sustained, which may reflect the greater susceptibility of neonatal T cells to apoptosis post activation[79] and/or decreased production of IL-2.[92,93] In contrast, activation induced by TcR stimulation[94] and cross-linking CD2[93,95] or CD28[96] is reduced.

In addition to these deficiencies, neonatal T cells are hyperresponsive to IL-4[97] and hyporesponsive to IL-12[98] compared to adults, the latter being associated with reduced IL-12 receptor expression.[99] Neonates also have reduced capacity to produce IL-12, which can last into childhood; work from our laboratory has suggested that slow maturation of IL-12 synthetic capacity can be attributed to deficiencies in the number and/or function of dendritic cells.[100]

Neonatal T cells exhibit heightened susceptibility to anergy induction post stimulation with bacterial superantigen, employing protocols that do not tolerize adult T cells.[101,102] This has been ascribed to deficient IL-2 production[102] but may alternatively be related to developmentally related deficiencies in the Ras signaling pathway, which have been associated with secondary unresponsiveness to alloantigen stimulation by T cells from neonates.[103] Additional aberrations in intracellular signaling pathways reported in neonatal T cells include phospholipase C and associated Lck expression,[104] protein kinase C[105] and CD28, which is associated with dysfunction in FasL-mediated cytotoxicity[106] and reduced NFκB production.[96]

Profiles of chemokine receptor expression and responsiveness in neonatal T cells have been observed to differ distinctly from those in adults. In particular, adult peripheral blood T cells expressed CCR-1, -2, -5, -6 and CXCR-3 and CXCR-4, whereas those from cord blood expressed only CXCR-4, reflecting markedly attenuated capacity to respond to signals from inflammatory foci.[107] Additional differences have been observed between T cells from normal and preterm infants, particularly with respect to CCR4 and α4β7 expression.[108]

Evidence from a range of studies indicates that both cytotoxic effector functions[109,110] and capacity to provide help for B cell immunoglobulin production[109–113] are attenuated during infancy. These functional deficiencies are likely to be the result of a combination of factors that include decreased expression of CD40L,[109,111,112] reduced expression of cytokine receptors[99,114] and decreased production of a wide range of cytokines following stimulation.[89,92,115–121] The mechanism(s) underlying these reduced cytokine responses are unclear, but factors intrinsic to the T cells themselves,[89,122] as well as those involving accessory cell functions,[122–124] appear to be involved.

The IFN-γ gene is under tight regulation during fetal development, presumably to prevent rejection of the fetus by the mother's immune system that may result from excessive IFN-γ in the uterine environment.[125] Expression of IFN-γ is modulated in part at the epigenetic level via gene methylation, with transcriptional activity inhibited by hypermethylation of DNA. This laboratory has demonstrated hypermethylation at multiple CpG sites in the proximal promoter region of the IFN-γ gene in $CD4^+$ $CD45RA^+$ T cells in cord blood relative to their adult counterparts.[126] We subsequently demonstrated that in vitro differentiation of CD4(+) T cells down the Th1, but not Th2, pathway is accompanied by progressive demethylation of CpG sites in the IFN-γ promoter, which is most marked in neonatal cells.[127] While atopy development by age 2 was not associated with variations in methylation patterns in cord blood T cells, IFN-γ promoter methylation was reduced in CD8(+) T cells from atopic children in the age range in which hyperproduction of IFN-γ has recently been identified as a common feature of the atopic phenotype.

It has been proposed that many naïve neonatal T cells may have low-affinity TcRs and reduced affinity for T cell activation, and that expansion may take place without production of conventional memory T cells. If this is the case, cytokine responses to antigens in cord blood might have little relevance to immune responses to the same antigens later in childhood. It is possible that the relevance of cord blood responses to those in later life varies according to antigen. Findings from our laboratory have suggested that the allergen reactivity of neonatal T cells consists predominantly of a default response by recent thymic emigrants, which provide an initial burst of short-lived cellular immunity in the absence of conventional T cell memory.[128] This response appears to be limited by parallel activation of regulatory T cells, which arise as a result of these initial allergen encounters.[128,129] There is an inverse relationship between the numbers of circulating regulatory and memory $CD4^+$ T cells both during pregnancy[130] and postnatally.[131] The frequency of regulatory T cells at birth is inversely associated with gestational age[130,132–135] and this difference may persist for a significant period into infancy.[133]

Our studies in a longitudinal birth cohort comprising children at high risk (i.e. one or both parents allergic) examined how immune function in early childhood relates to infection and development of allergy. We found that priming of Th2 responses associated with persistent house dust mite (HDM)-IgE production in a high-risk cohort occurred entirely postnatally, as HDM reactivity in cord blood appeared to be nonspecific and was unrelated to subsequent development of allergen-specific Th2 memory or IgE.[31] However, a different picture emerged when polyclonal responses to mitogen were assessed by measuring PHA-induced cytokines from cultured cord blood mononuclear cells (CBMC) from cohort subjects, which correlated with frequency/intensity of respiratory infections up to age 5.[136] The ratio of PHA-induced IL-10 : IL-5 was highly predictive of subsequent severe infection, with high IL-5 responses associated with increased infection risk and the converse for high IL-10 responses. We suggest that the relevant underlying mechanisms may involve IL-10-mediated feedback inhibition of IL-5-dependent eosinophil-induced inflammation, which is a common feature of antiviral responses in early childhood.[136] Additionally, the same immunophenotype appears to be associated with reduced capacity to produce IL-21,[136] and it is significant that a series of studies point to a crucial role for this cytokine in resistance to persistent viral infection.[137–139] The relevance of cord blood responses to immune function in later life may depend upon environmental factors and associated exposures to infection during pregnancy. A study performed in a malaria-endemic region of Kenya examining mononuclear cell responses to malaria antigen found that the fine specificity of lymphocyte proliferation and cytokine secretion was similar in cord and adult blood mononuclear cells.[140] Stimulation with overlapping peptides to identify dominant malaria T cell epitopes also showed that cord blood cells from neonates whose mothers who had been malaria-infected during pregnancy were

https://CafePezeshki.IR

4-fold more likely to acquire a peptide-specific immune response. It was therefore proposed that the fetal malaria response functions in a competent adaptive manner, which may help to protect neonates from severe malaria during infancy.[140]

Recent research has identified a new subset of T helper cells that produce IL-17. These 'Th17' cells appear to mediate tissue inflammation by supporting neutrophil recruitment and survival, proinflammatory cytokine production by structural cells and matrix degradation (reviewed in reference 141). Studies have shown that all IL-17-producing cells originate exclusively from $CD161^+$ naïve $CD4^+$ T cells of umbilical cord blood and the postnatal thymus in response to a combination of IL-1β and IL-23.[142] It has also been shown that human naïve $CD4^+$+ T cells can give rise to either Th1 or Th17 cells in the presence of IL-1β and IL-23, with IL-12 presence determining Th1 development. Additionally, a subset of IL-17-producing cells possessed the ability to produce IFN-γ even after their development from $CD4^+$ T cells, perhaps representing an intermediate Th1/Th17 phenotype.[142] A recent study comparing T cells from preterm and term infants with those from adults also suggests that Th17 cell capacity may be inversely related to developmental age, leading to a relative Th17 bias in early life,[143] and this may reflect parallel developmental kinetics for the Th17-trophic cytokines IL-6 and IL-23.[144] Expression of full Th17 activity in infants may require specific stimuli such as viral infection, exemplified by respiratory syncytial virus (RSV).[145]

Innate Immunity in Neonates

There is a high level of interconnectivity between the innate and adaptive arms of the immune system. Competent adaptive immune function is important for switching off innate immune responses to prevent them from overshooting and causing bystander damage to host tissues, while defects in innate immunity appear to play a role in the development of a number of inflammatory diseases including allergy. Toll-like receptors (TLRs) are central to the function of the innate immune system, and there are at least 10 known human TLRs that recognize pattern motifs present in bacteria, viruses or other prokaryotes. Many aspects of TLR-associated functions are inefficient in early life,[146] though patterns of functional maturation across the population are complex and heterogeneous.[144]

The capacity of the innate immune system to recognize and rapidly respond to pathogens via TLRs is a major determinant of risk for infection during this crucial period, exemplified by recent findings linking respiratory-related hospitalization in infants and reduced capacity of their monocytes for viral-induced IFN-γ production.[147] Infants, especially those born prematurely, are particularly susceptible to severe bacterial infections. A study investigating mechanisms behind this phenomenon demonstrated that TLR4 expression is dependent on gestational aging: preterm infants show decreased expression of TLR4 on monocytes compared to full-term newborns; both showed lower expression than adults.[148] Similarly, cytokine production following lipopolysaccharide (LPS) stimulation was significantly lower in whole blood cultures from preterm compared to full term infants; both had lower production than adults. Subsequent studies examining TLR2 expression found that although TLR2 levels did not differ between preterm and full-term neonates, levels of the proximal downstream adapter molecule myeloid differentiation factor MyD88 were significantly reduced in preterm newborns, along with cytokine responses to TLR2 ligand.[149]

Studies examining the effect of breastfeeding on neonatal innate immune response have found that breast milk from days 1 to 5 postpartum negatively modulated TLR2 and TLR3 ligand responses, while enhancing those of TLR4 and 5.[150] Breast milk has been found to contain sCD14 and sTLR2 in addition to unidentified TLR-modulatory factors.[151,152] It has been suggested that the differential modulation of TLR function by breast milk may serve to promote efficient response to potentially harmful LPS-producing Gram-negative bacteria via TLR4 while allowing the establishment of Gram-positive bifidobacteria as the predominant intestinal microflora.[150]

Neonatal immune responses to microbial stimuli appear to be affected by maternal allergy. Children with atopic mothers have been observed to have significantly lower expression in cord blood monocytes of TLR2 and TLR4 than their mothers both before and after microbial stimulation, a disparity that was not seen between nonatopic mothers and their children.[153] In addition, CMBC from children with atopic mothers produced less IL-6 in response to peptidoglycan stimulation than those from children with nonatopic mothers.[153] In another study, CBMC stimulation with the TLR2 ligand peptidoglycan led to secretion of IL-10 and induction of FOXP3 that varied according to maternal atopy; CBMC from newborns with maternal atopy showed reduced induction of these cytokines compared to those without maternal atopy.[154]

A study from our laboratory focussed on the ontogeny of the innate immune system and examined the cytokine secretory capacity of mononuclear cells from subjects at various ages between birth and adulthood.[155] Cells were primed with IFN-γ then stimulated with LPS; production of IL-6, IL-10, IL-12, IL-18, IL-23, TNF-α and myxovirus resistance protein A (MXA: a cytokine induced by type I interferon in response to virus infection) was measured and compared. The developmental pattern between 1 year and 13 years showed that levels of all cytokines increased with age, with levels of some cytokines further increasing in adulthood. However, a subset of cytokines showed hyperexpression in CBMC. There appeared to be major differences in developmental regulation between the MyD88-dependent (TNF-α, IFN-γ, IL-6 and IL-10) cytokines, which were hyperexpressed by CBMC relative to infant peripheral blood mononuclear cells (PBMC), compared to the MyD88-independent cytokines (IL-12, IL-18, IL-23 and MXA) which were expressed at lower levels in both CBMC and PBMC from infants than in PBMC from older age groups,[155] and similar dichotomous patterns of production capacity in neonates between different classes of cytokines have been reported in several more recent studies.[156–160] A factor present in neonatal plasma has recently been implicated in the polarization of neonatal cells toward the low IL-12/high IL-10 producer phenotype,[161] but this finding has yet to be confirmed.

There appears to be a gradual maturation of phagocytic capacity by innate immune cells over time. The phagocytic activity of fetal neutrophils and monocytes has been observed to be significantly lower than that of healthy neonates and adults, and a direct relationship between gestational age and number of phagocytosing granulocytes has been demonstrated.[162] Similarly, the activity of NK cells in infants is correlated with gestational age[40,163–165] and is significantly impaired at baseline compared to children and adults.[34] However, following stimulation with priming agents exemplified by IL-18

https://CafePezeshki.IR

and IL-12[163] or single-stranded RNA,[166] neonatal cells rapidly develop higher levels of IFN-γ and cytolytic activity than are seen in adults, suggesting that this arm of innate immunity may play a significant role in host defense during this life period.

A series of recent studies have added a further layer of complexity to this picture, with the demonstration that developmental heterogeneity across the spectrum of innate immune functions also varies in relation to ethnic background and/or geographic location of study groups;[167–170] similar observations apply to innate regulatory T cell activity in early life.[168]

B Cell Function in Early Life

Certain aspects of B cell function in neonates appear unique in relation to adults. In particular, large numbers of neonatal B cells express CD5,[171,172] together with activation markers such as IL-2R and CD23.[171] It has been postulated that these $CD5^+$ B cells act as a 'first line of defense' in primary antibody responses in neonates utilizing a preimmune repertoire, in contrast to $CD5^-$ B cells in which response patterns are acquired following antigen contact.[173] Unlike adult B cells, these neonatal B cells proliferate readily in the presence of IL-2 or IL-4 without requirement of further signals.[171,174–176] An additional (albeit less frequent) neonatal B cell subset expresses IgD, IgM, CD23 and CD11b, is CD5 variable, and spontaneously secretes IgM antibodies against a range of autoantigens.[171]

Conventional B cell function, that is, antibody production following infection or vaccination, is reduced in infants relative to adults,[72] and some in vitro studies suggest that this may be related to a defect in isotype switching.[177] The relative contributions of the T cell and B cell compartments to this deficiency in immunoglobulin production are widely debated, but the consensus is that both cell types play a role.

As noted previously, T cells in infants do not readily express high levels of CD40L[109–113] unless provided with particularly potent activating stimuli.[178] CD40L represents a critical signal for T helper cell-induced class switching[179] and the generally low expression on neonatal T cells may thus be a limiting factor in the process. Reduced T cell cytokine production[89,92,115–121] may further exacerbate the problem. However, although immunoglobulin production by neonatal B cells is low in the presence of neonatal T helper cells, production levels can be markedly improved if mature T helper cells or adequate soluble signals are provided.[113,174,180] However, the neonatal B cells still fail to reach adult-equivalent levels of production, suggesting that an intrinsic defect also exists. In this regard, it is pertinent to note that functional immaturity within the B cell compartment has recently been identified as a predictor of high risk for later development of allergic disease.[181]

Growing interest in the human microbiome in health and disease has reawakened interest in the role of gut flora in the development of the overall B cell repertoire,[182] in particular the stimulatory effect of early gut colonization on B memory cell expansion.[183,184] An additional area of B cell immunobiology that is set to have a major impact in the area of immune development and allergy pertains to the activity of regulatory B cell populations, which are hypothesized to play a direct role in control of allergic inflammation;[185,186] moreover, a related population of B cells has been identified in neonatal thymic tissue, which appears to stimulate the generation of regulatory T cells.[187]

Antigen-Presenting Cell Populations

The key 'professional' antigen-presenting cell (APC) populations in this context are the mononuclear phagocytes (MPCs), dendritic cells (DCs) and B cells. The precise role of each cell type in different types of immune response is not completely clear, although it is evident that DCs represent the most potent APC for priming the naïve T cell system against antigens encountered at low concentrations (e.g. virus and environmental allergens).

Ontogenic studies on human MPCs have been essentially limited to blood monocytes. Although neonatal populations appear comparable to those of adults in number and phagocytic activity,[188,189] they display reduced chemotactic responses[190] and reduced capacity for secretion of inflammatory cytokines such as TNF-α.[191] Their capacity to present alloantigen to T cells is reportedly normal,[192] but they display reduced levels of MHC class II expression.[193] Several studies have implicated poor accessory cell function of infant blood monocytes as a co-factor in the reduced IFN-γ responses of infant T cells to polyclonal mitogens such as PHA,[122–124] possibly as a result of diminished elaboration of co-stimulator signals. Macrophage populations at mucosal sites such as the lung and airways have important immunoregulatory roles in adults,[194] but it is not clear whether these mechanisms are operative in early life. A murine study from our group indicates lower levels of expression of immunomodulatory molecules, including IL-10 and nitric oxide, by lung macrophages during the neonatal period.[195]

B cells are also recognized as important APCs, in particular for secondary immune responses.[196,197] In murine systems, it has been demonstrated that neonatal B cells function poorly as APCs relative to their adult counterparts and do not reach adult-equivalent levels of activity until after weaning.[188,198]

As noted previously, DCs are the most potent APC population in adult experimental animals for initiation of primary immunity and in this regard have been designated as the 'gatekeepers' of the immune response.[199] The distribution and phenotypes of these cells appear comparable in murine and human tissues, and it is accordingly reasonable to speculate that the proposed role of murine DCs as the link between the innate and adaptive arms of the immune system[199–202] is also applicable in man. Importantly, in the context of allergic disease, comparative studies on DCs from mucosal sites in humans and experimental animals suggest very similar functional characteristics.[203]

DCs commence seeding into peripheral tissues relatively early in gestation,[204] and at birth recognizable networks of these cells can be detected in a variety of tissues including epidermis,[204–206] intestinal mucosa[207,208] and the upper and lower respiratory tract.[209,210] The cells within these DC networks in perinatal tissues are typically present at lower densities and express lower levels of surface MHC class II relative to adults,[205,206,210] hinting at developmentally related variations in function phenotype. Recent murine studies have emphasized these differences. Notably, the phenomenon of neonatal tolerance in mice has recently been ascribed to the relative inability of neonatal DCs from central lymphoid organs to present Th1-inducing signals to T cells, leading to the preferential generation of Th2-biased immune responses.[211] Of particular relevance to studies on susceptibility to infectious and allergic diseases in infancy, our group has demonstrated that in the rat the airway mucosal DC compartment develops very slowly postnatally, not attaining adult-equivalent levels of tissue density, MHC class II

https://CafePezeshki.IR

expression or capacity to respond to local inflammatory stimuli until after biologic weaning.[210,212]

Data based initially on immunohistochemical studies of autopsy tissues[213,214] and subsequently verified by airway biopsy studies[215] suggest that the kinetics of postnatal maturation of airway DC networks in humans may be comparably slow.

Reports suggest that the numbers of circulating HLA-DR$^+$ plasmacytoid and myeloid DCs are reduced at birth relative to adults,[216,217] with mDCs showing diminished APC activity.[218,219] Additionally, analysis of cord blood monocyte-derived DC functions indicates diminished expression of HLA-DR, CD80 and CD40 and attenuated production of IL-12p35 in response to stimuli such as LPS, poly(I : C) and CD40 ligation.[220] However, studies using human CD8$^+$ T cell clones to compare the ability of neonatal and adult DCs to present and process antigen using the MHC class I pathway found that neonatal DCs were not defective in their ability to perform these functions.[221] Studies have shown that synergistic stimulation of neonatal DCs by ligands for multiple TLRs is required for efficient differentiation, signaling and T cell priming; membrane-associated TLR4 and intracellular TLR3 were found to act in synergy with endosomal TLR4 to induce functional maturation of neonatal DCs.[222] Interestingly, cord blood monocyte-derived DCs have also been shown to express higher levels of IL-27 following TLR stimulation, which may compensate for the diminished ability of neonatal DCs to produce IL-12.[223]

Granulocyte Populations

Eosinophils, mast cells and basophils play key roles in the pathogenesis of allergic disease, performing important functions in relation to host resistance to certain pathogens, and are thus relevant to this discussion. In particular, hyperreactivity within this granulocyte compartment, exemplified by exaggerated airway eosinophil responses to viral infections as highlighted in recent studies on RSV,[224,225] is widely considered a harbinger of the early stages of asthma pathogenesis in children.

Eosinophilia in the first year of life has been linked to enhanced risk for later development of atopic diseases in a range of studies but few direct mechanistic data are available. Several earlier observations are suggestive of developmentally related problems in eosinophil trafficking in early life; inflammatory exudates in neonates frequently contain elevated numbers of eosinophils,[226–228] and eosinophilia is common in premature infants.[229,230] The mechanisms underlying these developmental variations in eosinophil function are unclear, but some evidence suggests a role for integrin expression involving Mac-1[231] and L-selectin.[232] Developmental defects in this compartment may additionally be more frequent in the offspring of atopic mothers[233,234] and may thus be part of the suite of mechanisms that mediate genetically determined high risk for allergic disease.

Adult mucosal tissues contain discrete populations of mucosal mast cells (MMCs) and connective tissue mast cells (CTMCs), respectively, within epithelia and underlying lamina propria. No direct information is available on the ontogeny of these mast cells (MCs) in human tissues, but indirect evidence suggests that they seed into gut tissues during infancy in response to local inflammatory stimulation.[235] Our group has examined the kinetics of postnatal development of MCs in the rat respiratory tract, and has reported that both MMC and CTMC populations develop slowly between birth and weaning.[236] MC-derived proteases appear transiently in serum around the time of weaning in the rat, suggesting that the immature MC populations may be unstable or are undergoing local stimulation at this time,[237] and a similar transient peak of MC tryptase is observed in human serum during infancy.[238]

Direct functional studies on MCs from immature subjects are lacking. However, a 2001 report employed oligonucleotide microarray technology to examine IL-4-induced gene expression in cultured MCs derived from cord blood versus adult peripheral blood; the results indicate that expression of FcεR1α is 10-fold higher in adult-derived MCs.[239] This suggests that during infancy the capacity to express IgE-mediated immunity may be restricted, but confirmation of this possibility must await further detailed studies.

Postnatal Maturation of Immune Functions and Allergic Sensitization

Studies from a number of groups have highlighted the importance of the early postnatal period in relation to the development of long-lasting response patterns to environmental allergens. In particular, it is becoming clear that initial priming of the naïve immune system typically occurs before weaning and may consolidate into stable immunologic memory before the end of the preschool years. Given that the underlying immunologic processes involve coordinated operation of the full gamut of innate and adaptive immune mechanisms, issues relating to developmentally determined functional competence during this life phase may be predicted to be of major importance.

In relation to initial priming of the T cell system against allergens, reports from numerous groups indicate the presence of T cells responsive to food and inhalant allergens in cord blood.[240–244] Cloning of these cells and subsequent DNA genotyping indicated fetal as opposed to maternal origin,[245] and the array of cytokines produced in vitro in their responses is dominated by Th2 cytokines, although IFN-γ is also observed, suggestive of a Th0-like pattern.[245] The issue of how initial priming of these cells occurs remains to be resolved. It is possible that transplacental transport of allergen, perhaps conjugated with maternal IgG, may be responsible, and some indirect evidence based on in vitro perfusion studies has been published to support this notion.[246] Moreover, the use of sensitive microassays has detected the presence of low levels of allergen-specific (particularly food allergen) IgE antibodies in cord blood which are unrelated to maternal antibody profiles, arguing against cross-contamination,[29,30] though this has been disputed.[247] Furthermore, prospective tracking of the postnatal appearance of aeroallergen-specific IgE antibody, and corresponding allergen-specific Th memory, shows strong concordance between these phenomena, commencing some time (depending on the specificity) between birth and age 6 months.[248] Alternatively, initial priming of T helper cells that drive production of these neonatal antibody responses may be against cross-reacting antigens as opposed to native allergen, and the uncertain relationship between maternal allergen exposure and newborn T cell reactivity is consistent with this view.[249,250] The T cell epitope map of the typical cord blood T cell response to ovalbumin (OVA), involving multiple regions of the OVA molecule,[251] suggests major qualitative differences relative to conventional adult T cell responses.

https://CafePezeshki.IR

Regardless of how initial T cell responses are primed, it is clear that direct exposure to environmental allergens during infancy drives the early responses down one of two alternate pathways. In the majority of (nonatopic) subjects, the Th2 cytokine component of these early responses progressively diminishes, and by age 5 years in vitro T cell responses to allergens comprise a combination of low-level IFN-γ and IL-10 production.[251–253] In contrast, a subset of children develop positive skin prick test (SPT) reactivity to one or more allergens, and in vitro stimulation of PBMC with the latter elicits a mixed or Th0-like response pattern comprising IL-4, IL-5, IL-9, IL-10, IL-13 and IFN-γ.[253] This latter pattern closely resembles that seen in the majority of adult atopic patients, and much more commonly develops in atopic family history positive (AFH^+) children than in their AFH^- counterparts.

It is increasingly debated whether it remains useful to describe these differing responses in human atopic and nonatopic patients within the framework of the murine Th1/Th2 paradigm, which was based upon the concept of reciprocal and/or antagonistic patterns of Th memory expression. In this context, studies from our group[254,255] indicate that reciprocal patterns of expression of the transcription factor GATA3, analogous to those that distinguish Th1 from Th2 polarized cell lines (with regard to down-regulation vs up-regulation, respectively, post stimulation), are reiterated during the allergen-specific recall responses of $CD4^+$ T cells from nonatopic versus atopic subjects. Moreover as noted above, hyperexpression of this Th2 master regulator is a feature of T cells in the infant period[77] during which allergen-specific Th memory priming is most commonly initiated.[248] This suggests that the Th1/Th2 model still provides a potentially useful framework for the study of allergic responses, despite the strong likelihood of significant interspecies differences.

The central issue in relation to understanding the initial phase of allergic sensitization in childhood concerns the molecular basis for genetic susceptibility to development of Th2-polarized memory against inhalant allergens, and the key to the resolution of this puzzle may lie in a more comprehensive understanding of the mechanisms that drive postnatal maturation of adaptive immune function. In this regard, we have reported earlier that genetic risk for atopy was associated with delayed postnatal maturation of Th cell function, in particular Th1 function, and that this may increase risk for consolidating Th2-polarized memory against allergens during childhood. The evidence originally presented was based on decreased peripheral blood T cell cloning frequency and diminished IFN-γ production by T cell clones in AFH^+ infants relative to their AFH^- counterparts,[89] and these findings have been substantiated in several independent laboratories employing bulk culture studies with neonatal PBMC.[256–261]

We have proposed that this phenomenon may derive from inappropriate postnatal persistence of one or more of the mechanisms responsible for selective damping of T cell function, in particular that relating to Th1 immunity, during fetal life.[262] A possible contributor may be reduced expression of protein kinase C (PKC) ζ in immature T cells, which is associated with prolongation of Th2 polarization, particularly in infants of allergic mothers.[263] Alternatively, given that the postnatal maturation of adaptive immunity is essentially driven by microbial signals from the outside environment,[262,264,265] one or more deficiencies in relevant receptors or downstream signaling pathways in microbial sensing cells within the adaptive immune system[266] may retard this process. Genetic variations described in CD14 may be an example,[267,268] and similar variants in one or more of the TLR genes constitute additional likely candidates. These possibilities are of particular interest in light of reports that environmental exposure to airborne bacterial lipopolysaccharide in childhood may be protective against Th2-mediated sensitization to inhalant allergens.[269,270] European 'farmer-mother' studies have demonstrated that the combination of prenatal and postnatal exposure to inhaled and ingested microbial breakdown products is associated with strong protective effects against development of allergic diseases during early childhood.[271] A range of immune-associated mechanisms may contribute to these effects including modulation of TLR function initially in decidual tissue at the fetomaternal interface[272,273] and subsequently within the developing innate immune system of the offspring.[274,275] These exposures appear to stimulate the postnatal development of regulatory T cell function,[276,277] which has previously been identified as deficient in children at high risk of development of allergic diseases.[39,278,279] It is pertinent to note that these exposures have also been observed to enhance postnatal maturation of IFN-γ-producing capacity,[280] a lack of which has been identified as a risk factor for allergy by our group and others. Longitudinal studies have suggested that Th1 deficiency may be transient and reversible, such that by 18 months of age Th1 function in children with atopic family history is equivalent to or greater than that in children without atopic family history.[281] We found in studies focussing on CBMC from AFH^+ children that early development of sensitization within this low-IFN-γ-producing group is maximal among those who later show the highest IFN-γ responses, suggesting a potentially dualistic role for IFN-γ in atopy pathogenesis.[282] This conclusion is reinforced by the results of other studies in older (school age) children that suggest a positive role for IFN-γ in airway symptomatology in atopics.[283,284] It is also feasible that IL-17[285] and TNF-α[286] responses may play a similar dualistic role in disease pathogenesis.

Further research is required to elucidate the complex regulatory mechanisms that govern generation of different patterns of allergen-specific Th memory during childhood. However, it is also becoming clear that an additional, and related, set of complexities needs to be considered. It is now evident that only a subset of atopic patients progress to development of severe persistent allergic diseases, in particular atopic asthma,[287] and it is likely that these subjects suffer additional and/or particularly intense inflammatory insults to target tissues. In this context, epidemiologic evidence suggests that risk for development of persistent asthma is most marked in children who display early allergic sensitization to inhalants[288,289] and who develop severe wheezing and lower respiratory tract infections during infancy.[289–291] This has given rise to the suggestion that development of the airways remodeling characteristic of chronic asthma[292] may, in many circumstances, be the long-term result of inflammation-induced changes in lung and airway differentiation during critical stages of early growth during childhood. Resistance to respiratory infections is also mediated by the same Th1 mechanisms identified as attenuated in children at risk of atopy,[293] suggesting that the same set of genetic mechanisms may be responsible for airways inflammation induced via the viral infection and atopic pathways in children at high risk of asthma (Box 6-2).

In this regard, a rapidly emerging area of interest relates to the role of vitamin D and resistance to infections and allergic

https://CafePezeshki.IR

BOX 6-2 KEY CONCEPTS

ROLE OF IMMUNE DEVELOPMENTAL FACTORS ON ALLERGIC RESPONSE

- Dendritic cells (DCs) are the most potent antigen-presenting cells for priming naïve T cells against antigens encountered at low concentrations
- Neonatal DCs present weak Th1-inducing signals to T cells, leading to preferential generation of Th2 immune responses
- Slow postnatal maturation of IFN-γ production capacity is linked to genetic risk for atopy
- Maturation of adaptive immunity is driven by microbial signals. Microflora in the gut, nasopharynx and lower airways are likely to contribute to these signals; the demonstration of a unique placental microbiome raises the question of whether this process could begin *in utero*
- A deficiency in microbial receptors (e.g. CD14, Toll receptors) or downstream signaling pathways may prevent the development of polarized Th1 responses
- Atopy may be associated with reduced diversity of commensal bacteria in early life
- Appropriate levels of vitamin D during immune development may be important to boost innate immune defenses against infection and to promote tolerance versus sensitization to allergens. An optimal vitamin D range for immune function has not been defined and could vary between individuals due to genotype-vitamin D interactions

diseases during childhood. Vitamin D is a potent immunomodulator; the active form (1,25(OH)2-vitamin D) complexes with its receptor in most known cell types, including immune cells, to initiate transcription of many genes.[294] Vitamin D induces epithelial and immune cells to produce antimicrobial peptides such as cathelicidin and defensin, which mediate killing of viruses and bacteria.[295] This mechanism is active at birth,[296] and low vitamin D at birth has been associated with increased respiratory infections in early life.[297] Vitamin D also promotes immune tolerance to allergens by up-regulating regulatory T cells[298] and suppressing IgE production.[299] A positive correlation has been observed between vitamin D and IL-10 levels in cord blood,[300] though another study found no associations between vitamin D and immune cell populations in cord blood.[301] Supplementation of pregnant mothers with vitamin D has been associated with increased production of tolerogenic antigen-presenting cells in cord blood, identified by expression of ILT3 and ILT4 transcripts.[302]

The question of whether insufficient vitamin D during immune development can predispose children to allergy and asthma is a hot topic, and one that is currently unresolved as cohort studies have yielded conflicting results.[303,304] While this may in part be explained by inconsistencies in vitamin D measurement, heterogeneity between cohort populations is likely to be an important factor given that some associations between vitamin D and clinical outcomes are modified by specific genotypes.

An additional variable that merits more detailed research in this context is the role of airway DC populations. In the adult, these cells regulate the Th1/Th2 balance in immune responses to airborne antigens[305] and also mediate primary and secondary immunity to viral pathogens.[199] However, airway DC networks develop very slowly postnatally, apparently 'driven' by exposure to inhaled airborne irritants[162] including bacterial lipopolysaccharides,[306,307] and also by viral infections.[215] Hence the rate at which this key cell population gains competence to respond to maturation-inducing stimuli and then to orchestrate appropriately balanced T cell responses against viral pathogens, allergens and also bacterial pathogens within the nasopharyngeal microbiome[308] may be a key determinant of overall susceptibility to allergic disease. Variations in the genes that govern the functions of these cells in early life are thus likely to be of major importance in the etiology of a variety of disease processes, in particular atopic asthma and related syndromes.

Conclusions

Only a subset of patients with atopy develop more severe allergic diseases, and the ability to identify these patients early, and to choose treatment strategies accordingly, could potentially improve patient outcome. A variety of independent studies suggest that prospective evaluation of blood IgE levels, particularly in early childhood, may significantly aid in early identification of at-risk subjects.[309]

7 Approach to the Child with Recurrent Infections Including Molecular Diagnostics

HOWARD M. LEDERMAN

KEY POINTS

- Chronic/recurrent respiratory tract infections are common problems for children with allergy but may also be the presenting symptoms of an underlying defect in host defense such as primary and secondary immunodeficiency, cystic fibrosis, ciliary dyskinesia and dysfunctional swallowing.
- Diagnosis of an underlying disorder is essential for optimal clinical management.
- Presenting features of immunodeficiency include increased susceptibility to infection (chronic or recurrent infections, infections of unusual severity, infections caused by opportunistic pathogens), autoimmune/inflammatory disorders and syndrome complexes.
- The types of infections and other symptoms should guide the choice of screening laboratory tests.
- Mutation analysis can confirm the diagnosis and facilitate genetic counseling and screening of other family members who may be asymptomatic.

Many children who present for allergy evaluation have chronic/recurrent respiratory tract infections. Allergy may predispose the patient to such symptoms because swelling of the nasal mucosa causes obstruction of the sinus ostia and eustachian tubes. However, one must be alert to the possibility of other underlying problems, including primary immunodeficiency diseases, secondary immunodeficiency caused by other illnesses or medications, cystic fibrosis, ciliary disorders and pulmonary aspiration. Environmental factors such as exposure to cigarette smoke, day care and the number of household members must also be considered. This chapter provides an approach to evaluating children for these disorders.

Definition of Recurrent Infections

It is difficult to define increased susceptibility to infection with precision (Box 7-1).[1] For example, chronic/recurrent otitis media is very common in the first two years of life but thereafter decreases in frequency. Rather than defining an arbitrary number of ear infections that is 'too many', the nature and pattern of those infections provide a more reliable guide to identify the child who deserves further evaluation. Ear infections that increase in frequency after the age of 2 years, are associated with infections at other sites or occur in the context of failure to thrive should raise the suspicion of an underlying disorder. Similarly, it is unusual for a child to have more than one episode of pneumonia per decade of life, chronic or recurrent sinusitis or bronchitis.

Other clues to an abnormal susceptibility to infection include a history of infections at multiple anatomic locations or relatively unusual infections such as sepsis, septic arthritis, osteomyelitis and meningitis. In some instances, patients may present with one or more infections that are unusually severe, lead to an unexpected complication (e.g. pneumonia with empyema or otitis media with mastoiditis) or are caused by an organism of relatively low virulence (e.g. *Aspergillus* or *Pneumocystis jirovecii*).

Sometimes, the most challenging aspect of evaluating the past medical history is assessing the reliability of the data. It may be difficult to distinguish pneumonia from atelectasis with fever in children with reactive airway disease. Sinusitis is easily mistaken for purulent rhinitis, unless a computed tomography scan documents sinus involvement. Diarrhea may be the result of infection or an adverse effect of antibiotic therapy. Finally, the infections in a patient with an immunodeficiency may not be severe or progressive because of rapid institution of antibiotic therapy. Indeed, many patients ultimately diagnosed with a primary immunodeficiency present with an infection history that is not distinguishable from normal children.

It is also important to account for environmental exposure. There is an obvious explanation for frequent infections in an infant attending a large daycare center during the winter months, whereas the same number of infections might raise concern in an only child cared for in the home. Similarly, exposure to cigarette smoke and drinking from a bottle in a supine position are known risk factors for a variety of respiratory tract symptoms including infections. A sometimes useful clue is whether the child has had distinctly more infections than his/her siblings by a comparable age.

Early diagnosis of an underlying disorder is critical because it may lead to more effective approaches to therapy and appropriate anticipatory guidance. Furthermore, because some underlying disorders are inherited in Mendelian fashion, early diagnosis is essential for making genetic information available to the families of affected individuals.

The Clinical Presentation of Underlying Disorders

ALLERGY

Patients with allergic disease, rhinitis and/or asthma often have symptoms of both acute and chronic sinusitis.[2] There is little to

https://CafePezeshki.IR

BOX 7-1 GUIDELINES FOR IDENTIFYING CHILDREN WITH INCREASED SUSCEPTIBILITY TO INFECTION

- **Frequency**
  - More than one episode of pneumonia per decade of life
  - Increasing frequency of otitis media in children older than 2 years
  - Persistent otitis media and drainage despite patent tympanostomy tubes
  - Persistent sinusitis despite medical and, when appropriate, surgical treatment
- **Severity**
  - Pneumonia with empyema
  - Bacterial meningitis, arthritis or osteomyelitis
  - Sepsis
  - Mastoiditis
- **Infection with opportunistic pathogens**
  - *Pneumocystis jirovecii* pneumonia
  - Mucocutaneous candidiasis
  - Invasive fungal infection
  - Vaccine-acquired poliomyelitis
  - Bacille Calmette-Guérin infection after vaccination
- **Infections at multiple anatomic locations**
- **Lack of other epidemiologic explanations (e.g. daycare center, exposure to cigarette smoke, environmental allergies)**
- **Anatomic or physiologic features suggestive of a syndrome complex**
- **Failure to thrive**

distinguish the symptoms or mucopurulent discharge in patients with immunodeficiency compared with those with allergic disease. Similarly, radiographic studies do not discriminate between the two. History is important because flare-ups of sinusitis often accompany exacerbations of the underlying allergic symptoms, and patients may report more symptomatic improvement when treated with corticosteroids than when treated with antibiotics. In general, a history of atopy makes a diagnosis of immunodeficiency less likely because the ability to produce specific IgE antibodies usually indicates normal B and T cell function. However, there are several exceptions to this generality. These include Wiskott-Aldrich syndrome (thrombocytopenia, eczema, immunodeficiency), hyper-IgE syndromes (severe atopic dermatitis and a history of retained primary teeth, bone fractures, pneumonia sometimes with empyema, or chronic/recurrent cutaneous viral infections such as warts and molluscum contagiosum) and the syndrome of X-linked immunodeficiency/dysregulation with polyendocrinopathy and enteropathy or IPEX[3] (males who present early in life with severe atopic dermatitis, food and environmental allergies in association with endocrinopathy, especially insulin-dependent diabetes, and chronic diarrhea).

Recurrent sinopulmonary infections are also the most frequent illnesses associated with selective IgA deficiency, and IgA deficiency and allergy may be associated with each other. Even in blood bank donors in whom IgA deficiency was accidentally discovered, allergy may be twice as common as in healthy donors.[4] The most common allergic disorders in IgA-deficient individuals are rhinosinusitis, eczema, conjunctivitis and asthma.[5]

Because of the association between allergy and sinusitis, a careful history may often be sufficient, obviating the need for extensive testing for immunodeficiency. Screening for IgA deficiency may be of some help in understanding the association between the two in IgA-deficient individuals. Management of sinusitis should be medical with avoidance of surgery, unless all else fails.

BOX 7-2 CLINICAL FEATURES OF IMMUNODEFICIENCY

- **Increased susceptibility to infection**
  - Chronic/recurrent infections without other explanations
  - Infection with organism of low virulence
  - Infection of unusual severity
- **Autoimmune or inflammatory disease**
  - Target cells (e.g. hemolytic anemia, immune thrombocytopenia, thyroiditis)
  - Target tissues (e.g. rheumatoid arthritis, vasculitis, systemic lupus erythematosus)
- **Syndrome complexes**

IMMUNODEFICIENCY

The primary immunodeficiency diseases were originally viewed as rare disorders, characterized by severe clinical expression early in life. However, it has become clear that these diseases are not as uncommon as originally suspected, that their clinical expression can sometimes be relatively mild, and that they are seen nearly as often in adolescents and adults as they are in infants and children.[6–8] In fact, the presentation of immunodeficiency may be so subtle that the diagnosis will be made only if the physician is alert to that possibility.

Patients with primary immunodeficiency diseases most often are recognized because of their increased susceptibility to infection, but they may also present with a variety of other clinical manifestations (Box 7-2). In fact, noninfectious manifestations, such as autoimmune disease, may be the first or the predominant clinical symptom of underlying immunodeficiency. Other immunodeficiency diseases may be diagnosed because of their known association with syndrome complexes.

INFECTION

An increased susceptibility to infection is the hallmark of the primary immunodeficiency diseases. In most patients, the striking clinical feature is the chronic or recurring nature of the infections rather than the fact that individual infections are unusually severe.[1] However, not all immunodeficient patients are diagnosed after recurrent infections. In some, the first infection may be sufficiently unusual to raise the question of immunodeficiency. For example, an infant who presents with infection caused by *P. jirovecii* or another opportunistic pathogen is likely to be immunodeficient even if it is his or her first recognized infection.

AUTOIMMUNE/CHRONIC INFLAMMATORY DISEASE

Immunodeficient patients can present with autoimmune or chronic inflammatory diseases. It is thought that the basic abnormality leading to immunodeficiency may also lead to faulty discrimination between self and non-self and, thus, susceptibility to develop an autoimmune disease. The manifestations of these disorders may be limited to a single target cell or organ (e.g. autoimmune hemolytic anemia, immune thrombocytopenia, autoimmune thyroiditis, inflammatory bowel

https://CafePezeshki.IR

disease) or may involve a number of different target organs (e.g. vasculitis or systemic lupus erythematosus). The autoimmune and inflammatory diseases are more commonly seen in particular primary immunodeficiency diseases, most notably common variable immunodeficiency,[9] selective IgA deficiency, chronic mucocutaneous candidiasis[10] and deficiencies of early components (C1 through C4) of the classical complement pathway.[11]

Occasionally, a disorder that appears to be autoimmune in nature may in fact be due to an infectious agent. For example, the dermatomyositis that sometimes occurs in patients with X-linked agammaglobulinemia (XLA) is actually a manifestation of chronic enterovirus infection and not an autoimmune disease.

SYNDROME COMPLEXES

Immunodeficiency can be seen as part of a constellation of signs and symptoms in a syndrome complex.[12] In fact, the recognition that a patient has a syndrome in which immunodeficiency occurs may allow a diagnosis of immunodeficiency to be made before there are any clinical manifestations of that deficiency (Table 7-1). For example, children with the DiGeorge syndrome are usually identified because of the neonatal presentation of congenital heart disease, hypocalcemia, or both. This should lead to T lymphocyte evaluation before the onset of infections. Similarly, a diagnosis of Wiskott-Aldrich syndrome can be made in young boys with eczema and thrombocytopenia even before the onset of infections.

Cystic Fibrosis

Cystic fibrosis (CF) is one of the most common autosomal recessive disorders among white populations, occurring with an incidence of almost 1 in 3,000 live newborns.[13] The classic presentation of CF with chronic/recurrent sinopulmonary infections caused by *Pseudomonas* and *Staphylococcus,* diarrhea with malabsorption and failure to thrive, is easy to recognize. Newborn screening and new methods for diagnosis have led to the recognition of a broader clinical phenotype, including patients whose first or only manifestation is chronic/recurrent sinusitis.[14,15] The diagnosis of CF should be considered in any patient with chronic/recurrent sinopulmonary infections, especially if *Pseudomonas, Staphylococcus* or *Burkholderia cepacia* is identified as a pathogen.

Abnormalities of Airway Anatomy and Physiology

A variety of anatomic abnormalities may increase a child's susceptibility to upper and lower respiratory tract infections. Some, such as craniofacial anomalies involving the palate and the nose, may be readily apparent on physical examination. Others, such as bronchogenic cysts and extralobar pulmonary sequestrations, may be suspected when recurrent infections occur at a single anatomic site.[16] Unilateral otitis media and sinusitis in a young child should prompt an investigation for a nasal foreign body.

Abnormalities of airway muscle function may cause similar symptoms. Swallowing dysfunction with aspiration may be obvious in a child with cerebral palsy who coughs and gags when eating. More subtle clues are a history of drooling or dysarthria.

Disorders of Ciliary Structure and Function

Primary ciliary dyskinesia (PCD) is a rare problem, estimated to occur with an incidence of less than 1 in 10,000 in the general population.[17] In most cases it is inherited as an autosomal recessive trait, but PCD is genetically and clinically heterogeneous. Affected individuals have chronic/recurrent rhinitis, otitis media, sinusitis, pneumonia and bronchiectasis that begin at an early age. In approximately half of the cases there are accompanying abnormalities of laterality such as situs inversus or heterotaxy, and complex congenital heart disease has been reported in approximately 10% of cases. Abnormal ciliary function of spermatozoa can cause infertility in males, and abnormal ciliary function in the fallopian tubes can cause ectopic pregnancy.

PCD can be caused by abnormalities of any of the ciliary structural proteins (inner or outer dynein arms, radial spokes or microtubules) or by disordered orientation of cilia on mucosal surfaces, preventing them from beating in a synchronized wave that clears mucus from the airways. Identification of genetic mutations may diagnose PCD despite normal ultrastructural findings by electron microscopy.[17]

TABLE 7-1 Examples of Immunodeficiency Syndromes that May Increase Susceptibility to Sinopulmonary Infections

Syndrome	Clinical Presentation	Immunologic Abnormality	Other Contributing Factors	Genes
Ataxia telangiectasia	Ataxia, telangiectasia	Variable B and T lymphocyte dysfunction	Dysfunctional swallow with pulmonary aspiration	*ATM*
DiGeorge syndrome	Congenital heart disease, hypoparathyroidism, abnormal facies	Thymic hypoplasia or aplasia	Craniofacial anomalies including cleft palate; physiologic abnormalities including dysfunction of soft palate	22q11 deletion, 10p14 deletion, and others
Dysmotile cilia syndromes	Situs inversus, male infertility, ectopic pregnancy, upper and lower respiratory tract infections	None		30 different genes
Hyper-IgE syndromes	Coarse facies, eczematoid rash, retained primary teeth, bone fractures, pneumonia, chronic or recurrent cutaneous viral infections	Elevated serum IgE, eosinophilia		*STAT3* (autosomal dominant) *DOCK8* (autosomal recessive)
Wiskott-Aldrich syndrome	Thrombocytopenia, eczema	Variable B and T lymphocyte dysfunction		*WAS*

https://CafePezeshki.IR

Secondary Immunodeficiency

Immunodeficiency may occur secondary to other illnesses[18] or medications.[19] A variety of infections (including HIV, measles and Epstein-Barr virus [EBV]) may cause either temporary or long-lived abnormalities of humoral and/or cell-mediated immunity. Malnutrition or malabsorption can cause hypogammaglobulinemia and impaired cell-mediated immunity. A number of medications, most notably corticosteroids and chemotherapeutic agents, are immunosuppressive; phenytoin and other anticonvulsants can cause IgA deficiency and rarely panhypogammaglobulinemia. Posttraumatic splenectomy, or the 'autosplenectomy' that occurs at an early age in sickle cell anemia, leads to an increased risk of sepsis. Susceptibility to specific infections is determined by the cause of the secondary immunodeficiency; that is, patients with acquired deficiency of humoral immunity are at highest risk for infections with encapsulated bacteria and enteroviruses, whereas patients with acquired deficiency of cell-mediated immunity are at risk for infection by a wide variety of bacterial, fungal and viral pathogens.

Laboratory Tests for Underlying Disorders

IMMUNODEFICIENCY

Although the clinician can suspect immunodeficiency after a careful review of the history and physical examination, specific diagnoses are rarely evident without use of the laboratory. However, the types of infections and other symptoms should help to focus the laboratory work-up on specific parts of the immune system (Table 7-2). For example, patients with antibody deficiency typically have sinopulmonary infections as a prominent presenting feature.[20] Deficiency of cell-mediated immunity predisposes individuals to develop infections caused by *P. jirovecii,* other fungi and a variety of viruses.[21] Abnormalities of phagocytic function should be suspected when patients have recurrent skin infections or visceral abscesses.[22] Patients with complement deficiency most often present with bacterial sepsis or immune complex-mediated diseases.[23] Patients who are deficient in mannose binding lectin may have recurrent respiratory tract infections, but only in the first several years of life.[24]

Screening tests that should be performed in almost all patients include a complete blood count with differential, and measurement of serum immunoglobulins. Other tests should be guided by the clinical features of the patient (Table 7-3). Finally, whenever primary immunodeficiency is suspected, consideration must also be given to secondary causes of immunodeficiency, including infection with HIV or EBV, therapy with antiinflammatory medications (e.g. corticosteroids) and other underlying illnesses (e.g. lymphoreticular neoplasms).

For individuals who have a syndrome complex that includes increased susceptibility to infection as well as atopic disease (e.g. Wiskott-Aldrich syndrome, IPEX, hyper-IgE syndromes[25]), measurement of mean platelet volume and *FOXP3* expression, and mutation analysis for the relevant genes (*WAS* for Wiskott-Aldrich syndrome; *FOXP3* for IPEX; *STAT3* and *DOCK8* for hyper-IgE syndrome) should be considered.

EXAMINATION OF THE PERIPHERAL BLOOD SMEAR

The complete blood count with examination of the blood smear is an inexpensive and readily available test that provides important diagnostic information relating to a number of immunodeficiency diseases. Neutropenia most often occurs secondary to immunosuppressive drugs, infection, malnutrition or autoimmunity but may be a primary problem (congenital or cyclic neutropenia). In contrast, persistent neutrophilia is characteristic of leukocyte adhesion molecule deficiency,[26] and abnormal cytoplasmic granules may be seen in the peripheral blood smear of patients with Chediak-Higashi syndrome.[27]

The blood is predominantly a 'T cell organ'; that is, the majority (50–70%) of peripheral blood lymphocytes are T cells, whereas only 5% to 15% are B cells. Therefore lymphopenia is usually a feature of T cell or combined immunodeficiency disorders such as DiGeorge syndrome or severe combined immunodeficiency disease.

Thrombocytopenia may occur as a secondary (usually autoimmune) manifestation of immunodeficiency but is often a presenting manifestation of the Wiskott-Aldrich syndrome. A unique finding in the latter group of patients is an abnormally small platelet (and lymphocyte) volume,[28] a measurement that is easily made with automated blood counters. Confirmation of the diagnosis should be made by mutation analysis.

Examination of red blood cell morphology can yield clues about splenic function. Howell-Jolly bodies may be visible in peripheral blood in cases of splenic dysfunction or asplenia.[29] However, the converse is not always true, and the absence of

TABLE 7-2 Patterns of Illness Associated with Primary Immunodeficiency

	ILLNESSES	
Disorder	**Infection**	**Other**
Antibody	Sinopulmonary (pyogenic, encapsulated bacteria) Gastrointestinal (enteroviruses, *Giardia*)	Autoimmune disease (autoantibodies, inflammatory bowel disease)
Cell-mediated immunity	Pneumonia (pyogenic bacteria, *Pneumocystis jirovecii,* viruses) Gastrointestinal (viruses) Skin, mucous membranes (fungi)	
Phagocytosis	Skin, reticuloendothelial system, abscesses (*Staphylococcus,* enteric bacteria, fungi, mycobacteria)	
Complement	Sepsis and other blood-borne encapsulated bacteria (*Streptococcus, Pneumococcus, Neisseria*)	Autoimmune disease (systemic lupus erythematosus, glomerulonephritis)

TABLE 7-3 Screening Tests for Underlying Disorders

Suspected Abnormality	Diagnostic Tests
Antibody	Quantitative immunoglobulins (IgG, IgA, IgM) Antibody response to immunization
Cell-mediated immunity	Lymphocyte count T lymphocyte enumeration (CD3, CD4, CD8) T lymphocyte function in vitro: proliferation to mitogens and antigens Human immunodeficiency virus serology and viral load
Complement	Total hemolytic complement (CH_{50})
Phagocytosis	Neutrophil count

Howell-Jolly bodies does not ensure that splenic function is normal.

EVALUATION OF HUMORAL IMMUNITY

Measurement of serum immunoglobulins is an important screening test to detect immunodeficiency for three reasons: (1) more than 80% of patients diagnosed with a primary disorder of immunity will have abnormalities of serum immunoglobulins; (2) immunoglobulin measurements yield indirect information about several aspects of the immune system because immunoglobulin synthesis requires the coordinated function of B and T lymphocytes and antigen-presenting cells; and (3) the measurement of serum immunoglobulin levels is readily available, reliable and inexpensive. Neither serum protein electrophoresis nor immunoelectrophoresis is sufficiently sensitive or quantitative to substitute for quantitative measurements of serum IgG, IgA and IgM levels. This will identify patients with panhypogammaglobulinemia as well as those with deficiencies of an individual immunoglobulin class, such as selective IgA deficiency. Interpretation of results must be made in view of the marked variations in normal immunoglobulin levels with age,[30] therefore age-related normal values must always be used for comparison. Different reference ranges are necessary in the first year of life for very low birth-weight, premature infants.[31]

It is almost always important to assess the ability to make antibody to vaccines in addition to measuring immunoglobulin levels. Live viral (e.g. oral polio, measles, mumps, rubella, varicella) and bacterial (e.g. bacille Calmette-Guérin) vaccines should never be used for the evaluation of suspected immunodeficiency because they may cause disseminated infection in an immunocompromised host. Antibody levels generated in response to childhood immunization with tetanus toxoid, pneumococcal or *Hemophilus influenzae* polysaccharide/protein conjugate vaccines are usually the most convenient to measure. In children over the age of 18 to 24 months it is also important to assess antibody responses to polysaccharide antigens, because these responses may be deficient in some patients who can respond normally to protein and polysaccharide/protein conjugate antigens.[32] For this purpose, antibody can be measured in response to immunization with the 23-valent pneumococcal capsular polysaccharide vaccine. Alternatively, because the ABO blood group antigens are polysaccharides, quantifying isoagglutinin titers (usually of the IgM class) can assess antipolysaccharide antibody. However, the value of the latter test in the young child is limited because many normal children do not have significant isoagglutinin titers.[33] There are a few patients who make normal antibody responses to vaccines but do not have long-term immunologic memory. These individuals can be identified only by re-checking antibody levels 6 to 12 months after immunization. Most patients with hypogammaglobulinemia and impaired antibody responses will have common variable immunodeficiency,[9] a syndrome for which no genetic etiology can be established in the vast majority of cases. The diagnosis can be made only after excluding other primary (e.g. transient hypogammaglobulinemia of infancy[34] in children less than 3 years old, and X-linked agammaglobulinemia in males) and secondary (e.g. protein-losing enteropathy) causes. Males with panhypogammaglobulinemia and absent B lymphocytes on flow cytometry should be tested for mutations in the *BTK* gene, which if present would confirm the diagnosis of X-linked agammaglobulinemia.

Selective deficiencies of IgG subclasses have been described. However, the clinical significance of an IgG subclass deficiency in the presence of normal antibody responses to protein and polysaccharide antigens is unclear, and therefore IgG subclass measurements are rarely useful.[35]

EVALUATION OF CELL-MEDIATED IMMUNITY

Testing for defects of cell-mediated immunity is relatively difficult because of the lack of good screening tests. Lymphopenia is suggestive of T lymphocyte deficiency because T lymphocytes constitute the majority (50–70%) of peripheral blood mononuclear cells. However, lymphopenia is not always present in patients with T lymphocyte functional defects. Similarly, the lack of a thymus silhouette on chest radiography is rarely helpful in the evaluation of T lymphocyte disorders because the thymus of normal children may rapidly involute after stress and provide the appearance of thymic hypoplasia.

Information about the T cell compartment may be obtained by subset analysis of peripheral blood T lymphocytes by flow cytometry.[36] Patients with severe combined immunodeficiency and DiGeorge syndrome generally have decreased numbers of CD3, CD4 and CD8 T lymphocytes, whereas patients infected with HIV have a selective loss of CD4 lymphocytes. Further analysis of T cell numbers can evaluate expression of the α/β or γ/δ T cell receptor, and the distribution of CD45RA (naïve) and CD45RO (memory) subsets. With increasing availability of antibodies specific to cell surface proteins, subtle defects associated with deficiencies of specific subsets of T cells are being described, such as deficiencies of regulatory T cells in IPEX.[3]

Because enumeration does not indicate function, assessment of the in vitro proliferative response of T cells to mitogens (phytohemagglutinin A, concanavalin A) or antigens (tetanus toxoid, candida) or other stimuli is essential.[37] Delayed-type hypersensitivity (DTH) skin testing with a panel of antigens can be used to screen for cell-mediated immune function but there are significant limitations to its use, including the lack of standardized reagents, and false-negative results due to lack of prior exposure to antigen, young age and difficulties with intradermal injection.[38–40]

Individuals who have low numbers of T lymphocytes and/or impaired function should be evaluated for a combined immunodeficiency disorder. Flow cytometry is used to assess the number and percentage of T, B and NK cells in peripheral

https://CafePezeshki.IR

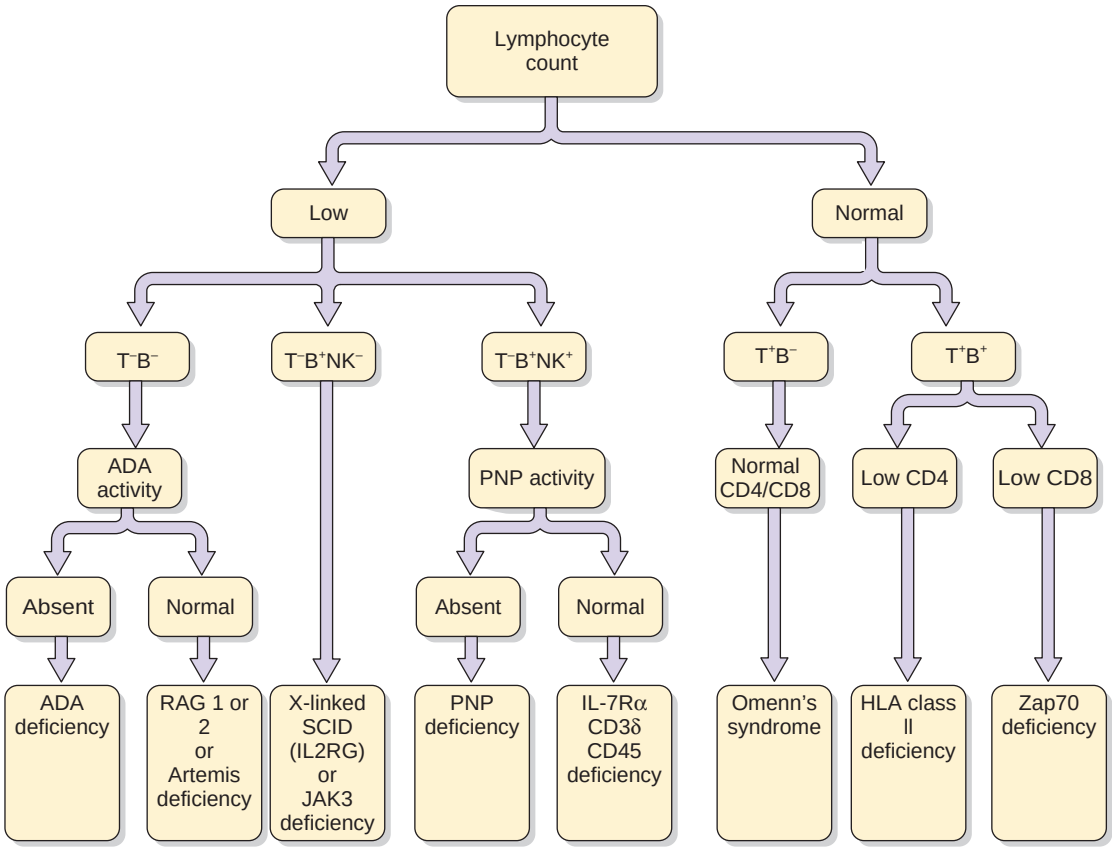

Figure 7-1 Algorithm for evaluating the most common deficiencies of cell-mediated immunity. *ADA* – Adenosine deaminase; *PNP* – purine nucleoside phosphorylase.

blood, and those results can guide the selection of molecular diagnostics (Figure 7-1). Individuals with low T lymphocyte counts but normal numbers of B and NK cells, especially in the presence of congenital heart disease, facial dysmorphism, hypocalcemia, abnormal speech or learning disorders should be tested with fluorescent in situ hybridization to detect a 22q11 deletion associated with DiGeorge syndrome.[41] This will identify the majority of such cases, but a comparative genomic hybridization microarray may be needed to detect very small deletions at that locus or deletions at other sites, and should be pursued if the clinical suspicion is high.

EVALUATION OF THE COMPLEMENT SYSTEM

Most of the genetically determined deficiencies of complement can be detected with the total serum hemolytic complement (CH_{50}) assay.[42] Because this assay depends on the functional integrity of all of the components of the classical complement pathway (C1 through C9), a genetic deficiency of any of these components leads to a marked reduction of the CH_{50}. Consumption of components (e.g. in autoimmune disease) generally reduces, but does not eliminate, complement activity. Mannose binding lectin can be measured by ELISA. Alternative pathway deficiencies (e.g. factor H, factor I and properdin) are extremely rare; they may be suspected if the CH_{50} is in the low range of normal and the serum C3 level is low. AH_{50} is an assay of alternative pathway complement activity that is helpful. The final identification of the specific complement component that is deficient usually rests on both functional and immunochemical tests, and specific assays have been developed for each of the individual components.

EVALUATION OF PHAGOCYTIC CELLS

Evaluation of phagocytic cells usually entails assessment of both their number and function. Disorders such as congenital agranulocytosis or cyclic neutropenia that are characterized by a deficiency in phagocytic cell number can be easily detected by evaluating a white blood cell count and differential. Beyond that, assessment of phagocytic cell function is relatively specialized because it depends on a variety of in vitro assays, including measurement of directed cell motility (chemotaxis), ingestion (phagocytosis) and intracellular killing (bactericidal activity).[43] The most common of the phagocyte function disorders, chronic granulomatous disease, can be diagnosed by the nitroblue tetrazolium (NBT) dye test[44] or by using the flow cytometric dihydrorhodamine (DHR)[45] test, both of which measure the oxidative metabolic response of neutrophils and monocytes. A western blot or molecular analysis can confirm the diagnosis and identify the pathogenic mutation in the NADPH oxidase pathway (gp91, p22, p47 or p67). Patients with gp91 deficiency generally have a more severe course.

Evaluation of Cilia

For suspected ciliary dyskinesia, ciliary structure and function must be assessed. Structure is assessed by electron microscopy

https://CafePezeshki.IR

of tissue obtained from the nasal mucosa, tonsils, adenoids or bronchial mucosa. Because tobacco smoke, other pollutants and infection may cause secondary abnormalities of cilia, it is sometimes difficult to find an appropriate tissue to sample. The microscopic examination should look for the presence of an anatomic defect that is consistent from cilia to cilia, such as the absence of dynein arms, and assess the orientation of cilia on the epithelium. With secondary causes, the structural abnormalities vary from cilia to cilia.[46] At the same time that tissue is obtained for electron microscopy, epithelial cell brushings from the nasal turbinates or bronchi can be examined for ciliary waveform and beat frequency. Assessments of mucociliary clearance can be made by placing a small particle of saccharin on the anterior portion of the middle turbinate and measuring the time until the patient tastes the saccharin.[47] For this test, the subject must sit quietly without sniffing or sneezing, and it is therefore difficult to perform in young children. A sweet taste should be evident within 1 hour in normal subjects, but the test has a very high rate of false-positive results. In individuals with a high suspicion for one of the ciliary defects, genetic screening for one of the mutations may be necessary.

Cystic Fibrosis

In most cases, the diagnosis of CF can be made by measuring the chloride concentration in sweat after iontophoresis of pilocarpine.[48] A minimum acceptable volume or weight of sweat must be collected to ensure an average sweat rate of greater than 1 g/m^2/min, and the diagnosis can be made with certainty if the sweat chloride concentration is greater than 60 mmol/L. However, this test may be falsely negative, especially among those patients who have an atypical clinical presentation. If the clinical suspicion of CF is high, especially in the absence of some of the more common CF symptoms, other useful diagnostic tests include mutation analysis of the CF transmembrane conductance regulator (CFTR) gene and/or measurement of potential differences across the nasal epithelium (nasal PD). The genetic test is commercially available; the measurement of nasal PD is not widely available and should still be considered a research tool.

Evaluation for Human Immunodeficiency Virus and Other Immunosuppressive Virus Infections

Many techniques for the diagnosis of viral infection focus on the serologic detection of antibodies to viral proteins. There are, however, several problems with sole reliance on antibody detection techniques. First, antibody tests will not detect infection in patients during the interval between the time of infection and seroconversion. For HIV infections, 95% of individuals will seroconvert within 6 months of infection, although a so-called 'window period' of as long as 35 months has been reported.[49,50] Second, if a virus induces immunodeficiency, it may inhibit the production of antiviral antibodies.[51] Thus, in a patient with known or suspected immunodeficiency, viral cultures as well as tests to detect viral antigens and nucleic acids should be performed in addition to serologic tests.[52]

Molecular Diagnostics

The molecular basis is known for the majority of recognized primary immunodeficiency diseases. Multiple gene defects underlying certain diseases (e.g. severe combined immunodeficiency disease, chronic granulomatous disease, and hyper-IgE syndromes) have been identified. Determination of the genotype should be sought whenever possible to confirm the clinical diagnosis. In some cases it may provide critical prognostic information (e.g. the significant risk of malignancy when *DOCK8*, but not *STAT3*, is the cause of hyper-IgE). In other cases, it may lead to a specific therapy (e.g. enzyme replacement therapy, bone marrow transplantation or gene therapy). In all cases, knowing the genotype allows for genetic counseling and carrier testing, as well as prenatal or early postnatal diagnosis.

There are two general approaches to molecular diagnosis. A specific combination of clinical and laboratory features will lead to an almost certain diagnosis (e.g. severe hypogammaglobulinemia and absent B cells in a male infant is X-linked agammaglobulinemia until proven otherwise) or a paradigm exists to guide molecular diagnostic testing (e.g. the pattern of T, B and NK cell deficiency guides the evaluation for SCID, see Figure 7-1). Sometimes, an unusual phenotype or a usual phenotype whose suspected gene defect cannot be identified will lead to an unbiased genomic analysis (whole genome single neucleotide polymorphism or whole exome sequence) and identification of a disease-causing mutation.

BOX 7-3 KEY CONCEPTS

Identification of Underlying Disorders in Children with Recurrent Infections

- **Children with chronic/recurrent infections may have one of the following underlying defects**
  - Allergy
  - Immunodeficiency (primary or secondary)
  - Cystic fibrosis
  - Ciliary dysmotility
  - Localized abnormalities of anatomy or physiology
- **Immunodeficient patients present with a variety of symptoms**
  - Increased susceptibility to infection
  - Autoimmune or inflammatory disorders
  - Syndrome complexes
- **Recurrent infections at a single anatomic site should prompt investigation of the anatomy and physiology of that site**

Conclusions

The majority of children with recurrent respiratory tract infections will have environmental risk factors such as exposure to daycare or cigarette smoke, or are atopic with associated problems with allergies. It is the task of the allergist to identify individuals who are most likely to have an underlying deficiency of host defense and to perform appropriate screening tests for such disorders. Early identification is critical for optimal clinical management and genetic counseling (Box 7-3).

8 Antibody Deficiency

FRANCISCO A. BONILLA

KEY POINTS

- A clinician must maintain an index of suspicion for immunodeficiency when confronted with patients with infections considered unusual with respect to frequency, severity, response to treatment, or organism.
- The possibility of antibody deficiency in particular should be considered when the history includes pyogenic upper and lower respiratory tract infections.
- Early diagnosis is critical for reducing morbidity and mortality rates for immunodeficiency diseases.
- To provide the most efficient and complete approach to diagnosis and management, referral to a clinical immunology specialist is indicated where there is clear evidence for, or suspicion of, antibody or other immunodeficiency syndrome.
- Intravenous or subcutaneous immunoglobulin replacement therapy and antibiotic prophylaxis are the main modalities for management of antibody deficiency disorders.
- With intravenous immunoglobulin (IVIG) and antibiotics, many patients with agammaglobulinemia or hypogammaglobulinemia may lead normal or near-normal lives.

Primary immunodeficiency diseases arise from inherited or spontaneous genetic lesions affecting immune system function. These may be subdivided into defects of adaptive and innate immunity. Defects of adaptive immunity are further subdivided into humoral, cellular and combined (humoral and cellular) immunodeficiencies resulting mainly from lymphocyte dysfunction. Disorders of innate immunity result from defects of phagocytes, the complement system or signaling systems such as Toll-like receptors.[1,2] Humoral immunodeficiencies, also called antibody deficiencies, are characterized by low serum levels of one or more immunoglobulin classes and/or relative impairment of antibody responses to antigen challenge. This may arise as the result of a defect intrinsic to the antibody-producing cells (B cells) or of a failure of communication between T cells and B cells (T cell help for antibody production). Cell-mediated immunity is intact.

The most common complications of humoral immunodeficiency are recurrent bacterial infections of the upper and lower respiratory tract.[3,4] In severe forms of antibody deficiency, repeated lung infections lead to bronchiectasis.[5] In these patients, airway and systemic inflammation are exaggerated in comparison to patients having bronchiectasis associated with other (non-immune deficient) processes. Chronic lung disease and diminished pulmonary function and reserve account for a large proportion of the morbidity and impaired quality of life.[5]

Other than the respiratory tract, organ systems frequently infected include the gastrointestinal tract, skin, and the central nervous and musculoskeletal systems. These infections are generally caused by the same organisms virulent in immunocompetent hosts, predominantly encapsulated bacteria such as *S. pneumoniae, H. influenzae, S. aureus* and *N. meningitidis.* Viral infections are usually cleared normally by these patients, although some enteric viruses (particularly echoviruses) may cause severe disease. Antibody deficient individuals have a higher frequency of recurrence with the same agents, since they do not produce neutralizing antibodies or B cell memory. Additional infectious diseases may be associated with particular syndromes.[1,2]

The most severely affected patients have frequent pneumonias and other invasive bacterial infections and frequent severe viral infections. Treatment-resistant recurrent otitis media and sinusitis are also frequently seen. There are no validated clinical criteria for predicting which children with recurrent otitis media or sinusitis or pneumonias will have an identifiable immunologic defect. A high index of suspicion for antibody deficiency should be maintained in cases of recurrent, refractory or severe respiratory and other infections.

Estimates of the incidence and prevalence of immunodeficiency overall range from about 1 : 10 000–1 : 2000.[6] These estimates are based on survey and registry data; there are no prospective studies to measure incidence formally. Table 8-1 contains a classification of humoral immunodeficiencies according to known gene defects, as well as clinically defined entities.

X-LINKED AGAMMAGLOBULINEMIA

Ogden Bruton published the classic description of this disorder in 1952; therefore this condition is often called 'Bruton's agammaglobulinemia'.[7] It is caused by a defect in a signal transducing protein known as Bruton's tyrosine kinase (BTK).[8] BTK is expressed in B cells, monocytes, macrophages, mast cells, erythroid cells and platelets; it transduces signals from the B cell immunoglobulin receptor. Without BTK, B cell development is impeded at an early stage.

Only males are affected, and they are often asymptomatic during infancy. In this period, they are protected by maternal antibodies acquired during gestation. After birth, maternal IgG gradually disappears, and infectious complications usually begin by the age of 9 to 18 months. The absence of tonsils or palpable lymph nodes is notable on examination. Laboratory investigation reveals absent or very low serum levels of immunoglobulins and B cells.

Despite normal cellular immunity, patients with X-linked agammaglobulinemia (XLA) are prone to certain viral infections, including chronic enteroviral meningoencephalitis and vaccine-associated paralytic poliomyelitis. Additional infections described in these patients include mycoplasma or ureaplasma

https://CafePezeshki.IR

TABLE 8-1 Classification of Humoral Immunodeficiencies

Disease	Gene
KNOWN GENETIC BASIS	
X-linked (Bruton's) agammaglobulinemia (XLA), Bruton's tyrosine kinase	*BTK*
Autosomal agammaglobulinemia:	
Immunoglobulin M constant region (Cμ)	*IGHM*
Signal transducing molecule Igα	*CD79A*
Signal transducing molecule Igβ	*CD79B*
Surrogate light chain component λ5	*IGLL1*
B cell linker protein	*BLNK*
PI3 kinase regulatory subunit 1	*PIK3R1*
Transcription factor 3	*TCR3*
Translocation of LRRC8	*LRRC8*
Hyper-IgM syndrome (HIM)	
X-linked (XHIM, HIM1), tumor necrosis factor superfamily member 5 (CD154, CD40 ligand)	*TNFSF5*
Autosomal recessive:	
Activation-induced cytidine deaminase (HIM2)	*AICDA*
Tumor necrosis factor receptor superfamily member 5 (CD40) (HIM3)	*TNFRSF5*
Uracil nucleoside glycosylase (HIM5)	*UNG*
Common variable immunodeficiency-like disorders	
Inducible T cell co-stimulator	*ICOS*
CD19	*CD19*
CD20	*CD20*
CD21	*CD21*
CD81	*CD81*
NF-κB2	*NFKB2*
Transmembrane activator and calcium mobilizing ligand interactor (TACI, also tumor necrosis factor receptor superfamily 13B)	*TNFRSF13B*
B cell activating factor (BAFF) receptor	*TNFRSF13C*
TNF-related weak inducer of apoptosis (TWEAK)	*TNFSF12*
Lipopolysaccharide responsive beige-like anchor protein	*LRBA*
Other	
Protein kinase C-δ	*PRKCD*
PI3 kinase catalytic subunit δ	*PIK3CD*
UNKNOWN GENETIC BASIS	
Common variable immunodeficiency	
IgA deficiency	
IgG subclass deficiency	
Specific antibody deficiency with normal immunoglobulins	
Transient hypogammaglobulinemia of infancy	
Hypogammaglobulinemia, unspecified	

arthritis.[9] Opportunistic infections such as *Pneumocystis jiroveci* pneumonia are rare.[10]

About half of XLA patients have a family history of affected male relatives on the maternal side.[11] Autosomal forms of agammaglobulinemia must be distinguished in males without such a history. It is desirable to confirm the diagnosis at the molecular level whenever possible. BTK is expressed in platelets and monocytes and may be detected by flow cytometry.[12] These tests are useful for screening males and detecting carrier females who have two populations (BTK^+ and BTK^-) of monocytes or platelets as a result of random X chromosome inactivation. Female carriers of XLA show nonrandom X chromosome inactivation in their B cells, and this can also be used for carrier detection.

Some patients with *BTK* mutations have an 'atypical' phenotype with low numbers of B cells and low-level antibody production.[12] In general, mutations that permit low-level function of BTK are more often associated with higher B cell numbers, immunoglobulin levels and antibody formation. Some of these atypical XLA cases may be misdiagnosed as having common variable immunodeficiency (see below). However, even siblings with identical mutations may show divergent clinical features.

AUTOSOMAL AGAMMAGLOBULINEMIA

A few patients have agammaglobulinemia (AGAM) with autosomal (mostly recessive) patterns of inheritance. Mutations of the immunoglobulin (Ig)μ heavy chain locus *(IGHM)*,[13,14] and defects of λ5 (surrogate light chain),[14] Igα (CD79a) and Igβ (CD79b), all prevent formation of the pre-B cell Ig receptor. Mutations in *BLNK* (encoding B cell linker protein)[14] and in *PIK3R1* (encoding regulatory subunit 1 of phosphoinositol-3′ kinase) disrupt B cell signaling and lead to agammaglobulinemia.[15] All of these disorders have recessive inheritance. The only defined autosomal dominant monogenic agammaglobulinemia is due to defects of transcription factor 3 *(TC3)*.[16] Finally, a single female patient has been described with a translocation interrupting the gene encoding leucine rich repeat containing 8 (LRRC8).[17] All of these autosomal defects arrest B cell development at early stages within the bone marrow.

COMMON VARIABLE IMMUNODEFICIENCY

The diagnosis of common variable immunodeficiency (CVID) encompasses an unknown number of genetically and etiologically distinct conditions having in common a (relatively) late-onset humoral immunodeficiency, most often in the first or third decade of life.[18] Due to rapid development of the immune system in childhood, and frequent resolution of hypogammaglobulinemia in young children,[19] it is not considered appropriate to confer a diagnosis of CVID under 4 years of age.[20]

CVID is defined by laboratory and clinical criteria; there is no universal consensus on the necessary elements establishing the diagnosis.[20] All patients have low IgG and impaired antibody response. Some authorities require that IgA also be low to establish the diagnosis, while others accept that IgA and/or IgM may be normal or low. Not all patients with CVID have infections, nor are symptoms a component of the definition (i.e. one may have 'asymptomatic' CVID).

Many CVID patients have recurrent sinopulmonary bacterial infections. Additional manifestations include asthma, chronic rhinosinusitis, inflammatory bowel disease, and recurrent or chronic arthropathy. The apparent 'atopic' symptoms mimicking asthma and chronic rhinosinusitis found in about 10% of patients do not involve allergen-specific IgE. Autoimmune cytopenias also occur with increased frequency. In addition, noncaseating granulomatous disease resembling sarcoidosis may involve the skin or viscera, even in children.

Lymphoproliferation may cause splenomegaly, adenopathy and intestinal lymphonodular hyperplasia, and CVID patients also have a higher incidence of lymphoid and gastrointestinal malignancy. The relative risk of lymphoma is estimated to be 10–20-fold greater than in the general population.[21] Most of these are B cell non-Hodgkin's lymphomas not associated with Epstein-Barr virus (EBV).[22]

Numbers of peripheral B and T cells are variable in CVID; particular abnormalities may correlate with phenotype. After activation, B cells may 'switch' isotype production from IgM and IgD to IgG, IgA or IgE (see section on hyper-IgM

https://CafePezeshki.IR

syndromes). Memory B cells express the surface marker CD27. Levels of 'switched' ($IgM^{-}IgD^{-}$) memory ($CD27^{+}$) cells correlate with disease phenotype. Levels below 1–2% of B cells are associated with a higher rate of severe infection, autoimmune disease, lymphoproliferation and lymphoma.[23,24] The T cell phenotype is also variable. Low levels of naïve ($CD45RA^{+}$) CD4 T cells correlate with these complications.[25]

Causative genetic lesions have been identified in about 1% of patients with CVID or CVID-like syndromes. These include defects of inducible T cell co-stimulator (ICOS) [26] and several surface glycoproteins important for B cell activation including CD19,[27] CD20,[28] CD21[29] and CD81.[30] Other monogenic forms of CVID-like hypogammaglobulinemia include defects of protein kinase C δ,[31] NF-κB2[32] and the lipopolysaccharide responsive beige like anchor protein (LRBA).[33]

Additional genetic associations occur in subgroups of CVID patients. Some functionally important polymorphisms of the transmembrane activator and calcium mobilizing ligand interactor (TACI) are found in a higher proportion of CVID patients (5–10%) in comparison to the general population (1%).[34] This molecule, also called tumor necrosis factor receptor superfamily member 5 (TNFRSF5), is expressed on activated B cells. Patients with CVID may be homozygous or heterozygous for polymorphisms in TACI. However, these alterations in TACI are not disease-causing; some healthy individuals harbor the same genetic changes.[35]

X-linked lymphoproliferative disease (XLP) arises from defects in the SLAM (signaling lymphocytic activation molecule)-associated protein (SAP) signal transducing molecule. Some of these patients have dysgammaglobulinemias of various types, and a few had been classified as having CVID before the discovery of the genetic basis of XLP.[36] It is important to rule out XLP in males with a CVID phenotype because prognosis and therapy are distinct for these disorders. Rarely, patients with XLA may be misdiagnosed as having CVID.[37]

The occurrence of thymoma and hypogammaglobulinemia with low B cell numbers has been designated Good's syndrome.[38] It is unknown if these patients have genetic or immunologic distinctions from CVID. Disseminated and opportunistic infections (such as *P. jiroveci* pneumonia) occur more frequently in Good's syndrome and prognosis is worse than that for most CVID patients. Approximately 10% of CVID patients have severe CD4 lymphocytopenia (<200 cells/μL) and/or an opportunistic infection. Several complications (intestinal disease, splenomegaly, lymphomas and granulomas) are more frequent in this subset.[39] This has been called 'late onset combined immunodeficiency' (LOCID) and is similar to Good's syndrome, with the exception of thymoma.

IgA DEFICIENCY

Human IgA is divided into two subclasses – IgA1 and IgA2 – encoded by separate genes. IgA1 constitutes 80% to 90% of serum IgA; both contribute equally to secretory IgA. Both subclasses are affected in IgA deficiency (IGAD). Very low levels of IgA (<7 mg/dL) are found in about 1:500–700 Caucasians.[40] This is called selective IgA deficiency (IGAD). Clinical associations with levels of IgA above this threshold but below the normal range ('low' IgA) are not well established. As with CVID, due to rapid immune system development in children and wider normal ranges of immunoglobulin levels in early childhood, it is not appropriate to confer a diagnosis of IGAD below the age of 4 years.[2] Many individuals with IGAD are asymptomatic. However, more than 80% have clinical manifestations similar to CVID or IgG subclass deficiency including viral and bacterial upper and lower respiratory tract infections, atopic disease and autoimmunity.[41]

Autoimmune syndromes in IGAD include rheumatoid arthritis, systemic lupus erythematosus, Sjögren syndrome, insulin-dependent diabetes mellitus and other endocrinopathies, pernicious anemia, hemolytic anemia, Crohn's disease and autoimmune hepatitis.[41–43] The forms of malignancy associated with CVID do not appear to occur with greater frequency in IGAD in comparison to the general population.[44] Rare cases of IGAD may evolve into CVID or improve over time.[45] About one third of IGAD patients have a concomitant IgG subclass deficiency (see below). This association is more frequently accompanied by deficits in specific antibody production and significant infectious complications in comparison to the absence of IgA alone.[46,47] The same T and B cell abnormalities found in CVID patients are observed in those with IGAD, albeit in a smaller proportion in comparison to controls.[48]

No disease-causing single gene defects underlying IGAD have been defined. The polymorphisms of *MSH5* described above are associated with the A1-B8-DR3 extended HLA haplotype and have also been found in individuals with IGAD. IGAD has been reported in patients after chemotherapy[49] or treatment with anticonvulsants such as phenytoin.[50] In the latter case, the effect was reversible with drug discontinuation.

IgG SUBCLASS DEFICIENCY

Human IgG is divided into four subclasses designated IgG1, IgG2, IgG3 and IgG4, each encoded by different Ig constant region genes. Each represents approximately 67%, 23%, 7% and 3% of the total, respectively.[51] IgG subclasses are produced in different relative amounts depending on the antigenic stimulus. For example, IgG1 predominates in responses to soluble protein antigens, and responses to pneumococcal capsular polysaccharides consist almost entirely of the IgG2 subclass.

A consensus definition of IgG subclass deficiency does not exist. In contrast to CVID or IGAD, a clinical significance of abnormal IgG subclass levels has not been established outside the context of recurrent infections. Thus, this should be considered an element of the definition. In a patient with recurrent infections, a disproportionately low level (<2 SD below the mean or <5th percentile) of one or more IgG subclasses with a normal total serum IgG may constitute an IgG subclass deficiency (IGGSD). Levels should be abnormal on at least two measurements more than 1 month apart. Many authorities insist that impaired vaccine response (usually to polysaccharide antigens) also be included in the definition. In one recent case-control study of patients with recurrent respiratory infections, pneumococcal polysaccharide responses did not correlate with IgG2 or IgG3 serum levels.[52] This emphasizes the importance of direct assessment of vaccine response in patient evaluation, rather than relying on subclass measurement alone.

Diagnostic controversy arises due to interlaboratory variation in immunoglobulin subclass determinations and differences in normal ranges depending on age and ethnicity. As with CVID and IGAD, caution should be exercised when conferring this diagnosis in patients less than 4 years of age. Furthermore, since low subclass levels are defined based on population statistics, most individuals with isolated low IgG subclass levels are

https://CafePezeshki.IR

asymptomatic, rendering its significance questionable in patients with recurrent infections. However, some studies show a higher prevalence of subclass deficiency in groups of patients with chronic or recurrent sinopulmonary bacterial infections.[53,54] Not all of these patients have impaired specific antibody responses. Thus, the connection between IgG subclass deficiency and susceptibility to infection or other disease may be difficult to demonstrate.

Individuals with IGGSD most often present with recurrent sinopulmonary infections of varying severity caused by common respiratory bacterial pathogens.[55] Additional manifestations include frequent viral infections, recurrent diarrhea (infectious or allergic) and atopic diseases such as asthma and allergic rhinitis, and autoimmunity.[56] Lymphoproliferative disease has been reported in association with IGGSD, although its significance is unknown.[22]

IgG subclass deficiencies occur in various patterns. Low IgG2 is most common in children (male > female). It may occur in isolation but is also frequently associated with IgG4 and/or IgA deficiency.[57] Selective IgG3 deficiency is found more commonly in women and may be associated with low levels of IgG1.[58] Recurrent infections have also been reported in association with only low IgG4.[59] Young children with IGGSD often improve with time: 50% to 70% (depending on the pattern of Ig abnormalities) achieve normal serum levels by age 6.[47]

Abnormalities of lymphocyte populations have not been established in IGGSD. Some have found low levels of switched memory B cells (as in CVID) in some individuals with IGGSD.[60] IGGSD is not commonly the result of genetic lesions in the human Ig heavy-chain locus. In fact, most individuals with deletions in this locus with restricted IgG subclass expression are asymptomatic.[61] Mutations preventing expression of cell surface IgG2 have been found in a few reported cases of IgG2 deficiency.[62]

SPECIFIC ANTIBODY DEFICIENCY WITH NORMAL IMMUNOGLOBULINS

Some patients with recurrent infections and poor antibody responses (mainly to polysaccharide antigens) have normal levels of antibody classes and subclasses. This is called 'specific antibody deficiency with normal immunoglobulins' (SADNI) or 'functional antibody deficiency'.[63] In one tertiary care center, SADNI was the most frequent diagnosis among patients evaluated for immunodeficiency (23%).[64] In another recent study, poor response to pneumococcal polysaccharides was found in 58% of 24 children evaluated for chronic productive cough.[63] In a larger cohort of 129 adult patients with chronic rhinosinusitis, more than 11% had a diagnosis of SADNI.[65] In one retrospective study of 72 patients, approximately 8% exhibited autoimmunity and 5% had chronic enteropathy.[66] Abnormalities of lymphocyte populations are not well described, though low levels of switched memory B cells are found in some patients.[67]

TRANSIENT HYPOGAMMAGLOBULINEMIA OF INFANCY

In humans, IgG is transported from the mother to the fetus during gestation. Maternal antibody has a half-life in the infant between 20 and 30 days. A nadir of IgG occurs at 3 to 9 months of age as maternal IgG is cleared and newborn production begins. Transient hypogammaglobulinemia of infancy (THI) is an IgG deficiency that begins in infancy and resolves spontaneously by 5 years of age.[68] Thus, the diagnosis can be confirmed only after IgG levels normalize. By definition, IgG is lower than normal for age. Many of these children are asymptomatic. Beginning at about 6 months of age, many (>90%) of these IgG-deficient children manifest the types of recurrent infections associated with hypogammaglobulinemia.[69] Severe infections are not often seen, but vaccine strain polio meningoencephalitis has been reported in one case of THI.[70] Fifty to eighty per cent of patients are atopic and autoimmunity may be seen in a small fraction (4%).[69,71]

Patients with higher initial IgG levels and males normalize more rapidly.[68,71] High total B cells, low memory B cells and reduced CD19 on B cells have been described in patients with THI.[69,71–73]

Many studies indicate mainly normal vaccine responses in THI, but one study documented poor responses to Hib vaccine in a majority and to tetanus in one third of patients.[71] Those with low levels of IgA and IgM and poor vaccine responses had longer time to resolution and a higher rate of persistent hypogammaglobulinemia.[19,68,69,71]

HYPER-IgM SYNDROMES

The eponym 'hyper-IgM syndrome' is applied to immunodeficiency with defective Ig class switching. In primary antibody responses, IgM is produced initially; IgG and other isotypes are produced later. This is called *class switching* and requires genetic rearrangement to juxtapose the Ig variable region gene with a new heavy-chain gene. If this process fails, IgM predominates in antibody responses without other isotypes being produced. The X-linked hyper-IgM syndrome (abbreviated XHIM or HIM1) is an immunodeficiency resulting from defects in TNFSF5 (tumor necrosis factor superfamily member 5).[74] This is also called CD154 or CD40 ligand (CD40L). This is truly a combined immunodeficiency because the interactions of T cells with antigen-presenting cells and mononuclear cells are impaired. However, HIM1 is often classified with antibody deficiencies because hypogammaglobulinemia is such a prominent feature.

Usually within the first 2 years of life, patients with HIM1 develop recurrent bacterial infections generally seen in hypogammaglobulinemia.[74] They also have opportunistic infections from fungal pathogens such as *Pneumocystis*, *Histoplasma* and others.[75] Additional infections include erythrovirus and sclerosing cholangitis due to *Cryptosporidium*. Noninfectious complications include neutropenia and hepatic and hematologic malignancies.

In HIM1, IgG is low and IgM is normal or high; more than half of patients lack IgA.[74] Specific antibody formation is often impaired. Patients make IgM antibody in response to immunization or infection but little IgG. Antibody levels wane rapidly, and there are no memory responses. Secondary lymphoid tissues are poorly developed and do not contain germinal centers. The diagnosis is established by demonstrating a failure of T cells to express CD40L after stimulation. The diagnosis should be confirmed with molecular genetic study.

Forms of hyper-IgM syndrome with autosomal (mostly recessive) inheritance have also been described. 'Hyper-IgM syndrome type 3' (HIM3) results from mutations in the gene encoding tumor necrosis factor receptor superfamily member

https://CafePezeshki.IR

5 (TNFRSF5), also known as CD40.[76] Because this is the ligand for TNFSF5 (HIM1), the same cellular interactions are affected.

Two additional forms of autosomal hyper-IgM syndrome are due to mutations of the genes encoding activation-induced cytidine deaminase (AID) and uracil nucleoside glycosylase (UNG).[76,77] These are called HIM2 and HIM5, respectively. Bacterial sinopulmonary infections occur in these patients along with diarrhea, failure to thrive and lymphadenopathy. These defects affect only class-switch machinery in B cells; T cell function is completely intact and opportunistic infections are not observed.

Another form of hyper-IgM syndrome (unknown defect) has been designated 'hyper-IgM syndrome type 4'.[78,79] This is a milder antibody deficiency with residual IgG production and an intrinsic B cell class-switch defect with normal T cell function. Immune function may normalize over time in some patients.[78]

A few patients have been described with a hyper-IgM phenotype and defects of PI3 kinase catalytic subunit δ (PI3KCD).[80]

Differential Diagnosis

Clinical entities that mimic antibody deficiency are listed in Box 8-1. The most frequent presentation of antibody deficiency includes recurrent, frequent and severe respiratory tract infections with encapsulated bacteria.[3,4] Additional bacterial infections may occur in other sites, along with frequent viral infections and noninfectious complications. Of course, antibody deficiency may accompany cellular immunodeficiency (i.e. combined immunodeficiency). Normal cellular immune function should be confirmed in all cases of abnormal humoral immunity (Figure 8-1).

Secondary or acquired antibody deficiency is more prevalent than primary humoral deficiency in adults; the opposite is true for children. Secondary antibody deficiency can occur with abnormal loss of lymph or plasma (lymphangiectasia, nephrosis, protein-losing enteropathy).[81] Hypogammaglobulinemia also occurs with malignancy (e.g. chronic lymphocytic leukemia) or following chemotherapy or immunomodulation (e.g. rituximab) for cancer or autoimmune disease, or immunosuppressive therapy following solid organ transplantation. With abnormal protein loss, vaccine antibody levels are preserved, unless hypogammaglobulinemia is profound. The opposite is true for other causes of secondary hypogammaglobulinemia.

Complement deficiency presents with infections characteristic of antibody deficiency.[82] Patients with phagocyte defects may also present with respiratory bacterial infections.[83] However, they frequently present with distinct infectious complications such as deep-seated abscesses or cellulitis, which are not as often seen in antibody deficiencies (although they do occur occasionally).

Some nonimmune disorders such as cystic fibrosis and ciliary dysfunction mimic antibody deficiencies.[84,85] Nasopharyngeal anatomic defects, hyperplasia of lymphoid tissue or allergic rhinosinusitis may cause Eustachian tube or ostiomeatal obstruction and lead to recurrent or chronic otitis media and/or sinusitis. Depending on clinical features, some or all of these disorders should be investigated in patients with normal humoral immunity with infections characteristic of antibody deficiency.

BOX 8-1 DIFFERENTIAL DIAGNOSIS OF RECURRENT RESPIRATORY TRACT BACTERIAL INFECTIONS

- Primary humoral immunodeficiency
- Secondary or acquired humoral immunodeficiency
- Primary combined immunodeficiency
  - Severe combined immunodeficiency
  - Wiskott-Aldrich syndrome
  - DiGeorge syndrome
  - Ataxia-telangiectasia
  - Many others
- Secondary or acquired combined immunodeficiency
- Complement deficiency
- Phagocytic cell defect
  - Chronic granulomatous disease
  - Leukocyte adhesion defect
  - Chédiak-Higashi syndrome
  - Neutropenia
- Allergic rhinosinusitis
- Anatomic obstruction of Eustachian tube or sinus ostia (tumor, foreign body, lymphoid hyperplasia)
- Cystic fibrosis
- Ciliary dysfunction

Evaluation

Figure 8-1 shows an algorithm for evaluation of patients with suspected humoral immunodeficiency. Some combined immunodeficiencies have clinical features that should prompt investigation of cellular immune function.[2] This algorithm assumes that there are no such features because evaluation of cellular immunity would be undertaken immediately in such cases. The following annotations correspond to the numbered elements in Figure 8-1.

1. The descriptions of the diseases mentioned point out the elements of a history that should arouse suspicion of antibody deficiency, the main element being recurrent respiratory tract bacterial and viral infections. Physical examination is nonspecific, showing only the presence or sequelae of infections. Visible or palpable lymphoid tissue may be scarce or absent in some cases, especially in areas rich in B cells (e.g. tonsils). This is most often seen in agammaglobulinemia. Specific diagnosis rests on the laboratory evaluation.
2. The laboratory examination of humoral immunity consists of measuring the levels of various Ig isotypes (IgG, IgA, IgM and IgG subclasses) in serum, as well as a measure of specific antibody production with both protein and polysaccharide antigens. Significant disease may result from selective inability to respond to polysaccharide antigens (Table 8-2). Antibodies to protein vaccine antigens such as tetanus and diphtheria toxoids are often determined. Antibodies against the capsular polysaccharide (polyribose phosphate [PRP]) of *H. influenzae* type B (Hib) may also be measured. Note that Hib vaccines couple the PRP to a protein carrier, and PRP titers, although specific for a polysaccharide, are indicative of immune response to a protein. Similar considerations apply to measurement of antibodies against conjugated pneumococcal capsular polysaccharides (as in Prevnar vaccines). Antibody levels measured after immunization with unconjugated pneumococcal

https://CafePezeshki.IR

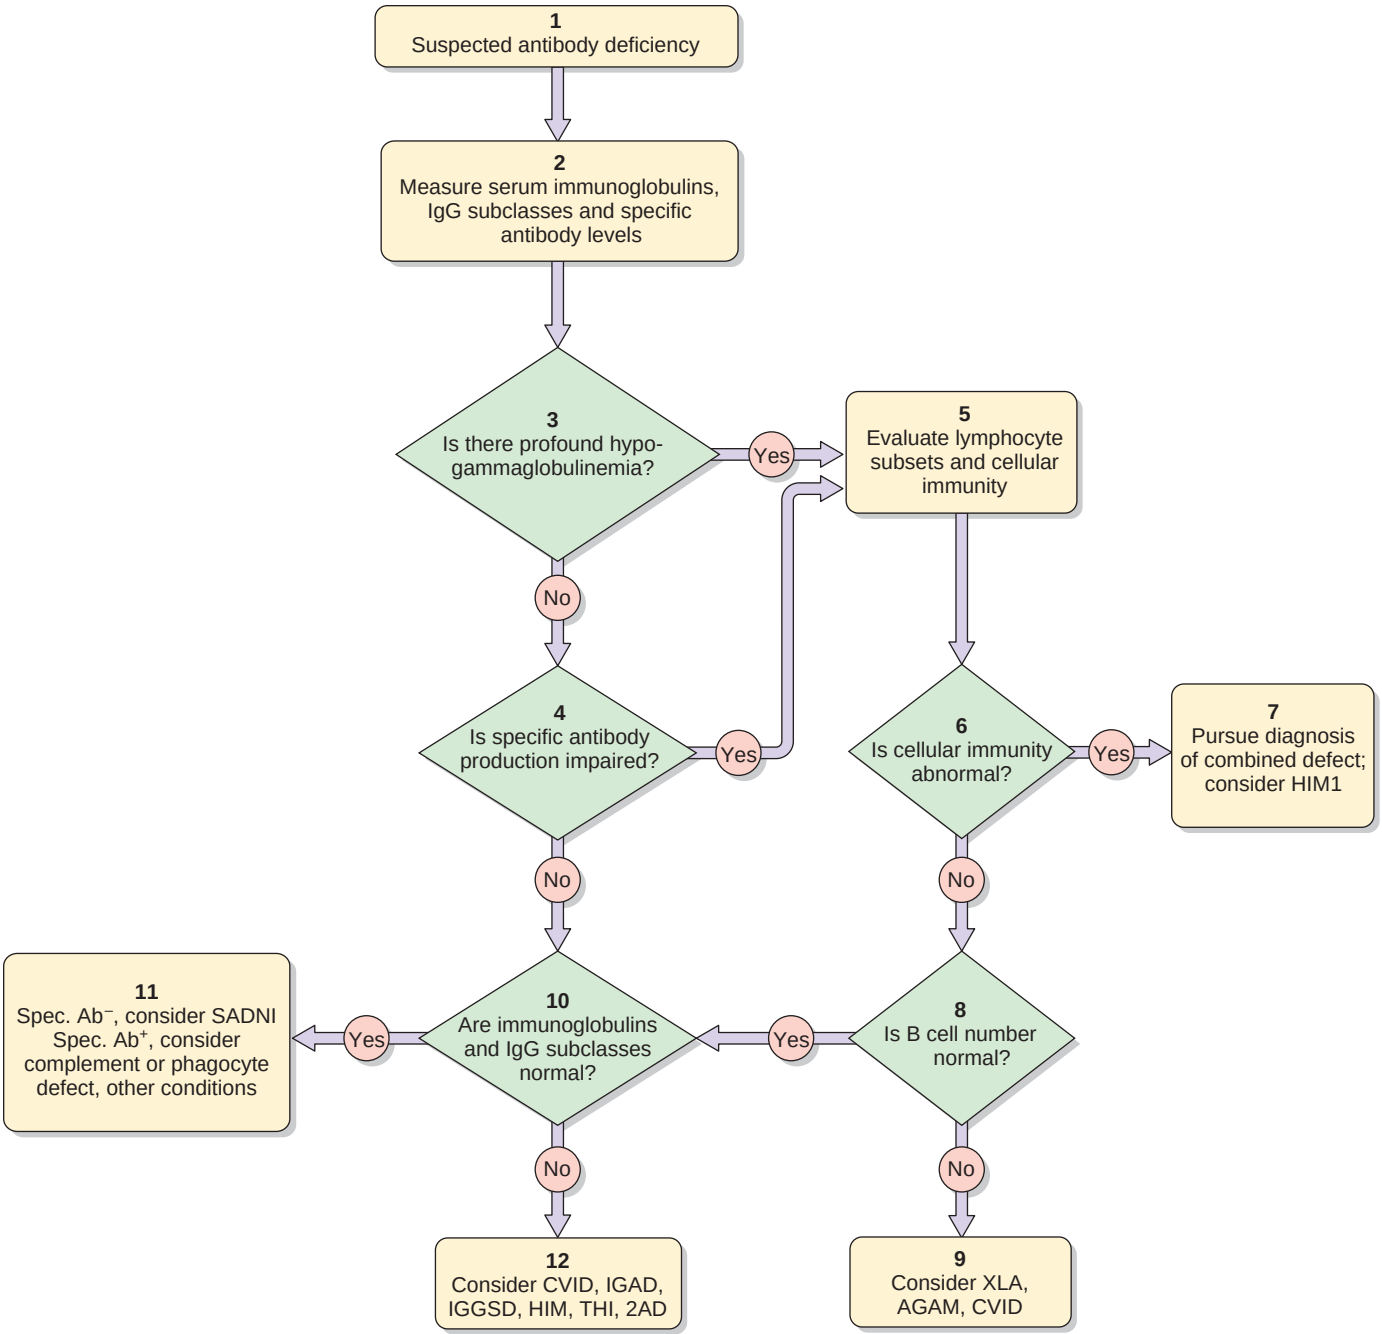

Figure 8-1 Algorithm for evaluation of the patient with suspected antibody deficiency (see text for annotations and abbreviations).

vaccines are indicative of polysaccharide responses. If initial measurements of antibodies are low, response to booster immunization should be assessed. Post vaccination levels may be determined after 3 to 6 weeks. Polysaccharide antibody responses are reliable in normal children beyond the age of 1 year.[86] Serum isohemagglutinins are naturally occurring antibodies against ABO blood group antigens. They are produced in response to polysaccharide antigens of gut flora, and measurement is sometimes a useful indicator of polysaccharide immunity.[87]

Following immunization with a conjugate pneumococcal vaccine (e.g. Prevnar 13), 0.35 μg/mL is considered protective for invasive disease with respect to a single serotype.[88] Seroconversion rates in a healthy population depend on serotype and many healthy children do not respond to all types. Criteria of normal response with respect to the proportion of serotypes have not been established. Following immunization with a polysaccharide pneumococcal vaccine (e.g. Pneumovax), 1.3 μg/mL is considered protective for invasive disease with respect to a single serotype.[89] The most recent guidelines for assessing response to pneumococcal polysaccharide vaccine[90] indicate:

- Mildly deficient response is concentration >1.3 μg/mL for >50% of serotypes with a 2-fold rise in level for <50% of types under age 6 (70% over age 6).

TABLE 8-2 Reference Ranges for Serum Immunoglobulins and Specific Antibody Levels*

Age	IgG (mg/dL)	IgA (mg/dL)	IgM (mg/dL)
0–1 mo	700–1300	0–11	5–30
1–4 mo	280–750	6–50	15–70
4–7 mo	200–1200	8–90	10–90
7–13 mo	300–1500	16–100	25–115
13 mo–3 yr	400–1300	20–230	30–120
3–6 yr	600–1500	50–150	22–100
6 yr–adult	639–1344	70–312	56–352

Age	IgG1 (mg/dL)	IgG2 (mg/dL)	IgG3 (g/dL)	IgG4 (mg/dL)
Cord	435–1084	143–453	27–146	1–47
0–3 mo	218–496	40–167	4–23	1–120
3–6 mo	143–394	23–147	4–100	1–120
6–9 mo	190–388	37–60	12–62	1–120
9 mo–2 yr	286–680	30–327	13–82	1–120
2–4 yr	381–884	70–443	17–90	1–120
4–6 yr	292–816	83–513	8–111	2–112
6–8 yr	422–802	113–480	15–133	1–138
8–10 yr	456–938	163–513	26–113	1–95
10–12 yr	456–952	147–493	12–179	1–153
12–14 yr	347–993	140–440	23–117	1–143
Adult	422–1292	117–747	41–129	10–67

	Tetanus toxoid (IU/mL)	PRP (Hib) (ng/mL)	Pneumococcus
Protective level	0.15	1000	See notes for Figure 8-1

	ISOHEMAGGLUTININ TITER	
Age	Anti–A	Anti–B
0–6 mo	Unpredictable	Unpredictable
6 mo–2 yr	≥1:4–8	≥1:4–8
2–10 yr	1:4–256	1:16–256
10 yr–adult	≥1:4–8	≥1:4–8

*These are normal ranges from the laboratories of Children's Hospital, Boston, MA (except isohemagglutinins, see Fong SW, Qaqundah BY, Taylor WF: *Transfusion* 1974;14:551.) Normal ranges are method dependent and should be validated for each laboratory. These reference ranges are intended for educational purposes only.

- Moderately deficient response is concentration >1.3 μg/mL for <50% of types under age 6 (70% over age 6).
- Severely deficient response is concentration >1.3 μg/mL for fewer than 3 serotypes at any age.
- Poor memory response is an initial 'normal' response which falls below criteria after 6 months.

3. Hypogammaglobulinemia with IgG <100 mg/dL in an infant or <200–300 mg/dL in an older child or adult should prompt additional evaluation of lymphocyte populations and cellular immune function to investigate combined immunodeficiency and B cell number.
4. Specific antibody responses may be impaired as a result of the failure of T cell help for antibody production, even if serum Ig levels are normal or near normal. This situation should also prompt an evaluation of cellular immunity.
5. Cellular immunity is evaluated because of either severe hypogammaglobulinemia or impaired specific antibody production.
6. and 7. If cellular immunity is abnormal, then the eventual diagnosis will be a form of combined immunodeficiency. Recall that HIM1 and HIM3 are combined immunodeficiencies.
8. Cellular immunity is normal; it is important to determine if there is impaired B cell development.
9. B cells are absent or severely reduced in XLA or autosomal agammaglobulinemia. A history of affected male relatives on the mother's side establishes the diagnosis of XLA.[11] Demonstration of maternal carrier status is also presumptive evidence. This can be shown by nonrandom X chromosome inactivation in B cells, or the presence of two populations (BTK^+ and BTK^-) in monocytes or platelets by flow cytometry.[12,91,92] The diagnosis should be confirmed by molecular analysis. B cells may be low in some cases of CVID.[20]
10. At this point, either there is not severe hypogammaglobulinemia and antibody formation is not impaired, or antibody is reduced, a cellular immunologic evaluation is normal, and the B cell number is normal. Most

https://CafePezeshki.IR

of the remaining diagnoses are clinically defined, in part, by the serum Ig profile.

11. If antibody formation is impaired (Spec.Ab$^-$) and serum immunoglobulins are normal, then the diagnosis is SADNI. Otherwise, all measurements are normal (Spec. Ab$^+$), and alternative explanations for recurrent infections should be sought. See the discussion on differential diagnosis.
12. There is an immunoglobulin abnormality, with or without demonstrable impairment of specific antibody production. Possible diagnoses include CVID, a form of HIM, IGAD, IGGSD, THI and secondary antibody deficiency.

Treatment

Therapeutic considerations for antibody deficiency are summarized in Box 8-2. There are two principal modalities to treat patients with antibody deficiencies: antimicrobial therapy (and prophylaxis)[93] and IgG replacement.[94,95] Human polyclonal IgG for therapeutic use has been available for decades and is administered every 2 to 4 weeks via an intravenous infusion, or every 1 to 14 days via subcutaneous infusion. The principal mechanism of benefit of IgG replacement is via passive immunity, i.e. providing protective antibody that patients are incapable of producing themselves. IgG therapy is the subject of Chapter 15.

Antibiotics are used to treat infectious complications before or during IgG replacement. The choice of antibiotic depends on the site of infection, severity, past history of infections and antibiotic use, hypersensitivity and microbiologic sensitivity data, where available. Doses do not need to be adjusted for immunodeficiency, however resolution may be slower in comparison to immunocompetent patients, and treatment may need to be prolonged. In general, one should consider doubling the usual duration of therapy for respiratory tract infections, especially sinusitis, as relapse is likely with shorter courses of antibiotics.

BOX 8-2 THERAPEUTIC PRINCIPLES FOR ANTIBODY DEFICIENCY

AVOID INFECTION

Isolate from obviously contagious individuals
Avoid large institutional settings for child or elder care
Practice appropriate public and personal hygiene

THERAPY FOR EXISTING INFECTIONS

Antibiotics, standard dose regimens are appropriate, consider extended (double length) course

PREVENTION OF INFECTIONS

Immunoglobulin replacement (see Chapter 15)
Antibiotic prophylaxis

Antibiotic	Children	Adults
Amoxicillin (consider with clavulanate, if necessary)	10–20 mg/kg daily or bid	500 mg daily or bid
Trimethoprim (TMP)/ sulfamethoxazole (dosing for TMP)	5 mg/kg daily	160 mg daily
Azithromycin	10 mg/kg weekly or 5 mg/kg every other day	500 mg weekly or 250 mg every other day
Clarithromycin	7.5 mg/kg daily or bid	500 mg daily or bid

Agammaglobulinemia, CVID and HIM are indications for replacement therapy with IgG.[2] The value of IgG replacement for therapy of IGAD, IGGSD, SADNI and THI is not as clear. With some exceptions (mainly in the case of IgG subclass deficiency) IgG replacement is not considered appropriate in IGAD as there is little benefit. These patients and those with IGGSD, SADNI and THI are best managed initially with therapeutic and prophylactic antibiotics[93] and evaluation to rule out other predisposing factors. In the case of patients with IGGSD, SADNI or THI treated with antibiotic prophylaxis, if infections continue to occur with unacceptable frequency or severity, if antibiotics are not tolerated, or especially if antibody responses to immunization are poor, IgG replacement is indicated.

Even with IgG replacement at appropriate doses, sinopulmonary infections may continue at an unacceptable rate, especially in those with more severe disease such as agammaglobulinemia, or CVID or HIM, or with lung damage such as bronchiectasis.[93,95] In these circumstances, antibiotic prophylaxis may be used in addition to IgG. In some patients, this may be required as a permanent adjunct to IgG replacement. For others, it may be possible to administer prophylaxis for several months at a time (e.g. during the winter), or for a few years, after which a patient may tolerate discontinuation. It is always important to consider other potential predisposing factors to chronic rhinosinusitis or bronchitis and to consider additional therapies such as topical nasal or inhaled corticosteroids.[2,20]

Autoimmune, inflammatory or malignant complications of antibody deficiency are generally treated as they would be in other (non-immunodeficiency) contexts. For these types of complications no standardized regimen has been developed specifically for antibody deficient patients. Granulomatous disease in CVID often responds well to immunosuppressive therapy such as steroids, cyclosporine A, thioguanines and rituximab.[96,97] Individuals with preexisting immunodeficiency are at greater risk for infectious or malignant complications of immunomodulatory therapies and they should be monitored very carefully in this regard.

Stem cell therapy is generally not considered for patients with antibody deficiency.[2] One exception may be CVID. Some patients with severe complications of CVID (refractory autoimmune disease or marrow aplasia) have received stem cell therapy.[98] Results have been mixed, but some successful outcomes have been achieved. Stem cell replacement is not yet a standard therapy for CVID; it should be considered on a case-by-case basis.

Immunoglobulin replacement and anti-infective therapy and chemoprophylaxis are the mainstays of therapy for the majority of patients with all forms of HIM.[74,76,77] Recall that HIM due to defects of CD40L or CD40 are combined immunodeficiencies and require prophylaxis against *Pneumocystis jiroveci* pneumonia. Neutropenia in these patients sometimes responds to granulocyte colony-stimulating factor (G-CSF, or filgrastim). Due to the importance of the T cell defect in these patients, stem cell therapy should be considered for any who have suitable donors.[74] Stem cell therapy is not indicated for HIM due to defects of AID and UNG.

Conclusions

There are no prospective studies that define the incidence of antibody deficiency. Diagnostic controversy exists with respect to what constitutes clinically significant rates or severity of

https://CafePezeshki.IR

infection, and there are no criteria regarding such histories with proven sensitivity or specificity leading toward diagnosis of antibody deficiency. Thus, it is important to maintain an index of suspicion in cases where an infectious predisposition appears to exist.

Antibody deficiency is the most prevalent form of primary immunodeficiency and will be encountered by every practicing allergist/immunologist. Simple tools (measurement of serum immunoglobulins and vaccine responses) serve to classify many patients; some may require more specialized evaluation (e.g. flow cytometry and/or functional testing). Nevertheless, screening tests differentiate those requiring more urgent evaluation from those who may be followed over time and managed conservatively, at least initially.

Many infants and young children with antibody deficiency improve over time and may no longer suffer from recurrent infections after several years. No large long-term prospective studies have been undertaken to determine whether or not these individuals go on to suffer excessive immunologic disorders or malignancies in comparison to the general population. It is unlikely that a primary antibody deficiency diagnosed in an older child or adult will improve over time. Although it may be reassuring that a large proportion of younger patients appear to improve with time, this will certainly not be the case for all. Even for patients who are destined to 'recover', early diagnosis is critical for preventing significant morbidity and mortality.

9 T Cell Immunodeficiencies

LUIGI D. NOTARANGELO

KEY POINTS

- Defects of T cell development and/or function cause increased susceptibility to infections of bacterial, viral and fungal origin, and are often associated with autoimmune manifestations and malignancies.
- The most severe forms of these disorders, severe combined immunodeficiency (SCID), are fatal unless immune reconstitution is attained, typically with hematopoietic stem cell transplantation (HSCT) or in selected cases with gene therapy or enzyme replacement therapy.
- Newborn screening based on enumeration of T cell receptor excision circles (TRECs) permits early identification of SCID and thereby allows adoption of therapeutic interventions aimed to reduce the risk of infection while preparing for HSCT, resulting in improved overall survival.
- Several forms of T cell immunodeficiency are associated with other hematopoietic and non-hematopoietic defects, whose severity may have a significant impact on prognosis and outcome.
- Hygiene measures, antimicrobial prophylaxis, regular immunoglobulin replacement therapy and nutritional support are cardinal aspects of treatment for patients with T cell deficiencies, along with HSCT.

T lymphocytes are an essential component of adaptive immunity. Through cytolytic activity and secretion of T_H1 (interferon [IFN]-γ) and T_H17 (interleukin [IL]-17, -22) cytokines they mediate resistance to viruses, mycobacteria and fungi. In addition, interaction of T_H2 cells with B lymphocytes and antigen-presenting cells, and release of soluble mediators such as IL-4 and IL-10 promote T-dependent antibody responses and contribute to defense against extracellular pathogens. Consequently, defects in T cell development and/or function result in severe combined immunodeficiency (SCID), with increased susceptibility to severe infections from early in life.[1]

In addition, impaired development and/or function of regulatory T (T_{REG}) lymphocytes, which play a crucial role in immune homeostasis, causes autoimmunity. This chapter will discuss the etiology, clinical presentation, diagnostic approach and main principles of treatment for congenital T cell disorders. For a more detailed discussion of hematopoietic stem cell transplantation (HSCT) and gene therapy the reader is referred to Chapter 16.

Severe Combined Immunodeficiency

ETIOLOGY

SCID is a heterogeneous group of disorders that present with a distinct immunologic phenotype (Table 9-1). Molecular and cellular mechanisms responsible for SCID include:

- *Defects of lymphocyte survival*: adenosine deaminase (ADA) deficiency, reticular dysgenesis
- *Signaling defects*: X-linked SCID, JAK3 deficiency, IL-7R deficiency, CD45 deficiency
- *Defects of expression and signaling through the pre-T cell receptor (pre-TCR) and the TCR*: defects of RAG1, RAG2, Artemis, Cernunnos, DNA ligase IV (LIG4), DNA protein kinase catalytic subunit (DNA-PKcs), defects of CD3 chains (CD3δ, CD3ε, CD3ζ), defect of TCR α constant (TRAC) chain, CD45 deficiency.

Hypomorphic mutations in these genes may allow for residual T cell development, with or without immune dysregulation. These conditions, and other defects at later stages in T cell development, will be discussed separately in this chapter (see 'Other Combined Immunodeficiencies').

SCID Caused by Adenosine Deaminase Deficiency

Adenosine deaminase (ADA) mediates conversion of adenosine into inosine, and of deoxyadenosine into deoxyinosine. Deficiency of ADA, inherited as an autosomal recessive trait, accounts for 5% to 10% of all cases of SCID. Lack of ADA results in intracellular accumulation of deoxyadenosine and of its phosphorylated metabolites, among which dATP is particularly toxic to lymphoid precursors.[2] Consequently, complete ADA deficiency is characterized by extreme lymphopenia (T^- B^- NK^- SCID) and extra-immune manifestations (reflecting the housekeeping nature of the *ADA* gene) from early in life. However, partial defects of the enzyme may result in less severe clinical presentation (delayed or late-onset forms) that may even present in adulthood.[3]

Reticular Dysgenesis

This rare form of autosomal recessive SCID is characterized by severe lymphopenia and agranulocytosis, associated with sensorineural deafness.[4] The disease is caused by mutations of the *AK2* gene, encoding for adenylate kinase 2 that controls intramitochondrial levels of ADP. AK2 deficiency results in increased cell death in lymphoid progenitors and in myeloid precursors committed to neutrophil differentiation.[5,6]

X-Linked Severe Combined Immunodeficiency (SCIDX1, γc Deficiency)

SCIDX1 is the most common form of SCID in humans, with an estimated incidence of 1 : 100,000 to 1 : 150,000 live births. Inherited as an X-linked trait, it is characterized by complete absence

https://CafePezeshki.IR

of both T and NK lymphocytes, with preserved number of B lymphocytes (T^- B^+ NK^- SCID). The disease is caused by mutations in the *IL2RG* gene that encodes for the IL2 receptor common gamma chain (IL-2Rγ_c, γ_c).[7] The γ_c chain is constitutively expressed by T, B and NK cells, as well as myeloid cells and other cell types, including keratinocytes. The γ_c protein is an integral component of various cytokine receptors, namely IL-2R, IL-4R, IL-7R, IL-9R, IL-15R and IL-21R. In all of these receptors, the γ_c is coupled with the intracellular tyrosine kinase Janus-associated kinase (JAK)-3, that mediates signal transduction.[8] Lack of circulating T and NK cells in SCIDX1 males reflects defective signaling through IL-7R and IL-15R, respectively.

JAK-3 Deficiency

JAK-3 is a cytoplasmic tyrosine kinase that is physically and functionally associated with the γ_c in all of the γ_c-containing cytokine receptors.[9] Mutations of the *JAK3* gene result in a clinical and immunologic phenotype (i.e. T^- B^+ NK^- SCID) that is undistinguishable from SCIDX1,[10,11] but has an autosomal pattern of inheritance.

IL-7Rα Deficiency

IL-7Rα deficiency results in an autosomal recessive form of SCID characterized by lack of circulating T lymphocytes, with preserved number of B and NK cells (T^- B^+ NK^+ SCID).[12] IL-7 is produced by stromal cells in bone marrow and in the thymus, and provides survival and proliferative signals to IL-$7R^+$ lymphoid progenitor cells.

T^- B^- SCID Caused by Defective VDJ Recombination

B and T lymphocytes recognize foreign antigen through specialized receptors, the immunoglobulin (Ig) and the T cell receptor (TCR), respectively. These receptors are encoded by variable/diversity/joining (VDJ) gene segments that undergo somatic rearrangement through a mechanism known as VDJ recombination.[13] This process is initiated when the lymphoid-specific recombinase activating gene 1 (RAG1) and RAG2 proteins recognize specific recombination signal sequences (RSS) that flank each of the V, D and J gene elements and introduce a DNA double-strand break in this region.[14] Subsequently, a series of ubiquitously expressed proteins (including Ku70, Ku80, DNA-PKcs, XRCC4, DNA ligase IV, Artemis and Cernunnos/XLF) involved in recognition and repair of DNA damage mediate the final steps of the VDJ recombination process.

Defects of V(D)J recombination cause complete absence of both T and B lymphocytes, with preserved presence of NK cells (T^- B^- NK^+ SCID). *RAG1* and *RAG2* mutations do not affect mechanisms of DNA double-strand break (dsb) repair and hence are not associated with increased cellular radiosensitivity.[15] By contrast, defects of Artemis, LIG4, Cernunnos/XLF or DNA-PKcs cause increased radiosensitivity, reflecting impaired dsb repair.[16–20] Of note, hypomorphic mutations in the *RAG1/2* genes and in the Artemis-encoding *DCLRE1C* gene have been associated with variable clinical and immunologic phenotypes, ranging from Omenn syndrome to expansion of TCR$\gamma\delta^+$ T cells to delayed onset immunodeficiency with granuloma and/or autoimmunity.[21,22]

CD3/TCR Deficiencies

The CD3 complex consists of CD3γ, δ, ε and ζ chains and is required to mediate signaling through the pre-TCR and the TCR. In humans, defects of the CD3 δ, ε or ζ chains cause autosomal recessive T^- B^+ NK^+ SCID.[23–25] In contrast, CD3γ deficiency is associated with a partial T cell lymphopenia and a variable clinical phenotype.[26,27]

CD45 Deficiency

Two unrelated patients have been reported in whom SCID was caused by the complete absence of the CD45 protein, a phosphatase that modulates signaling through the TCR/CD3 complex.[28,29] The immunologic phenotype is characterized by complete lack of T cells, with normal to increased B cell counts.

OTHER COMBINED IMMUNODEFICIENCIES

Omenn Syndrome and Other Conditions Associated with Hypomorphic RAG Mutations

Omenn syndrome (OS) is a combined immunodeficiency characterized by generalized erythroderma, lymphadenopathy, hepatosplenomegaly, respiratory infections, diarrhea, failure to thrive, hypoproteinemia with edema, and eosinophilia[30] (Figure 9-1). IgE serum levels are often elevated, and T lymphocytes have an oligoclonal repertoire.

In most cases, OS is due to hypomorphic mutations in *RAG1* and *RAG2* genes,[31] however it may be caused also by hypomorphic defects in other genes, including *DCLRE1C*,[32] *IL7R*,[33] *LIG4*,[34] *RMRP*,[35] *IL2RG*,[36] *ADA*,[37] *ZAP70*[38] and *AK2*.[39] Impaired thymic expression of AIRE, a transcription factor involved in expression and presentation of self-antigens, has been reported in patients with OS, and may favor survival of autoreactive T cell clones.[40]

Figure 9-1 Typical clinical features in an infant with Omenn syndrome. Note generalized erythroderma with scaly skin, alopecia and edema.

https://CafePezeshki.IR

Patients with hypomorphic mutations in the *RAG1/2* genes may also present with other clinical and immunologic phenotypes. Expansion of TCRγδ$^+$ T cells has been frequently reported after cytomegalovirus (CMV) infection and may associate with autoimmunity (especially cytopenias).[41,42] In other cases, RAG deficiency may present with granulomatous lesions and/or autoimmunity.[21,22,43] The severity of the clinical phenotype of RAG deficiency correlates, at least in part, with the residual levels of recombination activity of the mutant protein.[44] However, environmental factors are also important, because patients with similarly severe mutations may present with distinct phenotypes.[45]

Nucleoside Phosphorylase Deficiency

Purine nucleoside phosphorylase (PNP) converts guanosine into guanine and deoxyguanosine to deoxyguanine. Autosomal recessive PNP deficiency causes accumulation of phosphorylated deoxyguanosine metabolites (and of dGTP in particular) that inhibit ribonucleotide reductase, whose activity is essential to DNA synthesis. PNP deficiency is particularly deleterious to developing T lymphocytes and to central nervous system cells, causing severe T cell lymphopenia and neurologic deterioration.[46]

TCRα Constant Chain (TRAC) Gene Defect

A homozygous splice-site mutation of the TCRα constant (*TRAC*) gene, causing loss of the transmembrane and intracytoplasmic domain, has been reported in two patients.[47] All T cells expressing CD3 at normal density coexpressed TCRγδ; an unusual population of CD3^{low} T cells expressed TCRαβ. In vitro lymphocyte proliferation to mitogens and antigens was decreased.

Defects of TCR Signaling

Stimulation of T cells through TCR results in activation of the p56lck kinase, which mediates tyrosine phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) in the CD3-γ, -δ, -ε and -ζ chains. The Zeta-associated protein of 70 kDa (ZAP-70) is then recruited to the CD3/TCR complex,[47] allowing activation of downstream signaling molecules such as linker for activation of T cells (LATs) and SLP-76.[48] Autosomal recessive ZAP-70 deficiency is characterized by lack of CD8$^+$ T cells; CD4$^+$ T lymphocytes are present but nonfunctional.[49–51]

Deficiency of p56lck has been demonstrated in a child with recurrent infections and autoimmunity, associated with CD4$^+$ T cell lymphopenia, oligoclonal T cell repertoire and impaired T cell proliferation.[52]

The Ras homolog family member H (RHOH) is a small GTPase that plays an important role in T cell activation. A homozygous nonsense mutation of the *RHOH* gene in two young adult siblings was associated with marked reduction of naïve CD4$^+$ T cells, restricted T cell repertoire, expansion of memory T cells, including T_{EMRA} (CD8$^+$ CD45RA$^+$ CCR7$^-$ CD244$^+$) cells, and impaired in vitro T cell proliferation.[53] The clinical phenotype was characterized by warts, Burkitt's lymphoma, psoriatic-like skin rash and lung granulomatous disease.

The macrophage stimulating 1 (MST1) molecule is involved in intracellular signaling. Patients with MST1 deficiency show increased susceptibility to recurrent bacterial and viral infections (including warts and molluscum contagiosum), as well as autoimmunity, associated with severe reduction of naïve T cells, increased proportion of CD8$^+$ T_{EMRA} cells, restricted T cell repertoire, impaired proliferation to mitogens, increased apoptosis of T lymphocytes and reduced number of memory B cells.[54–56]

The interleukin-2-inducible T cell kinase (ITK) is activated in response to TCR stimulation and participates in intracellular signaling. ITK deficiency is characterized by increased risk of infections (especially due to herpesviruses) and prominent immune dysregulation, associated with a reduced number of naïve CD4$^+$ cells, defective T cell proliferation and progressive hypogammaglobulinemia. There is an increased risk of Epstein-Barr virus (EBV)-driven lymphoproliferative disease, with frequent pulmonary involvement.[57–60]

DOCK8 Deficiency

The dedicator of cytokinesis 8 (DOCK8) protein plays an important role in intracellular signaling and cytoskeleton reorganization. Mutations of the *DOCK8* gene cause a severe autosomal recessive immunodeficiency, with increased incidence of skin abscesses, mucocutaneous candidiasis and especially cutaneous viral infections, eczema, severe food allergy and markedly elevated IgE levels and eosinophilia.[61,62] There is a high risk of human papillomavirus (HPV)-associated squamous cell carcinoma. Vascular thrombosis in the central nervous system, autoimmune cytopenias and other autoimmune manifestations have been also reported. The immunologic phenotype is characterized by multiple abnormalities,[61–68] with reduced number of naïve T cells, increased proportion of CD8$^+$ T_{EMRA} cells, and defective in vitro T cell proliferation to CD3/CD28 stimulation. Deficiency of T_H17 cells accounts for the increased risk of candidiasis. Migration of T cells and dendritic cells to inflamed/infected tissues is defective. NK and NKT cell function is also compromised. Immunoglobulin levels are variable, although low serum IgM levels are frequently seen. B cell response to TLR9 activation is severely compromised. Antibody responses to T-dependent antigens may be initially normal, but are not sustained over time. The disease has a dismal prognosis, but can be treated by HSCT.[69]

Human 'Nude' Phenotype (FOXN1 Defect)

FOXN1 is a transcription factor that controls development of thymic epithelial cells. Mutations of the *FOXN1* gene cause a severe T cell immunodeficiency with complete lack of CD8$^+$ T cells, associated with alopecia.[70] Treatment is based on thymus transplantation.[71]

Coronin-1A Deficiency

Coronin-1A is an actin regulator that regulates T cell survival and migration. Mutations of the *CORO1A* gene cause immunodeficiency with increased risk of EBV lymphoproliferative disease, associated with profound naïve T cell lymphopenia, oligoclonal T cell repertoire and severe reduction of iNKT cells and mucosa-associated invariant T (MAIT) cells.[72,73]

Major Histocompatibility Complex (MHC) Class II Deficiency

Lack of MHC class II molecules expression on the surface of thymic epithelial cells results in an inability to positively select CD4$^+$ thymocytes and, hence, in the very low number of circulating CD4$^+$ lymphocytes. In addition, the ability to mount antibody responses is also impaired.

MHC class II deficiency has an autosomal recessive pattern of inheritance and may be caused by mutations in

https://CafePezeshki.IR

the *CIITA*, *RFXANK*, *RFX5* and *RFXAP* genes, which encode for transcription factors that govern MHC class II antigen expression.[74–77]

MHC Class I Deficiency

Human leukocyte antigen (HLA) class I molecules play an essential role in presenting antigenic peptides to cytotoxic T lymphocytes and in modulating the activity of natural killer (NK) cells. HLA class I molecules are composed of a polymorphic heavy chain, associated with β2-microglobulin (β2M). The assembly of HLA class I molecules occurs in the lumen of the endoplasmic reticulum (ER), where they are loaded with peptides derived from the degradation of intracellular organisms. These peptides are transported into the ER via transporter associated with antigen presentation (TAP) proteins.[78] TAP consists of two structurally related subunits (TAP1 and TAP2). In addition, the tapasin protein plays an important role in the loading process. Defects in TAP1, TAP2 or tapasin result in impaired peptide-HLA class I/β2M complex formation with reduced surface expression of HLA class I molecules. Patients with MHC class I deficiency have recurrent sinopulmonary infections and deep skin ulcers, associated with a reduced number of circulating $CD8^+$ T cells.[79–81]

Deficiency of Calcium-Release Activated Channels (CRAC) and of Magnesium Flux

Lymphocyte activation depends on calcium mobilization. In particular, TCR-induced activation results in release of Ca^{2+} from the ER stores. Depletion of these Ca^{2+} stores is sensed by the STIM proteins, which oligomerize and bind to the ORAI proteins that form the pore of the Ca^{2+}-release activated channels (CRAC) located in the cell membrane, allowing Ca^{2+} entry. Mutations of the *STIM1* and *ORAI1* genes cause an autosomal recessive immunodeficiency with increased risk of infections, hypogammaglobulinemia, impaired antibody responses and profoundly reduced in vitro T cell proliferation.[82–84] Autoimmune manifestations (especially cytopenias) are common, in particular in patients with STIM1 deficiency. Extra-immune manifestations include nonprogressive myopathy and ectodermal dysplasia.

The magnesium transporter 1 (MAGT1) protein conducts Mg^{2+} across the cell membrane, allowing downstream signaling. Mutations of the X-linked *MAGT1* gene in humans cause immunodeficiency with increased susceptibility to viral and bacterial infections, and to EBV-driven lymphoproliferative disease.[85,86] $CD4^+$ T cell lymphopenia has been frequently observed. NK cytolytic activity in response to NKG2D engagement is reduced.[87]

Immunodeficiency with Immune Dysregulation due to Impaired IL-2 Signaling

IL-2 signaling maintains peripheral immune homeostasis. Deficiency of the α chain of the IL-2 receptor (IL-2Rα, CD25) causes immune dysregulation and lymphoproliferation, often associated with early-onset viral and bacterial infections, oral thrush and chronic diarrhea, associated with lymphadenopathy and hepatosplenomegaly.[88,89]

STAT5b is a transcription factor that is activated in response to growth hormone (GH) and cytokines, including IL-2. STAT5b deficiency is characterized by short stature with GH insensitivity, and a variable degree of immune deficiency and immune dysregulation.[90]

IL-21 Receptor (IL-21R) Deficiency

Loss-of-function mutations of IL-21R have been reported in four patients with sclerosing cholangitis due to *Cryptosporidium*, recurrent pneumonia, chronic diarrhea and failure to thrive.[91] The proportion of switched memory B cells was reduced. T cell proliferation to mitogens was preserved, but proliferation to antigens was impaired.

CD27 Deficiency

CD27 is a costimulatory molecule. *CD27* mutations are responsible for an autosomal recessive combined immunodeficiency with EBV lymphoproliferative disease, reduced T cell proliferation to mitogens and antigens, and progressive hypogammaglobulinemia.[92,93]

T cell Defects with Impaired NF-κB Activation

The MALT1, BCL-10, and CARD11 proteins form a complex that is activated in response to TCR stimulation, allowing nuclear translocation of NF-κB. Autosomal recessive *MALT1* deficiency causes recurrent bacterial, viral and fungal infections.[94] In spite of normal T and B lymphocyte count, proliferative responses to CD3 stimulation and antigens are decreased, and specific antibody responses are also impaired.

CARD11 deficiency causes increased susceptibility to opportunistic infections.[95,96] A reduced number of memory T cells, and hypogammaglobulinemia with increased proportion of transitional B cells are present.

Mutations of the *IKBKB* gene, encoding for the IKKβ component of the IKK complex, have been reported in four unrelated infants with early-onset infections and hypogammaglobulinemia.[97] Immunologic abnormalities included lack of memory T and B cells and of T_{REG} lymphocytes, and defective in vitro T cell proliferation to CD3 stimulation.

Immunodeficiency due to Activating PI3K-δ Mutations

Phosphatidylinositol-3-OH kinases (PI3K) include a series of molecules that participate in cell signaling, enabling generation of PIP_3 from PIP_2, and activation of mTOR and AKT. Heterozygous, gain-of-function mutations of the *PI3KCD* gene, encoding for the p110δ subunit of phosphatidylinositol-3-OH kinase (PI3K), cause increased susceptibility to recurrent respiratory tract infections, EBV lymphoproliferative disease (frequently associated with hepatosplenomegaly and lymphadenopathy) and CMV viremia.[98–100] Reduction of naïve $CD4^+$ cells, expansion of memory and T_{EMRA} $CD8^+$ cells, and decreased number of switched memory B cells have been reported. IgM serum levels are increased. Constitutive activation of AKT is associated with increased activation-induced cell death of patients' lymphocytes. Treatment with rapamycin, an mTOR inhibitor, may reduce lymphoproliferation and organomegaly.

Cytidine 5′ Triphosphate Synthase 1 (CTPS1) Deficiency

Autosomal recessive mutations of the *CTPS1* gene, involved in the synthesis of cytidine 5′ triphosphate (CTP), cause early-onset viral and bacterial infections and an increased risk of EBV-driven non-Hodgkin B cell lymphoma, associated with CD4 lymphopenia, increased proportion of effector memory T cells, absence of iNKT and MAIT lymphocytes, impaired

https://CafePezeshki.IR

BOX 9-1 KEY CONCEPTS

Clinical and Laboratory Elements in the Diagnosis of SCID

CLINICAL FEATURES

- Positive family history (X-linked, other siblings affected, parental consanguinity)
- Presentation early in life (within the first 4 to 6 months of age)
- Severe respiratory infections (interstitial pneumonia)
- Protracted diarrhea
- Failure to thrive
- Persistent candidiasis
- Skin rash, erythroderma may be present

DIAGNOSTIC CRITERIA (ELABORATED BY THE PIDTC)[102]

Typical SCID

- Absence or very low number of T cells ($CD3^+$ cells <300/μL) *and*
- Absent or very low T cell function (PHA response <10% of lower limit of normal)

OR

- T cells of maternal origin present

Omenn Syndrome

- Generalized skin rash
- Absence of maternal engraftment
- Autologous T cells detectable, ≥300/μL
- Absent or low (≤30% of normal) T cell proliferation to recall antigens[a]

Leaky SCID

- Reduced number of autologous T cells (<1,000/μL for up to 2 years; <800/μL for age >2 up to 4 years; <600/μL for age >4 years)
- Absence of maternal engraftment
- Low T cell function (PHA response <30% of lower limit of normal)

Reticular Dysgenesis

- Absence or very low number of T cells ($CD3^+$ cells <300/μL)
- No or very low T cell function (PHA response <10% of lower limit of normal)
- Severe neutropenia (absolute neutrophil count <200 cells/μL)
- Sensorineural deafness and/or absence of granulopoiesis at bone marrow examination and/or a deleterious *AK2* mutation

[a]If proliferation to antigens was not tested, the diagnosis of Omenn syndrome can be supported by the presence of at least four of the following criteria, at least one of which must be among those marked by an asterisk: hepatomegaly; splenomegaly; increased IgE level; increased absolute eosinophil count; *oligoclonal T cells; *>80% of the $CD3^+$ or $CD4^+$ T cells are $CD45R0^+$; *PHA response <30% of lower limit of normal; *proliferative response in mixed leukocyte reaction is <30% of lower limit of normal; *mutation in SCID-causing gene.

proliferation to mitogens and antigens, and reduced number of memory B cells.[101]

DIFFERENTIAL DIAGNOSIS OF SCID AND OTHER COMBINED IMMUNODEFICIENCIES

SCID and other combined immunodeficiencies are characterized by typical clinical signs (Box 9-1), with early-onset severe infections sustained by bacteria, viruses and fungi, including opportunistic pathogens (such as *Pneumocystis jirovecii,* CMV), and growth failure[103] (Figure 9-2). Skin manifestations (rash, generalized erythroderma, alopecia) are also common and may reflect the presence of autoreactive T cell clones (such as in OS) or true graft-versus-host disease (GvHD) caused by transplacental passage of alloreactive maternal T lymphocytes.[104] Other manifestations of maternal T cell engraftment include liver dysfunction, cytopenia (as a result of bone marrow aggression) and eosinophilia.[104]

Figure 9-2 Typical appearance of an infant with severe combined immunodeficiency (SCID). Note severe growth failure and respiratory distress.

Typical clinical and laboratory features are present in some forms of SCID. Cupping and flaring of the ribs and liver dysfunction are often present in ADA deficiency.[105] Autoimmune hemolytic anemia and regression of psychomotor skills are observed in PNP deficiency.[106] Sensorineural deafness is part of reticular dysgenesis,[4] whereas microcephaly and growth abnormalities are seen in patients with defects of DNA repair.[16,18,19] Alopecia is observed in patients with FOXN1 deficiency.[69] Nonprogressive myopathy is a characteristic feature of CRAC channel defects. Severe food allergy is common in DOCK8 deficiency. Autoimmunity is a hallmark of CD25 or STAT5B deficiencies, as well as of defects of Ca^{2+} signaling (especially STIM1), but is frequently seen also in patients with *RAG* mutations.

SCID is a medical emergency. Therefore, all infants with a possible diagnosis of SCID need to be carefully and rapidly evaluated by means of appropriate laboratory assays (see Box 9-1 and below) and careful family history. The differential diagnosis includes other conditions with increased risk of infections (congenital heart disease, pulmonary defects, cystic fibrosis, HIV infection and other secondary immune deficiencies). For patients with generalized erythroderma due to Omenn syndrome or to maternal T cell engraftment, the differential diagnosis includes severe allergy, ichthyosis, IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked)[107] and Netherton's syndrome.

EVALUATION AND MANAGEMENT

A correct diagnosis of SCID should be established as soon as possible in order to offer an optimal perspective on treatment. TRECs are a by-product of V(D)J recombination and are present in newly generated T lymphocytes. No or low levels of TRECs are detected in infants with SCID, and newborn screening for SCID based on enumeration of TRECs in dried blood spots collected at birth is currently widely used in the USA.[108] However, confirmation of SCID requires additional tests. Severe lymphopenia is observed in most SCID infants.[109] However, a

https://CafePezeshki.IR

normal (or nearly normal) number of lymphocytes may be seen in some forms of combined immunodeficiency (OS, MHC class II deficiency, ZAP-70 deficiency) or in infants with maternal T cell engraftment. In most cases, enumeration of total ($CD3^+$) T lymphocytes, $CD4^+$ and $CD8^+$ T cell subsets (including analysis of naïve T cells), B ($CD19^+$) lymphocytes and NK ($CD16^+$) cells will reveal the diagnosis of SCID and also orient toward specific gene defects. Early in life the vast majority of T lymphocytes are naïve T cells ($CD45RA^+$); by contrast, patients with OS or with maternal T cell engraftment show an increased proportion of activated/memory ($CD45R0^+$) T cells. Moreover, in vitro lymphocyte proliferation to mitogens is markedly reduced in patients with SCID, including those with maternal T cells. Selective deficiency of $CD4^+$ lymphocytes may suggest MHC class II deficiency, whereas deficiency of $CD8^+$ T cells is observed in ZAP-70 deficiency and in MHC class I deficiency.

Measurement of enzymatic ADA and PNP activity, and of dATP and dGTP levels in red blood cells, is important to reach a final diagnosis of ADA or PNP deficiency.

Distinguishing typical SCID from leaky forms of the disease has important implications. Patients with persistence of autologous, partially functioning, T cells typically require use of chemotherapy in preparation for HSCT, whereas no conditioning is strictly required in babies with SCID. The Primary Immune Deficiency Treatment Consortium (PIDTC) has identified criteria to distinguish SCID from atypical forms of the disease.[102]

Ultimately, mutation analysis represents an important diagnostic tool to confirm the diagnosis of SCID and related disorders (Table 9-1).

TREATMENT

Optimal treatment of SCID is based on HSCT, as discussed in greater detail in Chapter 16. Prior to HSCT, SCID infants need to be protected from infections (Box 9-2). Prophylactic trimethoprim-sulfamethoxazole is effective in preventing *P. jirovecii* pneumonia (PJP). Regular administration of intravenous immunoglobulins, reinforcement of hygiene measures, and nutritional support may help improve the health status of SCID infants while waiting for HSCT. Blood products need to be irradiated because alloreactive T cells contained in the transfusion would invariably cause rapidly fatal GvHD.

Alternative therapeutic approaches are available in selected cases. Patients affected with ADA deficiency who do not have an HLA-identical donor may be treated with weekly intramuscular injections of polyethylene glycole-conjugated ADA (PEG-ADA).[110]

Successful immune reconstitution has been achieved after gene therapy in 17 of 20 infants with X-linked SCID,[111,112] however, 5 of these 20 patients have developed leukemic proliferation due to insertional mutagenesis.[113,114] New trials with self-inactivating vectors are currently under way. In contrast, no case of leukemia has been observed in approximately 40 patients who have received gene therapy for ADA deficiency at multiple centers.[115–117]

BOX 9-2 THERAPEUTIC PRINCIPLES

Treatment of Infants with SCID

- Always consider an infant with putative SCID as a medical emergency.
- Treat any infections promptly and aggressively.
- Take into account the high frequency of *Pneumocystis jirovecii* pneumonia (PJP). Take appropriate measures to evaluate this possibility (chest X-ray, bronchoalveolar lavage). If PJP is suspected or proven, use trimethoprim-sulfamethoxazole (20 mg/kg/d IV).
- If growth failure is present, start parenteral nutrition.
- Start prophylaxis of PJP with trimethoprim-sulfamethoxazole (5 mg/kg/d).
- Start prophylaxis of fungal infections with fluconazole (5 mg/kg/d).
- Give intravenous immunoglobulins regularly (400 mg/kg/21 days).
- Isolate the infant in a protected environment (laminar flow unit).
- Always irradiate blood products, if transfusions are necessary.
- Avoid administration of live-attenuated vaccines.
- Immediately plan for hematopoietic cell transplantation once the diagnosis of SCID has been established.

DiGeorge Syndrome

DiGeorge syndrome (DGS) is characterized by thymic hypoplasia, hypoparathyroidism with consequent hypocalcemia, congenital heart disease (especially interrupted aortic arch type B or truncus arteriosus) and facial dysmorphisms (micrognathia, hypertelorism, antimongoloid slant of the eyes, and ear malformations) (Figure 9-3).[118] Feeding problems, microcephaly, speech delay and neurobehavioral problems (including bipolar disorders, autistic spectrum disorders and schizophrenia) are frequently observed.[118] The majority of patients have a partial monosomy of the 22q11 region of chromosome 22. Most patients have residual thymus and a milder immunodeficiency (partial DGS),[118] whereas approximately 1% of the patients

Figure 9-3 Facial dysmorphic features in an infant with DiGeorge syndrome. Note hypertelorism, enlarged nasal root, anteroverted nostrils, low-set ears and micrognathia.

https://CafePezeshki.IR

show complete absence of the thymus and extreme T cell lymphopenia (complete DGS).[119] In some cases, patients with complete DGS may develop a variable number of oligoclonal, activated and functionally anergic T lymphocytes. This phenotype is also referred to as 'complete atypical DGS' and may clinically manifest with skin erythroderma and lymphadenopathy, resembling OS.[119] DGS patients with low TRECs at birth may be more prone to viral infections.[120]

Heart defects should be treated aggressively. Hypocalcemia requires supplementation with calcium and vitamin D. If a significant immune defect is present, prophylaxis of *P. jirovecii* pneumonia with trimethoprim-sulfamethoxazole is indicated. Live attenuated vaccines can be safely administered to patients with partial DGS who have good cellular immunity; however, these vaccines are contraindicated in patients with complete DGS. Thymic transplantation is the treatment of choice for patients with complete (typical or atypical) DGS, and results in good (75%) long-term survival and immune reconstitution.[119] Unmanipulated bone marrow transplantation from HLA-identical donors can also lead to immune reconstitution in patients with complete DGS, through a mechanism that involves peripheral expansion of T lymphocytes contained in the graft.[121]

Syndromes with Significant T Cell Deficiency

IMMUNO-OSSEOUS SYNDROMES

Cartilage Hair Hypoplasia

Cartilage hair hypoplasia (CHH) is an autosomal recessive disease characterized by short-limbed dwarfism, light-colored hypoplastic hair and a variable degree of immunodeficiency, associated with an increased occurrence of bone marrow dysplasia, malignancies and Hirschsprung's disease. The disease is caused by mutations of the gene encoding for the untranslated RNA component of the ribonuclease mitochondrial RNA processing (*RMRP*) complex.[122,123]

The majority of CHH patients have a limited susceptibility to bacterial and viral infections; however, some may present with severe infections early in life and show an immunologic phenotype of SCID, OS or selective $CD8^+$ lymphocytopenia,[124,125] which may require HSCT.

Schimke Syndrome

Schimke syndrome is an autosomal recessive disease characterized by dwarfism with progressive renal failure, facial dysmorphisms, lentigines, immunodeficiency and increased occurrence of bone marrow failure and of early-onset atherosclerosis.[126] The syndrome is caused by mutations of the *SMARCAL1* gene that encodes for a chromatin remodeling protein.[126] T cell lymphopenia is common and may occasionally be severe enough to cause SCID. Recurrent bacterial, viral or fungal infections are seen in almost half of the patients.

COMBINED IMMUNODEFICIENCY WITH MULTIPLE INTESTINAL ATRESIAS

This autosomal recessive disease is caused by mutations of the tetratricopeptide repeat domain 7A (*TTC7A*) gene,[127] resulting in increased Ras homolog family member A (RHOA) signaling and disruption of intestinal epithelial apicobasal polarity.[128] Numerical and functional defects of T and B lymphocytes and abnormalities of thymic architecture are present.[129]

IMMUNODEFICIENCY SYNDROMES WITH DEFECTIVE DNA REPAIR

Ataxia-telangiectasia (AT) is an autosomal recessive disorder characterized by telangiectasia, progressive ataxia, recurrent respiratory tract infections and increased susceptibility to tumors.[130] The disease is caused by mutations of the *ATM* gene, which encodes for a large protein that participates in the repair of DNA breakage and controls cell cycle and cellular apoptosis.[131]

Nijmegen breakage syndrome (NBS) is another cellular radiosensitivity syndrome, characterized by microcephaly, growth retardation, bird-like facies and increased susceptibility to infections and tumors. The disease is caused by mutations of the *NBS1* gene, which encodes for nibrin.[132]

A subgroup of patients with an *AT-like disorder* have been identified in whom the defect was in the *hMRE11* gene, which encodes for another component of the DNA repair machinery that associates with nibrin.[133]

DNA ligase IV (LIG4) is an enzyme involved in nonhomologous DNA end-joining and V(D)J recombination. Deficiency of LIG4 is characterized by microcephaly, growth abnormalities, increased susceptibility to malignancies and pancytopenia.[134] Some patients may present with T^- B^- SCID or OS.[19,34]

Patients with AT have increased serum levels of alpha-fetoprotein (AFP), and development of reciprocal chromosomal translocations (mostly involving chromosomes 7 and 14) in a fraction of T lymphocytes is common. Laboratory investigations in patients with AT, AT-like disease or NBS show progressive reduction of the T cell number (particularly the $CD4^+$ subset) with impaired in vitro proliferative response to mitogens. Low TREC levels at birth may be seen in patients with AT,[135] therefore this condition must be included in the differential diagnosis of disorders that may be identified through newborn screening for SCID.

At present, there is no definitive cure for AT and NBS. Use of prophylactic antibiotics, chest physiotherapy and administration of intravenous immunoglobulins may decrease the risk of infections, but the prognosis remains poor, and infections and tumors are the main causes of death.[130] Exposure to ionizing radiation should be avoided, if possible.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked disorder characterized by eczema, congenital thrombocytopenia with small-sized platelets, and immune deficiency. The *WAS* gene is located on the X chromosome and encodes for a protein involved in cytoskeleton reorganization in hematopoietic cells.[136] Most patients with typical WAS have mutations that impair expression and/or function of the WAS protein (WASP). However, some missense mutations are associated with a milder phenotype (isolated X-linked thrombocytopenia, XLT) (Figure 9-4).[137]

The immune deficiency of WAS may manifest as recurrent bacterial and viral infections, autoimmune manifestations and increased occurrence of tumors (leukemia, lymphoma). Immunologic laboratory abnormalities include lymphopenia (particularly among $CD8^+$ lymphocytes), impaired in vitro proliferation to immobilized anti-CD3, reduced serum IgM with

https://CafePezeshki.IR

Figure 9-4 Severe vasculitis and petechiae in a child with Wiskott-Aldrich syndrome.

increased levels of IgA and IgE, and inability to mount effective antibody responses, especially to T-independent antigens.[136] Analysis of intracellular WASP expression by flow cytometry may assist in the diagnosis; absence of the protein is most often associated with a severe clinical phenotype, whereas XLT patients tend to show residual protein expression that is usually associated with missense mutations in exons 1 and 2 of the gene.[137] Somatic reversion, leading to WASP expression in a proportion of cells (mostly in T lymphocytes), has been observed in several patients, but its implications on the evolution of the clinical phenotype are unclear.[138]

The mainstay of treatment of WAS is HSCT, but promising results have been recently reported with gene therapy using a lentiviral vector (see Chapter 16). Administration of intravenous immunoglobulins, regular antibiotic prophylaxis, topical steroids to control eczema, and use of vigorous immune suppression for autoimmunity are the hallmarks of conservative treatment. Splenectomy may be indicated in case of severe and refractory thrombocytopenia; however, it carries the risk of overwhelming sepsis.

Hyper-IgM Syndromes due to CD40 Ligand (CD40L) or to CD40 Deficiency

CD40 ligand (CD40L, CD154) is a cell surface molecule predominantly expressed by activated $CD4^+$ T lymphocytes. Interaction of CD40L with its counter-receptor CD40 (expressed by B and dendritic cells, macrophages, endothelial cells and some epithelial cells) is essential for germinal center formation, terminal differentiation of B lymphocytes and effective defense against intracellular pathogens. Mutations in the *CD40LG (TNFSF5)* gene, mapping at Xq26, result in X-linked hyper-IgM syndrome (HIGM1), characterized by an increased occurrence of bacterial and opportunistic infections, chronic diarrhea (often sustained by *Cryptosporidium*), liver/biliary tract disease and susceptibility to liver and gut tumors.[139,140]

Presentation early in life with opportunistic infections (PJP) requires differential diagnosis with SCID and other forms of severe T cell defects. The typical immunoglobulin profile (undetectable or very low serum IgG and IgA, with normal to increased IgM) may also be observed in common variable immunodeficiency or in autosomal recessive hyper-IgM caused by defects in the *AID, UNG* or *CD40* genes. Neutropenia is a common finding. The diagnosis of HIGM1 is made based on the demonstration of defective expression of CD40L (but not of other activation markers) on the surface of T cells following in vitro activation, and is eventually confirmed by mutation analysis.[139]

Treatment is based on regular use of intravenous immunoglobulins, prophylactic trimethoprim-sulfamethoxazole and use of sterile/filtered water to prevent *Cryptosporidium* infection. Monitoring of liver/biliary tract morphology and function by ultrasound scanning, measurement of appropriate laboratory parameters of liver and biliary tract function, and, when indicated, liver biopsy are also advised. Severe neutropenia may be treated with recombinant granulocyte colony-stimulating factor (G-CSF). In spite of these measures, the long-term prognosis is poor because of severe infections and liver disease. The only curative approach is HSCT, and better results are achieved when transplantation is performed prior to development of lung problems or *Cryptosporidium* infection.[141]

Conclusions

Irrespective of the specific definitive diagnosis, all forms of T cell immunodeficiencies are characterized by significant morbidity and some of them also by high early-onset mortality rates, emphasizing the critical role played by T lymphocytes in ensuring effective immune defense mechanisms and in maintaining homeostasis. Consequently, it is a primary physician's responsibility to perform accurate clinical and laboratory evaluation of patients with a putative T cell immunodeficiency. Whereas clinical history and physical examination may disclose the diagnosis in some forms of T cell immunodeficiency (e.g. WAS, AT and CHH), laboratory evaluation is most often required to provide a definitive diagnosis. In spite of the heterogeneity of this group of disorders, simple laboratory assays (total lymphocyte count and subsets distribution, in vitro proliferative responses) are usually sufficient to confirm the suspicion. It is noteworthy that some forms of T cell immunodeficiencies (SCID in particular) represent true medical emergencies and warrant prompt and accurate evaluation and treatment by HSCT. Based on recent experience, it is likely that gene therapy may be successfully applied in a broader group of disorders in the near future.

10 Complement Deficiencies

KATHLEEN E. SULLIVAN

KEY POINTS

- SLE and neisserial infections are the common complement deficiency phenotypes seen in Allergy Immunology practices.
- CH50 and AH50 assays represent logical initial studies to diagnose many complement deficiencies.
- Management of infection risk and autoimmunity are evolving but are critically important.

The complement system was first identified at the end of the 19th century as a serum activity that 'complemented' the action of antibody in the lysis of Gram-negative bacteria. During the next 100 years there was a growing appreciation that complement not only played an important role in host defense against infection but also was important in the generation of inflammation, the clearance of immune complexes and apoptotic cells, and the production of a normal humoral immune response.

Pathophysiology of Increased Susceptibility to Infection

An increased susceptibility to infection is a prominent clinical expression of most of the complement deficiency diseases. The activation of the complement system by microorganisms results in the generation of cleavage products and macromolecular complexes that possess opsonic activity (C3b), anaphylatoxic activity (C4a, C3a, and C5a), chemotactic activity (C5a) or bactericidal/bacteriolytic activity (C5b, C6, C7, C8 and C9) (Table 10-1). All play a role in the host's defense against infection. Its protective effects are critical in the generation of the initial inflammatory response to infection, prevention of spread of the infection from the initial site of infection to other areas of the body and clearance of the microorganism from the bloodstream. Furthermore, it appears to play its most important role in the early stages of infection, and the generation of opsonic activity is among its most critical functions. The opsonic function of C3b renders the pathogen more easily phagocytosed.

The nature of the infections in complement-deficient individuals generally reflects the specific roles of the deficient component in host defense. For example, C3 is responsible for generating complement-mediated opsonic activity. Thus, patients with C3 deficiency are unduly susceptible to infection from encapsulated bacteria (e.g. *Streptococcus pneumoniae, Haemophilus influenzae* and *Neisseria meningitidis),* organisms for which opsonization is a critical host defense mechanism.[1–3] In contrast, patients with deficiencies of C5, C6, C7, C8 or C9 possess C3 and their susceptibility is limited to *Neisseria*. Bactericidal activity, mediated by C5b through C9, is critical to defense against this genus. Interestingly, although a number of Gram-negative bacteria are susceptible to the bactericidal activity of complement, the susceptibility of patients with deficiencies of C5 through C9 appears to be limited to *Neisseria* spp.[1,2] The infections seen in complement-deficient individuals can be localized (e.g. pneumonia or sinusitis), although systemic infections (e.g. bacteremia/sepsis, meningitis or osteomyelitis) are common and often are recurrent.[4]

A number of studies have examined the prevalence of complement deficiencies among patients with characteristic infections. Although complement-deficient patients do not appear to be sufficiently common among patients with *single* episodes of pneumococcal, streptococcal or *H. influenzae* sepsis and/or meningitis to justify routine screening of patients with these infections, complement deficiencies are sufficiently common among patients with systemic neisserial infections to make routine screening worthwhile.[5–7] For example, estimates of the prevalence of complement deficiencies among patients with a single episode of meningococcal sepsis have varied from 5% to 15%. A study from South Africa demonstrated that 13% of patients with meningococcal disease had either C5 or C6 deficiency.[8] Not unexpectedly, the prevalence is as high as 40% if the patient has had recurrent meningococcal sepsis, has an infection with an uncommon serotype or has a positive family history of meningococcal systemic infections.[9–12]

Pathophysiology of Systemic Autoimmune Disorders

Systemic lupus erythematosus (SLE) is common in patients with deficiencies of C1, C4, C2 and C3. A variety of pathophysiologic mechanisms exist by which complement deficiencies can lead to the development of systemic autoimmune disorders. The two most attractive relate to the role of the complement system in the processing and clearance of immune complexes and apoptotic cells.

The complement system is a major factor in the processing and clearance of immune complexes via a variety of mechanisms. First, immune complexes carrying C3b can be ingested by phagocytic cells.[13,14] Second, the activation of C3 by immune complexes maintains them as soluble complexes.[15] Third, humans possess receptors (CR1) for cleavage products of C3 on their erythrocytes, and circulating immune complexes containing C3b can reversibly bind to those receptors.[16] As erythrocytes

https://CafePezeshki.IR

TABLE 10-1 Functions of Complement Components

Components	Functions
C4a, C2a, C3a	Anaphylatoxins, histamine release
C3b	Opsonin, costimulation of B cells
C5a	Chemotaxis
C5, C6, C7, C8, C9	Membrane attack complex, lysis

carrying immune complexes pass through the liver, the immune complexes are picked off the surface by Kupffer cells, ingested and processed, thus effectively removing them from the circulation and preventing their deposition in other organs such as the kidney.[17]

The most important mechanism driving the susceptibility to systemic autoimmune disorders is the failure to clear apoptotic cells. The early components of the classical pathway, especially C1q, participate in the clearance of apoptotic cells.[18,19] As cells undergo apoptosis, intracellular constituents are reorganized and appear on the surface of the cell in blebs. Autoantigens targeted in patients with SLE are often found on the surface in these blebs, rendering a normally 'invisible' antigen 'visible'.[20] Thus patients deficient in these components may develop SLE because they lack an important mechanism of clearance of apoptotic cells. Also contributing to the development of autoantibodies directed to nuclear antigens is the potential role of complement mediating B cell tolerance in the bone marrow.[21]

There are some clinical and laboratory features that are characteristic of SLE seen in complement-deficient individuals. For example, the SLE seen in C2-deficient patients is frequently associated with photosensitive dermatitis. It is not uncommon for C2-deficient patients to have low (or absent) titers of antinuclear antibody (ANA) or antibodies to double-stranded DNA (dsDNA), whereas the prevalence of anti-Ro antibodies in C2-deficient patients with lupus is greater than in non-C2-deficient patients.[22,23] Patients deficient in C1 or C4 usually have an early onset of clinical symptoms with prominent cutaneous manifestations.[24,25] SLE in C1- or C4-deficient individuals can be severe.

Pathophysiology of Atypical Hemolytic Uremic Syndrome (HUS)

Factor H deficiency has been found to be the underlying basis for 15% to 30% of patients with atypical HUS.[26,27] The term atypical HUS refers to the fact that there is no antecedent diarrheal illness, which is seen in most sporadic forms of HUS.[28] The basis for the HUS in factor H deficiency is thought to be an inability to protect fenestrated endothelium in the glomerulus from complement-mediated damage.[29] Microtrauma arises frequently due to the high oncotic pressure and the damaged basement membrane is able to support complement activation if not protected by factor H. Interestingly, recurrent atypical HUS has been seen in patients with antibodies to factor H. Also supporting a role for factor H in the protection of basement membranes is the finding of a common polymorphism associated with macular degeneration.[30] The central region of the retina is gradually destroyed by a process that leaves a deposit of protein, termed drusen. These deposits contain complement components. It has been hypothesized that the abnormal factor H provides less protection to the choroidal vessels, allowing smoldering complement activation and gradual damage to the endothelium. Additional complement regulatory protein deficiencies associated with atypical HUS alter the deposition of factor H or the function of the assembled complex. This activation of complement on endothelial cells is associated with microthrombi, and polymorphisms and mutations in plasminogen (which degrades thrombi) have also been found in atypical HUS.[31]

TABLE 10-2 Clinical Characteristics of Inherited Complement Deficiency Diseases

Component	Inheritance	Major Clinical Expression
CLASSICAL PATHWAY		
C1q, C1r, C1s, C4, C2	Autosomal recessive	SLE and bacterial infections with encapsulated organisms
C3	Autosomal recessive	Glomerulonephritis, severe bacterial infections HUS can be due to gain-of-function mutations
TERMINAL COMPONENTS		
C5, C6, C7, C8, C9	Autosomal recessive	Neisseria
REGULATORY PROTEINS		
C1 inhibitor	Autosomal dominant	Angioedema
Factor B	Autosomal dominant Gain-of-function	HUS
Factor H	Variable	Infections and HUS
Factor I	Variable	Infections and HUS
MCP	Variable	Atypical HUS
Properdin	X-linked recessive	Neisseria
Factor D	Autosomal recessive	Neisseria

Inherited Complement Deficiencies

Genetically determined deficiencies have been identified for most of the individual components of complement. Most are inherited as autosomal recessive traits, although one is inherited as an X-linked recessive trait (properdin deficiency), one is inherited as an autosomal dominant trait (C1 esterase deficiency), and the defects associated with HUS have variable patterns of inheritance (Table 10-2). Except where noted, the mutations are diverse and can lead to either absence of protein or production of a dysfunctional protein.

C1q DEFICIENCY

C1q is one of the three subcomponents of C1; the other two are C1r and C1s. C1q is composed of six identical subunits, each of which is composed of three different polypeptide chains, C1qA, C1qB and C1qC.[32] IgG or IgM, after engaging antigen and forming an immune complex, binds C1q, which then activates C1r, in turn activating C1s. Activated C1s then cleaves both C4 and C2, creating the bimolecular enzyme C4b2a, which

https://CafePezeshki.IR

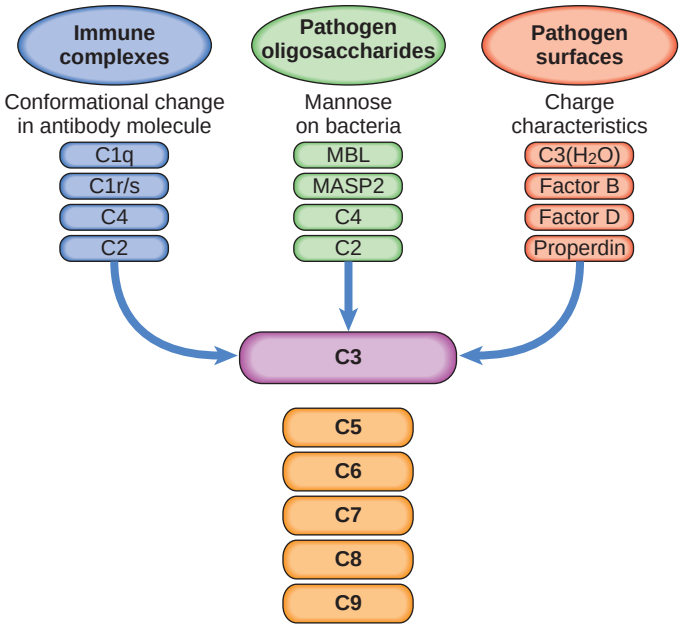

Figure 10-1 The complement cascade. The classical pathway is activated primarily by antibody while the mannan binding lectin (*MBL*) and alternative pathways are activated directly by pathogens. In each case, the activation arm leads to cleavage of C3 and deposition of C3b onto the surface of the pathogen where it can act as an opsonin and costimulate B cells.

activates C3 and ultimately the terminal components (C5 through C9) via the classical pathway (Figure 10-1). Thus, C1q plays a critical role in activation of the classical pathway and the generation of the biologic activities of C3 and C5 through C9. In addition, recent studies have shown that C1q recognizes apoptotic cells and targets them for clearance.[18,33]

C1q-deficient individuals have markedly reduced serum total hemolytic activity and C1 functional activity. In most affected individuals, C1q protein level is also markedly reduced, but in some patients a dysfunctional immunoreactive protein is produced. There is a founder mutation in Turkey.[34–37]

The most prominent clinical manifestation of C1q deficiency is SLE. C1q-deficient patients carry the highest risk (>90% prevalence) of SLE among the complement deficiencies.[1,2,38] C1q-deficient patients have impaired clearance of the immune complexes and apoptotic cells and fail to tolerize B cells properly. The age of onset of SLE tends to be earlier, usually prepubertal, and the disease tends to be more severe.[39] Anti-dsDNA antibodies may be negative.

C1q-deficient individuals also have an increased susceptibility to encapsulated bacteria, reflecting their inability to activate the classical pathway and efficiently generate opsonically active C3b. In fact, nearly one third of C1q-deficient patients have significant bacterial infections and 10% have died of infections.[1,2,38] C1q, almost uniquely among complement components, is produced in substantial amounts by hematopoietic cells and a recent report documented a cure of SLE in a C1q-deficient patient who received a hematopoietic stem cell transplant.[40]

C1r/C1s DEFICIENCY

The C1 complex is composed of six C1q subunits and two subunits each of C1r and C1s. The genes for C1r and C1s are closely linked on chromosome 12 and encode highly homologous serine proteases. C1q, after it binds to an immune complex, activates C1r, which in turn activates C1s. It is C1s that cleaves C4 and C2, resulting in the assembly of the C3 cleaving enzyme C4b2a.

Patients with C1r deficiency have markedly reduced levels of total hemolytic complement activity and C1 functional activity.[38] Deficiency of C1r or C1s leads to reduced levels of the other, suggesting that neither is stable if not in the heterodimer.

The most common clinical expression of C1r/s deficiency has been SLE.[1,2,38] Some patients have also presented with glomerulonephritis or bacterial infections.

C4 DEFICIENCY

The fourth component of complement (C4) is encoded by two closely linked genes *(C4A* and *C4B)* located within the major histocompatibility complex (MHC) on chromosome 6. Although the protein products of the two loci share most of their structure and function, there are four amino acid differences between them. The larger cleavage product of C4 is C4b which forms part of the bimolecular enzyme C4b2a that is responsible for activation of C3 and C5 through C9 via the classical pathway. It therefore plays an important role in the generation of the biologic activities of C3 and C5 through C9.

Because C4 is encoded by two distinct genes, patients with complete C4 deficiency are homozygous deficient at both loci *(C4A*Q0, C4B*Q0/C4A*Q0, C4B*Q0)*.[24,41] In contrast to the rarity of patients with complete C4 deficiency, individuals who are heterozygous for either C4A or C4B deficiency are relatively common. Approximately 13% to 14% of the population is heterozygous for C4A deficiency and 15% to 16% is heterozygous for C4B deficiency, with the corresponding frequencies for homozygous-deficient individuals being 1% and 3%. Individuals who have complete C4 deficiency (i.e. are homozygous deficient for *both* C4A and C4B) have little, if any, total hemolytic activity in their sera and markedly reduced levels of C4 protein and functional activity. As a result of the absence of C4, these individuals have a markedly decreased ability to generate serum opsonic, chemotactic, tolerogenic and bactericidal activities via activation of the classical pathway.[42]

C4A deficiency is often the result of a large gene deletion[43] or a 2-base pair (bp) insertion in exon 29.[44] Some instances of C4B deficiency are the result of gene deletions. Finally, gene conversions can cause either C4A or C4B deficiency.[45]

Patients with complete C4 deficiency may present with SLE and/or an increased susceptibility to infection. The onset of SLE is usually early in life and is characterized by prominent cutaneous features such as photosensitive skin rash, vasculitic skin ulcers and Raynaud's phenomenon. Anti-dsDNA antibody may be absent.[39] Patients with complete C4 deficiency also have an increased susceptibility to bacterial infections and most deaths in C4-deficient patients are the result of infection.

Individuals who are homozygous deficient for C4A lack the isotype that is most efficient in interacting with proteins. The prevalence of homozygous C4A deficiency in patients with SLE is thought to be increased.[46–49] Interestingly, patients with SLE who have C4A deficiency have less neurologic and renal disease but more photosensitivity than other patients with SLE, and they have a lower prevalence of anticardiolipin, anti-Ro, anti-dsDNA and anti-Sm antibodies.[50,51]

https://CafePezeshki.IR

In contrast to individuals with homozygous C4A deficiency, homozygous C4B-deficient individuals lack the C4 isotype that interacts most efficiently with polysaccharides. There is an increased prevalence of homozygous C4B deficiency in children with bacteremia and/or bacterial meningitis.[52,53]

C2 DEFICIENCY

The second component of complement (C2) is encoded by a gene within the MHC on chromosome 6. Like C4, C2 is cleaved by C1s into two fragments, the larger of which (C2a) forms part of the C3-cleaving enzyme of the classical pathway, C4b2a. Thus C2, like C4, plays a critical role in generating the biologic activities of C3 and the terminal components C5 through C9.

C2-deficient patients usually have absent total hemolytic activity and less than 1% of the normal levels of C2 protein and function.[54] Serum opsonic, chemotactic and bactericidal activities are usually present but not generated as quickly or to the same degree as those in individuals who possess C2.

The majority of C2-deficient individuals (>95%) have the same molecular genetic defect, a 28-bp deletion at the 3′ end of exon 6, which causes premature termination of transcription.[55,56] The deletion is associated with a conserved MHC haplotype consisting of *HLA-B18, C2*Q0, Bf*S, C4A*4, C4B*2,* and *DR*2*.[45–47] This haplotype has a strong association with autoimmunity. C2 deficiency is the most common of the genetically determined complete complement deficiencies in Caucasians and the gene frequency of this deletion is between 0.05 and 0.007 in individuals of European descent, which translates into a prevalence of homozygotes of approximately 1 : 10,000.[56,57]

The most common clinical manifestation of C2 deficiency is SLE. Patients with C2 deficiency manifest many of the typical clinical features of SLE, although photosensitive cutaneous lesions are more common.[58,59] They also have a lower prevalence of anti-DNA antibodies than other patients with SLE, but the prevalence of anti-Ro and -La antibodies is higher.[39] Unlike C1 and C4 deficiencies, the SLE is not necessarily more severe than typical SLE.

An increased susceptibility to infection is also a prominent clinical presentation of C2 deficiency. The infections are usually caused by encapsulated pyogenic organisms such as *Pneumococcus, Streptococcus* and *H. influenzae* and are blood-borne, such as sepsis, meningitis, arthritis and/or osteomyelitis. Infection is the leading cause of death.[58,59] A recently described phenomenon in C2 deficiency that is likely common to other early component deficiencies is the accelerated atherosclerosis which significantly contributes to mortality.[59]

C3 DEFICIENCY

The majority of serum C3 is derived from hepatic synthesis, although synthesis by monocytes, fibroblasts, endothelial cells and epithelial cells may contribute to local tissue content of C3. Whether activated by the classical or alternative pathways, C3 is cleaved into two fragments of unequal sizes. The smaller, C3a, is an anaphylatoxin, whereas the larger, C3b, is an opsonin and also forms part of the classical and alternative pathway enzyme (C4b2a3b) that activates C5 and the membrane attack complex. Thus, C3 is not only critical in generating C3-mediated serum opsonizing and anaphylatoxic activities, but also in generating the chemotactic and bactericidal activities of C5 through C9.

Patients with C3 deficiency usually have less than 1% of the normal level of C3 in their sera. Similarly, serum opsonic, chemotactic and bactericidal activities are also markedly reduced. The mutations responsible for C3 deficiency in humans have been diverse. However, there is a relatively common 800-bp deletion found among Afrikaans-speaking South Africans (gene frequency of 0.0057).[60,61]

C3-deficient patients have very severe infections.[62] Patients tend to present in very early childhood. Although the most common infections are blood-borne infections caused by pyogenic bacteria such as *Pneumococcus, H. influenzae* and *Meningococcus,* localized infections such as pneumonia and sinusitis have also been reported.

Autoimmune diseases are also relatively common in patients with C3 deficiency. Some patients have arthralgias and vasculitic skin rashes (similar to serum sickness), associated with active infection. Most patients have membranoproliferative glomerulonephritis. True SLE is less common in C3 deficiency than in the other early component deficiencies.

The membranoproliferative glomerulonephritis in C3 deficiency[62] is characterized by proliferation, an increase in the mesangial matrix, and electrodense deposits in both the mesangium and subendothelium of the capillary loops. Immunofluorescent studies have revealed the presence of immunoglobulins in the kidney, and circulating immune complexes may be present in the serum, suggesting that membranoproliferative glomerulonephritis in these patients is the result of immune complex deposition.

C5 DEFICIENCY

The gene encoding the fifth component of complement (C5) is on the short arm of chromosome 9. When C5 is activated, it is cleaved into two fragments of unequal size. The smaller fragment, C5a, is a potent chemotactic fragment, and the larger, C5b, initiates assembly of the membrane attack complex, C5b through C9, and is critical for bactericidal activity (Figure 10-1).

The most common clinical expression of C5 deficiency is an increased susceptibility to systemic neisserial infections.[1,2]

C6 DEFICIENCY

The genes for C6 and C7 are located near each other on the long arm of chromosome 5. C6 participates in the formation of the membrane attack complex and therefore plays a critical role in the generation of bactericidal activity. The usual form of C6 deficiency is characterized by absent total serum hemolytic activity and very low levels (<1%) of serum C6. Another form of C6 deficiency, subtotal C6 deficiency (C6SD), is characterized by 1% to 2% of the normal levels of C6 and levels of total hemolytic activity that are reduced but present.[63]

The most common mutation causing C6 deficiency is a single base pair deletion at position 879.[64,65] Interestingly, the mutations among African Americans are different from those in the African population.[66,67] C6SD is the result of a loss of the splice donor site of intron 15 and results in a truncated C6 that can support some lytic activity.[63]

C6 deficiency is one of the most common complement deficiencies. Among African Americans in the USA, it is reported to be as common as 1 : 1,600 individuals (0.062%).[67] It is thought to be uncommon among individuals of European

https://CafePezeshki.IR

descent. Like other terminal components, C6 deficiency is associated with systemic neisserial infections.

C7 DEFICIENCY

C7 participates in the formation of the membrane attack complex and therefore is critical to the generation of serum bactericidal activity. Patients who are deficient in C7 have markedly reduced serum total hemolytic activity and C7 levels. As expected, their serum bactericidal activity is similarly reduced.[68]

Like other patients with deficiencies of the terminal components (C5, C6, C7, C8 and C9), the most prominent clinical manifestation of C7 deficiency is an increased susceptibility to systemic neisserial infections. A few patients have presented with SLE, rheumatoid arthritis, pyoderma gangrenosum and scleroderma, but it is unclear whether these are pathophysiologically related to the C7 deficiency.

C8 DEFICIENCY

C8 is comprised of three different polypeptide chains (α, β and γ), which are encoded by separate genes *(C8A, C8B* and *C8G)*. The genes *C8A* and *C8B* map to the short arm of chromosome 1, and the gene *C8G* maps to the long arm of chromosome 9. The alpha and gamma chains are covalently linked to form one chain (C8 α–γ), which is joined to the C8 β chain by noncovalent bonds. C8 is an integral part of the pore-forming membrane attack complex C5b-9 and, as such, plays a critical role in the generation of complement-mediated bactericidal activity.

There are two forms of C8 deficiency and each is inherited as an autosomal recessive trait. In one form, patients lack the C8 β subunit, whereas in the other form the α–γ subunit is deficient.[69,70] In either form, total hemolytic activity is absent from the serum, as is functional C8 activity. However, some C8 antigen can usually be detected in C8 β deficiency because patients possess the C8 α–γ subunit. In contrast, patients with C8 α–γ deficiency usually have undetectable C8 antigen with standard immunochemical techniques. As expected, patients with either form of the deficiency have a marked reduction in serum bactericidal activity.

C8 β deficiency is more common among individuals of European descent and C8 α–γ deficiency is more common among individuals of African descent. Approximately 86% of C8 β-null alleles are the result of C-to-T transition in exon 9, which results in the generation of a premature stop codon.[70,71] Only a limited number of patients with C8 α–γ deficiency have been examined, and in most instances an intronic mutation alters the splicing of exons 6 and 7 of the C8A chain and creates an insertion that generates a premature stop codon.[72]

As in deficiencies of other components of the membrane attack complex, systemic neisserial infections have been the predominant clinical presentation of C8 deficiency.[72]

C9 DEFICIENCY

The gene for C9 is located on the short arm of chromosome 5. The protein product has sequence homology to other members of the membrane attack complex. Affected individuals have markedly reduced levels of both C9 antigen and functional activity. However, the hemolysis of antibody-sensitized erythrocytes can occur with the insertion of a membrane attack complex lacking C9 (i.e. C5b-8) and thus is not strictly dependent on C9. Therefore, patients with C9 deficiency have some total hemolytic activity, although it is reduced to between one third and one half of the lower limit of normal.[73–76] Similarly, their sera possess some bactericidal activity, although the rate of killing is significantly reduced.

Genetically determined C9 deficiency is uncommon in general, but is relatively common among individuals of Japanese and Korean descent.[74,77] A nonsense mutation in exon 4 has a gene frequency of 1 : 1,000 in Japanese populations.[74,78] Individuals with C9 deficiency have an increased susceptibility to systemic neisserial infections, although the susceptibility appears to be mitigated by the residual bactericidal activity in these individuals.[79,80]

MANNAN BINDING LECTIN DEFICIENCY

Mannan binding lectin (MBL) deficiency was initially identified in a cohort of hospitalized patients with infectious diseases. It is now known that it is quite common, with 2% to 7% of people having MBL deficiency.[81] There are structural polymorphisms that destabilize the higher order complexes and several promoter mutations that compromise production. The mutations/polymorphisms exist in haplotypes of varying severity.

MBL deficiency has, at most, a modest effect on infection susceptibility. Similarly, it represents a modest risk factor or disease modifier in autoimmune diseases such as SLE or rheumatoid arthritis.

MANNAN BINDING LECTIN ASSOCIATED SERINE PROTEASE 2 (MASP2) DEFICIENCY

Mutations and polymorphisms in MASP2 are common and have variable effects on function.[82] MASP2 cleaves C4 and C2 to form the same C3 convertase as the classical pathway. The Asp105Gly variant in MASP2 leads to impaired binding to MBL. Although it was originally described in a patient with recurrent pneumonia and ulcerative colitis, subsequent studies have not identified an increased susceptibility to infection.[83–85]

C1 ESTERASE INHIBITOR DEFICIENCY

C1 esterase inhibitor (C1-INH) is encoded by a gene on the long arm of chromosome 11. C1-INH binds covalently to C1r and C1s, leading to dissociation of the C1 macromolecular complex and inhibition of the enzymatic actions of C1r and C1s. Genetically determined C1 esterase inhibitor deficiency is inherited as an autosomal dominant trait. In the most common form (type I), accounting for approximately 85% of the patients, the sera of affected individuals are deficient in both C1-INH protein (5–30% of normal) and C1-INH function.[86,87] In the other less common form (type II), a dysfunctional protein is present in normal or elevated concentrations, but the functional activity of C1-INH is markedly reduced.[88,89] In either case, C4 levels are usually reduced below the lower limit of normal, both during and between attacks, because of the uncontrolled cleavage by C1s.

C1-INH is the major inhibitor of kallikrein and C1, and therefore diminished levels of C1-INH lead to unregulated activation of the classical pathway and kallikrein after exposure to a mild trigger (Figure 10-2).[90–92] Complement anaphylatoxins are thought to play a minor role in the process and bradykinin is the major mediator of the angioedema.[93]

https://CafePezeshki.IR

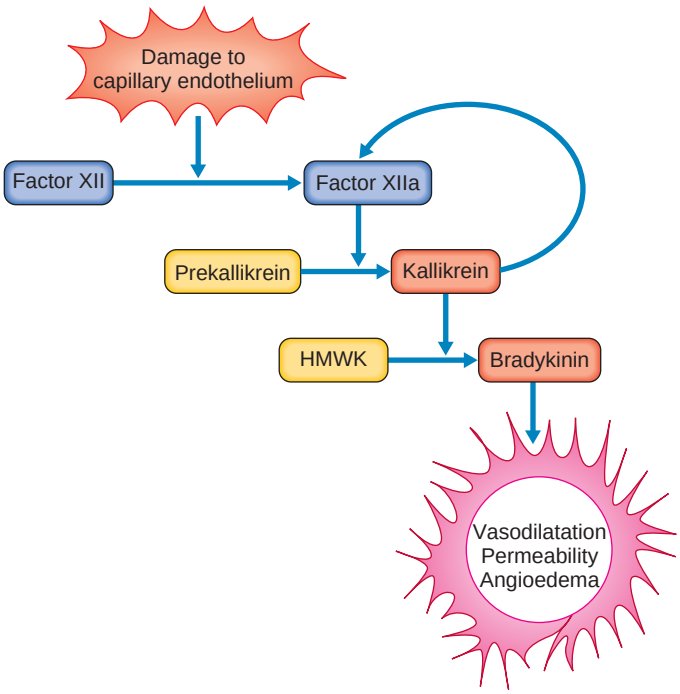

Figure 10-2 The role of C1 inhibitor in angioedema. The edema in C1 inhibitor deficiency is due primarily to activation of bradykinin. Factor XII (Hageman factor) is activated by exposure to damaged capillary vessels. Kallikrein performs two roles: it acts to cleave bradykinin from high molecular weight kininogen *(HMWK)*, and it acts to enhance factor XIIa activation.

C1-INH deficiency is responsible for most cases of the clinical disorder of hereditary angioedema (HAE). The clinical symptoms of HAE are the result of submucosal or subcutaneous noninflammatory edema.[94] The three most prominent areas of involvement are the skin, upper respiratory tract and gastrointestinal tract.[95]

Attacks involving the subcutaneous tissue may involve an extremity, the face, or genitalia. In some instances, there may be changes immediately preceding the edema such as subtle mottling, a transient serpiginous erythema or frank erythema marginatum. The edema usually expands outward from a single site and may vary in size from a few centimeters to the involvement of a whole extremity. The lesions are characteristically nonpruritic. However, early in the development of the lesion, there may be a feeling of tightness in the skin because of the accumulation of subcutaneous fluid. Attacks usually progress for 1 to 2 days and resolve over an additional 2 to 3 days.

Attacks involving the upper respiratory tract represent a significant cause of morbidity and occasionally death. In one series published in 1976, pharyngeal edema had occurred at least once in nearly two thirds of the patients.[87] Laryngeal edema, accompanied by hoarseness and stridor, occurs and progresses to respiratory obstruction. This is a life-threatening emergency. In fact, in that same series, tracheotomies had been performed in 1 of every 6 patients with HAE.[87] Today, with improved treatment, this is becoming less common.

Symptoms in the gastrointestinal tract are related to edema of the bowel wall and may include anorexia, dull aching of the abdomen, vomiting and, in some cases, crampy abdominal pain. Abdominal symptoms are often prominent in childhood and can occur in the absence of concurrent cutaneous or pharyngeal involvement. In some instances, abdominal symptoms may be the only symptoms the patient has ever had, leading to difficulty in diagnosis.[96] The abdominal pain may be so severe that it mimics an acute abdomen and some patients have suffered unnecessary exploratory laparotomies prior to their diagnosis of HAE.

Although the onset of symptoms occurs in more than half of the patients before adolescence, some patients do not experience their first symptoms until they are well into adult life. In just over half of the patients, no specific event can be clearly identified as initiating attacks, although anxiety and stress are frequently cited. Dental extractions and tonsillectomy can initiate edema of the upper airway, and cutaneous edema may follow trauma to an extremity. Some patients report attacks after the use of tight-fitting clothing or shoes, whereas others have related cold exposure to the onset of symptoms.[97]

A potential source of diagnostic confusion is the association of HAE with SLE, presumably because the secondary reduction of C4 predisposes to SLE. These patients can be quite difficult to diagnose and manage.

FACTOR H DEFICIENCY

The basis for the HUS in factor H deficiency is thought to be an inability to protect fenestrated endothelium in the glomerulus from complement-mediated damage (see 'Pathophysiology of atypical hemolytic uremic syndrome').[29]

Neisserial infections are also seen in patients with factor H deficiency, and the mutations in patients with HUS and neisserial infections are distinct. The infections arise due to unregulated consumption of C3.[62,98,99]

HUS is a microangiopathy typically associated with hemolytic anemia, thrombocytopenia and renal failure. Atypical HUS has a mortality rate of 25% and half of the patients develop renal failure.[28,100] Factor H deficiency is responsible for 15% to 30% of patients with atypical HUS.[26] Both autosomal recessive and heterozygous mutations have been seen. The age of onset is quite young in most cases and the disease is often recurrent.[101] Normal complement (C3, AH50 and factor H) levels are sometimes seen and the only way in which this disorder can be confidently identified is with direct mutation analysis. A common tyrosine-to-histidine polymorphism of factor H was identified as a significant risk factor for macular degeneration in a genome-wide linkage study.[102]

FACTOR I DEFICIENCY

The gene for factor I is located on the long arm of chromosome 4. Factor I is a serine protease that cleaves C3b to produce iC3b, an inactive cleavage product that cannot function in the C3-cleaving enzyme of the alternative pathway. Patients with factor I deficiency have uncontrolled activation of C3 via the alternative pathway.[103,104] Patients with factor I deficiency therefore have a secondary consumption of C3 with markedly reduced levels of C3 in their sera and a corresponding decrease in serum opsonic, bactericidal and chemotactic activity.[103,104] In general, the patients with atypical HUS due to factor I deficiency have heterozygous mutations and the mutations do not localize to a specific protein domain.[105] The mutations associated with infection and atypical HUS are distinct.

An increased susceptibility to infection is a common presentation.[103] Like patients with C3 deficiency, factor I deficient patients have infections caused by encapsulated pyogenic bacteria such as *Streptococcus, Pneumococcus, Meningococcus* and *H.*

https://CafePezeshki.IR

influenzae, organisms for which C3 is an important opsonic ligand. Also like patients with C3 deficiency, some patients have had elevated levels of circulating immune complexes. In fact, there has been one report of a transient illness resembling serum sickness characterized by fever, rash, arthralgia, hematuria and proteinuria.

A second presentation is atypical HUS. Factor I deficiency is responsible for 5% to 10% of patients with atypical HUS.[26,106,107] These patients have a phenotype indistinguishable from that of patients with factor H deficiency.

MEMBRANE COFACTOR PROTEIN (CD46) DEFICIENCY

Membrane cofactor protein is a widely expressed glycoprotein that inhibits complement activation on host cells. It is a cofactor for factor I-based cleavage of C3b and C4b. Deficiencies of membrane cofactor protein (MCP) are associated with atypical HUS although the presentation is usually later and milder than in patients with factor H or factor I deficiencies.[101,108–110] MCP mutations account for approximately 10% of all atypical HUS. MCP is expressed on renal tissues and therefore renal transplantation can be successful. Traditional complement analyses are normal although the mechanism of disease is thought to be the same as for factor H and factor I deficiencies.

PROPERDIN DEFICIENCY

Properdin is the only gene of the complement system that is encoded on the X chromosome. Properdin stabilizes the alternative pathway C3 and C5 convertases by extending the half-lives of the C3 and C5 converting enzymes. Properdin deficiency is inherited as an X-linked recessive trait. The protein may be absent or reduced in the serum, depending on the specific mutation. Patients with properdin deficiency have absent function of the alternative pathway. Similarly, serum bactericidal activity for some strains of meningococci is reduced in properdin-deficient serum.[111]

Approximately 50% of the patients described with properdin deficiency have had systemic meningococcal disease.[1,2,111] Isolated cases of SLE and discoid lupus have also been seen in properdin-deficient patients, but these may represent ascertainment bias.

FACTOR D DEFICIENCY

Neisserial infections are seen in factor D deficiency.[1,2,112] Systemic streptococcal infections have also been seen. Other complement levels are typically normal in factor D deficiency, however there is almost no ability to activate the alternative pathway.

Management of Genetically Determined Complement Deficiencies

Prevention of Infectious Diseases

Two strategies have been attempted to reduce susceptibility to infections and/or modify the clinical course of infections in patients with genetically determined deficiencies of complement. One strategy is to immunize these patients against common bacterial pathogens such as *Pneumococcus, H. influenzae* and *Meningococcus.* Unfortunately, because the complement system participates in the generation of a normal immune response,[113] complement-deficient patients may not respond as well as complement-sufficient hosts.[114] Another limitation to the use of immunization in complement-deficient patients is that the vaccines may not include all of the serotypes to which complement-deficient patients are susceptible. Although there are limitations, data support the use of repeated meningococcal vaccination to mitigate the risk of infection for patients with terminal complement component deficiencies.[115] The Centers for Disease Control recommend a two dose series of the quadrivalent conjugated meningococcal vaccine before 2 years of age for high-risk patients. A subsequent dose after 3 years and then every 5 years is the current recommendation. It seems reasonable to consider repeated vaccination for *Pneumococcus* and *H. influenzae* for patients with defects in early complement components. Guidelines should be monitored and protocols amended as necessary because nonconjugated vaccine administration can interfere with subsequent conjugated vaccine responses.[115–117]

A second strategy in the prevention of infection is the use of prophylactic antibiotics. Because patients with complement deficiencies have a high risk of recurrent episodes of bloodborne infections and because immunizations may not afford them complete protection, some patients have been placed on antibiotic prophylaxis. Any recommendation for antibiotic prophylaxis must be viewed in the context of the emergence of antibiotic resistance among bacteria.

Management of Autoimmune Disorders

Regardless of the disorder, autoimmune conditions are most often treated with the same immunosuppressive agents and antiinflammatory medications as one would use in a complement-sufficient patient. Most autoimmune disorders are associated with an increased risk of atherosclerosis in their own right and the early complement component deficiencies appear to add to that risk. Therefore, aggressive management of cardiac risk factors is advisable.

Management of Angioedema

The treatment of C1-INH deficiency is different from that of other complement deficiencies in that there are specific measures available to ameliorate symptoms and to prevent recurrence.[118] In some patients, episodes of angioedema may be sufficiently frequent or difficult to manage to justify long-term prophylaxis. Attenuated androgens such as oxandrolone and danazol are highly effective[119,120] and act by increasing transcription of the normal allele of *C1INH*.[121] However, because of their androgenic effects, their use has declined significantly, especially in females.

Another class of agents historically used for long-term prophylaxis is the antifibrinolytic agents.[122,123] Tranexamic acid and aminocaproic acid act by blocking plasmin generation. Although their efficacy is less than that of attenuated androgens, the incidence of side-effects is also less than that of attenuated androgens. For this reason, these agents may be used in childhood, although they are quite difficult to obtain in the USA. C1 inhibitor concentrate is approved both for use as prophylaxis and treatment of acute attacks.[124,125] Twice-weekly intravenous administration and cost for prophylaxis will be barriers for some patients.

Management of angioedema also requires education of the family and cautions against estrogen-containing birth control pills, undue exposure to trauma and use of angiotensin

https://CafePezeshki.IR

converting enzyme inhibitors.[118] All of these are known to precipitate episodes.

In some instances, patients may require short-term prophylaxis for surgery or oral procedures. Attenuated androgens, fibrinolytic agents, fresh frozen plasma (FFP) and C1 esterase concentrate have all been used successfully for short-term prophylaxis, but most major medical centers now use C1 inhibitor concentrate. Recent guidelines can be helpful.[118]

Acute attacks can be emergencies and patients should have an action plan that includes contingencies for airway involvement. C1 esterase inhibitor concentrate is an effective acute treatment.[96,126] Ecallantide and icatibant are also approved for treatment. Ecallantide is a kallikrein inhibitor and icatibant is a bradykinin receptor antagonist. The former requires a healthcare worker to administer and monitor for anaphylaxis, an uncommon adverse event. Icatibant has a slower onset of action but has the advantage of self administration. Epinephrine, antihistamines and corticosteroids are of no proven benefit in C1-INH deficient patients. FFP has some advocates, however there are limited clinical data on its use.[127]

Management of HUS

As is done for thrombotic thrombocytopenic purpura (TTP), most patients with atypical HUS receive apheresis and FFP replacement for acute episodes.[101,108] Factor H replacement may be of benefit, and FFP may be used to replace factor H. In the case of MCP deficiency, where the affected protein is membrane bound, it is less clear that pheresis and FFP would provide benefit, but it could potentially act to clear inciting agents or complement activation products. Eculizumab, a C5 inhibitor, has been approved as treatment for atypical HUS due to complement deficiencies.[128] The appropriate use of eculizumab in this setting is still being defined. For patients with factor H or factor I deficiency and end-stage renal disease, renal transplantation is not recommended. In contrast, renal disease in MCP typically does not recur in the transplanted kidney.

Secondary Complement Deficiencies

Secondary complement deficiencies are relatively common. Any pathologic process that results in activation of the complement cascade or interferes with the synthesis of complement components, such as liver disease, can result in a secondary complement deficiency.

THE NEWBORN

In full-term infants, the levels of most components of either the classical or alternative pathways are 50% to 80% of adult levels.[129] However, both C8 and C9 seem to be more severely depressed, with levels in full-term newborn infants as low as 28% and 10%, respectively, of maternal levels.[130,131] The serum levels of individual components of complement in premature infants have also been studied. C4, C3, C7, C9, factor B, properdin and C1 esterase inhibitor have been detected in fetal serum as early as the end of the first trimester or the beginning of the second trimester.[132,133]

NEPHROTIC SYNDROME

Loss of complement proteins in the urine, particularly factor B,[134] contributes to the increased susceptibility to infection.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a systemic disorder in which immune complexes are generated and deposited in end organs, leading to the classical inflammatory pathologic changes. The immune complexes may activate the complement cascade, leading to consumption of individual components such as C3 and C4. The activation and consumption of the complement system typically precedes clinical flare, and the degree of hypocomplementemia, specifically levels of C3 and C4, generally reflects the degree of clinical activity.[135–138] Although complement activation as a result of the circulating immune complexes is particularly characteristic of SLE, it has also been described in juvenile rheumatoid arthritis, Sjögren's syndrome, a variety of vasculitides, and mixed connective tissue disease. Hypocomplementemia as a result of immune complex formation is seen less frequently in other autoimmune diseases.

SERUM SICKNESS

Serum sickness is the consequence of immune complex formation in response to the administration of drugs (e.g. penicillin, cefaclor and minocycline), foreign proteins (e.g. antithymocyte globulin, therapeutic monoclonal antibodies or antivenoms) or, in some instances, infections.[139,140] Although rash, fever and arthralgia/arthritis are the most common clinical findings, severe cases may progress to renal involvement.[141] Immune complexes are present in the circulation early in the process. Most cases have significant hypocomplementemia which, when it occurs, is characterized by low CH50, C3 and C4 levels.[142,143]

SEPSIS

Acute bacterial sepsis, specifically Gram-negative sepsis, may be associated with transient hypocomplementemia characterized by low levels of C3 and C4, as well as low total hemolytic activity (CH50).[144] The hypocomplementemia is most commonly found in patients who have some degree of cardiovascular compromise and is strongly correlated with the severity of the shock and morbidity.

CIRRHOSIS

Patients with cirrhosis have decreased serum concentrations of C3, C4 and total hemolytic activity due to diminished synthesis.[145] There is a correlation between the low levels of C3 and a predisposition to spontaneous bacterial peritonitis and mortality in cirrhosis.[146]

CARDIOPULMONARY BYPASS, EXTRACORPOREAL MEMBRANE OXYGENATION AND HEMODIALYSIS

These interventions bring the patient's blood in contact with artificial surfaces or membranes. As a result, there may be activation of the complement system. As a consequence of the activation of the complement system, there also is generation of biologically active cleavage products such as C3a and C5a. A number of studies have suggested that the generation of these anaphylatoxins is responsible for the generalized inflammatory response that follows cardiopulmonary bypass (postperfusion syndrome) and hemodialysis (pulmonary neutrophil sequestration).[147]

https://CafePezeshki.IR

MALNUTRITION

Malnutrition (both kwashiorkor and marasmus) is associated with decreased levels of serum total hemolytic complement activity as well as most of the individual components of complement, such as C3 and C5.[148,149] The degree of the decrease in complement components, such as C3, correlates strongly with serum albumin, suggesting that the decrease is the result of poor synthetic function in the liver.

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Paroxysmal nocturnal hemoglobinuria (PNH) is characterized by recurrent episodes of hemoglobinuria due to intravascular hemolysis and is associated with acquired somatic mutations of *PIG-A* or *PIG-T* in a clone of bone marrow progenitor cells.[150,151] The protein product of *PIG-A* is required for GPI anchored proteins. C8 binding protein, DAF and CD59 are GPI anchored proteins that protect hematopoietic cells from complement-mediated lysis. The red cells are the most vulnerable because they have no ability to repair membrane damage. PNH can be associated with complement dysfunction. Inherited CD59 deficiency has been associated with a PNH-like syndrome.[152]

Laboratory Assessment of Complement

A CH50 assay consists of adding patient serum to antibody-coated sheep red cells. Complement activation of C1 to C9 leads to lysis. A CH50 result reports the dilution of serum capable of lysing 50% of the sheep cells coated with immunoglobulin (e.g. rabbit IgM anti-sheep red blood cell [RBC] antibodies). The function of the alternative pathway is measured by RBC lysis in the absence of immunoglobulin. With the exception of C9 deficiency, genetic deficiencies of any of the classical initial pathway or terminal (C5–C8) cascade components lead to a CH50 of zero or near zero. A finding of low levels of CH50 or AH50 should be repeated and appropriate handling of the serum should be ensured. Complement components are consumed quickly once blood has been drawn. Other causes of low, but not absent, CH50 results are complement consumption due to infection or autoimmune disease. Less common, but medically more important, are the regulatory protein defects leading to consumption of C3 such as factor D, factor H and factor I deficiency. C9 deficiency also leads to a reduction in both the CH50 and AH50 (Figure 10-3). Nephritic factors (antibodies to complement components) can lead to a chronically low CH50, AH50 or both.

Once an abnormal CH50 or AH50 has been confirmed, nephelometry is used to define the serum levels of certain components (C3 and C4 primarily) and enzyme-linked immunosorbent assays (ELISAs) are available for certain other components. Individual component functional assays are not widely available but are available through reference laboratories. Once the specific diagnosis is established, the management path becomes clearer.

Patients with recurrent sinopulmonary infections are infrequently found to have complement deficiencies. For patients with recurrent sepsis/systemic infection or sepsis on the background of autoimmune disease (or a family history of autoimmune disease), the frequency of identifying a complement

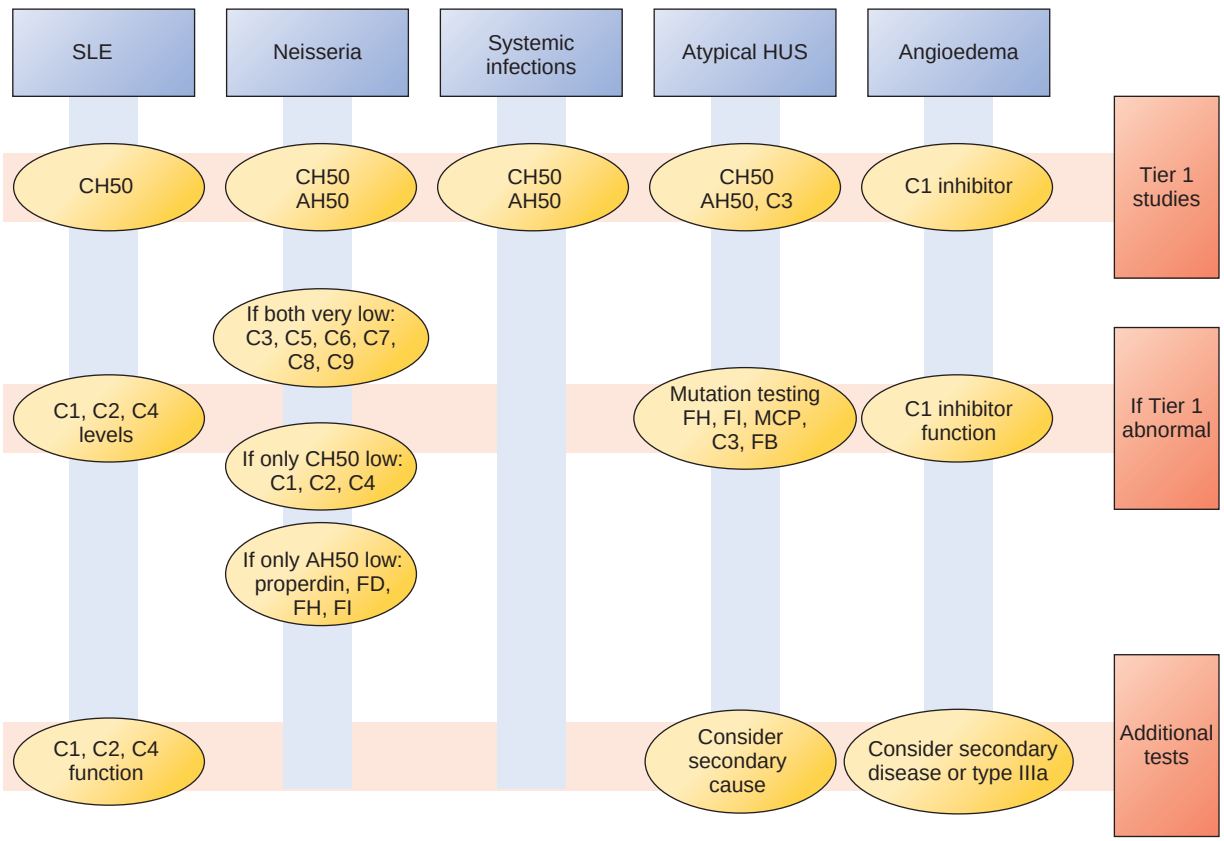

Figure 10-3 A potential algorithm for the evaluation of patients with suspected complement deficiency.

https://CafePezeshki.IR

defect is probably higher although there are no data to support this approach.[153] Patients with a single meningococcal infection, either meningitis or meningococcemia, probably deserve an evaluation in nonendemic areas.[154,155] The evaluation would include a CH50 and AH50. There is general consensus that patients with meningococcal disease with an unusual serotype, with meningococcal disease on the background of a positive family history or recurrent meningococcal disease, should have an evaluation with a CH50 and AH50. In these patient groups, the frequency of complement deficiency approaches 50%.[155,156] Chronic meningococcemia appears to be another condition with a high frequency of complement deficiency.[10]

Most Caucasian SLE cohorts have approximately 1% to 2% of patients with complement deficiency (generally C2 deficiency).[56,138] Given the high rate of infection, it is important to identify these patients. Patients with C1 and C4 deficiencies tend to have severe disease with early presentations and therefore testing pediatric-onset severe SLE might be more revealing of complement deficiencies. An additional category where a CH50 assay might be considered is in the evaluation of patients with clinical symptoms suggestive of SLE but with negative ANA and anti-dsDNA. While these autoantibodies are often thought of as important indicators of SLE, complement-deficient patients have them less frequently and it might support the diagnosis of SLE to know that the patient had a complement deficiency.

All patients with atypical HUS should have a complement evaluation. A CH50, an AH50 and a C3 level should be obtained. In many cases, these will be normal and measurement in serum and/or mutation analysis of factor H, factor I, MCP, C3 and factor B will most often be required. Patients with membranoproliferative glomerulonephritis type II should also be evaluated when the clinical suspicion of a complement deficiency or nephritic factor exists.

When angioedema occurs in the setting of a known allergic response, it is much less likely to be due to C1 inhibitor deficiency. Patients with recurrent angioedema in the absence of allergic reactions, patients with a family history of angioedema, patients with angioedema preceded by a reticular rash and patients with angioedema after trauma should all have an evaluation. Note that HAE is not associated with urticaria. Angioedema associated with urticaria is extremely unlikely to represent HAE. A simple but rather insensitive screen is to measure C4 levels. C4 is typically decreased at baseline but is diminished even more during an acute attack owing to consumption. A more specific strategy is to measure C1 inhibitor antigen and functional levels.

Conclusions

Complement represents a bridge between innate and adaptive immunity. It is important for the phagocytosis of immune complexes, opsonization of bacteria, lysis of bacteria, solubilizing of immune complexes and elimination of apoptotic cells. Complement deficiencies manifest themselves either as susceptibility to recurrent infections or as susceptibility to autoimmune/immune complex-mediated diseases (Box 10-1). Deficiencies of early components of the classical complement cascade (C1, C2, C4 and C3) are associated with both autoimmune/immune complex diseases and susceptibility to infections. Deficiencies of components of the alternate pathway (factor H, factor I, factor D and properdin) and of late components of the complement system C5 to C9 are associated with susceptibility to infections, primarily to neisserial infections in the case of deficiency of C5 through C9. The diagnosis of a complement component deficiency must be entertained in all patients with recurrent severe bacterial infections, particularly in the face of elevated or upper-range levels of serum immunoglobulins and adequate antibody titers. The diagnosis of a deficiency in the early components of the classical complement cascade must be entertained in cases of SLE with a history of significant infection, and defects in regulatory proteins should be sought in cases of atypical HUS. A diagnosis of C1 esterase inhibitor deficiency must be considered in cases of nonpruritic angioedema in the absence of urticaria, particularly in the presence of a similar family history and in cases precipitated by trauma. Fortunately, treatment and education regarding risk can be life saving.

BOX 10-1 KEY CONCEPTS

Clinical Presentations of Complement Deficiencies

- Increased susceptibility to systemic or deep bacterial infection
  - Classical complement component deficiencies are associated with systemic infections with encapsulated organisms
  - Terminal component deficiencies are associated with susceptibility to infection with *Neisseria*
- Systemic lupus erythematosus, especially with early components of the classical pathway
- Hereditary angioedema is due to haploinsufficiency of C1 esterase inhibitor, a regulatory protein
- Atypical hemolytic uremic syndrome, predominantly with defects of factors H and I and membrane cofactor protein

ACKNOWLEDGMENTS

Jerry Winkelstein's wisdom and passion for complement are gratefully acknowledged. He co-authored the original version of this chapter.

11 Defects of Innate Immunity

SERGIO D. ROSENZWEIG | STEVEN M. HOLLAND

KEY POINTS

- White blood cells (lymphoid or myeloid) can suffer from quantitative or functional congenital disorders.
- The type of cells or mechanisms that are mainly affected will define the spectrum of infectious diseases a particular patient will suffer.
- The pathophysiology, clinical manifestations and approaches to diagnosis of classic innate immunity defects (e.g. neutropenias, CGD, LAD and mucocutaneous candidiasis among other syndromes) are discussed.
- Recently recognized genetic diseases (e.g. IRF8, ISG15 and some forms of mucocutaneous candidiasis are presented.

This chapter focuses on neutrophils and monocytes, and disorders that arise from their quantitative or functional defects. Mature neutrophils develop in the bone marrow from a myeloid stem cell over 14 days, during which time proliferation, differentiation and maturation occur. Mature neutrophils, with their load of primary, secondary and tertiary granules, are released into the bloodstream where they stay 6 to 10 hours before exiting by diapedesis. In tissues, these cells work in ways that are primarily phagocytic, bactericidal, fungicidal or in the removal of damaged tissue. Neutrophil disorders can be divided into quantitative (increase or decrease) and functional (failures in specific metabolic or interactive pathways). Quantitative disorders include neutrophilia (>7,000 neutrophils per microliter in adult patients) and neutropenia (mild: <1,500 neutrophils per microliter, moderate: 500–1,000 neutrophils per microliter, severe: <500 neutrophils per microliter). With very few exceptions (e.g. chronic idiopathic neutrophilia, leukocyte adhesion deficiencies, myeloproliferative diseases) neutrophilia is dependent on causes extrinsic to the neutrophils (e.g. acute or chronic infection, steroids, epinephrine). On the other hand, the causes of neutropenia are multiple and can be intrinsic or extrinsic to neutrophils or their progenitors (Box 11-1). Neutropenia usually falls into categories of decreased production or increased destruction, or a combination of the two.

Qualitative myeloid disorders include defects in motility (adhesion, chemotaxis), defects in phagocytosis, defects of granule synthesis and release, and defects in killing (see Box 11-1).

A neutrophil disorder should be suspected in patients with recurrent, severe, bacterial or fungal infections, especially those caused by unusual organisms (e.g. *Chromobacterium violaceum*) or in uncommon locations (e.g. liver abscess; Table 11-1). Viral and parasitic infections are not increased in these patients.

Initial laboratory evaluation should take into account the clinical presentation to direct where the defect is likely to be. Some assays, such as repeated white blood cell (WBC) counts with differentials or microscopic evaluation of neutrophils, are relatively simple and can readily exclude neutropenia or some granule defects. Flow cytometry requires a careful consideration of which markers to examine. Functional assays, such as oxidative burst testing, phagocytosis or chemotaxis, are the most challenging because few laboratories perform them routinely (Table 11-2). We will consider some of the clinical, diagnostic and management aspects of a few of the best characterized myeloid disorders.

Severe Congenital Neutropenia

Severe congenital neutropenia (SCN) comprises a heterogeneous group of disorders that share the common characteristics of bone marrow granulocytic maturation arrest at the promyelocyte or myelocyte stage, severe chronic neutropenia (fewer than 200 neutrophils per microliter) and increased susceptibility to acute myeloid leukemia.[1,2]

In 1956 Kostmann described a Swedish kindred with severe congenital neutropenia inherited in an autosomal recessive pattern.[3] Klein and colleagues identified homozygous mutations in the antiapoptotic molecule HAX1 in patients with autosomal recessive SCN, which was confirmed to be the cause in the original Kostmann pedigree as well.[4] Some patients with HAX1 deficiency also suffer from cognitive problems and/or epilepsy.[5]

Among patients with SCN, single allele mutations in the G-CSF receptor (GCSFR, 1p35-p34.3) have been associated with the development of acute myeloid leukemia.[6] However, not all patients with SCN develop mutations in the G-CSF receptor, indicating that these mutations are somatic mutation epiphenomena that occur in the setting of SCN but do not cause it.[7] Autosomal recessive mutations in the glucose-6-phosphatase catalytic subunit 3 (G6PC3) also cause congenital neutropenia along with cardiac and urogenital malformations.[8]

Horwitz and colleagues[9] and Dale and colleagues[10] found that 22 of 25 patients with dominant or spontaneous SCN had heterozygous mutations in the gene encoding neutrophil elastase (*ELA2*). Interestingly, mutations in this gene are also responsible for cyclic neutropenia. *ELA2* mutations are responsible for more than 50% of SCN cases in Caucasian patients.[11]

The clinical manifestations of SCN appear promptly after birth: 50% of affected infants are symptomatic within the first month of life, and 90% within the first 6 months; omphalitis, upper and lower respiratory tract infections, and skin and liver

https://CafePezeshki.IR

BOX 11-1 NEUTROPHIL DISORDERS: CAUSES

NEUTROPHILIA

Usually dependent on causes *extrinsic* to the neutrophils (e.g. acute or chronic infection)

NEUTROPENIA

Caused by defects *intrinsic* to the neutrophils or their progenitors (severe congenital neutropenia, cyclic neutropenia, neutropenia associated with other well-defined syndromes [e.g. Schwachman syndrome, Fanconi's syndrome, dyskeratosis congenita, Chédiak-Higashi syndrome, reticular dysgenesis, WHIM syndrome])

Caused by defects *extrinsic* to the neutrophils or their progenitors (infections, drugs, immune mediated, metabolic diseases, nutritional deficiencies, bone marrow infiltration)

MOTILITY DISORDERS

Adhesion: Leukocyte adhesion deficiency 1, 2 or 3

Chemotaxis: Leukocyte adhesion deficiency 1, 2 or rac2; localized juvenile periodontitis, neutrophil β-actin deficiency, secondary to extensive burns, secondary to alcohol consumption

PHAGOCYTOSIS DISORDERS

Leukocyte adhesion deficiency 1 (complement-mediated only); secondary to antibody deficiencies; complement deficiencies; mannose binding protein deficiency

DISORDERS OF GRANULE FORMATION AND CONTENT

Chédiak-Higashi syndrome; specific granule deficiency

MICROBICIDAL DISORDERS

Chronic granulomatous disease; myeloperoxidase deficiency; glucose-6-phosphate dehydrogenase deficiency, glutathione pathway deficiencies

abscesses are common. Subcutaneous recombinant granulocyte-colony stimulating factor (G-CSF; 5 μg/kg/day) has dramatically changed the prognosis of these patients.[1,2] Since the advent of recombinant G-CSF, reductions in the number of infections and hospitalization days and an increase in life expectancy have been described.[1,2]

Devriendt and colleagues[12] described a family with an X-linked form of severe congenital neutropenia (XLN) caused by mutations in the Wiskott-Aldrich syndrome protein (WASP). In contrast to the WASP mutations that produce classical Wiskott-Aldrich syndrome or X-linked thrombocytopenia, most of which are caused by mutations resulting in reduced WASP transcription or translation, the mutation causing XLN (Leu270Pro) creates a constitutively active mutant protein.

Two families with heterozygous mutations in *GFI1* and congenital neutropenia and monocytosis have been described.[13] *GFI1* mutations act in a dominant-negative way, i.e. inheritance is autosomal dominant. Reticular dysgenesis is an autosomal recessive severe combined immunodeficiency characterized by early myeloid arrest, neutropenia, lymphopenia and sensorineural loss (see Chapter 9).

Cyclic Neutropenia/ Cyclic Hematopoiesis

Cyclic neutropenia/cyclic hematopoiesis is inherited as an autosomal dominant trait and characterized by regular cyclic fluctuations in all hematopoietic lineages. However, clinical manifestations are almost exclusively associated with variations in neutrophils. Neutrophil counts cycle on average every 21 days (range 14 to 36 days), including periods of severe neutropenia (<200/μL) that last from 3 to 10 days.[14,15] Mutations in *ELA2* (neutrophil elastase 2, 19p13.3) have been identified in all pedigrees analyzed.[10,11] Most patients have manifestations of neutropenia in early childhood. Oral ulcerations, gingivitis, lymphadenopathy, pharyngitis/tonsillitis and skin lesions are the most frequent findings. Early loss of permanent teeth as a consequence of chronic gingivitis and periapical abscesses is common.[16] Bone marrow aspirates obtained during periods of neutropenia show maturation arrest at the myelocyte stage or bone marrow hypoplasia.[17]

Granulocyte-colony stimulating factor (G-CSF) improves peripheral neutrophil counts and decreases morbidity in cyclic neutropenia patients. Infections and hospitalizations appear to lessen naturally with age.[16]

Large granular lymphocytosis is a cause of adult onset cyclic or sustained neutropenia. This disease is caused by clonal expansion of CD8 T cells or NK cells with a tropism for neutrophils and sometimes other marrow elements. This diagnosis is suspected in an adult with new onset neutropenia and is confirmed by identification of clonal CD8 T cells infiltrating bone marrow, often in lymphoid aggregates.[18]

Warts, Hypogammaglobulinemia, Infections and Myelokathexis (WHIM) Syndrome

Myelokathexis (from the Greek, meaning 'retained in the bone marrow') is a congenital disorder with severe chronic neutropenia. Unlike other forms of congenital neutropenia, bone marrow aspirates from myelokathexis patients show myeloid hypercellularity with increased numbers of granulocytes at all stages of differentiation. A significant number of patients with myelokathexis also have warts, hypogammaglobulinemia and infections of varying severity. Most WHIM patients have heterozygous deletions affecting the chemokine receptor CXCR4.[19] Enhanced CXCR4 activity delays release of mature neutrophils from the bone marrow, resulting in peripheral neutropenia.[20,21] Recurrent sinopulmonary infections are frequent. Memory B cells are also depressed in this disease, in part accounting for the humoral defects.[22] During episodes of infection, neutrophil counts typically increase compared to baseline levels. Steroids, subcutaneous epinephrine, intravenous endotoxin, as well as G-CSF and GM-CSF, can mobilize mature neutrophils from WHIM bone marrow. Sustained therapy with G-CSF or GM-CSF increases the number of neutrophils in the peripheral blood and decreases the number of infections. Plerixafor (Mozobil®), a small molecule that binds and blocks CXCR4 and is used for hematopoietic stem cell mobilization for transplantation, has also been shown to have a beneficial effect in WHIM patients.[23,24]

Immune-Mediated Neutropenias

ALLOIMMUNE NEONATAL NEUTROPENIA

Alloimmune neonatal neutropenia (ANN) is produced by the transplacental transfer of maternal antibodies against NA1 and NA2, two isotypes of the immunoglobulin receptor FcγRIIIb, causing destruction of neonatal neutrophils.[25–29] If the mother does not express FcγRIIIb on her own neutrophils, she may

https://CafePezeshki.IR

TABLE 11-1 Infections and WBC Defects: Features Highly Suspicious of Phagocyte Disorders. (A) Severe Infections, (B) Recurrent Infections, (C) Infections Due to Specific Microorganisms, (D) Unusually Located Infections

(A) SEVERE INFECTIONS		(B) RECURRENT INFECTIONS		(C) SPECIFIC INFECTIONS		(D) UNUSUALLY LOCATED INFECTIONS	
Type of Infection	**Diagnosis to Consider**	**Site of Infection**	**Diagnosis to Consider**	**Microorganism**	**Diagnosis to Consider**	**Site of Infection**	**Diagnosis to Consider**
Cellulitis	Neutropenia, LAD, CGD, HIES	Cutaneous	Neutropenia, CGD, LAD, HIES	*Staphylococcus epidermidis*	Neutropenia, LAD	Umbilical cord stump	LAD
Colitis	Neutropenia, CGD	Gums	LAD, neutropenia, neutrophil motility disorders	*Serratia marcescens, C. violaceum, Nocardia, Burkholderia cepacia, Granulibacter bethesdensis*	CGD	Liver abscess	CGD
Osteomyelitis	CGD, MSMD pathway defects	Upper and lower respiratory tract	Neutropenia, HIES, functional neutrophil disorders	*Aspergillus*	Neutropenia, CGD, HIES	Gums	LAD, neutropenia, neutrophil motility disorders
		GI tract	CGD, MSMD pathway defects (salmonella)	Nontuberculous mycobacteria, BCG	MSMD pathway defects, SCID, CGD		
		Lymph nodes	CGD, MSMD pathway defects (mycobacteria)	*Candida*	Neutropenia, CGD, MPO, CMC		
		Osteomyelitis	CGD, MSMD pathway defects				

CGD – Chronic granulomatous disease, *CMC* – chronic mucocutaneous candidiasis, *HIES* – hyper-IgE syndrome, *LAD* – leukocyte adhesion deficiency, *MPO* – myeloperoxidase deficiency, *MSMD* – Mendelian susceptibility to mycobacterial diseases, *SCID* – severe combined immunodeficiency.

TABLE 11-2 Laboratory Evaluation of Patient with Suspected Neutrophil Disorder

Test	If Normal, It Excludes...
WBC count and differential (repeated)	All forms of neutropenia
Neutrophil morphologic evaluation	Specific granule deficiency, Chédiak-Higashi syndrome
Flow cytometry	
CD18	LAD 1 (complete)
CD15s (sialyl-Lewis^X)	LAD 2
Dihydrorhodamine (DHR) oxidation	CGD (MPO deficiency, severe G6PD deficiencies and glutathione pathway deficiencies have abnormal DHR oxidation as well)
STAT-1 phosphorylation	Complete IFNGR1, IFNGR2 deficiency
STAT-4 phosphorylation	Complete IL-12Rβ1 and Tyk2 deficiency
Bone marrow aspirate	
Neutrophil maturation	Severe congenital neutropenia, cyclic neutropenia
Neutrophil retention	WHIM syndrome
Nitroblue tetrazolium reduction	CGD (severe G6PD deficiencies and glutathione pathway deficiencies have abnormal NBT reduction as well)

*Patients should be evaluated considering their familial history, physical examination and associated co-morbid factors.

elaborate antibodies against paternally encoded FcγRIIIb expressed on fetal neutrophils. These complement-activating antineutrophil antibodies can be detected in 1 in 500 live births, making the potential incidence of ANN high. This disease should be considered in the evaluation of all infants with neutropenia, with or without infection. Antibody-coated neutrophils in ANN are phagocytosed in the reticuloendothelial system and removed from the circulation, leaving the neonate neutropenic and prone to infections. Omphalitis, cellulitis and pneumonia may be the presenting infections within the first 2 weeks of life. The diagnosis can be made by detection of neutrophil-specific alloantibodies in maternal serum. Parenteral antibiotics (even in the absence of other signs of sepsis) and G-CSF should be included in the initial management of ANN. As expected, ANN tends to improve spontaneously with the waning of maternal antibody levels, but this process may take months.[29]

PRIMARY AND SECONDARY AUTOIMMUNE NEUTROPENIA

Autoimmune neutropenia (AIN) is a rare disorder, caused by peripheral destruction of neutrophils and/or their precursors by autoantibodies present in patient serum or mediated by large granular lymphocytes ($CD3^+/CD8^+/CD57^+$ T cells) in the bone marrow. Autoimmune neutropenia can be either primary or secondary. When the neutropenia is an isolated clinical entity it

https://CafePezeshki.IR

is primary AIN, and when associated with another disease, it is secondary AIN.

Primary Autoimmune Neutropenia

Primary AIN is the most common cause of chronic neutropenia (absolute neutrophil count <1500/μL lasting at least 6 months) in infancy and childhood. There is a slight female predominance and it has been reported in about 1:100,000 live births, ten times more frequently than SCN. Antibodies directed against different neutrophil antigens can be detected in almost all patients. Approximately one third of these autoantibodies are anti-NA1 and -NA2 isoforms of FcγRIIIb (the same targets recognized in ANN). Almost 85% of these antibodies are IgG. Other antigens toward which autoantibodies can be found are CD11b/CD18 (Mac-1), CD32 (FcγRII) and CD35 (C3b complement receptor). The average age at diagnosis for primary AIN is 8 months. The majority of patients present with either skin or upper respiratory tract infections. Infrequently, some patients may suffer from severe infections such as pneumonia, meningitis or sepsis. The diagnosis may be incidental, as patients may remain asymptomatic despite low neutrophil counts. Monocytosis is also frequent. Neutrophil counts are usually below 1,500/μL, but the majority of patients have >500 neutrophils/μL at the time of diagnosis. The neutrophil count may increase 2-fold to 3-fold during severe infections and return to neutropenic levels following resolution. The bone marrow may be normal or hypercellular. The cause of this disease remains unknown. Detection of granulocyte-specific antibodies is key to the diagnosis of primary AIN and may require repeated testing.[30]

AIN is usually a self-limited disease. The neutropenia remits spontaneously within 7 to 24 months in 95% of patients, preceded by the disappearance of autoantibodies from the circulation. Symptomatic treatment with antibiotics for infections is usually sufficient. Treatment for severe infections or in the setting of emergency surgery often now includes G-CSF.[30]

Secondary Autoimmune Neutropenia

Secondary AIN can be seen at any age but is more common in adults and has a more variable clinical course. Various systemic and autoimmune diseases such as systemic lupus erythematosus, Hodgkin's disease, large granular lymphocyte proliferation or leukemia, Epstein-Barr virus infection, cytomegalovirus infection, HIV infection and Parvovirus B19 infection have been associated with secondary AIN.[30] These patients are predisposed to the development of other autoimmune problems as well. Antineutrophil antibodies typically have pan-FcγRIII specificity, rather than specificity to the FcγRIII subunits, making the resulting neutropenia more severe. Anti-CD18/11b antibodies have been detected in a subset of patients. Secondary AIN responds best to therapy directed at the underlying cause.[30]

Defects of Granule Formation and Content

CHÉDIAK-HIGASHI SYNDROME

Chédiak-Higashi syndrome (CHS) is a rare and life-threatening autosomal recessive disease, characterized by oculocutaneous albinism, pyogenic infections, neurologic abnormalities and a late-onset hemophagocytic syndrome-like 'accelerated phase'. The disease is caused by mutations in the lysosomal trafficking regulator gene, *LYST* or *CHS1*.[31,32] Patients show hypopigmentation of the skin, iris and hair due to giant and aberrant melanosomes (macromelanosomes). Hair color is usually light brown to blonde, with a characteristic metallic silver-gray sheen. Under light microscopy, CHS hair shafts show pathognomonic small, irregular aggregates of clumped pigment spread throughout the shaft (Figure 11-1).[33–35]

Figure 11-1 Pigment distribution in hair. Normal hair (A) shows opacity typically located in the cortex of the hair shaft. In Chédiak-Higashi syndrome (B) small aggregates of clumped melanin are haphazardly distributed all along the hair shaft. (20 × magnification).

Giant azurophil granules formed from the fusion of multiple primary granules are seen in neutrophils, eosinophils and basophils. Mild neutropenia due to intramedullary destruction is also common. Progressive neuropathy of the legs, cranial nerve palsies, seizures, mental retardation and autonomic dysfunction are also common.

The accelerated phase, one of the main causes of death in CHS, is clinically indistinguishable from other hemophagocytic syndromes, with fever, hepatosplenomegaly, lymphadenopathy, cytopenias, hypertriglyceridemia, hypofibrinogenemia, hemophagocytosis and tissue lymphohistiocytic infiltration. Etoposide (VP16), steroids and intrathecal methotrexate (when the CNS is involved) have been effective treatments. However, without successful bone marrow transplantation, the accelerated phase usually recurs.

NEUTROPHIL-SPECIFIC GRANULE DEFICIENCY

Neutrophil-specific granule deficiency is a rare, heterogeneous, autosomal recessive disease characterized by the profound reduction or absence of neutrophil-specific granules and their contents.[36] In several cases a homozygous, recessive mutation was found in *C/EBPε*.[37,38] However, not all cases have mutations in *C/EBPε*, suggesting genetic heterogeneity.

Bilobed neutrophils are common (pseudo-Pelger-Huët anomaly), eosinophils may be unapparent in peripheral smears, and there is increased susceptibility to pyogenic infections of

https://CafePezeshki.IR

the skin, ears, lungs and lymph nodes. Neutrophils have very low specific granule contents (e.g. lactoferrin) and low to absent defensins, a primary granule product. Hemostasis abnormalities, caused by reduced levels of platelet-associated high-molecular-weight von Willebrand factor and platelet fibrinogen and fibronectin, have been reported.[39]

Aggressive diagnosis of infection, prolonged and intensive therapy, and early use of surgical excision and debridement are necessary. Unrelated bone marrow transplantation corrected neutrophil-specific granule deficiency (*C/EBPε* mutation negative) in a 13-month-old patient with intractable diarrhea and severe infections.[40]

Defects of Oxidative Metabolism

CHRONIC GRANULOMATOUS DISEASE

Chronic granulomatous disease (CGD) predisposes to recurrent life-threatening infections caused by catalase-positive bacteria and fungi, and exuberant granuloma formation due to defects in the NADPH oxidase.[38] The NADPH oxidase exists as a heterodimeric membrane-bound complex embedded in the walls of secondary granules, and four distinct cytosolic proteins. These structural components are referred to as *phox* proteins (*ph*agocyte *ox*idase). The secondary granule membrane complex is also called cytochrome b_{558}, composed of a 91-kDa glycosylated β chain ($gp91^{phox}$) and a 22-kDa non-glycosylated α chain ($p22^{phox}$), which together bind heme and flavin. The cytosol contains the structural components $p47^{phox}$ and $p67^{phox}$, and the regulatory components $p40^{phox}$ and rac. On cellular activation the cytosolic components $p47^{phox}$ and $p67^{phox}$ associate with $p40^{phox}$ and rac, and these proteins combine with the cytochrome complex ($gp91^{phox}$ and $p22^{phox}$) to form the intact NADPH oxidase. Superoxide is formed and, in the presence of superoxide dismutase, is converted to hydrogen peroxide, which, in the presence of myeloperoxidase and chlorine, is converted to bleach. It has been postulated that production of reactive oxygen species is most critical for microbial killing through the activation of certain primary granule proteins inside the phagosome.[41] This hypothesis for NADPH oxidase-mediated microbial killing suggests that the reactive oxidants are most critical as intracellular signaling molecules, leading to activation of other pathways rather than exerting a microbicidal effect per se.

Mutations in five genes of the NADPH oxidase have been found to cause CGD. Mutations in the X-linked $gp91^{phox}$ account for about two thirds of cases. The remainder are autosomal recessive; there are no autosomal dominant cases of CGD.[38] A single case of $p40^{phox}$ deficiency has been reported.[42] The frequency of CGD in the USA is higher than 1:200,000. Clinically, CGD is quite variable but the majority of patients are diagnosed as toddlers and young children.[43] Infections and granulomatous lesions are the usual first manifestations. The lung, skin, lymph nodes and liver are the most frequent sites of infection (Table 11-3). The majority of infections in CGD in North America are caused by only five organisms: *Staphylococcus. aureus, Burkholderia cepacia* complex, *Serratia marcescens, Nocardia* and *Aspergillus*.[43] Trimethoprim-sulfamethoxazole prophylaxis has reduced the frequency of bacterial infections, especially with staphylococcus. On prophylaxis, staphylococcal infections are essentially confined to the liver and cervical lymph nodes.[43] Staphylococcal liver abscesses encountered in CGD are dense, caseous and difficult to drain, and previously required surgery in almost all cases.[44] More recently, however, focusing on the dysregulated inflammatory response in CGD, a combination of steroid and antibiotic therapy has obviated the need for surgery in almost all cases.[45]

TABLE 11-3 Prevalence of Infection by Site in 368 Patients with Chronic Granulomatous Disease

Type of Infection (Most Frequent Microorganisms Isolated)	Total (*N* = 368) No. (%)
Pneumonia (*Aspergillus* spp; *Staphylococcus* spp; *Burkholderia cepacia*; *Nocardia* spp; *Mycobacteria* spp)	290 (79%)
Abscess (*Staphylococcus* spp; *Serratia* spp; *Aspergillus* spp)	250 (68%)
Suppurative adenitis (*Staphylococcus* spp; *Serratia* spp; *Candida* spp)	194 (53%)
Osteomyelitis (*Serratia* spp; *Aspergillus* spp; *Paecilomyces* spp; *Staphylococcus* spp)	90 (25%)
Bacteremia/fungemia (*Salmonella* spp; *Burkholderia cepacia*; *Candida* spp; *Staphylococcus* spp; *Pseudomonas* spp)	65 (18%)
Cellulitis (*Chromobacterium violaceum* and *Serratia marcescens* were identified in one case each)	18 (5%)
Meningitis (*Candida* spp was identified in three cases)	15 (4%)
Other†	112 (30%)

Modified from Winkelstein JA, Marino MC, Johnston RB Jr, et al. Medicine (Baltimore) 2000;79:155–69.

*These data include patients on variable prophylactic regimens, if any, and are meant to portray the natural history of disease over the last 20 years.

†Includes impetigo, sinusitis, otitis media, septic arthritis, urinary tract infection/pyelonephritis, gingivitis/periodontitis, chorioretinitis, gastroenteritis, paronychia, conjunctivitis, hepatitis, epididymitis, empyema, epiglottitis, cardiac empyema, mastoiditis and suppurative phlebitis.

The gastrointestinal (Figure 11-2A) and genitourinary (Figure 11-2B) tracts are frequently affected by inflammatory and granulomatous manifestations in CGD patients. Gastrointestinal inflammatory manifestations occur in up to 43% of X-linked and 11% of autosomal recessive cases.[46] Recent analysis of older $p47^{phox}$ deficient patients suggests that even in that group the rate of inflammatory bowel disease is almost 40% by later adulthood (SMH, personal observation). Abdominal pain is the most common gastrointestinal symptom; diarrhea, nausea and vomiting also occur. Colonic granulomatous lesions mimicking Crohn's-like inflammatory bowel disease (IBD), oral ulcers, esophagitis, gastric outlet obstruction, villous atrophy, intestinal strictures, fistulae and perirectal abscesses also occur. The extraintestinal manifestations of Crohn's (pyoderma, arthritis) are typically absent.

Most CGD-associated IBD manifestations are responsive to steroids. Prednisone (1 mg/kg/day for several weeks followed by progressive tapering) usually resolves the symptoms. Unfortunately, relapses occur in nearly 70% of patients.[45] Low-dose maintenance prednisone may control symptoms without an apparent increase in serious infections. Sulfasalazine, mesalazine, 6-mercaptopurine, azathioprine and cyclosporine are effective second-line treatment options. The use of TNF-α

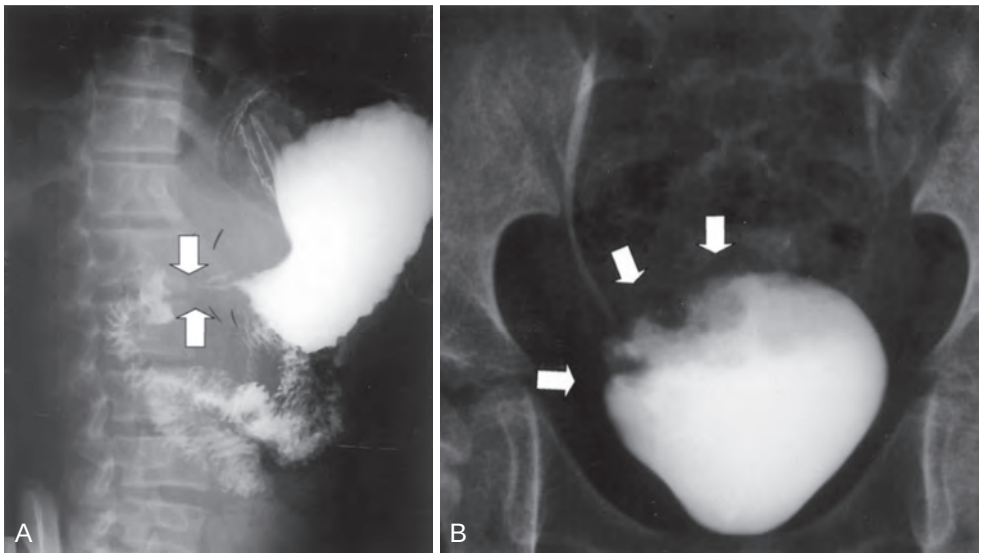

Figure 11-2 Gastrointestinal and genitourinary obstructive lesions in chronic granulomatous disease. **(A)** High-grade obstruction of the gastric outlet in a 17-year-old boy with gp91^{phox} deficient CGD *(arrows)*. He had early satiety, weight loss and intermittent vomiting for several weeks. He improved rapidly on steroid therapy. **(B)** Extensive bladder granuloma formation in the superior aspect of the bladder in a 3-year-old boy with gp91^{phox} deficient CGD *(arrows)*. Note the mildly dilated ureter on the obstructed side. This child presented with dysuria and right hydronephrosis that responded promptly to steroids.

blocking antibodies in severe cases of IBD in CGD patients have been associated with symptom control in anecdotal reports but there were also severe infections with typical CGD pathogens.[47] Therefore, intensified prophylaxis and vigilance for intercurrent infections are needed in the setting of these potent immunosuppressives.

Genitourinary strictures and granulomas occur in up to 18% of CGD patients, mostly in the cytochrome b558-mutated patients.[48] Steroid therapy similar to that used for gastrointestinal manifestations usually controls these complications.[49,50]

Inflammatory retinal involvement is found in up to 24% of X-linked CGD patients. Interestingly, this has also been detected in three X-linked CGD female carriers. These lesions are typically nonprogressive and asymptomatic and need no specific treatment. However, two CGD patients needed enucleation for painful retinal detachments.[51,52] These retinal lesions have been found to have bacterial DNA within them, but the importance of this finding is unclear since they rarely change after discovery.[53]

Autoimmune disorders such as idiopathic thrombocytopenic purpura and juvenile rheumatoid arthritis are more common in CGD than in the general population.[46,54,55] Discoid and systemic lupus erythematosus occur in CGD patients and in X-linked CGD female carriers.

The X-linked carriers of gp91^{phox} have one population of phagocytes that produces superoxide and one that does not, giving carriers a characteristic mosaic pattern on oxidative testing. Infections are not usually seen in these female carriers unless the normal neutrophils are below 10%, in which case these carriers are at risk for CGD type infections.[43,56]

The diagnosis of CGD is usually made by direct measurement of superoxide production, ferricytochrome c reduction, chemiluminescence, nitroblue tetrazolium (NBT) reduction or dihydrorhodamine oxidation (DHR). The DHR assay is preferred because of its relative ease of use, its ability to distinguish X-linked from autosomal patterns of CGD on flow cytometry, and its sensitivity to even very low numbers of functional neutrophils.[57,58] Of note, several other conditions, such as glucose-6-phosphate dehydrogenase deficiency, myeloperoxidase deficiency, and synovitis, acne, pustulosis, hyperostosis and osteitis (SAPHO) can also affect the respiratory burst.[54,55]

Male sex, earlier age at presentation and increased severity of disease suggest X-linked disease, but the precise gene defect should be determined in all cases for the purposes of genetic counseling and prognosis. Autosomal recessive forms of CGD (mostly p47^{phox} deficient) have a significantly better prognosis than X-linked disease.[59]

Prophylactic trimethoprim-sulfamethoxazole (5 mg/kg/day based on trimethoprim in two doses) reduces the frequency of major infections from about once every year to once every 3.5 years.[60] It reduces staphylococcal and skin infections without increasing the frequency of serious fungal infections in CGD.[60] Itraconazole prophylaxis prevents fungal infection in CGD (100 mg daily for patients <13 years or <50 kg; 200 mg daily for those ≥13 years or ≥50 kg).[61] IFN-γ also reduces the number and severity of infections in CGD by 70% compared to placebo, regardless of the inheritance pattern of CGD, sex or use of prophylactic antibiotics.[62] Therefore, our current recommendation is to use prophylaxis with trimethoprim-sulfamethoxazole, itraconazole and IFN-γ (50 μg/m^2) in CGD. Because the differential diagnosis for a given process in these patients includes bacteria, fungi and granulomatous processes, a microbiologic diagnosis is critical. Leukocyte transfusions are often used for severe infections, but their efficacy is anecdotal.

Winkelstein and colleagues reported that mortality in the USA from the 1970s through 1990s was around 5% per year for the X-linked form of the disease and 2% per year for the autosomal recessive varieties.[43] The accumulated European experience from 1954 to 2003 found that autosomal recessive CGD patients had an average life expectancy of 50 years, while X-linked CGD patients had an average life expectancy of close to 38 years.[63] Mortality in CGD correlates with noncirrhotic portal hypertension and progressive damage of the hepatic microvasculature. Local or systemic infections, in addition to drug-induced liver injury, may be underlying conditions. A

https://CafePezeshki.IR

history of liver abscess, alkaline phosphatase elevations and platelet decrease over time were individually associated with mortality in CGD patients.[64]

Successful hematopoietic stem cell transplantation (HSCT) provides a cure for CGD. Gungor and colleagues reported on 56 pediatric and adult European CGD patients transplanted with stem cells from matched siblings or matched unrelated donors, even in the setting of active inflammatory and infectious complications. They had an overall success rate of 93% with modest toxicity.[65]

Vectors providing normal *phox* genes can reconstitute NADPH oxidase activity in deficient cells, establishing the proof-of-principle for gene therapy in CGD. Several gene therapy protocols have been attempted, but they have been hampered by either retroviral-mediated myeloproliferative disease or poor persistence of transduced cells.[66,67] However, there are examples of at least transient benefit from gene therapy.[68] Newer protocols are using lentiviral vectors to avoid leukemogenesis and mild bone marrow ablation to permit more definitive engraftment.[69]

MYELOPEROXIDASE DEFICIENCY

Myeloperoxidase (MPO) deficiency is the most common primary phagocyte disorder. It is an autosomal recessive disease with variable expressivity: 1:4,000 individuals have complete MPO deficiency, and 1:2,000 have a partial defect.[70] Myeloperoxidase catalyzes the conversion of H_2O_2 to hypohalous acid. In those MPO-deficient patients who have had clinical findings, infections caused by different *Candida* strains were the most common: mucocutaneous, meningeal and bone infections, as well as sepsis, have been described.[71–74] Diabetes mellitus appears to be a critical co-factor for *Candida* infections in the context of MPO deficiency. A definitive diagnosis is established by sequencing of the MPO gene, neutrophil/monocyte peroxidase histochemical staining or specific protein detection. There is no specific treatment for MPO deficiency; diabetes should be sought and controlled, and infections should be treated.

LEUKOCYTE ADHESION DEFICIENCY TYPE 1 (LAD1)

LAD1 is an autosomal recessive disorder produced by mutations in the common β2 chain (CD18) of the β2 integrin family (*ITGB2*, 21q22.3; Table 11-4).[75] Each of the β2 integrins is a heterodimer composed of an α chain (CD11a, CD11b or CD11c), noncovalently linked to the common β2 subunit (CD18). The α-β heterodimers of the β2 integrin family include CD11a/CD18 (lymphocyte-function-associated antigen-1, LFA-1), CD11b/CD18 (macrophage antigen-1, Mac-1 or complement receptor-3, CR3) and CD11c/CD18 (p150,95 or complement receptor-4, CR4). CD18 is required for normal expression of the α-β heterodimers. Therefore, mutations resulting in failure to produce a functional β2 subunit lead to either very low or no expression of CD11a, CD11b and/or CD11c, causing LAD1.[75]

The severe phenotype of LAD1 is caused by < 1% of normal expression of CD18 on neutrophils whereas the moderate phenotype shows from 1% to 30% of normal expression.[76] However, patients with normal β2 integrin expression but without functional activity have also been described. Therefore, expression of CD18 alone is not sufficient to exclude the diagnosis of LAD1; functional assays must be performed if the clinical suspicion is high.[76,77]

Patients with the severe phenotype of LAD1 characteristically have delayed umbilical stump separation and omphalitis, persistent leukocytosis (>15,000/μL) even in the absence of infection, and severe, destructive gingivitis and periodontitis with associated loss of dentition and alveolar bone. Recurrent infections of the skin, upper and lower airways, bowel and perirectal area are common and usually caused by *S. aureus* or Gram-negative bacilli, but not by fungi. Infections tend to be necrotizing and may progress to ulceration (Figure 11-3). Typically, no pus is seen in these lesions and there is almost complete absence of neutrophil invasion. Aggressive medical management with antibiotics and neutrophil transfusions, and prompt surgery, when indicated, are required. Impaired healing of infectious, traumatic or surgical wounds is also characteristic of LAD1. Scars tend to acquire a dystrophic 'cigarette paper' appearance. Patients with the moderate phenotype tend to be diagnosed later in life, have normal umbilical cord separation, have fewer life-threatening infections and live longer. However, leukocytosis, periodontal disease and delayed wound healing are still common.[76]

Flow cytometry of LAD1 blood samples shows reduction (moderate phenotype) or near absence (severe phenotype) of CD18 and its associated molecules CD11a, CD11b and CD11c on neutrophils and other leukocytes. LAD1 patients show

TABLE 11-4 Leukocyte Adhesion Deficiency Syndromes

Leukocyte Adhesion Deficiency (LAD)	Type 1 (LAD1)	Type 2 (LAD2 or CDG-IIc)	Type 3 (LAD3)	Rac2 Deficiency
OMIM	116920	266265	612840	602049
Inheritance pattern	Autosomal recessive	Autosomal recessive	Autosomal recessive	Autosomal dominant
Affected protein(s)	Integrin β2 common chain (CD18)	Fucosylated proteins (e.g. sialyl-Lewis^x, CD15s)	Kindlin 3	Rac2
Neutrophil function affected	Chemotaxis, tight adherence	Rolling, tethering	Chemotaxis, adhesion	Chemotaxis, superoxide production
Delayed umbilical cord separation	Yes (severe phenotype only)	Yes	Yes	Yes
Leukocytosis/ neutrophilia	Yes	Yes	Yes	Yes

OMIM – Online Mendelian inheritance in man.

https://CafePezeshki.IR

Figure 11-3 Ulcerative perirectal lesion in an 18-year-old boy with LAD1. No pus was seen and there was poor inflammation in the surrounding tissues.

diminished neutrophil migration in vivo and in vitro.[71] Complement-mediated phagocytosis is severely impaired because of the absence of the complement receptor CD18/CD11b (CR3/Mac-1).

Somatic reversion of the mutation has been reported in LAD1 involving cytotoxic T lymphocytes.[78] However, bone marrow transplantation is the only definitive treatment.[79] Results on laboratory and animal gene therapy studies in LAD1 are provocative, but not yet available as a clinical indication.[80]

LEUKOCYTE ADHESION DEFICIENCY TYPE 2 (LAD2) OR CONGENITAL DISORDER OF GLYCOSYLATION TYPE IIC (CDG-IIC)

LAD2, or CDG-IIc, is a very rare autosomal recessive inherited disease in which fucose metabolism is primarily affected because of mutations in the GDP-fucose transporter gene, *FUCT1*[81,82] (see Table 11-4).[83,84] Lack of the GDP-fucose transporter leads to a lack of expression of sialyl-Lewis^x and other fucosylated proteins, impairing leukocyte rolling and adhesion. The phenotype is characterized by infections of the skin, lung and gums, leukocytosis and poor pus formation, as well as cognitive impairment, short stature, distinctive facies and the Bombay (hh) blood phenotype. The frequency and severity of infections tend to decline with time.[85] Fucose supplementation has had variable results.[86,87]

LEUKOCYTE ADHESION DEFICIENCY TYPE 3 (LAD3)

LAD3 deficiency (previously known as LAD1 variant) resembles LAD1 on the one hand, but is associated with a syndrome similar to Glanzmann's thrombasthenia (a β3 integrin-related bleeding disorder) on the other. These patients present in infancy with severe bleeding and infections. Mortality is high, even with stem cell transplantation. LAD3 is due to mutations in *FERMT3*, the gene encoding kindlin-3, a molecule responsible for β1, β2 and β3 integrin activation in leukocytes and platelets.[83,84]

RAC2 DEFICIENCY

Ambruso and colleagues[88] and Williams and colleagues[89] reported a male patient with an autosomal dominant mutation in the Rho GTPase *RAC2* gene (*RAC2*, see Table 11-4). This molecule is critical to the regulation of the actin cytoskeleton and superoxide production. The patient had delayed umbilical cord separation, perirectal abscesses, failure to heal surgical wounds and absent pus in infected areas, despite neutrophilia. Chemotaxis and superoxide production were impaired. In addition, the patient's neutrophils showed defective azurophilic granule release and impaired phagocytosis. He was cured by bone marrow transplantation. A second case was identified through newborn screening for T cell excision circles (TRECs), although it is still unclear why TRECs are low in RAC2 deficiency.[90]

SYNDROMES WITH SUSCEPTIBILITY TO ENVIRONMENTAL MYCOBACTERIA

The mononuclear phagocyte is crucial for protection against intracellular infections, for antigen presentation, and for lymphocyte stimulation, lymphocyte proliferation, cytokine production and response. Transcription factors binding to the GATA sequence are critical for early hematopoiesis of myeloid and lymphoid cells as well as for normal vessel development.[91] Mycobacteria infect macrophages leading to the production of IL-12p70, a heterodimer of IL-12p40 and IL-12p35. IL-12 stimulates T cells and NK cells through its cognate receptor (IL-12Rβ1 and IL-12Rβ2) to phosphorylate STAT4 and produce IFN-γ. IFN-γ acts through its heterodimeric receptor (IFNγR1/IFNγR2) to phosphorylate STAT1 and turn on interferon-responsive genes such as interferon response factor 8 (IRF8) and interferon stimulated gene 15 (ISG15) (Figure 11-4).[92,93] In response to diverse signals, NF-κB essential modulator (NEMO) mediates the activation of the central transcription factor NF-κB. This transcription factor is therefore central to both immune and somatic pathways.[94]

Patients with defects in *GATA2*, *IL12B*, *IFNGR1*, *IFNGR2*, *IL12RB1*, *STAT1*, *NEMO*, *IRF8* and *ISG15* have been identified through their susceptibility to mycobacteria, as well as other intracellular infections including *Salmonella*.[92,93,95,96] There is also a role for superoxide in the killing of mycobacteria, as reflected in the higher rates of tuberculosis in CGD and BCG infection in two families with unusual mutations in the *CYBB* gene.[97]

Haploinsufficiency for the transcription factor GATA2 leads to a late-onset immunodeficiency characterized by disseminated mycobacterial and viral (HPV, herpesviruses) infections often associated with diminished monocytes, B cells and NK cells in peripheral blood accompanied by myelodysplasia.[98]

Patients with autosomal recessive mutations leading to abolition of IFNγR1, IFNγR2 or STAT1 expression or function present early in life, especially if they receive BCG vaccination. In contrast, patients with an autosomal dominant mutation in *IFNGR1* as a result of a recurrent 4 base deletion (named 818del4) have only partial inhibition of receptor function. Patients with dominant *IFNGR1* mutations may present before the age of 7 with pulmonary nontuberculous mycobacterial infection but then characteristically go on to develop recurrent nontuberculous osteomyelitis.

https://CafePezeshki.IR

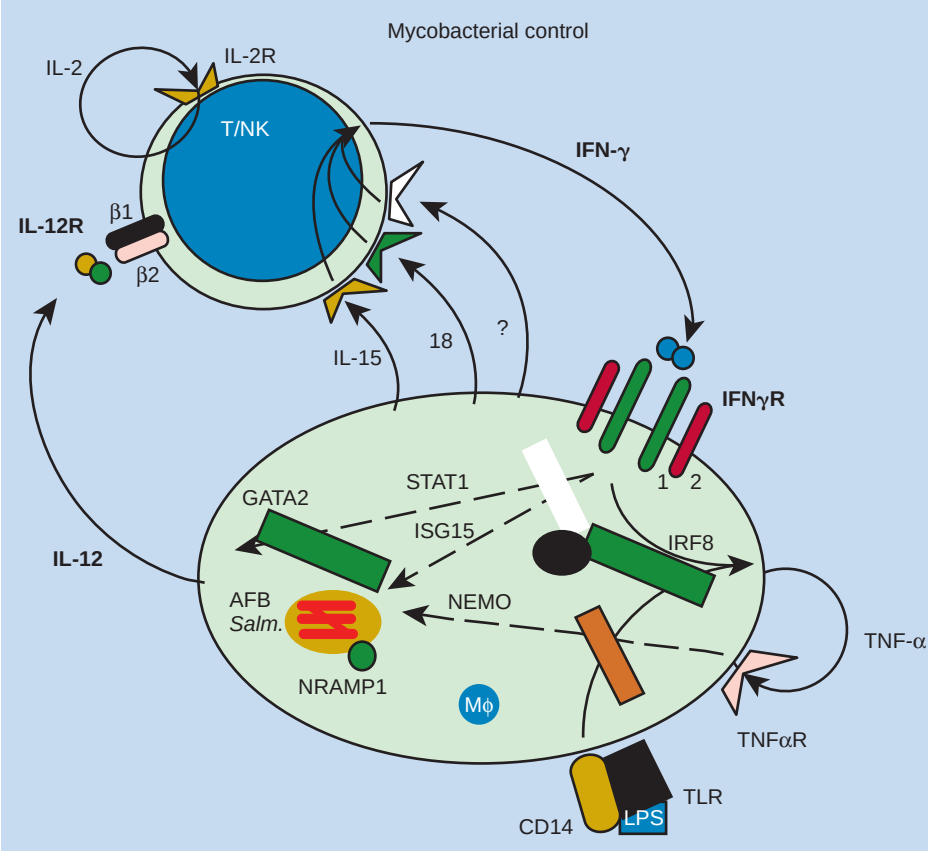

Figure 11-4 Schematic representation of the IFN-γ/IL-12 pathway. Ingested pathogens such as acid-fast bacilli *(AFB)* or salmonella *(Salm.)* stimulate IL-12 production by macrophages *(MΦ)*. Acting through its cognate IL-12 receptor, composed of the IL-12 receptor β1 chain (IL-12Rβ1) and the IL-12 receptor β2 chain (IL12Rβ2), IL-12 stimulates T and NK cells to produce IFN-γ and IL-2. Homodimeric IFN-γ binds to the interferon γ receptor complex *(IFN-γR)*. IFN-γ receptor 1 (IFN-γR1) is the binding chain whereas IFN-γ receptor 2 (IFN-γR2) is necessary to transmit the signal intracellularly through the signal transduction and activator of transcription 1 *(STAT1)*. The mechanisms by which IFN-γ stimulates intracellular microorganism killing are not fully understood, but are likely to be numerous (e.g. upregulation of MHC expression and IL-12 production, enhancing of antigen processing and reactive oxygen species production, reducing the phagosomal pH). IFN-γ also stimulates TNF-α production. TNF-α, acting through the TNF-α receptor (*TNF-αR*), also shows effects against intracellular infections. Patients with mutations in the NF-κB essential modulator *(NEMO)*, a protein critical in the TNF-α signaling pathway, have enhanced susceptibility to mycobacterial disease as well as other infections. IL-12 is not the only cytokine that stimulates IFN-γ production: IL-15, IL-18, and probably other factors have the same effect. The lack of mycobacterium-induced ISG15 secretion by leukocytes – granulocytes in particular – reduces the production of IFN-γ by lymphocytes, including natural killer cells, probably accounting for the enhanced susceptibility to mycobacterial disease. IRF8 is critical for the development of monocytes and dendritic cells and for antimycobacterial immunity. Lipopolysaccharide *(LPS)* stimulation through the CD14/Toll-like receptor 2 (TLR2) complex can also stimulate IL-12 production.

Patients with mutations in IL-12p40 or IL-12Rβ1 and those with dominant negative *STAT1* mutations usually have less severe phenotypes. In IL-12Rβ1 deficiency the risk for nontuberculous mycobacterial infection wanes after age 12.[99] IRF8 defects are quite rare. One homozygous child had severe BCG infection with myeloproliferation, while two others with dominant negative *IRF8* mutations developed mild but recurrent disseminated BCG.[92] The three patients reported with ISG15 defects had disseminated BCG shortly after vaccination but were eventually responsive to therapy.[93]

NEMO is encoded by a gene *(IKBKG)* on the X chromosome, and hypomorphic NEMO mutations cause disease in hemizygous males (hypomorphic mutations are mostly asymptomatic in females). Hemizygous males may have a complex phenotype including hypohidrotic ectodermal dysplasia, immune deficiency and, rarely, lymphedema with osteopetrosis. Almost 40% of males with hypomorphic mutations in NEMO develop mycobacterial infections, mostly with environmental organisms.[100] In heterozygous females, amorphic NEMO mutations are associated with incontinentia pigmenti.[101]

Flow cytometry is very efficient in detection of IFNGR1 defects, as this protein is expressed on all nucleated cells all the time. In the case of autosomal dominant IFNGR1 deficiency, the protein is overabundant on the cell surface and therefore very easy to detect.[102] In contrast, detection of IFNγR2 and IL-12Rβ1 often requires cell culture and proliferation. Detection of intracellular phosphorylated STAT1 after IFN-γ stimulation, or phosphorylated STAT4 after IL-12 stimulation, is an indirect means of demonstrating functional integrity of the IFN-γ and IL-12 receptors, respectively.[103,104] Direct detection of IL-12p40 or IL-12p70 can be used for the diagnosis of patients who are deficient in IL-12p40. Demonstrating defects in STAT1 requires research techniques.

Treatment of infection in these patients poses special problems. IFN-γ is of no help for the patients with complete IFNγR defects. However, in patients with autosomal dominant IFNγR1 deficiency, IL-12 defects or IL-12R defects, IFN-γ is usually effective. However, about 30% of those with IL-12Rβ1 deficiency die, suggesting complex modifying factors.[105] Bone marrow transplantation for IFNγR defects has

https://CafePezeshki.IR

been disappointing overall, for reasons that are still unclear. Long-term prophylaxis against environmental mycobacterial infections with a macrolide such as azithromycin or clarithromycin seems advisable.

HYPER-IgE SYNDROME (HIES; JOB'S SYNDROME)

Hyper-IgE (HIES or Job's) syndrome is due to heterozygous (autosomal dominant inheritance) mutations in *STAT3* and characterized by elevated serum immunoglobulin E (IgE), eczema, recurrent skin and lung infections, and somatic features including characteristic facies, scoliosis and fractures[106–108] (Table 11-5). Human mutations found thus far allow the production of full-length mutant STAT3 protein, which exerts dominant negative effects.

A newborn rash is usually the first manifestation of Job's syndrome. About one fifth have the rash at birth, and one quarter develop it in the first week of life. Mucocutaneous candidiasis is common, typically as oral thrush, vaginal candidiasis or onychomycosis; systemic *Candida* infections are very rare.[106] Cutaneous 'cold' abscesses are common and caused by *S. aureus* infections. Antistaphylococcal antibiotics or topical antiseptics, such as bleach baths, are effective.

Recurrent pneumonias caused by *S. aureus, Streptococcus pneumoniae* and *Haemophilus influenzae* typically start in childhood, with a paucity of symptoms. Pneumatoceles and bronchiectasis form during the healing process and usually persist once the infection has cleared. These anatomic abnormalities predispose the patient to Gram-negative bacterial (typically *Pseudomonas*) and fungal (typically *Aspergillus* or *Scedosporium* species) infections. The large cysts often become secondarily infected and may bleed, sometimes fatally. On the other hand, thoracic surgery can be complicated by poor healing of the remaining lung, often resulting in persistent air leak.[109] Antimicrobial prophylaxis to prevent *S. aureus* skin and lung infection (e.g. trimethoprim-sulfamethoxazole) may be broadened if Gram-negative lung infections occur. Antifungal prophylaxis to prevent pulmonary aspergillosis remains attractive but unproven, but it is highly effective in treating and preventing mucocutaneous candidiasis.

TABLE 11-5 Clinical Characteristics of Hyper-IgE Syndrome with *STAT3* Mutations

Clinical Findings in HIES	
Eczema	100%
Peak IgE > 2,000 IU/mL	97%
Eosinophilia	93%
Recurrent pneumonias	87%
Characteristic face	83%
Mucocutaneous candidiasis	83%
Pneumatoceles	77%
Retained primary teeth	72%
Pathologic fractures	71%
Focal brain hyperintensities	70%
Scoliosis (>16 years, >10°)	63%

Scoliosis, osteopenia, minimal trauma fractures, hyperextensibility, degenerative joint disease, craniosynostosis and Chiari 1 malformations also occur frequently but seldom need surgical correction.[110] The general mechanism underlying bone abnormalities is unknown and the role of bisphosphonates in treating the osteoporosis and minimal trauma fractures in HIES is undefined.

In childhood and adolescence, most Job's or HIES patients develop characteristic facial features including facial asymmetry, broad nose and deep-set eyes with a prominent forehead. Most patients retain some, if not all, of their primary teeth past the age of normal primary dental exfoliation; at times, layers of both primary and secondary teeth co-exist.[106,110] Vascular abnormalities are common in Job's including coronary artery aneurysms,[111] dilatations and tortuosities, carotid artery berry aneurysms and early-onset MRI T2-weighted hyperintensities (unidentified bright objects or UBOs).[112] As reported in other primary immunodeficiency diseases affecting lymphocytes, both Hodgkin's and non-Hodgkin lymphomas are significantly increased in Job's syndrome.[113]

DOCK8 deficiency is an autosomal recessive syndrome with IgE elevation, severe eczema and recurrent skin and lung infections. However, in distinction to Job's syndrome, DOCK8 deficiency is characterized by cutaneous viral infections (molluscum contagiosum, herpes simplex, HPV) and severe allergic diathesis.[114–116] Severe eczematoid rashes start early in life, although not necessarily in the newborn period. Unlike Job's syndrome, pneumonias due to *S. aureus, H. influenzae, Proteus mirabilis, Pseudomonas aeruginosa*, and *Cryptococcus* typically heal without pneumatocele formation. DOCK8 deficiency lacks the somatic features of Job's syndrome.

Tyk2 deficiency is another autosomal recessive syndrome with IgE elevation and susceptibility to infection. The few cases identified suggest that this may present either as an IgE elevation syndrome or one of mycobacterial susceptibility.[117,118]

Mucocutaneous Candidiasis

Candida species are commonly found on mucosal surfaces, where they are commensal. The innate response to *Candida* appears to depend heavily on the production of IL-17 by dedicated Th17 lymphocytes. Accordingly, those mutations that affect IL-17-producing T cells are strongly associated with mucocutaneous candidiasis.[119] *Candida* sensing at the cellular level seems to depend on the surface receptor dectin-1 and its signal transduction pathway including CARD9.[120] Mutations in dectin-1 have also been identified but their etiologic role in severe mucocutaneous candidiasis is hard to assign because of the common occurrence of some of these mutations.[121] Dominant negative mutations in *STAT3* (Job's syndrome) lead to impaired Th17 production and mucocutaneous candidiasis.[107,108] More surprising is the discovery that dominant gain-of-function mutations in *STAT1* also lead to Th17 deficiency and severe mucocutaneous candidiasis, apparently through the oversignaling of IFN-γ.[122,123] These syndromes are critical to consider, as homozygous recessive CARD9 deficiency can be associated with severe dermatophyte infections as well as fungal brain infections.[124] Dominant heterozygous gain-of-function *STAT1* mutations can be associated with disseminated coccidioidomycosis, disseminated histoplasmosis and progressive multifocal leukoencephalopathy.[125]

https://CafePezeshki.IR

BOX 11-2 KEY CONCEPTS

White Blood Cell Defects: Evaluation and Management

Patients with white cell defects usually present early in life with recurrent bacterial or fungal infections.

Certain infections, such as *B. cepacia, Nocardia*, or environmental mycobacteria should always prompt an inquiry into the possibility of an underlying immune defect.

Specific infection locations, such as omphalitis or osteomyelitis, should raise the suspicion of immune abnormalities.

Abnormal aspects of host response, such as lack of fever, local inflammation or pus, should immediately alert the clinician to the possibility of a white cell defect.

It is better to perform the right test once than the entire battery of immune defect tests several times. Careful consideration of the clinical and microbiologic presentation usually indicates the right path to pursue.

There is no substitute for the right drug, and that requires knowing the pathogen. Because the spectrum of infection in these diseases may range over several microbiologic kingdoms, empiric therapy is to be discouraged in favor of firm diagnoses.

Prophylactic antibiotics, antifungal agents and cytokines are highly successful in treating chronic granulomatous disease, and appear to be useful in some other immunodeficiencies as well.

A molecular diagnosis should be sought whenever possible. The expanding knowledge of genotype-phenotype relationships suggests that not all defects, even those within the same gene, are created equal.

BOX 11-3 THERAPEUTIC PRINCIPLES

- In general, attenuated or inactivated viral vaccines are not contraindicated in individuals with primary phagocyte disorders, because antiviral cell-mediated immunity is intact.
- BCG vaccination should be avoided in individuals with CGD or MSMD pathway defects, as well as in their newborn close relatives, until the defect is ruled out.
- Mulching and gardening should be avoided by individuals with increased susceptibility to *Aspergillus* infections, such as patients with CGD, HIES or neutropenia.
- Patients with white blood cell defects often fail to mount a normal inflammatory response, so clinicians and parents must keep a high index of suspicion for asymptomatic or hypo-symptomatic infection.
- Standard recommendations for duration of therapy of infections are based on experience in normal people. In the patient with a white cell defect, the host contribution to resolution of infection may be relatively small, resulting in a need for longer or more intensive antibiotic or antifungal therapy.
- When infections are necrotizing or poorly responsive to antibiotic therapy, surgery may be needed, even in situations in which it would not be needed in unaffected individuals (e.g. lymphadenitis in CGD often needs operative removal).
- Obtain experienced expert advice whenever possible.

Conclusions

Various defects of phagocytes have been elucidated over the last several decades. Despite the fact that profound neutropenia predisposes patients to most members of the bacterial and fungal kingdoms, metabolic defects in neutrophils and monocytes have relatively narrow spectra of infection. Some of these disorders have almost pathognomonic infection profiles (e.g. CGD, IFN-γ/IL-12 pathway defects). We have now put genetic faces to some of the names of these puzzling diseases. The simple recognition of genes and pathways should not be confused with careful and complete understanding of mechanism. The latter, despite all the complex diagrams, remains elusive (Boxes 11-2 and 11-3). Although we have been very successful at identifying rare and flagrant defects affecting white cells that lead to severe infections, the more subtle defects that cause recurrent staphylococcal infections, hydradenitis and infections in diabetes, to name only a few of the vexing problems that frequently confront the clinical immunologist, remain to be determined. Careful study of the known pathways, assiduous following of the ramifications of those pathways to the points where they merge with new pathways, and conscientious characterization of clinical phenotypes will lead to the discovery of these remaining immune defects. In the process we will gain new insights into exactly how we remain so remarkably healthy in the face of so many daily microbial challenges.

12 Rheumatic Diseases of Childhood: Therapeutic Principles

ROBERT P. SUNDEL

KEY POINTS

- Rheumatologic disorders are perpetuated by ongoing immune activation resulting from failure to clear triggering antigens combined with aberrant control mechanisms.
- The resulting chronic inflammation leads to local granuloma formation, scarring and fibrosis, as well as systemic symptoms such as fever, malaise, disrupted growth and elevated acute-phase reactants.
- Rheumatologic diseases are monitored by physical and laboratory examination of specific and nonspecific effects on involved organ systems.
- Early, aggressive therapy is aimed at preventing irreversible tissue damage and minimizing immunologic evasion of medication efficacy through epitope spreading and antibody affinity maturation.
- Therapy is seldom curative, so chronic treatment must be guided by optimizing medication benefits and minimizing their risks, especially those related to immunosuppression.
- The expanding therapeutic armamentarium against rheumatologic diseases is improving outcomes by targeting of pathogenic cells and cytokines using biologic response modifiers and small molecule inhibitors.
- Specific approaches to the most common pediatric rheumatologic disorders – juvenile arthritis, systemic lupus erythematosus and dermatomyositis – include agents providing symptomatic relief as well as more potent antiinflammatory and immunosuppressive disease modifying agents.

'Rheumatology' derives from the Greek word *rheuma*, meaning 'river' or 'flow'. It reflects the ancient belief that articular pain is caused by the settling of bad humors in the joints. In the almost two millennia since Galen introduced this term, understanding of how arthritis and related maladies develop has changed dramatically. What has not changed, however, is the broad spectrum of conditions falling within the purview of rheumatology.

Rheumatologic disorders are often equated with autoimmunity. In fact, while the former term is overly general and imprecise, the latter implies that we know more about the pathogenesis of these conditions than we really do. Most chronic inflammatory disorders are indeed marked by ongoing immune activation, but it is not clear that the process is either initiated or perpetuated by autoreactivity. Even where this may be the case, such as diseases marked by self-reacting lymphocytes or autoantibodies, an autoantigen is seldom identified. At the very least, exogenous factors such as infection or injury are often central to disease development. Accordingly, this chapter will focus on the most common pediatric inflammatory diseases, but it will stress the inflammatory and immunologic factors relevant to their diagnosis and treatment, rather than theoretical aspects of tolerance and self-recognition. The newest family of inflammatory disorders, autoinflammatory diseases, is addressed in Chapter 14, and connective tissue diseases and pain syndromes are not addressed because their care is driven more by empirical clinical experience than by immunologic principles.

Inflammation

Inflammation is the way the body reacts to infection, injury or irritation.[1] Although its cardinal signs – *dolor, calor, rubor* and *tumor* – are stereotypical and recognizable, the process itself is complex and protean. Further, the inflammatory response must operate within very tight constraints. It must have a rapid onset of action, lest an invading organism proliferate overwhelmingly before control is achieved. It must be restricted physically in order to minimize damage to distant, uninvolved tissues. And it must be limited temporally so that ongoing tissue destruction does not progress after the inciting trigger resolves. In view of the difficulty of achieving such tight regulation, it is not surprising that harmful pathology is a not-infrequent side-effect of inflammation.

Inflammation associated with rheumatologic diseases typically involves both the innate and the adaptive immune systems. Initially, cells at the point of contact with foreign antigens or disrupted tissue are activated when they recognize pathogen-associated molecular patterns (PAMPs) that are generally not present on normal host cells. Pattern recognition receptors on macrophages and dendritic cells lead to cellular activation and release of intercellular mediators, resulting in the manifestations of inflammation. Thus, complement breakdown products and bradykinin augment regional blood flow by dilating local vessels, leading to warmth and redness. These and other chemicals also cause pain and swelling and increase vascular permeability, allowing proteins to exude into local tissues. These substances, in turn, attract phagocytes and stimulate degranulation, releasing additional inflammatory mediators including chemokines and cytokines, attracting and activating lymphocytes and recruiting components of the adaptive immune system.

Among the cytokines most important to the inflammatory response are IL-1, IL-6 and TNF-α, which together are responsible for many of the characteristic systemic signs and

https://CafePezeshki.IR

symptoms including fever, anorexia and malaise. These cytokines also elicit the hepatic acute-phase response, down-regulating so-called 'housekeeping proteins' such as albumin and up-regulating synthesis of mediators of 'fight and flight' such as C-reactive protein (CRP, an opsonin for certain organisms), fibrinogen (facilitator of blood clotting) and ferritin (which deprives bacteria of free iron) (Figure 12-1).

Another important class of inflammatory mediators is the arachidonic acid metabolites, including leukotrienes and prostaglandins. Released by inflammatory cells, these mediators contribute to acute erythema and swelling by inducing vasodilation and capillary leak. Prostaglandin E_2 is of particular importance because it also sensitizes local nerve endings to pain and, with IL-1, mediates fever via effects on the hypothalamus.

As important as the initiation and augmentation of the inflammatory response may be, its timely disengagement and resolution are at least as essential for good health.[2] Much of this restoration of normal homeostasis is passive, a consequence of the short half-life of most inflammatory mediators. In addition, active controls are involved, such as antiinflammatory cytokines (e.g. IL-10) and antiinflammatory molecules (e.g. soluble TNF receptor, IL-1 receptor antagonist and resolvins). Finally, the disappearance of perpetuating mediators starves activated cells of essential growth factors, leading to programmed death (apoptosis) of accumulated inflammatory cells. In most situations, these controls are sufficient to allow the inflammatory response to fade and for damage to be repaired through healing, fibrosis and scarring.

Rheumatologic disorders are typically chronic conditions in which the usual control mechanisms fail to stem the inflammatory response. Many factors may lead to such ongoing inflammation. For example, the stimulus triggering inflammation may be recurrent or impossible to eliminate (i.e. uric acid crystals in gout or a modified self-antigen in diabetes). In the majority of rheumatologic diseases, however, the cause is not clear, with neither the triggering stimulus nor potential aberrations in control mechanisms fully understood. In such cases, persistent inflammation may result in granuloma formation, scarring and/or fibrosis locally, as well as malaise, fever, anorexia, weight loss and elevation of acute-phase reactants systemically. While the specific manifestations of various rheumatologic conditions vary, these hallmarks are typical of all forms of systemic inflammation.

Assessing Systemic Inflammation

As noted, cytokines and other mediators released by immune cells account for the clinical picture of systemic inflammation. Another clinical manifestation of inflammation is stunting of growth, apparently as a result of interference with normal anabolic hormones even in the setting of adequate dietary intake. The onset of a chronic inflammatory disease often can be pinpointed by careful review of the growth chart.

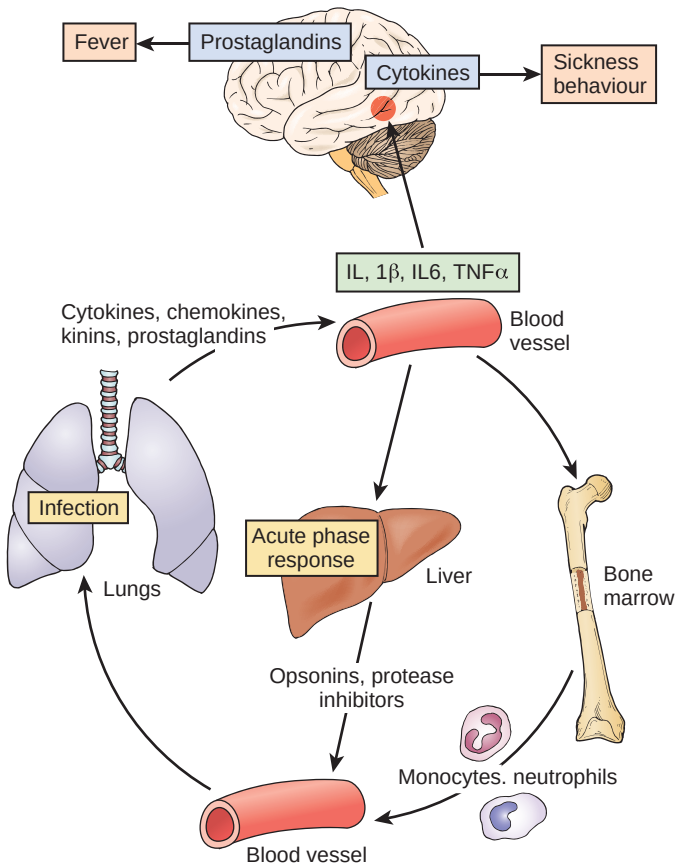

Figure 12-1 Hepatic acute-phase response (http://www.nature.com/nrn/journal/v4/n2/fig_tab/nrn1032_F2.html).

https://CafePezeshki.IR

The blood tests most often used to assess the degree of systemic inflammation are the erythrocyte sedimentation rate (ESR) and the CRP.[3] CRP is a product of the hepatic acute-phase response and rises within 48 hours of an inflammatory stimulus (Figure 12-2).[4] An elevated ESR is a rapidly quantifiable physical manifestation of elevation of a variety of acute-phase reactants, especially fibrinogen. This and other positively charged proteins tend to intercalate between negatively charged erythrocytes, facilitating the formation of red blood cell stacks (rouleaux) that sediment more rapidly than free-floating cells. Since the levels of these proteins take days to weeks to respond to an inflammatory stimulus, the ESR rises more slowly than the CRP in acute inflammation and remains elevated longer after the inflammation resolves. Nevertheless, ready availability and extensive experience with the ESR make it a useful, if nonspecific, clinical tool.

Humoral mediators are responsible for many other manifestations of acute inflammation such as leukocytosis, appearance of immature ('band') forms of white blood cells, and thrombocytosis. In additional, prolonged inflammation typically causes normocytic anemia (the anemia of chronic disease) and, in response to some inflammatory stimuli, elevated levels of serum immunoglobulins from B cell stimulation.

Principles of Antiinflammatory Therapy (Box 12-1)

Ideal therapy would target only aberrant manifestations of the inflammatory response while preserving basic regulatory and effector functions of immunity. Unfortunately, the aberration in the immune system responsible for specific inflammatory diseases is generally unknown, available agents do not distinguish between harmful and beneficial immune activity, and many drugs also have nonimmunologic side-effects. The result is that the risks of immune suppression are often considerable, and they must be balanced against the benefits of controlling inflammation when deciding upon therapy. Practical aspects of these considerations generally follow several basic principles:

1. *The least toxic medications should be used for the briefest period of time.* Unfortunately, most rheumatologic disorders are managed without expectation of cure. For unknown reasons, varying percentages of different conditions will remit over time, but rarely can such remissions be ascribed to the effects of treatment. At best, conditions may be stabilized as inflammation is controlled, ultimately minimizing the need for continuous immunosuppression. Thus, with antiinflammatory therapy likely to be needed indefinitely, minimizing the amount and intensity of antiinflammatory treatments is essential for avoiding complications due to effects on tumor surveillance and resistance to infections. While such risks are increased by combination immunosuppression, particularly the addition of steroids to other agents, in many cases disease activity also contributes to a patient's risk of developing opportunistic infections and malignancies. Thus, managing rheumatologic diseases remains very much an art rather than a science.

BOX 12-1 PRINCIPLES OF ANTIINFLAMMATORY THERAPY

1. The least toxic medications should be used for the briefest period of time.
2. Early, aggressive therapy offers the greatest chance of achieving a good outcome:
   a. Irreversible damage, which occurs early in the disease course, is avoided
   b. Evolution of the immune response increases resistance to therapy over time.
3. The uniqueness of the individual immune response necessitates a 'treat to target' approach.

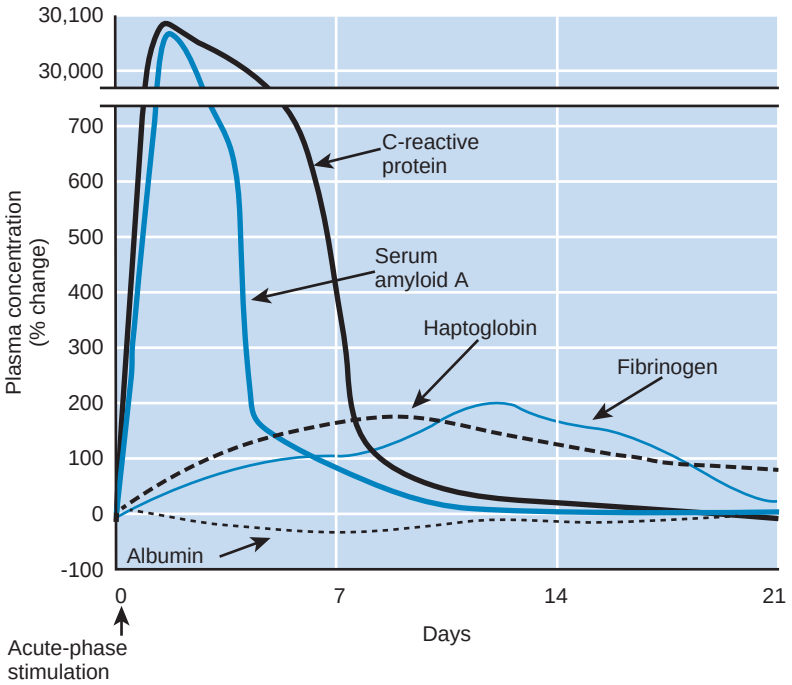

Figure 12-2 Time course of the acute-phase response.

https://CafePezeshki.IR

2. *Early, aggressive therapy offers the greatest chance of achieving a good outcome*:
   a. Rheumatologic disorders not only cause inflammation and the signs and symptoms with which it is associated, but over time they tend to cause irreversible tissue damage as well. While such damage occurs at varying rates in different conditions and different individuals, achieving disease control rapidly enough to avoid such damage is generally the best way to avoid chronic ill-effects of rheumatologic disorders. Often such damage occurs early in the disease course – for example, up to 50% of people with rheumatoid arthritis develop erosive changes within two years of disease onset.[5] As a result, earlier ideas of gradual intensification of therapy (the so-called 'reverse pyramid') have fallen out of favor. Instead, early initiation of optimally effective treatment, with subsequent tapering once disease control is achieved, is now preferred.
   b. The centrality of involvement of the immune system in the pathogenesis of rheumatologic disorders means that disease activity is not static. Rather, as long as a tissue is being targeted, the immune system is evolving to optimize the inflammatory attack. Affinity and avidity of antibodies increase over time (affinity maturation), and target epitopes are honed and extended (epitope spreading) to minimize immune evasion due to antigenic variation. Thus, there may be a 'window of opportunity' early in the course of inflammatory disorders during which autoimmunity may be controlled.[6] Over time, however, with broadening of the inflammatory response, such restoration of regulation may become increasingly difficult and require progressively more intense immunosuppression.
3. *The complexity and unpredictability of the immune process driving inflammation in rheumatologic disorders necessitates an individualized approach to therapy.* The many factors involved in the initiation and perpetuation of rheumatologic conditions – including host genetic and epigenetic factors, co-morbid medical conditions, variations in triggering events, and pharmacogenetic idiosyncrasies affecting response to medications – do not lend themselves to standardized protocols of treatment. Rather, the concept of 'treat to target' is now the preferred paradigm: therapeutic response is measured on an ongoing basis, and types and doses of medications are adjusted based on a patient's response rather than being continued for an arbitrary period of time before changes are made. No single approach is universally effective in all patients, and not all therapeutic regimens are equally beneficial. Thus careful monitoring as well as thorough familiarity with both theoretical and experimental effects of treatments are necessary to optimally treat rheumatologic conditions.

With these principles as a background, a general overview of the current panoply of antiinflammatory agents is offered below.[7] Following that is a discussion of the most common pediatric rheumatologic conditions, including specific information on their diagnosis and natural history, and empirical approaches to treatment.

Therapeutic Strategies (Box 12-2)

Inadequate understanding of fundamental disease mechanisms has limited treatment options for rheumatologic diseases. Since the initial use of corticosteroids almost 60 years ago, clinicians could offer little more than broad immunosuppression plus supportive care (e.g. physical therapy for rheumatoid arthritis) to mitigate end-organ damage. More recently, rapid advances in molecular immunology have brought us tantalizingly near to the Holy Grail of immunomodulation – the possibility of targeting only disease-mediating cells, leaving other facets of immunity unaffected. Although this possibility remains largely theoretical, new targeted approaches for reducing long-term disability and total exposure to immunosuppressive therapy are improving quality of life and long-term outcomes faster than ever before.[8]

BOX 12-2 ANTIINFLAMMATORY AGENTS (IN APPROXIMATE ORDER OF INCREASING POTENCY)

1. Inhibitors of arachidonic acid metabolism
   a. Nonsteroidal antiinflammatory drugs (NSAIDs)
   b. Cyclooxygenase (COX)-2 inhibitors
2. Immunomodulators
   a. Disease-modifying antirheumatic drugs (DMARDs)
   b. Calcineurin inhibitors
3. Targeted molecular therapies
   a. Monoclonal antibodies
      i. Cytokines
      ii. Costimulatory molecules
   b. Receptor antagonists
   c. Small molecules
      i. Protease inhibitors
      ii. Interfering RNA
4. Immunosuppressants
   a. Antimetabolites
   b. Cytoxic agents
   c. Corticosteroids
5. Immune reconstitution
   a. Stem cell transplant
   b. Bone marrow transplant

SYSTEMIC IMMUNOSUPPRESSION

The mainstay of treatment for systemic rheumatologic diseases remains immunosuppressive medications. These ameliorate the clinical and serologic effects of disease activity by targeting effectors of the immune response. Adverse effects of immunosuppression result from interference with protective immunity as well as pathologic autoimmunity and include the ongoing risk of infection and the cumulative potential for developing a malignancy due to diminished immune surveillance.

Corticosteroids, perhaps the least discriminating tool in the armamentarium, are used in doses ranging from daily low-dose oral regimens to 'pulsed' high-dose intravenous therapy. Traditional disease-modifying antirheumatic drugs (DMARDs) such as methotrexate, leflunomide, hydroxychloroquine and sulfasalazine are mildly immunosuppressive and cause minimally increased risks of infection. Their benefits are likely mediated through antiinflammatory and immunomodulatory effects rather than through immunosuppression per se. More potent immunosuppressive agents such as azathioprine, cyclosporin A, mycophenolate mofetil and cyclophosphamide are often necessary for treating more severe conditions such as vasculitis and systemic lupus erythematosus (SLE).

Plasmapheresis is an important treatment utilized to remove pathogenic antibodies and other humoral factors from the

https://CafePezeshki.IR

circulation.[9] It is employed when urgent measures are needed to stabilize a patient before longer-term interventions take effect, for example cases of acute hemorrhage from the pulmonary-renal syndromes, granulomatosis with polyangiitis (Wegener's granulomatosis) and Goodpasture syndrome. Intravenous immunoglobulin (IVIG) has immunomodulatory properties without the risks of immunosuppression, particularly useful in patients whose inflammatory condition is a result of an immunodeficiency (e.g. granulomatous common variable immunodeficiency).[10] Inexplicably, IVIG is superior to any other therapy in arresting acute inflammation and preventing target-organ damage in cases of Kawasaki disease, an inflammatory vasculitis of childhood.[11] While IVIG can also remove activated complement fragments that mediate inflammation in dermatomyositis, its role in other inflammatory disorders is far less prominent.

TARGETED MOLECULAR THERAPIES

During the past decade, a new generation of drugs targeting cytokines and lymphocyte receptors has dramatically altered the therapeutic landscape of rheumatology.[12] These so-called 'biologic response modifiers' (BRMs) are recombinant monoclonal antibodies and receptor antagonists that inhibit specific targets.[13] The impact of BRMs is perhaps most clearly evidenced by the fact that, as of 2007, eight of the 20 best-selling biotechnology drugs in the USA were therapeutic monoclonal antibodies.[14] Biologic drugs are discussed further in Chapter 17.

NOVEL THERAPEUTIC TARGETS

Novel targeted therapies for autoimmune diseases will broaden attempts to exploit cytokines and lymphocyte cell surface molecules involved in mediating inflammation and lymphocyte activation. Not only monoclonal antibodies but small molecule inhibitors and interfering RNA are being investigated.[15] The first such agent approved for a rheumatologic indication was tofacitinib, a Janus kinase (JAK) inhibitor, which was approved for treatment of rheumatoid arthritis in 2012. Protein kinase inhibitors interfere with phosphorylation of serine, threonine or tyrosine residues in proteins. This step is needed for proliferation or activation, so inhibitors of protein kinases may have therapeutic effects in rheumatologic and malignant disorders. Such agents are immunosuppressive and so risk of infections remains a serious concern, as with biologic agents. Their major advantage at present is the fact that they are not digested by enzymes of the gastrointestinal tract so they may be taken orally, unlike monoclonal antibodies.

Small molecule protein kinase inhibitors developed for the treatment of malignancies may have utility in autoimmune diseases. For example, patients with systemic sclerosis (SSc) demonstrate increased activity of the platelet derived growth factor receptor (PDGFR), possibly due to stimulatory autoantibodies. Studies have focused attention on imatinib (Gleevec®), a drug that inhibits multiple tyrosine kinases including PGDFR, as a possible therapy for SSc.[16] This kinase inhibitor has already had dramatic effects on the treatment of chronic myelogenous leukemia and gastrointestinal stromal tumors.

Proteasome inhibition and pharmacologic regulation of autophagy, a cellular recycling pathway in which cellular targets are delivered to lysosomes for degradation, represent additional autoimmune disease targets of interest. Bortezomib, a proteasome inhibitor approved for the treatment of multiple myeloma, inhibits degradation of pro-apoptotic factors, permitting activation of programmed cell death in rapidly dividing cells. This leads to depletion of short- and long-lived plasma cells and reduces autoantibody production, a possible explanation for the ability of bortezomib to protect lupus-prone mouse strains from the development of nephritis.[17] Hydroxychloroquine, a drug used to treat malaria for more than half a century, also blocks acidification of phagolysosomes. It is known to prolong remissions in SLE and may exert beneficial effects in other autoimmune diseases by modulating autophagy-mediated antigen presentation.[18] Future work may lead to therapies that capitalize on immune cell requirements for cellular recycling and unfolded protein response pathways in order to inhibit autoreactive responses without causing significant immunosuppression.

The ultimate approach to therapy of intractable immune activation or immune dysregulation is 'resetting' of the immune system in an attempt to restore normal regulatory controls.[19] Treatment of severe autoimmunity with stem cell transplantation remains experimental, largely because of the significant morbidity and mortality that still accompany this approach. Nonetheless, this approach has been used in cases of severe systemic juvenile rheumatoid arthritis (JRA), SSc, and SLE resistant to conventional therapy. For example, a recent report documented sustained clinical remission in seven patients with severe refractory SLE treated with immunoablation and autologous hematopoietic stem cell transplantation. Further, after transplantation, the patients demonstrated evidence of normalization of naïve lymphocyte populations and generation of thymic derived regulatory T cells.[20] Safer methods for reconstituting the bone marrow compartment, such as autologous stem cell reconstitution protocols, could provide a therapeutic alternative for the most difficult to treat patients.

Approaches to Specific Conditions

The final section of this chapter addresses specific therapeutic approaches to the three most common pediatric rheumatologic disorders. This represents a snapshot of a rapidly evolving discipline. Each new biologic agent or small molecule inhibitor has the potential to disrupt the existing paradigm by introducing dramatic improvements in the therapeutic risk-benefit ratio. The rapidity of such changes cannot be overstated. For example, within the past 15 years identification of the genetic basis of familial Mediterranean fever led to the description of an entire new class of disorders, the autoinflammatory conditions. In short order, this was followed by the introduction of biologic therapy as an almost miraculous, specific approach to conditions that had previously been untreatable, debilitating and often fatal. In view of this unprecedented rate of change, clinicians caring for children with rheumatologic conditions require guidelines to help navigate the rapidly expanding and increasingly complex rheumatologic armamentarium. These are offered below.

JUVENILE IDIOPATHIC ARTHRITIS (JIA)

Juvenile arthritis is the most common rheumatologic disorder of childhood, affecting as many as one in 1,000 children under the age of 16 years. From the first published case of arthritis developing in a child in 1864, descriptions have tended to

https://CafePezeshki.IR

include a variety of patterns that likely represent numerous different subtypes of juvenile arthritis.[21]

Unfortunately, with the pathogenesis of juvenile arthritis poorly understood, most classification schemes have categorized patients based on the number and pattern of joints involved, the populations being studied and the interests of the committee members categorizing them. Not surprisingly, genetic and immunologic data demonstrate significant overlap and imprecision when classification is based solely on such phenotypic patterns. Current classifications thus leave much room for improvement.[22] Nonetheless, whether a child is said to have psoriatic arthritis (based on the 1977 criteria of the International Leagues of Associations for Rheumatology), pauciarticular juvenile rheumatoid arthritis (based on the 1986 American College of Rheumatology criteria) or enthesitis-related arthritis (according to the 1993 International League of Associations for Rheumatology proposed classification of the idiopathic arthritides of childhood), management and therapy are largely similar across classification systems and disease subtypes.

Pauciarthritis

Arthritis involving fewer than five joints, known as oligoarticular or pauciarticular arthritis, is the most common form. The knee is most often affected, followed by the ankle, wrist and elbow. There are two peaks of onset: one between the ages of 1 and 5 years and the other between 12 and 16 years. Most patients present with a gradual onset of stiffness, swelling and diminished mobility, most prominent early in the day or after prolonged inactivity.

The extent to which children complain of pain varies, with younger children often limping but denying discomfort.

The degree of debility caused by arthritis is generally proportional to the number of joints involved. Pauciarthritis usually does not cause systemic symptoms such as fatigue, malaise, fevers or significant elevation of acute-phase reactants. Involved joints may grow more rapidly, however, due to increased blood flow and nutrient delivery to inflamed tissues, so asymmetric involvement persisting for more than a few months may lead to limb-length discrepancies and significant muscle atrophy.

In addition, pauciarthritis is associated with a significantly increased risk of developing chronic, asymptomatic anterior uveitis.[23] This occurs in up to 30% of children with pauciarthritis who are antinuclear antibody (ANA) positive, with up to one third of children diagnosed with anterior chamber inflammation before arthritis develops. About 50% of children with uveitis develop it roughly coincident with the onset of arthritis; onset more than 7 years after the diagnosis of arthritis is very rare. Early detection of the uveitis is important in preventing sequelae; 20% or more of those in whom diagnosis is delayed develop decreased visual acuity or even blindness. Unfortunately, chronic anterior uveitis is usually asymptomatic, so children with pauciarticular JIA should have slit lamp examinations by a pediatric ophthalmologist on a regular basis so that undetected inflammation does not cause irreversible ocular changes.

Polyarthritis

Polyarthritis affects five or more joints, both large and small, though typically in a symmetric pattern. Diagnosis requires clear evidence of joint inflammation (decreased function, swelling, stiffness and/or warmth), not merely pain. It is thus important to perform both a thorough history and a careful physical exam to distinguish arthritis from arthralgias. The more joints involved, the more likely the child is to have systemic features of disease, including malaise, fatigue and laboratory abnormalities.

About 10% of children with polyarthritis test positive for rheumatoid factor. This subtype of juvenile arthritis most closely resembles adult rheumatoid arthritis. In long-term follow-up studies, the presence of rheumatoid factors in serum correlates with more aggressive disease and a greater possibility of joint damage and disability. So-called 'seropositive' arthritis is also marked by antibodies to cyclic citrullinated peptide (CCP), another predictor of more aggressive and destructive arthritis.

Some cases of arthritis include prominent inflammation of the entheses (insertion sites of tendons and ligaments into bone), most often the Achilles tendon at the heel or the patellar tendon at the tibial tuberosity. Furthermore, the history frequently reveals other members of the family with ankylosing spondylitis, psoriasis, inflammatory bowel disease (IBD) or Reiter's disease. These individuals, in particular those with a strong family history, may be HLA-B27 positive. Neck, back and hip involvement is common in these so-called 'spondyloarthropathies', though sacroiliitis (often manifesting as lumbosacral pain) may not be present at disease onset.[24] Such axial involvement typically becomes symptomatic by mid-adolescence.

Systemic Onset Juvenile Idiopathic Arthritis

The third type of JIA, systemic-onset JIA or Still's disease (SoJIA), is the least common form.[25] Systemic complaints, particularly fever, often precede development of arthritis, so pediatricians are most likely to consider this diagnosis in children with a fever of unknown origin (FUO). SoJIA fevers are typically prolonged, minimally responsive to antipyretics, and hectic. Temperatures may reach 104° to 105° F once or twice a day, often at the same hour of the day, while dipping below normal between fevers, especially just before sunrise. Patients may experience chills and toxicity with the fevers, while such symptoms tend to improve during afebrile intervals. Appetite is frequently decreased, often accompanied by weight loss. Family history as well as a thorough review of systems and physical exam should focus on constitutional symptoms, delayed growth, poor weight gain, rashes, nail pits, oral lesions, nailbed capillary changes, clubbing, weakness and intestinal symptoms.

A diagnostic rash occurs in 90% of patients with systemic-onset JIA (Figure 12-3). The rash consists of evanescent 3- to 5-mm erythematous macular or barely papular lesions occurring most commonly on the trunk and proximal extremities. It may be asymptomatic or occasionally pruritic and is typically most prominent during fever elevations. Uncommonly, the rash can involve the face and hands and feet, but fixed lesions persisting for more than 24 hours in a location should stimulate a search for an alternative diagnosis. The rash is more likely to be atypical for the first several weeks of illness before evolving into the classic salmon pink exanthem. Similarly, early in the course of the illness a child may complain of joint pain, with frank arthritis not becoming evident for weeks or months. Less specific findings may include lymphadenopathy, hepatosplenomegaly or serositis with pericardial effusions.

Laboratory Assessment

The laboratory assessment of JIA should include a complete blood cell count (CBC), sedimentation rate and ANA, as well as

https://CafePezeshki.IR

Figure 12-3 Skin eruption in systemic juvenile idiopathic arthritis.

a rheumatoid factor and anti-CCP antibodies in children with symmetric polyarthritis. The white blood cell count is frequently elevated to 30,000/mm^3 or more in systemic JIA, with a marked left shift. If blood counts are unexpectedly low, evidence of myelophthisis or increased cellular turnover due to leukemia may be manifested by elevated lactic acid dehydrogenase (LDH) and/or uric acid levels. Acute-phase reactants including ESR, CRP and platelets are also strikingly elevated unless a complication leads to a consumptive process such as macrophage activation syndrome (MAS) or disseminated intravascular coagulopathy (DIC). Hematocrit and levels of housekeeping proteins such as albumin are decreased commensurate with the level of inflammation.[26] In cases of arthritis in which other systemic illnesses are suspected (e.g. SLE, myositis or IBD), additional studies may be necessary to assess kidney, gastrointestinal and muscle function.

In boys with onset at an older age and with axial or primarily lower-extremity joint involvement, a human leukocyte antigen (HLA-B27) test may be positive in support of the diagnosis of spondyloarthritis. Close follow-up of the axial joints is particularly important in such patients, though widespread screening is not indicated as approximately 9% of all Caucasians are HLA-B27 positive, only a minority of whom have spondyloarthritis. Conversely, some populations such as native Africans almost never carry this gene, yet they may develop ankylosing spondylitis and other forms of spondyloarthritis.

Early in the course of arthritis, radiographs of involved joints show little more than soft tissue swelling and periarticular osteopenia. Bone scans in perplexing patients usually show tracer uptake on both sides of the joint, which is consistent with arthritis and not indicative of osteomyelitis. Magnetic resonance imaging (MRI) or ultrasound scanning may be helpful in visualizing intra-articular effusions and synovitis in involved joints.

Treatment

Treatment of juvenile arthritis is directed at two discrete but related aspects of the condition, symptoms and joint damage. Nonsteroidal antiinflammatory drugs (NSAIDs) provide analgesia and some relief of inflammation. For younger children who require liquid medications, naproxen (≤10 mg/kg twice daily), ibuprofen (10 mg/kg up to three or four times daily) or meloxicam (0.25 mg/kg divided twice daily) are available, with a preference for medications with a longer half-life that require less frequent dosing. For older children, numerous NSAIDs formulated as tablets are available, including naproxen 250 to 375 mg twice daily, diclofenac 50 to 75 mg twice daily, tolmetin (30 mg/kg/day) and meloxicam 15 mg once a day, all approved for pediatric use. The COX2 inhibitor, celecoxib, has been approved for children over the age of 2 years. Celecoxib produces less gastric irritation than routine NSAIDs, and it does not affect platelet function. In severely symptomatic or debilitating cases of polyarthritis, a brief course of systemic steroids (usually at doses <1 mg/kg/day) may serve as a bridge until disease modifying agents become effective. Conversely, an intra-articular injection with triamcinolone hexacetonide or other steroid agents may be effective for a mono- or pauciarthritis.

Second-line therapy of JIA begins with low-dose methotrexate administered on a weekly basis.[27] Newer agents, including TNF inhibitors (e.g. etanercept and infliximab), are available for patients in whom methotrexate therapy fails. The newest biologic agents approved for the treatment of JIA are adalimumab and abatacept. Systemic-onset JIA is best treated with early initiation of anti-IL-1 agents such as anakinra (an IL-1 receptor antagonist) or canakinumab (anti-IL-1 monoclonal antibody), or the anti-IL-6 agent tocilizumab.[28]

In patients with axial involvement of the neck, lumbosacral spine, hips or sacroiliac joints, as well as prominent enthesitis, diligent physical therapy is essential for maintaining range of motion. In such cases of axial involvement, vertebral fusion may occur over time. Traditional DMARDs are significantly less effective than NSAIDs and TNF inhibitors, though the extent to which these can prevent ankylosis remains unclear.[29]

Prognosis

Overall, the prognosis for patients with JIA is markedly better than it was even 10 years ago. The expectation should be that any case of arthritis can be fully or largely controlled with aggressive treatment, and disability or chronic joint damage should be a rare outcome. Optimal results are more dependent upon state-of-the-art care in certain subtypes of juvenile arthritis, including systemic-onset JIA, pauciarticular JIA associated with chronic anterior uveitis, and rheumatoid factor-positive polyarticular JIA. Regardless, treatment with second-line agents has drastically reduced disability and the need for total joint replacement; up to 90% of children should have a favorable course and be able to maintain a normal lifestyle.

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is the prototype of autoantibody-mediated diseases, demonstrating diverse manifestations depending upon the specific organs targeted in a particular case.[30] In fact, diagnosis depends upon meeting a checklist of signs and symptoms: someone with seizures, a photosensitive skin rash and oral ulcers and someone else with renal failure and thrombocytopenia might both fulfill

https://CafePezeshki.IR

criteria for SLE despite having no characteristics in common. Several different mouse models mimic the human disease, and each one is caused by immunologic aberrations involving different regulatory mechanisms. Thus, SLE appears to be a final common pathway for a variety of immunoregulatory abnormalities, such as a lowered threshold for B cell activation, spontaneous T cell activation, and disruption of normal FAS-induced apoptosis.[31]

In humans, genetic factors are clearly important, with relatives of patients with SLE having a 30-fold increased risk of developing lupus. Nonetheless, concordance between identical twins is only about 25%, and environmental triggers (particularly viruses such as Epstein-Barr virus and certain medications), hormonal factors (with women of childbearing age having a 9-fold increased risk of developing SLE) and epigenetic changes (such as DNA methylation) all play important roles in the development of SLE. Overall, environmental and developmental factors appear to be central to the development of SLE, as only 10% of SLE cases occur before adulthood.

SLE is not a common disease. Estimates from several different series suggest that the annual incidence is approximately 0.36 cases per 100,000 children under the age of 16 years. More cases occur in African-American and Asian populations, but development under the age of 6 years is extremely rare in all ethnic groups. The female-to-male ratio among children is about 5:1, and it gradually increases after puberty.[32] Interestingly, this gender bias affects primarily mild cases of lupus; the likelihood of developing severe SLE is much more closely matched in boys and girls.

Diagnosis

Diagnosis of SLE is usually based upon demonstrating at least four of 11 criteria as developed by the American College of Rheumatology (Box 12-3). In fact, technically these are classification criteria, validated in adults and intended to ensure homogeneous populations for clinical trials. Nonetheless, they provide a useful basis for evaluating the possibility of lupus, as well as guidance for more definitive exclusion of other conditions.

Musculoskeletal symptoms are the most common manifestation of SLE. Painful but nonerosive arthritis, typically involving the small joints of the hands, develops at presentation or during the disease course in more than 90% of patients.[33] Three different types of rashes are characteristic of SLE and are included in the ACR classification criteria. A malar rash across the cheeks and over the bridge of the nose (thought to be reminiscent of a wolf bite and thus giving rise to the name 'lupus') is present in up to 50% of patients. The rash is more violaceous or bright pink than other erythematous facial rashes, and it is also marked by scaling and follicular plugging. The rash worsens and may blister with sun exposure, as do other photosensitive eruptions associated with SLE (Figure 12-4). Additionally, sunlight may trigger a systemic flare of SLE by damaging cutaneous tissue and releasing nuclear antigens, which are targeted by autoantibodies to form immune complexes. Thus, all children with lupus should protect their skin from ultraviolet exposure. The final rash characteristic of SLE, discoid lesions, may lead to significant scarring and altered pigmentation. It is one of the few rashes that typically affects the auricles of the ears, but it is far less common in children than in adults with lupus.

Involvement of the kidneys and the central nervous system are the most morbid manifestation of lupus, and the extent and severity of lupus nephritis and neuropsychiatric lupus largely determine the patient's prognosis. Initially, lupus nephritis may be asymptomatic or cause only mild nocturia due to tubular involvement affecting urinary concentration. Microscopic hematuria, proteinuria and cellular casts are indications of glomerular involvement. Hypertension is generally indicative of more severe renal involvement, and high blood pressure synergistically accelerates renal injury due to glomerulonephritis. Thus, it is important that this be carefully controlled, especially when corticosteroids are being used to treat systemic manifestations of SLE.

BOX 12-3 AMERICAN COLLEGE OF RHEUMATOLOGY 1997 CRITERIA FOR SYSTEMIC LUPUS ERYTHEMATOSUS

- Malar (butterfly) rash
- Discoid-lupus rash
- Photosensitivity
- Oral or nasal mucocutaneous ulceration
- Nonerosive arthritis
- Nephritis
  - Proteinuria 0.5 g/day
  - Cellular casts
- Encephalopathy
  - Seizures
  - Psychosis
- Pleuritis or pericarditis
- Cytopenias
- Positive immunoserology
  - Antibodies to dsDNA
  - Antibodies to Smith nuclear antigen
  - Positive tests for antiphospholipid antibodies (lupus anticoagulant or anticardiolipin antibodies)
- Positive antinuclear antibody

From Hochberg MC. Arthritis Rheum 1997;40:1725.

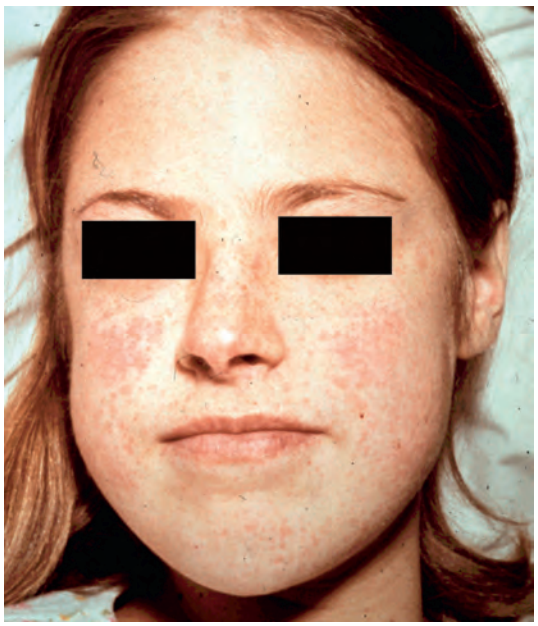

Figure 12-4 Rash in systemic lupus erythematosus.

https://CafePezeshki.IR

Chest pain may suggest lung or heart involvement in SLE. It may be caused by pleuritis, in which case shortness of breath and pain upon inspiration are the most typical symptoms. Physical examination may reveal diminished breath sounds indicating a pleural effusion, which can be documented by a chest x-ray. Pulmonary hemorrhage, a rare but potentially lethal manifestation of SLE, should be suspected in patients with cough, hypoxia and a rapid fall in hemoglobin. Hemoptysis may not be present. Costochondritis may mimic pleuritic chest pain, but on physical examination it is distinguished by the presence of discrete tender areas at the costochondral junctions along the sternum.

Pericarditis is the most common cardiac manifestation of SLE. Patients complain of precordial chest pain that is worse when leaning forward or lying in the recumbent position. A chest x-ray may show cardiomegaly, and an echocardiogram can confirm the presence of pericardial fluid. Electrocardiograms may show diminished voltages, but in general this is a less sensitive means of diagnosing pericarditis. Rarely a noninfectious endocarditis (Libman-Sacks endocarditis) may cause inflammation of the leaflets of the cardiac valves. If not treated aggressively, it can lead to acute valvular rupture and heart failure.

Neuropsychiatric involvement in SLE is rarely a presenting symptom, though headaches occur in 80% of patients during the course of the disease. Seizures, strokes, chorea and neuropathies may be caused by direct CNS involvement, but they may also be a complication of sepsis, uremia, thrombosis or hypertension. Differentiating the potential causes of neurologic and psychiatric manifestations of SLE is often very difficult, despite MR and CT imaging, neuropsychiatric testing and laboratory analysis of cerebrospinal fluid.[34]

Gastrointestinal involvement in SLE is uncommon, though acute pancreatitis with severe left upper quadrant pain penetrating to the back can be an emergent situation. Liver involvement may produce mild elevation of hepatocellular enzymes but rarely causes symptoms. Patients with longstanding, poorly controlled SLE, particularly those with neurologic involvement, may develop gastrointestinal hemorrhage due to intestinal vasculitis. This requires urgent and expert management: gastritis and other causes of gastrointestinal hemorrhage must be rapidly excluded in order to improve upon the reported 50% mortality rate.

Constitutional symptoms, though not specific for lupus, may significantly compromise quality of life by causing fever, weight loss and fatigue. The organic fatigue of SLE tends to occur in the afternoon and evening, Somnolence is generally responsive to treatment with steroids, but it may recur as therapy is tapered despite use of steroid-sparing agents.

Laboratory Assessment

Laboratory abnormalities, particularly cytopenias, are typically a prominent component of SLE. Up to 20% of adults presenting with thrombocytopenia eventually develop SLE, and adolescents presenting with new-onset idiopathic thrombocytopenic purpura, or with two or more cell lines down (Evans syndrome) should be screened with at least an ANA. A CBC will frequently show anemia, leukopenia or thrombocytopenia. Anemia is Coombs' positive in 15% of patients but more commonly it is simply a manifestation of chronic disease. Leukopenia may affect overall white cell numbers, but it most often disproportionately affects lymphocyte counts. Thus, lymphopenia below 1,000/mm^3 is a particularly helpful marker of possible SLE because it is seen in only a handful of other conditions including viral syndromes, immunodeficiencies, sarcoidosis and hematologic malignancies.

The sedimentation rate is elevated in 90% of patients with SLE. Although this is not a specific finding, in SLE the elevated ESR is generally caused by polyclonal hypergammaglobulinemia rather than elevated acute-phase reactants. As such, it is not a useful marker of disease activity or intercurrent infection. Because the ANA test is positive in almost 100% of children with SLE, a negative ANA dramatically decreases concern for the diagnosis. In SLE the titer of ANA is usually high (>1:160), but it may be diffuse, speckled or nucleolar, and thus the reported fluorescent pattern is seldom helpful in pinpointing the diagnosis.

False-positive ANAs are seen in 2% to 5% of children at any time, and in more than 20% at some point during childhood.[35] These are typically of lower titer (<1:320) than are pathologic ANAs in rheumatologic disorders, and they are most commonly caused by viral syndromes. Other causes include a 'familial ANA', as is seen in 15% of first-degree relatives of a person with SLE or mixed connective tissue disease. Less than one third of such people subsequently develop a systemic rheumatologic disorder. Repeat testing of children with low-titer positive ANAs is generally not necessary unless the clinical course suggests that an autoimmune process may be evolving.

In patients with a high-titer positive ANA, an ANA profile may provide increased disease specificity. Table 12-1 lists the elements of the ANA profile and their disease associations. Only 60% of patients fulfilling the diagnostic criteria for SLE will have specific identifiable autoantibodies on the ANA profile. Anti-dsDNA antibodies are a marker for worsening renal and cutaneous involvement, while other antibodies do not necessarily correlate with disease course.

In patients with lupus nephritis, routine urinalysis is the most sensitive indicator of both disease activity and response to therapy. Hematuria is usually microscopic. Cellular casts are helpful but depend on the freshness of the specimen. Proteinuria can be quantitated and followed with a spot protein-to-creatinine ratio. Values less than 0.2 are normal, and values greater than 2.0 are indicative of nephrotic levels of proteinuria. Timed collections of urine to quantify proteinuria are both tedious and frequently inaccurate. Similarly, serum creatinine levels provide accurate information, but the glomerular filtration rate must be below 50% of normal before it is reflected in an elevated serum creatinine. In case of doubt, timed creatinine clearances can provide additional information.

TABLE 12-1 Antinuclear Antibody Profile

Test	Disease Association
Anti-DNA	Systemic lupus erythematosus (SLE) with nephritis
Anti-SM (Smith)	SLE
Anti-SSA/anti-SSB	SLE with photosensitivity Sjögren's syndrome Neonatal SLE
Antiribonuclear protein	SLE and mixed connective tissue disease
Anticentromere or anti-SCL70	Scleroderma

https://CafePezeshki.IR

The serum C3 level is useful both for supporting the diagnosis of SLE and monitoring disease activity, though hypocomplementemia is not a criterion for classification. Antiphospholipid antibodies, on the other hand, are included among the criteria for SLE, as are false-positive serologic tests for syphilis, which measure the same phenomenon. These antibodies are clinically significant as well, as they contribute to an increased risk of venous and arterial thromboses. In vitro, however, they lead to a prolonged partial tissue prothrombin time that does not correct when samples are mixed with fresh plasma.

Treatment

Essentially all patients with SLE should be treated with an antimalarial agent, which is beneficial for cutaneous manifestations, joint symptoms and fatigue. More importantly, however, hydroxychloroquine and quinacrine decrease autoantigen presentation and serve to greatly increase the duration and resilience of disease remissions.[36] A prolonged trial, up to 6 months or more, may be required before the benefits of hydroxychloroquine are recognized. Hydroxychloroquine should be used at a dose of <7 mg/kg/day; above this level there is an increased risk of potentially irreversible retinal toxicity. Additional potential side-effects include nausea, abdominal pain, reversible palsy of ocular muscles and persistent skin graying (especially in sun-exposed areas). Quinacrine is used less commonly, primarily because it often causes yellowing of the skin. It is a useful alternative in patients who develop ocular toxicity from hydroxychloroquine, though it is not available in North America.

More severe manifestations of SLE, particularly nephritis and cerebritis, are generally treated with corticosteroids and immunosuppression.[37] For seriously ill children, more rapid control of symptoms can be achieved with intravenous methylprednisolone (30 mg/kg with a maximum dose of 1,000 mg) given once a day for 3 days. This is transitioned to high-dose prednisone, 2 mg/kg/day, divided once or twice daily.

While other agents do not provide the short-term efficacy and safety of steroids, reduction or discontinuation of steroids is essential to avoid serious side-effects during long-term treatment. A variety of agents, including azathioprine (AZA, Imuran®), mycophenolate mofetil (MMF, CellCept®) and cyclophosphamide (CTX, Cytoxan®), are effective steroid-sparing agents. Choice among these depends upon the extent of extrarenal involvement (for which MMF appears to be less effective) and severity (both the intensity of immunosuppression and the potential toxicity of CTX are generally greater than with the other agents). As in malignant conditions, a more potent medication may be used for 3 to 6 months to induce remission, and then be replaced by a safer agent for maintenance therapy. Azathioprine is most often the initial immunosuppressant at a dose of 2 to 3 mg/kg/day. Side-effects include bone marrow suppression, opportunistic infections, nausea and liver function abnormalities. MMF inhibits the enzyme inosine monophosphate dehydrogenase, leading to reduced synthesis of guanosine nucleosides. The dose is 600 to 800 mg/m^2 with a maximum of 1 to 1.5 g twice a day. Side-effects include bone marrow suppression, opportunistic infections and diarrhea. Methotrexate administered once a week may be beneficial for the arthritic manifestations of SLE, but it is seldom effective for treating major organ involvement such as kidney disease. Patients who fail management with azathioprine or MMF are candidates for treatment with cyclophosphamide, generally given as a monthly or biweekly intravenous pulse.

With control of symptoms and improvement in laboratory results (i.e. normal lymphocyte count, improved C3 levels and clearing of urinary sediment), the dose of prednisone is reduced and condensed to a single daily dose. The legion of steroid side-effects mandates a dose reduction to the lowest level that will keep the patient well. This is particularly important in children, who are prone to growth suppression and osteopenia with even very low steroid doses. In any case, ongoing treatment with an agent capable of maintaining remission is essential if toxic doses of steroids are to be avoided.

Many biologic agents are currently under study to modify aspects of the immune response in patients with SLE. Rituximab, a monoclonal antibody that depletes B lymphocytes, did not meet its endpoints in a pivotal trial for use in lupus nephritis despite initial optimism in patients with autoantibody-mediated diseases.[38] A newer nondepleting anti-B cell molecule, belimumab, did receive approval in 2013 as the first agent approved by the US Food and Drug Administration for treatment of SLE in 56 years.[39] It is an antibody targeting B cell activating factor (BAFF), also known as B lymphocyte stimulator (BLyS), a cytokine central to B cell survival, immunoglobulin class switching, and germinal center formation). A variety of novel treatments for SLE are in the pipeline.[40]

Prognosis

SLE often fluctuates in severity. The first year after diagnosis is typically the most difficult as evolving organ system involvement necessitates close monitoring and frequent medication adjustments. By the end of the second year, most patients will have defined individual disease manifestations and organ system involvement. For instance, new onset of renal disease or central nervous system disease is unusual after the first 2 years.

The prognosis for survival with SLE has improved markedly since the 1980s. Most series have shown a 10-year survival of 85% to 90%. Over this same interval, the causes of death in SLE patients have changed. End-stage renal disease was previously the major cause of death, but renal deaths are now rare with modern management including dialysis and kidney transplant. Serious systemic infections now account for most of the mortality in lupus. These infections result both from immune dysregulation resulting from the underlying disease and from immunosuppressive effects of medications necessary for disease control. In order to ameliorate these risks, immunization against pneumococcus and meningococcus is indicated in all patients. Additionally, pneumocystis prophylaxis should be considered in patients on high-dose steroid and immunosuppressant therapy. A second peak in mortality, typically beginning in the fourth decade of life, is caused by accelerated arteriosclerosis resulting from dyslipoproteinemia over decades of illness.

JUVENILE DERMATOMYOSITIS

Juvenile dermatomyositis (JDMS) is a rare idiopathic disease of childhood characterized by a pathognomonic rash and proximal muscle weakness.[41] It is distinguished from adult dermatomyositis by the absence of an association with malignancies, a unique vascular pathology and a more consistent response to therapy. The disease has a worldwide incidence of approximately 0.4 cases per 100,000 children under the age of 16 years; girls are more often affected than boys. The rash frequently begins before the child becomes noticeably weak.

https://CafePezeshki.IR

Diagnosis

Muscle disease in JDMS most often presents as the subacute onset of proximal muscle weakness. Neck, pelvis and core muscles are most affected. Children may first note decreased stamina when playing sports or walking in a mall. This progresses to increasing difficulty climbing stairs or rising from a chair. Shoulder girdle manifestations may include difficulty combing one's hair or reaching for items over the head. Untreated, the weakness tends to progress until children have difficulty getting off the floor or stabilizing their head while riding in a car. The weakness is usually out of proportion to soreness or tenderness of affected muscles. The distal muscles of the hands and feet are spared until very late in the course of the disease. Deep tendon reflexes and other aspects of the neurologic examination are typically normal until weakness is so severe that reflexes are difficult to elicit.

The rash in JDMS reflects the microangiopathy that mediates the disease. It is photosensitive, slightly pink or violaceous, and most commonly affects the extensor surfaces of the hands, elbows and knees. Many patients also develop a purplish discoloration of the upper eyelids known as a 'heliotrope' rash (named after the purple flower). Another characteristic cutaneous manifestation is a scaling, erythematous eruption of the knuckles known as Gottron's papules (Figure 12-5). The vascular nature of the condition is reflected in abnormalities of the nail bed capillaries, reflective of small vessel angiopathy seen only in SLE, scleroderma, dermatomyositis and mixed connective tissue disease.

In severe or poorly controlled cases of JDMS, patients may develop involvement of the muscles and vessels of the digestive tract. This is manifested as dysphagia (difficulty swallowing), dysphonia (a nasal quality to the voice) and dysmotility, leading to malabsorption, abdominal pain and diarrhea. Patients are at risk for aspiration and visceral perforation, and they require aggressive treatment to avoid severe sequelae. Children with persistent active muscle inflammation due to JDMS are also at risk of developing calcinosis. It may be limited to small, localized deposits or lead to extensive, debilitating subcutaneous calcifications involving much of the body. This is prevented by early, aggressive therapy to control the myositis;[42] calcinosis is very difficult to treat once established.

The cause of JDMS is unknown. Familial cases are rare, but some genes are over-represented among patients with inflammatory myopathies, especially certain HLA haplotypes.[43] The diagnosis is established using modified Bohan and Peter's criteria including demonstration of proximal muscle weakness, myositis and a characteristic rash.[44] Originally, these requirements were fulfilled by documenting elevated muscle enzymes, an abnormal electromyogram and, at times, a distinctive muscle biopsy. In children with characteristic cutaneous findings, evidence of muscle inflammation on MRI as well as elevation of muscle enzymes (CK, AST, ALT, LDH and/or aldolase) is now generally sufficient for a presumptive diagnosis of JDMS. In addition, the microangiopathic findings may be reflected in elevated levels of the von Willebrand factor antigen. Autoantibodies are often present, including a positive ANA in at least 10% of cases, myositis-specific antibodies in up to 63% of children, and myositis-associated antibodies in 10% of cases.[45] These markers may allow classification of children with inflammatory myopathies into groups more likely to respond to specific therapeutic agents.

Figure 12-5 Rash in juvenile dermatomyositis.

Differential Diagnosis

The differential diagnosis of JDMS includes other rheumatic diseases such as SLE and mixed connective tissue disease as well as polyarteritis nodosa, which may preferentially affect muscles early in the disease course. Muscle enzymes may be as high during the acute phase of viral myositis as in JDMS, but generally such infections cause more muscle pain. Neuropathic causes of weakness generally have more prominent distal involvement, while muscular dystrophies do not manifest the rash or angiopathy of JDMS.

Therapy

Early case series of JDMS were marked by mortality rates as high as 35%, generally due to gastrointestinal catastrophes, aspiration, respiratory failure or arrhythmias (due to involvement of the cardiac conducting system). With the introduction of pulsed-dose steroids for rapid control of muscle inflammation, followed by early substitution of steroid-sparing agents to minimize steroid side-effects, cures are now reported in up to 90% of children. Case reports document efficacy of a wide variety of immunosuppressive therapy in at least some cases, though most centers preferentially use methotrexate, calcineurin inhibitors (cyclosporine, tacrolimus) and/or IVIG. It is essential to control myositis fully to prevent development of calcinosis, so muscle enzymes and, if necessary, MRI changes in the proximal leg muscles are followed closely to detect residual muscle inflammation.

Skin involvement often is not synchronous with myositis, and agents effective in controlling muscle involvement are not necessary beneficial for the rash of JDMS. Hydroxychloroquine and topical tacrolimus are helpful, and in resistant cases IVIG or rituximab may be useful. Sunscreens are useful for minimizing photodamage, which can lead to chronic skin changes including thinning and dyspigmentation. Physical therapy is necessary to avoid or reverse contractures, but strengthening exercises should be avoided as long as muscle inflammation persists as they may exacerbate the myositis. Once all signs of active inflammation are controlled, resistive exercises are preferred to aid in muscle strength recovery.

Conclusions

This is a particularly exciting time to take care of children with inflammatory conditions. The rheumatologic illnesses

https://CafePezeshki.IR

account for a major proportion of chronic diseases of childhood, but for the first time, it is often possible to suppress symptoms safely and allow children to enjoy normal growth and development into adulthood. Further, the expectation is that within the not-too-distant future, everything from juvenile arthritis to systemic lupus erythematosus will be curable. As the genetic, environmental and epigenetic factors affecting inflammatory disorders are further elucidated, we may soon look back on rheumatology clinics much as we view sanatoriums and leper colonies.

Congenital Immune Dysregulation Disorders

THOMAS A. FLEISHER | JOAO BOSCO OLIVEIRA | TROY R. TORGERSON

KEY POINTS

- Monogenic defects have been identified that interfere with self tolerance.
- Human defects of self tolerance can affect both central and peripheral tolerance.
- Linking specific genetic defects to resulting autoimmunity patterns reveals specific self tolerance pathways.
- Additional genetic/environmental factors appear to impact monogenic autoimmune processes.
- It is likely that additional genetic defects resulting in autoimmunity will be identified.

Down-regulation of the immune response has become a subject of increased focus with this area of investigation complementing extensive work done to characterize the differentiation and activation of immune cells. Recently described prototypic human disorders that affect various immunoregulatory pathways have provided important insights into mechanisms required for tolerance and the control of immune responses. In this chapter we will discuss congenital disorders that impact central deletion of autoreactive T cells in the thymus as well as those that impact other mechanisms involved in the maintenance of tolerance in the periphery. In all of these disorders the clinical phenotype includes autoimmunity together with other manifestations.

Autoimmune Polyendocrinopathy, Candidiasis, Ectodermal Dystrophy (APECED)

APECED (OMIM #240300) is the prototypic disorder of defective central immune tolerance. It is an autosomal recessive disorder characterized by systemic autoimmunity that primarily affects endocrine organs, particularly the parathyroid and adrenal glands.[1,2] Hypoparathyroidism, adrenal insufficiency and chronic mucocutaneous candidiasis typically characterize the syndrome but patients may also have type 1 diabetes, gonadal failure, pernicious anemia, autoimmune hepatitis and cutaneous manifestations (Box 13-1).[1,2]

GENETICS AND IMMUNOPATHOGENESIS

APECED is caused by mutations in the gene encoding the autoimmune regulator (AIRE), a transcription factor that plays a role in ectopic expression of tissue-specific antigens by thymic medullary epithelial cells (mTEC). In mice, AIRE-mediated self-antigen expression in the thymus has been shown to play a significant role in negative selection of autoreactive T cell clones.[3,4] The mechanism by which AIRE causes expression of tissue-specific gene products may be by regulating large-scale access to chromatin.

Because naturally arising T regulatory (T_{REG}) cells are also thymically derived, AIRE may also play a role in generation of T_{REG} cells. This is supported by a transgenic mouse model with a monospecific T cell receptor: autoimmunity seen in *Aire*$^{-/-}$ mice results from a combination of defective negative selection and defective generation of antigen-specific T_{REG} cells.[5] The role of AIRE in generation and function of T_{REG} cells has also been investigated in APECED where a decreased percentage of $CD4^+CD25^{high}$ T cells was found. In addition, $CD4^+CD25^{high}$ T cells expressed less FOXP3 than control cells.[6] Furthermore, isolated T_{REG} cells from APECED patients had a decreased ability to suppress proliferation of effector T cells in vitro.[6] These data suggest that AIRE plays a significant role in the generation of functional T_{REG} cells in humans.

In addition to the recognized effector and regulatory T cell abnormalities observed in APECED, patients have a propensity to develop a broad range of pathogenic, tissue-specific autoantibodies including those directed at the parathyroids, adrenals, ovaries, lungs, gut and others.[7–9] In addition, neutralizing autoantibodies against type I interferons (α and ω), interleukin-17 (IL-17), and interleukin-22 (IL-22) have been identified in many APECED patients and are associated with chronic mucocutaneous candidiasis.[10–12]

DIAGNOSIS AND TREATMENT

APECED is typically suspected in patients who have two of the three basic symptoms: hypoparathyroidism (usually manifested by hypocalcemia), adrenal insufficiency and mucocutaneous candidiasis. Suspicion is raised further by the presence of other autoimmune manifestations and a definitive diagnosis can be made by sequencing of the *AIRE* gene.

Despite the impressive autoimmune phenotype, most of the therapy for APECED has focused on symptomatic treatment including calcium supplementation, steroid replacement and the management of diabetes and other endocrinopathies. Particularly problematic is the mucocutaneous candidiasis, which causes significant morbidity and increases the risk of oral malignancies. In many patients, the candidal species develop reduced sensitivity to azole antifungals over time.[13]

Immunosuppressants are not routinely used in APECED unless patients develop autoimmune hepatitis or renal disease, in which azathioprine and cyclosporin A (cyclosporine) have shown benefit.[2] Recent studies in *Aire*$^{-/-}$ mice have

BOX 13-1 KEY CONCEPTS

IMMUNOPATHOGENESIS OF APECED SYNDROME

- Endocrinopathy: hypocalcemia and adrenal insufficiency caused by autoimmunity to parathyroids and adrenals
- Chronic mucocutaneous candidiasis (CMC): caused by neutralizing autoantibodies to IL-17, IL-22 and other cytokines
- Autoimmunity: thymic selection defect prevents appropriate elimination of autoreactive T cells and generation of regulatory T cells

BOX 13-2 KEY CONCEPTS

IMMUNOPATHOGENESIS OF IPEX SYNDROME

- Enteropathy: severe watery diarrhea caused by autoimmune enteropathy
- Endocrinopathy: type I diabetes and thyroiditis caused by autoimmunity to pancreas and thyroid
- Autoimmunity: absence of functional regulatory T cells

demonstrated a significant role for B cells and autoantibodies in pathogenesis, and one recent case report demonstrated efficacy of B cell depletion therapy in an APECED patient with autoimmune lung disease.[14,15]

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked (IPEX)

IPEX syndrome (OMIM #304930) is the prototype of defective peripheral immune tolerance. The basic clinical triad of IPEX includes autoimmune enteropathy, early onset endocrinopathy and dermatitis (Box 13-2).[16–18] The enteropathy typically presents early in life as watery diarrhea, frequently resulting in malnutrition and failure to thrive. Type 1 diabetes is the most common endocrinopathy but clinical and/or laboratory evidence of thyroiditis is also common. Eczema is the most common dermatitis in IPEX but erythroderma, psoriasiform dermatitis and pemphigus nodularis have also been observed.[19–21]

In addition to the 'IPEX triad', most patients with IPEX also have other associated autoimmune disorders including autoimmune cytopenias, nephropathy or hepatic disease (Torgerson & Ochs, unpublished data). These conditions contribute substantially to the morbidity of patients with IPEX and increase the risk of death from disease. Patients with the classical form of the disease typically die secondary to malnutrition, electrolyte imbalance or infection before the age of 2 if not treated with aggressive immunosuppression.[21]

GENETICS AND IMMUNOPATHOGENESIS

IPEX is caused by mutations in the forkhead DNA-binding protein FOXP3, which is expressed by $CD4^+CD25^{high}$ regulatory T cells and is required for T_{REG} cells to develop suppressor function.[22–26] This has been shown most elegantly in two separate knock-in mouse models with $CD4^+$ T cells unable to express functional Foxp3. Despite this, the cells still acquired the expected cell surface phenotype of a T_{REG} ($CD25^{high}CTLA\text{-}4^{high}GITR^{high}$) but had no suppressive function and developed a gene expression profile suggestive of an effector/cytotoxic T cell resulting in systemic autoimmunity similar to *Foxp3*$^{-/-}$mice.[26]

Under quiescent conditions, FOXP3 expression is restricted primarily to T_{REG} cells, however it can also be inducibly expressed in a large percentage of human T cells upon activation.[27–30] Originally shown to be a transcriptional repressor acting on key cytokine genes,[31–33] recent genome-wide screening approaches suggest that FOXP3 functions more commonly as a transcriptional enhancer.[34,35]

Most pathologic mutations in FOXP3 cluster in three important functional domains of the protein: the C-terminal forkhead DNA-binding domain, the leucine zipper and the N-terminal repression domain.[36] Recent studies suggest that FOXP3 physically and functionally interacts with other transcription factors including NFAT, NF-κB, AML-1/RUNX1 and the retinoic acid receptor related orphan receptors RORα and RORγt to modulate gene transcription at key cytokine promoters.[31,32,37]

DIAGNOSIS AND TREATMENT

IPEX is generally suspected in any patient who demonstrates at least two of the three basic clinical features of IPEX including enteropathy, endocrinopathy (type 1 diabetes mellitus or thyroiditis) and dermatitis. Flow cytometry using intracellular staining for FOXP3 protein to identify $FOXP3^+$ T_{REG} cells is a valuable tool to rapidly screen for the absence of T_{REG}. Approximately 5–7% of the $CD4^+$ T cell population is positive for FOXP3 expression in healthy controls and a marked decrease suggests a diagnosis of IPEX that may be confirmed by sequencing of the *FOXP3* gene (Figure 13-1). Definitive diagnosis involves identification of a mutation in *FOXP3* (Torgerson, unpublished data).

From a clinical laboratory standpoint, the most consistent abnormality among IPEX patients is markedly elevated IgE while IgA is also modestly elevated in more than 50% of patients (Torgerson, unpublished data). There are no consistent abnormalities in absolute lymphocyte numbers and T cells usually proliferate normally in vitro.

Adoptive transfer studies in mice have demonstrated that the $CD4^+$ T cells from an affected *Foxp3*$^{-/-}$ male are capable of recapitulating the disease phenotype in a lymphopenic recipient.[38] Treatment of IPEX has therefore focused primarily on suppression of unregulated, auto-aggressive T cells using cyclosporin A, tacrolimus (FK506) or sirolimus (rapamycin).[15,16,39,40] These are often combined with steroids and/or other immunomodulatory agents including methotrexate or azathioprine.[40,41] In cases where there is evidence for pathogenic autoantibodies, rituximab (anti-CD20) has proven effective.[19] Immunosuppression is often effective initially and there is one report of a patient with IPEX being maintained for a prolonged period; however, most patients ultimately fail therapy.[42] Currently, bone marrow transplantation holds the only hope for a long-term cure[43–45] and reduced intensity regimens seem to be associated with better survival.[44,45] Rapid diagnosis and transplantation early in the course of disease, before the pancreatic islet cells are destroyed, should be the goal.

STAT1 Gain of Function (STAT1-GOF) Mutations

The signal transducer and activator of transcription (STAT) family of DNA-binding proteins are critical mediators of cytokine and growth factor signaling in cells. STAT1 is the primary

https://CafePezeshki.IR

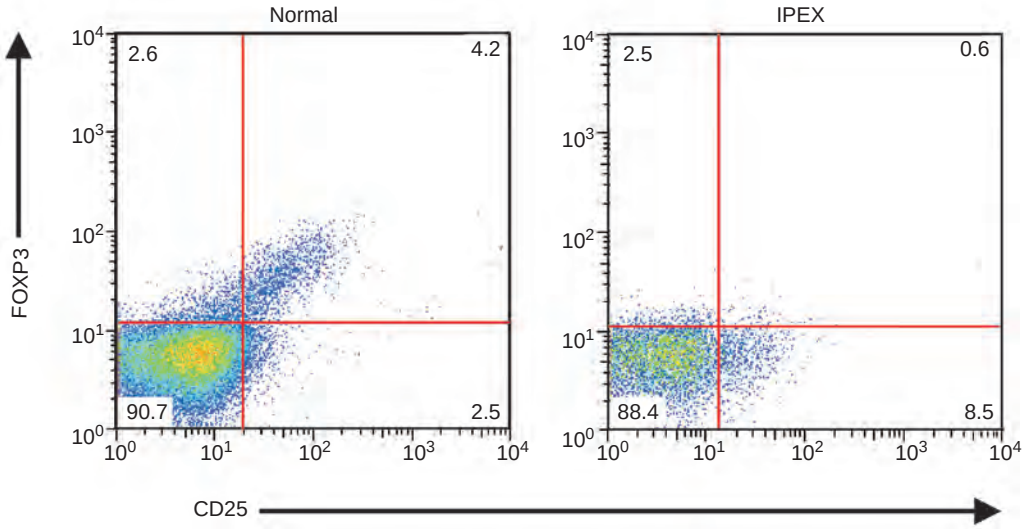

Figure 13-1 Absence of FOXP3⁺ regulatory T cells in IPEX. Peripheral blood mononuclear cells (PBMCs) from a normal individual and a patient with IPEX were fixed, permeabilized and stained for the presence of CD4, CD25 and FOXP3. After gating on the CD4⁺ T cell population, two-dimensional analysis demonstrates the absence of CD25⁺ FOXP3⁺ regulatory T cells in the PBMCs of a patient with IPEX syndrome due to a mutation in the polyadenylation site of the *FOXP3* gene.

transcription factor activated by interferons so it plays a major role in normal immune responses, particularly to viral, mycobacterial and fungal pathogens. Recently described autosomal dominant mutations that lead to a gain of STAT1 function (STAT1-GOF; OMIM #614162) typically present with CMC but may also have disseminated infections with dimorphic yeast or mycobacteria and variable forms of autoimmunity.[46,47] Recently, STAT1-GOF mutations were identified in a cohort of patients with IPEX-like autoimmunity (severe early-onset enteropathy, dermatitis, thyroiditis and type 1 diabetes).[48] All but one of the identified patients also had a history of CMC, although in some cases the CMC was mild or only occurred after treatment with antibiotics.

In addition to IPEX-like autoimmunity and CMC, patients had recurrent respiratory infections and bronchiectasis, herpesviral infections (HSV and VZV), short stature with growth-hormone insufficiency, and arterial aneurysms (cardiac and CNS) (Box 13-3).[48] Unlike IPEX, patients with STAT1-GOF mutations had more evidence of humoral immune dysfunction including poor vaccine responses, with more than half of the patients requiring treatment with immunoglobulin replacement therapy, and normal (or mildly elevated) serum IgE levels.

GENETICS AND IMMUNOPATHOGENESIS

Inheritance is autosomal dominant, caused by heterozygous missense mutations in the *STAT1* gene. All of the identified mutations that cause a gain of STAT1 function lie within the coiled-coil or DNA-binding domains of the STAT1 protein and many are associated with increased phosphorylation and delayed dephosphorylation of STAT1.[47] In most patients, the percentage of IL-17 secreting Th17 cells in the CD4⁺ T cell population is markedly reduced but not absent, likely contributing to the susceptibility to CMC. The mechanism of susceptibility to autoimmunity in this disorder is, however, less clear. Regulatory T cells are present in normal to near-normal numbers and appear to have normal function based on a limited number of evaluated patients.[48]

BOX 13-3 KEY CONCEPTS

IMMUNOPATHOGENESIS OF STAT1 GAIN-OF-FUNCTION SYNDROME

- Chronic mucocutaneous candidiasis (CMC): abnormal generation of functional Th17 cells
- Immunodeficiency: some patients make insufficient antibody responses to vaccination
- Autoimmunity: IPEX-like enteropathy and endocrinopathies, may be related to hyperactivation of STAT1 in response to interferons

DIAGNOSIS AND TREATMENT

Hyperphosphorylation and delayed dephosphorylation of the critical tyrosine residue at position 701 (pY701) has been observed in cytokine-stimulated cells from many patients with STAT1-GOF mutations and can be measured by flow cytometry.[47] Unfortunately, the utility of this assay as a screening test to identify patients with STAT1-GOF mutations is not yet clear, as it is not known whether the phosphorylation defect is consistent. As a result, sequencing of the *STAT1* gene remains the gold standard for diagnosis.

Treatment of CMC in this disorder typically requires chronic or intermittent antifungal therapy, with mixed success. Treatment of the IPEX-like autoimmunity requires aggressive immunosuppression although there has not been a regimen or class of agents that has shown consistent efficacy. Steroids, B cell depletion therapy, and T cell directed immunosuppression (tacrolimus, cyclosporine, etc.) have all been utilized with varying results. Bone marrow transplantation (BMT) using a matched sibling donor and a reduced intensity conditioning regimen has been reported in one Peruvian patient, with transient clinical improvement, but the patient ultimately died of a

https://CafePezeshki.IR

presumed respiratory infection following graft rejection.[49] At least three other patients with STAT1-GOF mutations have undergone successful BMT but are not yet reported suggesting BMT may be a viable approach in patients with severe disease.

Defects in IL-2 Signaling

Since the realization that mice lacking CD25 (the α-chain of the IL-2 receptor) have a phenotype similar to *Foxp3*$^{-/-}$ mice, there has been a suspicion that defects that blunt IL-2 signaling in T cells might lead to an IPEX-like presentation in humans (Figure 13-2).

CD25 DEFICIENCY

Three unrelated patients with CD25 deficiency (OMIM #606367) have now been described. Similar to IPEX, all three patients developed severe, chronic diarrhea and villous atrophy in infancy (1 month, 6 weeks and 8 months of age).[50–52] Two of the patients developed endocrinopathies including early-onset type 1 diabetes and thyroiditis and two developed significant skin disease including eczema, pemphigus nodularis and psoriasiform dermatitis.[50–52] All three patients developed autoantibodies, hepatosplenomegaly, lymphadenopathy and lymphocytic infiltrates in various organs indicative of ongoing immune dysregulation.[50–54] Unlike IPEX patients, serum IgE levels were either mildly elevated or normal.[51,52]

In addition to autoimmune features, all three CD25-deficient patients had infectious complications suggestive of a more extensive defect in cellular immunity (Box 13-4). Early-onset, recurrent CMV infections occurred in all patients although persistent thrush, candidal esophagitis, chronic gastroenteritis, *Pseudomonas*, staphylococcal and EBV infections were also seen.[50–53] One patient even failed to reject an allogeneic skin graft.[55]

Genetics and Immunopathogenesis

Inheritance is autosomal recessive leading to a complete lack of CD25 protein expression on activated T cells. Mutations included a homozygous four base pair deletion in the coding region of *CD25*, a homozygous mutation resulting in a single amino-acid substitution (p.S166N) and a compound heterozygous mutation.[50–54]

Recent studies in *Cd25*$^{-/-}$ mice have demonstrated that T_{REG} cell development is normal. These cells have normal suppressive function in vitro but survival, maintenance and competitive fitness of the mature T_{REG} cells is abnormal resulting in immune dysregulation.[55–57] Future efforts to assess T_{REG} cells in CD25-deficient patients should help to determine whether a similar mechanism is at play in humans.

Diagnosis and Treatment

All patients described to date lacked CD25 expression on T cells, suggesting that flow cytometry is an effective screening tool. Sequencing of the *CD25* gene is, however, recommended to confirm the diagnosis.

Because of the 'SCID-like' features of this syndrome, one patient underwent a successful bone marrow transplant from a matched sibling donor and has done well.[53,54] It is possible, however, that patients may respond to IL-2 therapy via the remaining low-affinity IL-2 receptor since the T cell proliferative defect was corrected in one patient ex vivo with high dose IL-2 or IL-15.

STAT5B DEFICIENCY

Deficiency of the STAT5B transcription factor (OMIM #245590) causes a rare autosomal recessive disorder reported in only a handful of patients.[58–60] STAT5B mediates signaling from the human growth factor receptors such that clinical features include dwarfism, prominent forehead, saddle nose and

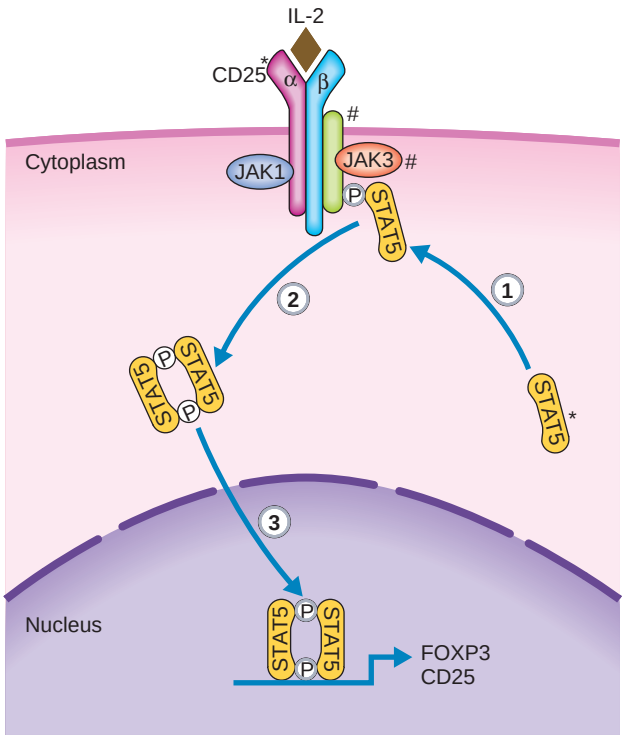

Figure 13-2 The role of CD25 and STAT5b in the IL-2 signaling pathway. The illustration demonstrates the relative positions of CD25 and STAT5 (marked by *) in the IL-2 signaling pathway. Binding of IL-2 to the IL-2 receptor (made up of an α-chain [CD25], a β-chain and a γ-chain [γc]) causes cross-phosphorylation of receptor chains on tyrosine by receptor-associated JAK1 and JAK3 kinases. Unphosphorylated STAT5 binds to phosphotyrosine residues on the activated receptor using its SH2 domain (1). STAT5 is then phosphorylated on tyrosine by the JAK kinases and released from the receptor where it dimerizes through binding of the SH2 domain on one subunit to the phosphotyrosine residue on the adjacent subunit and vice versa (2). Dimerized STAT5 accumulates in the nucleus where it directly binds to specific sites in the FOXP3 and CD25 promoters causing sustained expression of these two proteins in regulatory T cells (3). In contrast to deficiency in CD25 and STAT5b which causes an IPEX-like phenotype, mutations in the IL-2 receptor gamma chain or in JAK3 (both marked with #) cause a phenotype of severe combined immunodeficiency (SCID).

BOX 13-4 KEY CONCEPTS

IMMUNOPATHOGENESIS OF CD25 DEFICIENCY

- Autoimmunity: IPEX-like enteropathy and endocrinopathies, a result of regulatory T cell dysfunction
- Immunodeficiency: mild to moderate T cell lymphopenia and poor T cell proliferative responses in vitro associated with recurrent/chronic viral infections

https://CafePezeshki.IR

a high-pitched voice. Since STAT5B is also the primary transcription factor that mediates IL-2 stimulated gene transcription in T cells, most patients also have a marked immunodeficiency, with recurrent varicella virus, herpes virus and *Pneumocystis jiroveci* infections (Figure 13-2).[59–61]

In addition to immunodeficiency, most patients also have symptoms suggestive of immune dysregulation including chronic, early-onset diarrhea, eczema and lymphocytic interstitial pneumonitis (Box 13-5).[58–60] Mice lacking Stat5b have a significant reduction in the number of $Foxp3^+$ T_{REG} cells in thymus and spleen, resulting in splenomegaly and a marked increase of activated T cells in the periphery.[62–64]

Genetics and Immunopathogenesis

Two patients have been studied for the effect of STAT5B deficiency on T_{REG} cells. One had a homozygous missense mutation (A630P) and the second had a homozygous nonsense mutation (R152X). Both mutations resulted in markedly reduced or absent STAT5B expression.[63,65] These patients had significantly fewer $CD4^+CD25^{high}$ cells than normal controls, FOXP3 expression was decreased and the cells had no in vitro suppressive activity.[59,65] In addition, decreased CD25 expression (~20% of normal) was observed following T cell activation and is thought to synergize with the underlying STAT5B mutation to effectively abrogate IL-2 signals required for the maintenance of FOXP3 expression and T_{REG} function. Interestingly, signaling pathways required for IL-2 induced expression of other effector molecules, such as perforin, remained intact in STAT5B-deficient T cells.[65]

Diagnosis and Treatment

Diagnosis of STAT5B deficiency is suspected in patients with the overt physical features of dwarfism combined with a significant immunodeficiency. Patients typically have normal serum growth hormone levels but very low insulin-like growth factor 1 (IGF-1) levels.[63,64] Immunologically, patients generally have low NK cell numbers and modest T cell lymphopenia.[59,65] Sequencing of the *STAT5B* gene should be done to confirm the diagnosis.

Treatment of patients with STAT5B deficiency is generally focused on symptomatic therapy and prophylaxis against infections. There are no published reports of bone marrow transplantation (BMT) for STAT5B deficiency although murine studies demonstrate that BMT is curative in mice lacking Stat5a/5b. suggesting that this would correct the immune deficiency and dysregulation but not the growth abnormalities.[66]

BOX 13-5 KEY CONCEPTS

IMMUNOPATHOGENESIS OF STAT5B DEFICIENCY

- Growth abnormalities: dwarfism due to growth hormone insensitivity (growth hormone levels normal but insulin-like growth factor 1 levels very low)
- Autoimmunity: IPEX-like enteropathy plus other autoimmunity (particularly pulmonary) as a result of low regulatory T cell numbers
- Immunodeficiency: mild to moderate T and NK cell deficiency associated with recurrent/chronic viral and fungal infections

Autoimmune Lymphoproliferative Syndrome

Initial reports of patients presenting with lymphadenopathy and hepatosplenomegaly associated with autoimmune cytopenias and increased gammaglobulins were followed 25 years later by a report that identified similar patients also noted to have a marked increase in circulating α/β-$TCR^+CD3^+CD4^-CD8^-$ T cells. These α/β double negative T (DNT) cells normally constitute less than 1.5% of peripheral blood lymphocytes in adults (Figure 13-3).[67,68] The combination of findings led to the suggestion that this could represent the human equivalent to the *lpr* and *gld* murine models of autoimmunity.[68]

Following the discovery that mutations in the genes encoding FAS and FAS ligand caused disease in the murine autoimmunity models, two studies identified heterozygous *FAS* (*TNFRSF6*) mutations in these patients, yielding the term autoimmune lymphoproliferative syndrome (ALPS) to describe this disorder.[69,70] An increasing number of patients with mutations

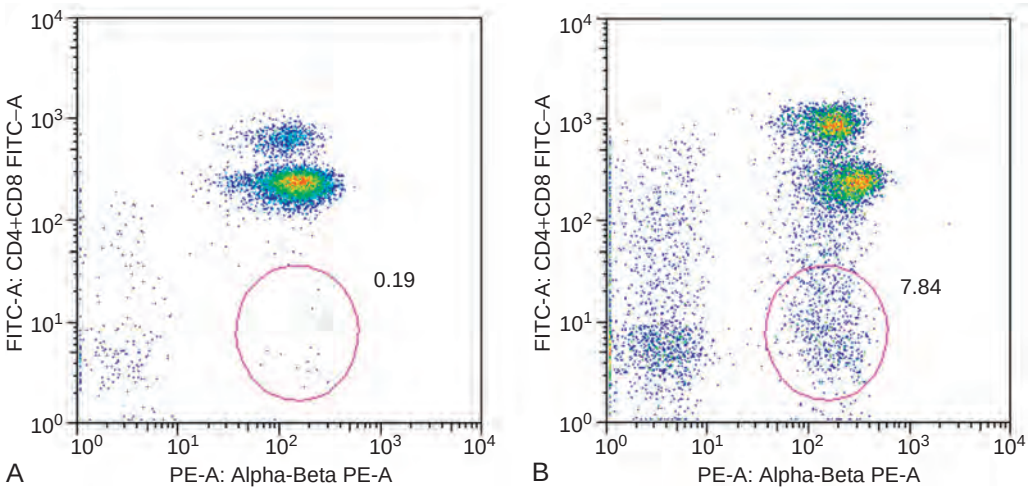

Figure 13-3 Double negative T cells in ALPS. Flow cytometric evaluation of peripheral blood from a control patient (**A**) and an ALPS patient (**B**) demonstrating the increase of mature lymphocytes expressing the T cell receptor $\alpha\beta$ (X axis), that lack CD4 and CD8 co-receptor expression (Y axis) in ALPS.

https://CafePezeshki.IR

in *FAS* have been identified, including some patients originally described by Canale and Smith.[71] However, patients with features of ALPS have been found without germline *FAS* mutations in whom defects in FAS ligand (FASLG) or the intracellular apoptotic protein, caspase 10 (CASP10), were identified.[72,73] Additionally, somatic mutations primarily in α/β DNT cells have been found in patients who presented with clinical ALPS without germline *FAS* mutations.[74,75] Additional patients who present with some ALPS features but additional distinctive features have been characterized with somatic defects in the *NRAS* and *KRAS* genes, a disorder associated with defective intrinsic, mitochondria-mediated lymphocyte apoptosis.[76,77] A small group of ALPS-like patients also have been identified with mutations in the gene encoding caspase 8 associated with features of immunodeficiency and now referred to as caspase eight deficiency state (CEDS).[78] Finally, there remain patients with an ALPS-like phenotype who have none of the defined genetic defects.

The typical clinical course in ALPS (OMIM #601859) begins within the first 5 years of life with nonmalignant, noninfectious peripheral lymphadenopathy.[79–81] This is often associated with splenomegaly and hypersplenism (Figure 13-4) that has been treated with splenectomy (no longer recommended due to the unusually high risk for *S. pneumoniae* related systemic infection).[81] Clinically apparent autoimmunity is seen in about 50% of the patients, most commonly presenting as Coombs positive autoimmune hemolytic anemia either alone or together with autoimmune thrombocytopenia. Some ALPS patients may also develop neutropenia that is either immunologically mediated or secondary to hypersplenism. Dermatologic findings seen in ALPS most commonly include urticarial rashes. Infrequent autoimmune disorders include glomerulonephritis, polyneuropathy, autoimmune hepatitis and Guillain-Barré syndrome. A life-threatening ALPS manifestation is the dramatically increased incidence of lymphoma with germline *FAS* mutations. The increased relative risk is 149 for Hodgkin's disease and 61 for non-Hodgkin's lymphomas (Box 13-6).[81]

The laboratory findings in ALPS are summarized in Box 13-7. Immunophenotyping reveals expansion of α/β DNT cells, often together with lymphocytosis. Other frequent abnormalities include an expansion of HLA-DR$^+$ and a decrease in the CD25$^+$ T cells plus very low numbers of CD20$^+$CD27$^+$ (memory) B cells.[82] A polyclonal increase in serum immunoglobulins is often observed, usually involving IgG and/or IgA. Autoantibodies directed against platelets and neutrophils not linked to the degree of cytopenias, as well as anti-phospholipid antibodies, are present in 70–80% of the patients.[83] IL-10 is markedly elevated in the serum of ALPS patients; that is at least in part from the α/β DNT cells and circulating monocytes.[84] More recently, elevated serum IL-18, soluble FASLG and vitamin B_{12} levels have been found. In the presence of elevated α/β DNT cells, these biomarkers strongly correlate with the presence of *FAS* mutations.[85,86] Histologically, the enlarged lymph nodes in ALPS show follicular hyperplasia and marked paracortical expansion with infiltrating α/β-DNT cells, immunoblasts and plasma cells.[87]

Figure 13-4 Lymphoid accumulation in ALPS. Positron emission tomography demonstrating increasing fluorodeoxyglucose uptake on cervical, axillary and inguinal lymph nodes as well as an enlarged spleen in ALPS.

BOX 13-6 KEY CONCEPTS

IMMUNOPATHOGENESIS OF AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

- Lymphadenopathy: persistence of lymphocytes that normally would die
- Autoimmunity: failure to eliminate autoreactive lymphocytes
- Lymphoma: inability to eliminate lymphocyte oncogenic mutations

BOX 13-7 LABORATORY FINDINGS IN AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

IMMUNOLOGIC

Lymphocytes
  Increase: α/β double negative T cells, CD8 T cells, B cells
  Decrease: CD4/CD25 T cells, CD27$^+$ B cells
Immunoglobulins: increased IgG, IgA, and IgE
Cytokines: increased levels of serum IL-10, IL-18
Increased soluble FAS ligand
Autoantibodies: directed at blood cells

HEMATOLOGIC

Lymphocytosis
Anemia
Thrombocytopenia
Neutropenia
Eosinophilia

CHEMISTRY

Increased vitamin B_{12} level

GENETICS AND IMMUNOPATHOGENESIS

The majority of ALPS patients have germline heterozygous *FAS* mutations with the majority affecting the intracellular domains of the gene (~73%) while a smaller number impact the transmembrane domains (~6%) and the extracellular domains (~21%).[79,81,88] The site of the mutation has a direct impact on the development of disease manifestation with mutations in the intracellular *FAS* domains correlating with higher penetrance and more severe clinical manifestations.[89] The intracellular mutations typically act in a dominant negative manner while extracellular mutations not affecting the pre-ligand assembly domain usually result in haploinsufficiency.[90,91]

Recently, somatic *FAS* mutations, detected primarily in α/β DNT cells, have been described in a number of patients with sporadic ALPS.[74,75] A minority of ALPS patients do not have germline or somatic *FAS* mutations. Evaluation of the gene encoding FASLG identified two patients with typical findings of ALPS associated with heterozygous mutations while homozygous *FASLG* mutations have been found in a limited number of patients with a severe ALPS phenotype.[76,92,93] Likewise, a small number of patients have been demonstrated to have a defect in the intracellular apoptotic protein, caspase 10 (Figure 13-5).[72] Recent work has identified somatic *NRAS* and *KRAS* mutations in patients with some ALPS features that are associated with an intrinsic pathway apoptotic abnormality. This group of patients is now classified separately as RAS-associated autoimmune leukoproliferative disease (RALD).[76,77,94] The current classification scheme for ALPS is:[94]

- ALPS-FAS: germline mutation in the gene encoding FAS *(TNFRSF6)*
- ALPS-sFAS: somatic mutation in the gene encoding FAS *(TNFRSF6)*
- ALPS-FASLG: mutation in the gene encoding FAS ligand *(TNFSF6)*
- ALPS-CASP: mutation in the gene encoding caspase 10 *(CASP10)*
- ALPS-U: unknown, no known mutation.

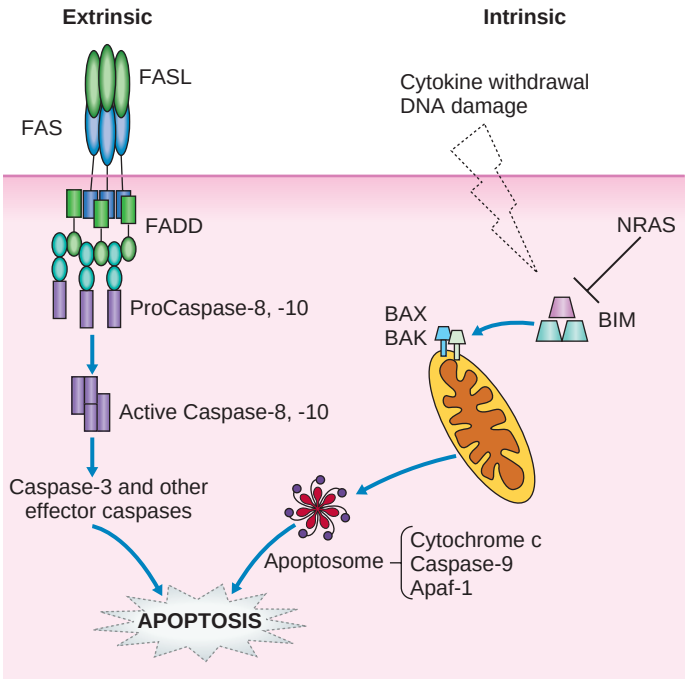

Figure 13-5 Lymphocyte apoptosis pathways. Lymphocytes have two main pathways of apoptosis, regulated either by surface receptors of the TNF superfamily (extrinsic pathway) or proteins of the BCL-2 family (intrinsic pathway). The majority of ALPS patients have a defect in the extrinsic pathway involving FAS but some ALPS patients also have been reported with a defect in the intrinsic pathway.

DIAGNOSIS AND TREATMENT

The initial presentation of lymphadenopathy often raises the issue of malignancy that generally requires a biopsy to differentiate. The initial findings can also be suggestive of a chronic viral infection such as Epstein-Barr virus (Box 13-8), although there is no evidence to support a role for EBV. The autoimmunity seen in ALPS patients is most commonly directed against erythrocytes and platelets. The laboratory findings associated with the autoimmunity do not distinguish ALPS patients from those who do not have this disorder.

The diagnostic triad for ALPS is nonmalignant, noninfectious lymphoaccumulation, defective in vitro FAS-mediated lymphocyte apoptosis, and increased levels of α/β DNT cells (Box 13-9). Flow cytometric evaluation of peripheral blood lymphocytes is necessary to evaluate for increased levels of α/β DNT cells (Box 13-7). The assessment of FAS-mediated lymphocyte apoptosis or identification of a *FAS* mutation (or other ALPS associated genetic defect) is required to establish this diagnosis. Mutation analysis should begin with *FAS* as the most common finding but if these studies are unrevealing, the next step when biomarkers are positive is purification of α/β DNT cells for *FAS* sequencing to exclude somatic mutations. If these studies also are negative, the genes encoding FASLG and caspase 10 should be sequenced. As previously noted, there remain patients who meet the criteria for diagnosis of ALPS without defined genetic abnormalities (ALPS-U).

The lymphoid expansion typically diminishes with age, thus therapy directed at this is generally not necessary. Splenomegaly is often associated with hypersplenism, but splenectomy should

be discouraged owing to the significant risk of infections post splenectomy.[81] The autoimmune cytopenias typically respond to corticosteroids, which also decrease lymphadenopathy (rapidly reappears after discontinuing therapy). Exacerbations are not uncommon in some patients who may become resistant to conventional therapy. Mycophenolate mofetil can be useful in thrombocytopenic patients unresponsive to conventional therapy[95,96] and rituximab has proven useful when mycophenolate mofetil is ineffective.[96] Finally, rapamycin has been used experimentally with improvement in lymphadenopathy as well as control of autoimmunity.[97] Importantly, the increased risk for the development of lymphoma appears to be lifelong and careful vigilance is required to monitor all individuals with germline *FAS* mutations.

RAS Associated Autoimmunity Lymphoproliferative Disorder

From a clinical standpoint, there exist a number of patients with some ALPS features but without defects in the FAS pathway. The genetic basis in some of these patients was established with the description of a patient whose disorder was caused by a somatic *NRAS* mutation.[76] The patient had persistent splenomegaly, minimally increased α/β DNTs, autoantibodies and a history of lymphoma. He also had unique features including a history of significant leukocytosis early in life, persistent monocytosis and lymph node histology without α/β DNT cell infiltration. Later, similar patients were found to have heterozygous mutations in *KRAS*.[77] The disease was named RAS associated autoimmune leukoproliferative disorder (RALD).[94]

The age at diagnosis can vary between 1 and 47 years of life. RALD presents with a generally mild degree of peripheral lymphadenopathy, significant splenomegaly and autoimmune cytopenias. In some patients, a history of recurrent mild upper and lower respiratory tract infections can be elicited.[76,77,98] Unlike ALPS, patients with RALD have transient or persistent elevation in granulocytes and monocytes. Some RALD patients have a clinical and laboratory phenotype early in life similar to juvenile myelomonocytic leukemia (JMML). However, unlike patients with JMML, the clinical course is chronic and benign. Immunophenotyping reveals mild to no elevation in α/β DNTs and an expansion of B cells with normal or modestly decreased total lymphocyte numbers. Autoantibodies are typically detected including anti-nuclear antibodies, rheumatoid factor, anti-phospholipid, anti-cardiolipin, anti-platelet, anti-neutrophil and/or anti-red cell antibodies.[76,77,98] ALPS biomarkers are normal, as is in vitro FAS-induced apoptosis. In contrast, RALD patients demonstrate ex vivo T cell resistance to IL-2 withdrawal-induced cell death, pointing to a fundamentally different apoptotic defect.[76,77] The histopathologic findings include nonspecific polyclonal plasmacytosis with reactive secondary follicles, but without the typical paracortical expansion with α/β DNT cells in ALPS. It is not known if these patients are at increased risk for hematological malignancy although there is one case report of a RALD patient developing juvenile myelomonocytic leukemia.[99]

All 12 patients with RALD in the NIH cohort harbor somatic, gain-of-function mutations in *KRAS* or *NRAS*, which are present only in blood cells. These mutations diminish RAS GTPase activity by over 300-fold and lock the molecule in an 'on' position.[100] This permanent activation state increases cell signaling through the RAS-ERK pathway, inducing apoptotic defects and increased cell proliferation.[76,77,98]

Protein Kinase C Delta Deficiency

An ALPS-like patient with lymphadenopathy, splenomegaly, multiple autoantibodies and elevated IgG was found to have a homozygous loss of function mutation in the gene encoding protein kinase C delta (*PKCδ*).[101] The mutation resulted in ex vivo B cell hyperproliferation and the lymph node histology of intense follicular hyperplasia and progressive transformation of germinal centers. Both of these findings mirror the *PKCδ* knockout mouse model. The defect also altered NK cell function, causing chronic EBV infection. Flow cytometry demonstrated expansion of $CD5^+CD20^+$ B cells and mild elevation of α/β DNT cells that were not present in the lymph nodes. This patient responded to rapamycin therapy with marked decrease in splenomegaly and hyperglobulinemia. An additional report identified a second patient with a homozygous loss of function *PKCδ* mutation who presented with a somewhat different clinical phenotype.[102] Additionally, three children from one consanguineous family have been reported with homozygous loss of function *PKCδ* mutations linked to mendelian systemic lupus erythematosus.[103] Taken together, these findings suggest that *PKCδ* plays a central role in B cell tolerance and prevention of self reactivity.

Conclusions

In recent years, identification of the genetic defects linked to patients with congenital systemic autoimmunity has led to the definition of a new class of PIDD (primary immunodeficiency disease) in which the defect impacts the regulatory compartment of the immune system. Lessons learned from these disorders have clarified aspects of thymic selection, T_{REG} function, FAS mediated apoptosis and intrinsic apoptosis mediated via RAS proteins. There are a number of unresolved issues that include defining other contributing genetic and/or environmental factors and clarifying the basis for the specific patterns of autoimmunity seen in these disorders. Studying these experiments of nature will continue to be a fertile field of investigation over the coming years as we strive to uncover the basic mechanisms of immune tolerance.

14 Autoinflammatory Disorders

FATMA DEDEOGLU | SUSAN KIM

KEY POINTS

- In the majority of the autoinflammatory diseases innate immune system dysregulation is the cause of the inflammation.
- Most of these conditions have a monogenic cause.
- Discovery of these genes leads to better understanding of the inflammatory pathways and the mechanisms of inflammation.
- These disorders both share common features such as fever, rash, serositis and musculoskeletal findings and also have disease-specific, unique features such as the type of rash, duration of fever and involved organ systems.
- Better understanding of the mechanisms of these conditions and the discovery of the genes have led to early recognition and better, more effective treatments with a subsequent decrease in morbidity and mortality and greatly improved outcomes and quality of life.

The finding of the 'familial Mediterranean fever' gene in 1997 triggered the discovery of additional genes and new inflammatory pathways, improving our understanding of inflammation and making possible more effective treatments in patients with these conditions. Periodic fever syndromes are now grouped under the term 'autoinflammatory disorders' (AD), a field which is a prime example of translational research and innovation.[1–4] Despite the achievement of significant milestones in this field, many questions remain unanswered, either due to complex and/or controversial genetic inheritance patterns (such as single mutation in a recessive disorder) or due to yet undiscovered pathways.

Unlike autoimmune conditions, autoantibodies or antigen-specific T cells are lacking, and monocytes and neutrophils are the major effector cells rather than lymphocytes. These syndromes are now considered inborn errors of innate immunity.[5]

Most of the known mutations found in AD involve proteins that modulate inflammation and apoptosis. Improved understanding of inflammatory pathways has led to the concept of autoinflammation, which now includes not only the monogenic conditions, such as familial Mediterranean fever (FMF), TNF receptor-associated periodic fever syndrome (TRAPS), familial cold autoinflammatory syndrome (FCAS) and mevalonate kinase deficiency (MKD – formerly known as hyper IgD syndrome-HIDS),[2,6] but also several polygenic and multifactorial conditions such as Crohn's disease and systemic onset juvenile idiopathic arthritis (SoJIA). The boundary between the autoimmune (adaptive immunity) and the autoinflammatory (innate immunity) diseases has become more obscure.[7] While immunodeficiencies with 'immune dysregulation' have been linked to AD, new autoinflammatory syndromes with features of immunodeficiency have also been described.[2,6,8]

Numerous attempts to group or classify autoinflammatory disorders have been made.[3,9–11] However, until we understand the inheritance patterns as well as the influence of the environment, epigenetic factors and their interactions, any classification modality will remain arbitrary or artificial. This chapter gives an overview of autoinflammatory disorders with a focus on the monogenic types.

Common Features

Periodicity and fever are the cardinal features of many AD, but some may have a more chronic and/or afebrile course. The inflammatory response is typically localized to serosa, skin, eyes, lymph nodes and the musculoskeletal, gastrointestinal and nervous systems. The majority of AD present with recurrent episodes of inflammatory states, typically with fever and elevated inflammatory markers (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR], serum amyloid A proteins [SAA]). Tables 14-1 and 14-2 summarize the typical features of these disorders. In addition, blood count abnormalities (leukocytosis, thrombocytosis, anemia) and elevated immunoglobulin levels are commonly seen. Patients are usually asymptomatic between the attacks, though in the severe forms longer duration of symptoms may occur.[12,13] Variability of features is seen within each syndrome, even within the same family. There may be a prodromal period with nonspecific features, such as fatigue and headaches.

When a patient presents with recurrent fevers, the differential remains broad and includes infectious, rheumatologic and oncologic/lymphoproliferative causes, as well as immunodeficiencies. The longer the period of repeated, stereotypical episodes, especially with fevers and systemic features affecting skin, mucosa, eyes, musculoskeletal, gastrointestinal and nervous systems, the greater the likelihood of an AD. Since the penetrance of the mutations is not 100% and de novo mutations may occur, a negative family history does not exclude a particular diagnosis. A family history of amyloidosis, chronic renal disease and deafness would strengthen the possibility.

When AD are considered, genetic testing may be helpful in confirming the diagnosis. However, up to 60% or more patients may have negative genetic testing, despite classic features consistent with a particular syndrome,[13] which could be a result of unknown genetic defects in the same inflammatory pathway, epigenetic factors, somatic mosaicism or phenotypic variability.

Genotype databases and other collaborative registries (e.g. Infevers: http://fmf.igh.cnrs.fr/infevers; Eurofever, EuroTRAPS) have been established and more than 1,000 sequence variants

TABLE 14-2 Autoinflammatory Diseases Mediated Via Other Mechanisms

	Blau Syndrome	TRAPS	Majeed Syndrome	PFAPA	PRAAS/CANDLE/JMP/ JASL	SAVI	DADA2
Typical age	< 5 years	< 20 years	< 2 years	Preschool age	< 1 year	Infancy	< 5 years
Fever duration	Continuous	7+ days	3–4 days	3–5 days	Variable	Variable, low-grade	Variable
Frequency	Continuous	Variable	1–2 months	1 month	Variable	Variable	Intermittent fevers
Ethnic/cultural/ regional predilection	All	Western European	Arabic	All	Unknown	Unknown	Unknown
Common clinical findings	Granulomatous uveitis, arthritis, lymphadenopathy	Periorbital edema, conjunctivitis, arthralgia, migratory myalgia, serositis, abdominal pain	Deforming arthritis, growth retardation, osteomyelitis, hepatosplenomegaly	Stomatitis, pharyngitis, cervical lymph node enlargement, fatigue, headache	Joint contractures, muscle atrophy, microcytic anemia, arthralgia, arthritis, basal ganglia calcification, failure to thrive, nodular episcleritis, conjunctivitis, keratitis	Severe cutaneous vasculopathy, interstitial lung disease	Vasculopathy/vasculitis early lacunar strokes, hepatosplenomegaly, mild immunodeficiency, cutaneous and systemic vasculitis, mild immunodeficiency
Skin manifestations	Maculopapular nodular rash	Migratory erythematous rash	Sweet's syndrome, pustulosis	Variable	Violaceous eyelids, annular plaques, early-onset pernio-like lesions, panniculitis-induced lipodystrophy	Cutaneous vasculopathy	Cutaneous vasculitis, livedo reticularis
Amyloidosis	Not noted	25%	Not noted	Not noted	Not noted	Not noted	Not noted
Inheritance	Autosomal dominant and de novo *NOD2*/CARD15 encoding NOD2	Autosomal dominant TNFFSF1A-encoding p55 TNF receptor	Autosomal recessive	Unknown	Autosomal recessive, PSMB-8 gene proteosome subunit-type 8	Autosomal dominant and de novo TMEM173	Autosomal recessive, CECR1
Treatment	Steroids, anti-TNF therapy	Steroids and possibly anti-TNF therapy, anti-IL-1 therapy	Steroids, NSAIDs, anti-IL-1 therapy	Tonsillectomy, steroids, cimetidine	Partial response to steroids, anti-TNF therapy, anti-IL-1 therapy, anti-IL-6 therapy	Interferon inhibitors/ JAK kinase inhibitors (e.g. tofacitinib)	Steroids

TRAPS – TNF receptor-associated periodic fever syndrome, PFAPA – periodic fevers, aphthous stomatitis, pharyngitis and adenitis, PRAAS – proteosome associated autoinflammatory syndromes, CANDLE – chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature, JMP – joint contractures, muscle atrophy, microcytic anemia and panniculitis-induced lipodystrophy, JASL – Japanese autoinflammatory syndrome with lipodystrophy, SAVI – STING-associated vasculopathy with onset in infancy, DADA-2 – deficiency of ADA2.

https://CafePezeshki.IR

of these diseases have been registered,[14] including many variants of unclear significance.

In recent years, based on the inheritance pattern, age of onset, duration, frequency and associated features of the attacks and ethnicity, *decision-making trees* have been proposed in the evaluation of patients with periodic inflammatory episodes,[15,16] but these algorithms are most applicable in areas of higher prevalence.

Pathogenesis

An exaggerated inflammatory response appears to occur, due to increased sensitivity to normal or insignificant stimuli, or due to the inability of the immune system to dampen normal responses in an efficient and timely manner. Most of the mutated proteins in these disorders are members of the death-domain fold (DDF) family, which are involved in apoptosis, NF-κB activation and proinflammatory cytokine production. More recently, another mechanism was found: the role of protein misfolding in increasing cellular stress, causing an increase in reactive oxygen species, which in turn triggers an exaggerated inflammatory response with only minimal secondary stimuli such as lipolysaccharide. In addition, defects in autophagy and proteasome function are other possible pathways causing autoinflammation.[17] There have been conflicting results of the studies; these may be related to differences in experimental models. It is possible that these proteins assume different roles under different situations and that the dosage of gene and other modifier genes have effects on the immune/inflammatory pathways contributing to the variable presentations of the diseases.[5,17–20]

Familial Mediterranean Fever (FMF)

FMF was the first described autoinflammatory disease: in 1908 by Janeway and Rosenthal in a Jewish girl, and in 1945 by Siegal. The initial spread of FMF can be traced back to Mesopotamia 2,500 years ago. It is an autosomal recessive condition reported worldwide, but most patients have ancestry in the Mediterranean basin, particularly in the Middle East, where the prevalence is 1:250 to 1:1,000,[21] with a carrier frequency as high as 1 in 3 to 5, suggesting survival via an enhanced innate immune response. Carriers of the FMF gene have a heightened inflammatory response, supporting this hypothesis.[22,23] After mapping of the FMF susceptibility locus to chromosome 16p in 1992,[24] the mutated gene, named *MEFV* (MEditerranean FeVer) was discovered by two independent groups using positional cloning in 1997.[25,26] The deduced protein *pyrin* (the Greek for 'fever')/*Marenostrin* (the Latin 'Mare Nostrum' for 'our sea') is 781amino acids long and is primarily expressed in the cytoplasm of neutrophils but is also found in other cells. Almost all mutations are missense mutations: via its N-terminal death domain (pyrin domain-PYD), pyrin interacts with the pyrin domain of the adapter protein ASC (apoptosis-associated speck-like protein) to assemble and activate inflammatory complexes. These proteins have been found to play a role in controlling IL-1β production by regulating caspase-1. The exact physiologic role and underlying mechanisms of mutated pyrin are not well understood. Pyrin mutations result in gain of function but the expression of the disease depends on how much mutated protein is produced.[17]

Mutations in position 694 usually cause a more severe phenotype, especially M694V. Low penetrance mutations, such as E148Q, are also described. The allele frequency of E148Q is 10% to 20% in Asians and 1% to 2% in Caucasians.[27,28]

FMF episodes may be triggered by physical or emotional stress, infections, exercise, menstruation and diet. An attack may be preceded by malaise, irritability and decreased appetite. Major features are fever and abdominal pain due to serositis, mostly peritonitis (95%), recurrent attacks of which may cause adhesions. Pleuritis, which is usually unilateral, is seen in about 40% of patients, while pericarditis is rare in FMF. Orchitis occurs in about 5% and is more common in children. Arthritis/arthralgia affects primarily the lower extremities and is transient, resolving without any sequelae, though some patients may develop chronic destructive arthritis. Exercise-induced myalgia may occur during an episode. The erysipelas-like rash, commonly seen around the ankles, is a relatively unique feature of FMF and occurs in about 20% to 30% of patients. Prolonged, severe muscle pain affecting lower extremities and abdominal muscles, known as protracted febrile myalgia, may rarely occur and is responsive to steroid therapy. Occasionally, there is an accompanying vasculitic rash.[29,30] Laboratory investigation reveals leukocytosis and elevated inflammatory markers. SAA and S100A2 levels[4,31,32] may be used to follow disease activity.

Diagnosis is still primarily clinical because about 25% of the patients have a negative genetic analysis for *MEFV* mutation. Furthermore, a significant number of patients with homozygosity never develop clinical features, while about 30% to 40% of the patients with FMF are heterozygotes. This variability is thought to be due to the dose effect of the mutated protein. Clinical criteria for diagnosis in adults were proposed by Livneh in 1997[33] and guidelines for diagnosis in children have been published.[34] Both sets of criteria are highly specific and sensitive in areas of high prevalence, but not in less prevalent areas. Certain vasculitides such as Henoch-Schönlein purpura (HSP) and polyarteritis nodosa (PAN) have increased frequency in FMF patients.[29] Behçet's disease is also more common in carriers and FMF patients.[35]

Colchicine is the mainstay of the treatment of FMF[28] and eliminates or substantially decreases symptoms in about 95% of patients. More importantly, regular use of colchicine prevents the development of amyloidosis, the major contributor to morbidity and mortality in these patients. Before colchicine use, up to 75% of patients would develop amyloidosis after the age of 40 years. Risk factors for amyloidosis include M694V mutation, male gender, SAA α/α genotype and family history of amyloidosis.[30,36] Environmental factors also play a crucial role in the development of amyloidosis.[22,37]

To date, the mechanism of action of colchicine in FMF is not well understood. Colchicine accumulates primarily in neutrophils and is postulated to affect neutrophil adhesion and mobility by binding to the cytoskeleton of the cells[30] and preventing microtubule elongation. It is generally well tolerated with minimal side-effects,[38] diarrhea being the most common (10–20%).[39] Acute toxicity from an overdose can be very serious since it has a narrow therapeutic window. Studies have suggested that it is safe to use during pregnancy and lactation and does not affect fertility.[40] Colchicine is used as a preventative therapy. Intermittent use or increasing the dose during attacks has no role in management of FMF. Colchicine resistance is rare (< 5%), therefore an alternative diagnosis or noncompliance should be considered in nonresponsive patients. IL-1-blocking drugs (anakinra, rilonacept, canakinumab) are the drugs of choice in colchicine resistant or intolerant patients.[40]

TNF Receptor-Associated Periodic Fever Syndrome (TRAPS)

TRAPS, an autosomal dominant AD, was formerly known as 'Hibernian fever'. It was first described in Ireland in 1982[41] and is most common in Irish and Scottish populations but is now known to occur worldwide (http://fmf.igh.cnrs.fr/ISSAID/infevers/).

The association of this syndrome with mutations in the *TNFRSF1A* gene on chromosome 12p13 was discovered in 1999.[42] This gene encodes the TNF receptor type 1 (also known as p55TNFR). Binding of TNF-α to its receptor initiates the intracellular activation cascade through the death domain, leading to the activation of both NF-κB and apoptosis pathways.

The pathogenesis of TRAPS is still not clear and several mechanisms have been proposed.[5,42–44] To date, more than 130 mutations have been described (http://fmf.igh.cnrs.fr/ISSAID/infevers/). Among these mutations R92Q is the most common variant in Caucasians and P46L in African-Americans. The R92Q substitution has been found in chromosomes of 1% to 35% of the general population.[45,46] These mutations may have reduced penetrance, leading to atypical presentations of TRAPS.[18]

Fevers in TRAPS generally last longer than those in other forms of periodic fever syndromes, ranging from 1 to 3 weeks. Attacks occur at irregular intervals from once to seven times a year. In a subset of patients, the symptoms are present continuously.[47] The age of onset is about 3 years (ranging from 1 to 63 years). Common features of TRAPS include severe abdominal pain (92%) due to serositis with risk of adhesions, painful centrifugally migrating myalgia (due to monocytic fasciitis) that can be associated with an overlying painful erythematous rash, ocular inflammation with conjunctivitis, uveitis, unilateral periorbital edema and arthralgia (less commonly arthritis) primarily affecting large joints. Other findings may include chest pain due to pleuritis, pericarditis, myocarditis and scrotal swelling. Similar to other AD, elevated inflammatory markers are found. In addition, some patients have low soluble TNF receptor levels between episodes. The risk of amyloidosis is greatest in patients with mutations involving cysteine substitutions, reported to be as high as 24% without treatment.[12,47]

Nonsteroidal antiinflammatory drugs (NSAIDs), steroids and colchicine are used with some success in this condition.[48] Etanercept, a dimeric fusion protein consisting of the p75 portion of TNFR linked to Fc portion of IgG1, decreases the severity of the attacks in the majority of patients but the effect seems to wane over time in some patients. Furthermore, the efficacy of this therapy may wane over time. Interestingly, infliximab and adalimumab, which are monoclonal antibodies against TNF-α, paradoxically trigger exacerbations of febrile episodes in some patients. Etanercept nonresponders may respond to the IL-1 receptor antagonists (anakinra).[13,48]

Mevalonate Kinase Deficiency (MKD)/Hyper IgD Syndrome (HIDS)

MKD, formerly known as HIDS because of the initial observation of elevated IgD levels in patients, was first described in 1984 in 6 Dutch patients.[49] An unexpected finding was that the gene causing MKD was found to encode mevalonate kinase, an enzyme in the cholesterol biosynthesis pathway.[50,51] The enzyme was already known to be implicated in mevalonic aciduria (MA), which is a metabolic disorder that presents in infancy with devastating neurologic abnormalities (mental retardation, cerebellar ataxia, cataracts, hypotonia, dysmorphic features) and eventually leads to early death. MA shares many of the features of HIDS, hence the name was changed to MKD. HIDS and MA are a phenotypic continuum of mevalonate kinase deficiency, from mild to severe disease.[52]

Heightened inflammatory response caused by abnormal functioning of an enzyme in the cholesterol biosynthesis pathway was ultimately shown to be connected to the IL-1β pathway.[50,53]

The most common mutation in MKD is at position V377I, a founder effect from a common ancestor. High frequency of this mutation in Northern Europe is thought to be a selective advantage related to higher consumption of saturated fat. Urine mevalonic acid level increases during the episodes in HIDS,[54] while it is persistently high in MA. Enzyme activity is 1–10% in HIDS but < 1% in MA. The activity of the mutated enzyme decreases even further with fevers. Mevalonic acid accumulates and end products, which are important in isoprenylation of proteins, decrease. The shortage of some of these end products, especially geranylated proteins, is involved in increased IL-1β production. Not every patient with MKD has elevated IgD levels, especially children.[55] Elevated IgD levels have also been described in infections such as tuberculosis and other inflammatory conditions, including other periodic fever syndromes. Polyclonal IgA elevation may also be seen in HIDS.

Onset is often in infancy (90%) and is characterized by fevers recurring every 4 to 8 weeks, accompanied by painful cervical lymphadenopathy (90%), abdominal pain and vomiting (70%), an often maculopapular, occasionally urticarial, purpuric and erythema nodosum type skin rash (60%), arthralgia/myalgia (80%), aphthous and/or genital ulcers (50%) and hepatosplenomegaly (30%). Chills and sweating are also common. Arthritis affecting large joints and pleuritis are less common.[55] Immunizations and other stressors such as trauma or infections usually trigger attacks. Features of MKD resemble those of periodic fever, aphthous stomatitis, pharyngitis and cervical adenitis (PFAPA). In the majority of the patients flare frequency decreases in adulthood. Amyloidosis is rare in MKD but not unheard of. Mild immunodeficiency features have been described in some patients.[6]

Effective treatment for HIDS is not available. Steroids, etanercept and colchicine are beneficial in a small group of patients. Lately anakinra has shown some promise. Simvastatin, an HMG-CoA reductase inhibitor, may help in some patients with HIDS but it may exacerbate the condition in some patients with MA. There are also anecdotal reports of benefit from the leukotriene inhibitor, montelukast.

Cryopyrin-Associated Periodic Syndromes (CAPS)

CAPS constitute a spectrum of conditions that share a similar genotype, with mutations in the gene encoding for cryopyrin (also known as *NLRP3*, *NALP3* and *PYPAF1*). Cryopyrin belongs to the NLR (nucleotide-binding domain and

https://CafePezeshki.IR

leucine-rich repeat) protein family[56] and is found primarily in activated T cells, monocytes, neutrophils and chondrocytes. These conditions are autosomal dominant, but de novo mutations may occur. Due to the association with cold exposure and development of fever, the protein was named as 'cryopyrin' and familial cold-induced urticaria was renamed as 'familial cold autoinflammatory syndrome'.

From *most* to *least* severe, the CAPS are neonatal onset multisystem inflammatory disease (NOMID), Muckle-Wells syndrome (MWS) and FCAS; however, CAPS represent a spectrum of pathology and there may be a clinical overlap among these conditions.

The first CAPS to be described was FCAS, as early as 1940.[57] MWS was first described in 1962 with a triad of urticaria, deafness and amyloidosis in nine members of a family over five generations.[58] NOMID was probably first reported in the literature in 1975: two siblings, born to nonconsanguineous parents, were described as having a Still's disease-like rash, deforming arthropathy, mental retardation and uveitis.[59]

Clinical similarities between these three phenotypically different entities led to the discovery that the underlying mutations were homologous. The mutations for CAPS were first reported in 1996 and later confirmed in 2000 and 2001.[60]

Cryopyrin contains three domains: an N-terminal pyrin domain (PYD), a nucleotide-binding oligomerization domain (NOD or NLRP3) and a leucine-rich repeat (LRR) region. Cryopyrin is an intracellular pattern recognition receptor and recognizes pathogen-associated molecular patterns and danger-associated molecular patterns (PAMPS and DAMPS) via LRR. Cryopyrin is integral in the activation of the cryopyrin inflammasome: it interacts with ASC (apoptosis-associated speck-like protein) and CARDINAL to form the activated complex with two procaspase molecules, generating active caspase-1 and leading to IL-1β and IL-18 activation. Studies suggest that the *CIAS1* mutation is a gain-of-function mutation, likely causing the loss of autoinhibition or the regulatory step in NLRP3 activation, allowing for the autoassembly and activation of the inflammasome without typical stimuli (PAMPS and DAMPS). These mutations, found on chromosome 1q, appear to lead to increased caspase-1 activation and thus increased IL-1β secretion. No typical mutation is found in up to half of patients with CAPS, but a recent analysis of NOMID patients found that nearly two thirds of mutation-negative patients had somatic mosaicism mutations in 4.2% to 35.8% of the cells.[61]

All three phenotypes of CAPS are associated with an urticaria-like skin rash that is characterized by interstitial and perivascular infiltrates primarily composed of neutrophils.[62] This rash forms erythematous flat wheals, often symmetric and sparing the face, typically nonpruritic rather burning or painful, and generally lasting for more than 24 hours.[63]

FCAS patients typically present in early infancy. Symptoms usually occur several hours following exposure to generalized cold. The urticarial rash, sometimes associated with swelling, is the most common feature. Arthralgia, myalgia, fever, conjunctivitis, fatigue, headache and nausea are common features. Attacks typically last 24 hours or less.

MWS patients typically present during adolescence with attacks lasting 24 to 48 hours at irregular intervals every few weeks. Arthralgia and myalgia accompany the fevers and rash during typical attacks. Progressive sensorineural hearing loss is common (75%), and different *NLRP3* mutations may predict the trajectory of hearing loss, with the T348M mutation at highest risk in one report.[64] About a third of patients develop secondary amyloidosis with nephropathy.

NOMID, also known as chronic infantile neurologic cutaneous and articular syndrome (CINCA), typically presents in early infancy and is associated with significant neurologic symptoms including chronic meningitis, increased intracranial pressure, developmental delay, seizures, papilledema, papillitis, uveitis, optic atrophy, blindness and sensorineural hearing loss, as well as daily fevers. These patients also have major bony abnormalities with dysmorphic features including frontal bossing, severe arthropathy and joint deformity. The arthropathy typically is symmetric, affecting large joints, and is caused by abnormal endochondral formation and bony overgrowth. Without treatment, patients suffer significant morbidity, and early death before adulthood occurs in 20% of affected individuals.

NSAIDs are typically inadequate to treat these conditions completely. Steroids may have some limited benefit. IL-1 Trap, or rilonacept, a fully human dimeric fusion protein, binds soluble IL-1 and prevents its interaction with cell surface receptors. It was approved by the US Federal Drug Administration (FDA) in 2008 for CAPS under orphan drug designation. Canakinumab, a human anti IL-1β monoclonal antibody with no cross-reactivity to other members of the IL-1 family, is effective in patients with CAPS[65] and was approved by the FDA for this indication in June 2009. Anakinra, an iIL-1 receptor antagonist, competitively inhibits the binding of IL-1α and IL-1β to the IL-1 receptor, was approved for NOMID in 2013 for children under orphan drug designation, and is efficacious in patients with CAPS. Anti-IL-1 therapy is not only effective for the acute symptoms, such as fevers, rash, arthritis and headaches, but also appears to halt the progression of arthropathy and central nervous system decline including developmental delay and vision and hearing loss.

NLRP12-Associated Autoinflammatory Disorder

NLRP12AD, also known as Guadeloupe-type fever syndrome, is a rare autosomal dominant disease with variable penetrance that results from mutations in the NLRP12 protein found on 19q13.42.[66] This protein is an intracellular sensor of the innate immune system and belongs to the Nod-like receptor (NLR) family, which regulates inflammatory processes through inhibition of NF-κB and IL-1β signaling and is distinct from the NLRP3 inflammasome. The exact role of NLRP12 remains unknown but there is thought to be a loss-of-function mutation that allows for the up-regulation of NF-κB and IL-1β. The pathogenesis of this condition is not yet fully understood.

The clinical presentation of this condition overlaps with cryopyrin-associated periodic syndromes (CAPS); prior to the discovery of this novel mutation in 2008, patients were categorized as 'mutation-negative' CAPS. As in MWS and FCAS, symptoms are typically induced by cold exposure and manifest with recurrent fevers lasting 5 to 10 days with associated rash, headache, lymphadenopathy, aphthous ulcers, abdominal pain and sometimes sensorineural hearing loss. The clinical phenotypes can be variable and may improve in adulthood. Patients typically do not respond to IL-1 blockade. Treatments used for this condition include avoidance of cold, antihistamines, NSAIDs and steroids.

https://CafePezeshki.IR

Deficiency of Interleukin-1-Receptor Antagonist (DIRA)

DIRA is a very rare condition that was first reported in 2009.[67,68] These patients present in early infancy mimicking sepsis with multifocal osteomyelitis, periostitis, pustular skin lesions, hepatosplenomegaly, thrombosis and multi-organ failure. DIRA shares many clinical features with NOMID but fever is generally absent or low grade. Osteolytic lesions, sclerosis and epiphyseal enlargement are seen on x-rays and acute-phase reactants are persistently elevated. Rare features are interstitial lung disease, CNS vasculitis and atlanto-axial subluxation.[2]

DIRA is autosomal recessive and is associated with deletion or truncating mutations in a 175-kb sequence of chromosome 2q13 that encompasses five IL-1 family members as well as the IL-1 receptor antagonist (*ILRN*). The *IL1RN* mutation appears to result in truncated proteins that are not secreted, leading to cells being hyperresponsive to IL-1α and IL-1β stimulation. Patients respond rapidly and dramatically to anti-IL-1 therapy, with full resolution of symptoms in the majority of patients.[67,68]

Blau Syndrome/Pediatric Granulomatous Arthritis

Blau syndrome is a systemic inflammatory condition which was first described in 1985: 11 family members over four generations had granulomatous disease of the skin, eyes and joints.[69] Early-onset sarcoidosis, considered to be the sporadic form, is caused by the same gain-of-function mutation.[70] Blau syndrome typically presents at less than 5 years of age and is characterized by a maculopapular rash, noncaseating granulomatous arthritis, uveitis and lymphadenopathy; fever may be absent. Noncaseating epithelioid granulomas are found on tissue biopsies. It is distinguished from the autoimmune condition, sarcoidosis, based on its early age of onset and lack of lung and hilar lymph node involvement.

Blau syndrome is an autosomal dominant condition, involving chromosome 16q12, and over 120 mutations have been described to date (http://fmf.igh.cnrs.fr/ISSAID/infevers/). The gene encodes NOD2 (also known as CARD15), which is expressed primarily in myeloid cells, Paneth cells of the small intestine and activated intestinal epithelial cells, and is a member of the NLR protein family.

Similar to cryopyrin, NOD2 appears to function as a cytoplasmic pattern recognition receptor; it recognizes PAMPS and is integral in NF-κB activation. Bacterial cell wall peptidoglycans such as muramyl dipeptide stimulate the NOD2 inflammasome.[71] Mutations appear to be gain of function due to loss of autoinhibition. However, patients do not appear to have excess IL-1β activity, so the underlying mechanism for this condition remains under study.[48,72]

In Crohn's disease (CD), another inflammatory granulomatous condition, mutations have been reported in the LRR region of *NOD2*. These mutations may theoretically lead to diminished intracellular sensing of bacteria, thereby leading to diminished activity of the NOD2 inflammasome (loss of function). The exact role of these mutations in CD remains under investigation.

Anecdotal evidence supports the use of steroids, immunomodulation with TNF-α inhibitors and possibly other immunomodulatory therapies, such as thalidomide, methotrexate and anti-IL-1 therapy, in the treatment of Blau syndrome.

Majeed Syndrome

Majeed syndrome is a very rare pyogenic autoinflammatory disease of most commonly Arabic populations, first described in 1989 in a consanguineous Kuwaiti family, where three children presented with congenital dyserythropoietic anemia, chronic recurrent multifocal osteomyelitis and neutrophilic dermatosis.[73]

Patients typically present at less than 2 years of age with chronic recurrent episodes of commonly metaphyseal sterile osteomyelitis, and fever, typically lasting several days, with associated destructive arthritis and deformities. Attacks may occur every 2 to 4 weeks, but continuous symptoms have also been reported. Pustular rashes, Sweet's syndrome, hepatosplenomegaly and cholestatic jaundice are also reported. Patients may have transient neutropenia in infancy. Chronic dyserythropoietic anemia may require regular transfusions.

Majeed syndrome is an autosomal recessive disorder involving the *LPIN2* gene with loss-of-function mutations on chromosome 18p.[74] The role of *LPIN2* in Majeed syndrome is not clear but it may play a role in cellular response to oxidative stress.

Systemic corticosteroids and NSAIDs appear to provide clinical improvement in patients. Data are limited with regard to disease-modifying antirheumatic agents or biologics although recently anti-IL-1 therapies have shown good results.[75]

Pyogenic Sterile Arthritis, Pyoderma Gangrenosum and Acne (PAPA)

PAPA was first recognized in 1975 and described in 1997[76] with the clinical features in its name. A very destructive arthritis is typically present, associated with pyoderma gangrenosum skin lesions and sterile muscle inflammation. Pathergy and ulcerations following pustule formation after vaccinations or trauma are common features. Rosacea and psoriasis may be seen in some patients. Arthritis tends to start early in life, and pyoderma gangrenosum and acne around puberty. About 20% to 40% develop sulfonamide-induced pancytopenia,[77] the cause of which is not clear. Leukocytosis and elevated acute-phase reactants are common.

PAPA is an autosomal dominant condition (chromosome 15q24–q25.1) and is associated with mutations with variable penetrance in PSTPIP1, which is highly expressed in neutrophils and T cells. The genetic association was described in 2002.[78] PSTPIP1 interacts with pyrin,[79] mutations lead to hyperphosphorylation, which appears to increase the interaction of PSTPIP1 with pyrin, reducing pyrin's regulatory effect on the NALP3/cryopyrin inflammasome (Figure 14-1). PSTPIP1 is also known as CD2-binding protein (CDBP1) and interacts with CD2, Wiskott-Aldrich syndrome protein (WASP) and FasL, implying a role in the adaptive immune system related to antigen recognition.

Anecdotal evidence suggests that steroids, anti-TNF therapy and anti-IL-1 therapy may be of benefit, especially for the arthritis, though anti-IL-1β therapy does not appear as effective

https://CafePezeshki.IR

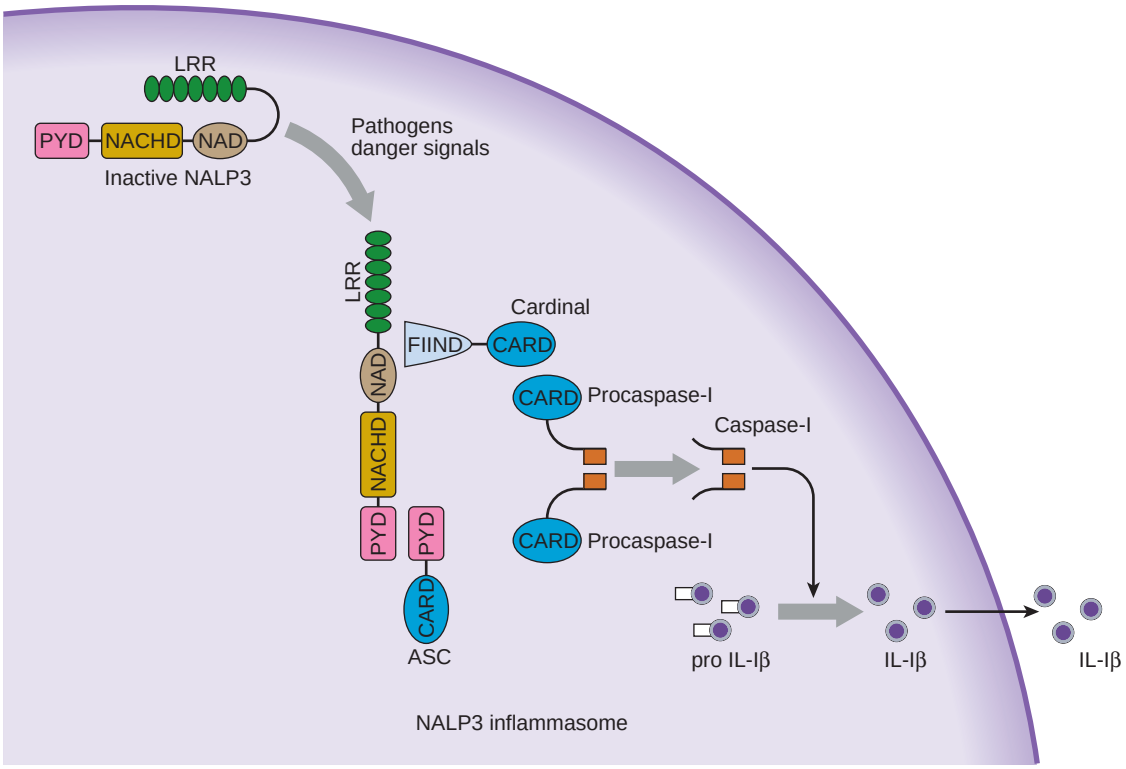

Figure 14-1 The NALP3/cryopyrin inflammasome. NALP3 is usually found in an inactive state and is activated by 'danger signals' such as peptidoglycans, ATP, uric acid crystals, bacterial RNA, etc., which leads to its unfolding and association with the remainder of the NALP3 inflammasome components FIIND (domain with function to find), CARDINAL, ASC and procaspase 1, via association between pyrin *(PYD)* and CARD domains. The NALP3 inflammasome induces the cleavage of procaspase-1 to caspase, leading to the activation of IL-1β from pro IL-1β.

as in CAPS, suggesting that the mutations implicated in PAPA have additional effects beyond IL-1 overexpression.[80]

SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis), CNO (chronic nonbacterial osteomyelitis) and PASH (pyoderma gangrenosum, acne, suppurative hidradenitis) should be considered in the differential diagnosis of PAPA.

Periodic Fevers, Aphthous Stomatitis, Pharyngitis and Adenitis (PFAPA)

PFAPA is the most common periodic fever/AD; its features are listed in its name. Marshall et al first described it in 1987,[81] followed by the publication of several other series.[82–84] Age of onset younger than 5 years is in the original diagnostic criteria but PFAPA has been described in older children and even in adults.[85] It has a male predominance and no known long-term sequelae. Strikingly regular intervals between episodes, usually every 4 weeks (3–8 weeks) as well as normal growth and development are signature features of PFAPA. Episodes usually last 4 to 6 days and frequently start and end abruptly. Constitutional symptoms such as malaise, chills and headache may also be present. Less commonly, gastrointestinal symptoms, rash and arthralgia may occur. Oral ulcers usually are shallow and lymphadenopathy is often bilateral and tender.[85] Leukocytosis and mild elevation of the inflammatory markers are seen in most patients. Recent studies show monocytosis and decreased lymphocyte and eosinophil counts during episodes.[86,87]

Almost all patients with PFAPA dramatically respond to one or two doses of corticosteroids (0.5–2 mg/kg prednisone or prednisolone), especially when given prior to the onset of fever.[82–84] Corticosteroid therapy does not prevent subsequent episodes, but patients continue to respond on subsequent cycles. In a subgroup of patients, the frequency of episodes increases with corticosteroid therapy. Treatment may include tonsillectomy with or without adenoidectomy[88–93] and may induce remission in patients. Efficacy of cimetidine in PFAPA is modest (29%).[94]

The etiology of PFAPA is unknown. Studies in recent years suggest an aberrant immune response involving possibly both innate and adaptive immunity.[88,95] Levels of IL-1β, IL-6, IP-10 (CXCL10), CXCL9 and G-CSF increase during episodes. Furthermore, the level of CXCL10 and G-CSF increase during episodes seems to differentiate PFAPA from other periodic fever syndromes.[86] These cytokines and chemokines are related to T cell activation and recruitment to the tissues, suggesting the role of adaptive immunity in the pathogenesis.[87,89] Tonsillar tissue shows lymphoid hyperplasia and chronic inflammation.[89]

Although the genetic basis of PFAPA has yet to be identified, familial cases have been described in recent years.[95] Some of the low penetrance mutations or variants of other monogenic periodic fever syndromes such as NOD2, MEFV and TNFRSF1A have been found in PFAPA patients.[96] In one recent study PFAPA patients carrying *MEFV* mutations had milder PFAPA episodes.[97]

PFAPA typically resolves by adolescence. Long-term follow-up of patients in one study showed resolution in 50 out of 59 patients by age 6.3 and by the age of 18 in the rest.[98]

Recently Discovered Autoinflammatory Disorders

DEFICIENCY OF IL-36 RECEPTOR ANTAGONIST (DITRA)

In 2011, predominantly homozygous mutations in the IL-36 receptor antagonist (IL36RN) gene were described, initially in 16 Tunisian family members with generalized pustular psoriasis (GPP)[99] and later in unrelated English patients. The phenotype includes sudden onset episodes of pustular rash accompanied by high grade fevers, and malaise, primarily triggered by infections but also by other stressors such as menstruation, pregnancy and withdrawal of retinoid therapy. Elevated inflammatory markers and leukocytosis are common. Secondary skin infections and sepsis have also been reported.

Following the discovery of *IL-36RN* mutations in patients with GPP, namely DITRA, mutations in this gene were also found in other pustular disorders[100] such as palmoplantar pustulosis, acrodermatitis continua of Hallopeau (ACH) and acute generalized exanthematous pustulosis (AGEP). Autosomal dominant gain-of-function mutations in *CARD14* have also been found in severe GPP and plaque psoriasis,[101] as well as pityriasis rubra pilaris.[102]

DEFICIENCY OF ADA2 (DADA2)

In 2014, two independent groups found autosomal recessively inherited loss-of-function mutations in the same gene, *CECR1* (cat-eye syndrome region, candidate1), encoding ADA2 (adenosine deaminase 2). These mutations cause two different, yet related phenotypes whose main feature is vasculopathy/vasculitis. One of the phenotypes includes intermittent fevers, early-onset lacunar strokes, hepatosplenomegaly and systemic vasculopathy with mild immunodeficiency.[103] The second phenotype is characterized by cutaneous and systemic polyarteritis nodosa with variable penetration.[104] ADA2 is a growth factor and also has catalytic activity.

PROTEOSOME ASSOCIATED AUTOINFLAMMATORY SYNDROMES (PRAAS)

Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE), joint contractures, muscle atrophy, microcytic anemia and panniculitis-induced lipodystrophy (JMP) syndrome, Nakajo-Nishimura syndrome and Japanese autoinflammatory syndrome with lipodystrophy (JASL; described first in 1939 in Japan) are rare related conditions[105] that were found to be the result of the same gene defect in 2010.[106–108] These autosomal recessive conditions are caused by mutations in the proteasome subunit beta-type 8 (*PSMB8*) gene, which encodes the β5i subunit of the proteosome. Immunoproteosomes are multiunit proteases which are evolutionarily conserved and key in nonlysosomal protein degradation in nucleated cells following activation. Functional assays demonstrate high levels of interferon gamma-inducible protein (IP-10), suggesting increased interferon responses in CANDLE syndrome patients, which is a novel mechanism in the pathogenesis of AD.[109]

Patients with PRAAS are reported to present in a similar fashion, typically in early infancy. They have recurrent fevers, rash manifested by annular plaques, early-onset pernio-like lesions, dactylitis, arthritis/arthralgia and elevated inflammatory markers. Other clinical features reported include basal ganglia calcification, hepatomegaly, splenomegaly, muscle atrophy, lymphadenopathy, failure to thrive and violaceous eyelids. Joint contractures and lipodystrophy may occur later, and there is early mortality related to multi-organ failure.

Treatment for PRAAS is limited but patients show partial response to high-dose steroids and a varied but limited response to biologic agents including anti-TNF, anti-IL-1 and IL-6 therapies.

STING ASSOCIATED VASCULOPATHY WITH ONSET IN INFANCY (SAVI)

In 2014, de novo mutations in the gene *TMEM173* encoding STING (stimulator of interferon genes) protein were discovered in patients with the phenotype of severe cutaneous vasculopathy, starting in infancy with systemic inflammation. Some patients have interstitial lung disease (ILD) as well.[110] STAT1 seems to be constitutively upregulated in these patients, suggesting mutations causing gain of function. Since interferon pathways are affected, SAVI is considered among the interferonopathies such as Aicardi-Goutieres syndrome.

Others

Some of the mutations/variants seen in monogenic AD have been shown to be more common in other well-known immune conditions (e.g. *MEFV* mutations in HSP and PAN). They have also been considered as modifier genes in newly described entities such as *MEFV* polymorphisms and *TNFRSF1A* mutations in IMAM (inflammatory myopathy with abundant macrophages).[111] In other cases an autoinflammatory arm has been added to already known related syndromes such as *SCLC29A3* gene mutation related syndromes which include H syndrome (inherited systemic histiocytosis, referring to the clinical findings of hyperpigmentation, hypertrichosis, hepatosplenomegaly, heart anomalies, hearing loss, hypogonadism, low height and hyperglycemia), pigmented hypertrichosis with type 1 diabetes, Faisalabad histiocytosis and sinus histiocytosis with massive lymphadenopathy.[112] Finally, very recently, novel mutations in the PAPA syndrome gene, *PSTPIP1*, have been shown to also cause hyperzincemia/hypercalprotectinemia, the phenotype of which includes hepatosplenomegaly, arthritis, anemia, cutaneous inflammation and failure to thrive.[113] *MVK* gene mutations were found in disseminated superficial porokeratosis (DSAP),[114] retinitis pigmentosa and early-onset inflammatory bowel disease.[115] Interestingly, in retinitis pigmentosa the enzyme activity is as low as in mevalonic aciduria, yet patients do not have the severe phenotype of mevalonic aciduria patients.[116]

Conclusions

Discoveries in relatively rare conditions that are well known clinically, such as FMF, can unveil the mechanisms of common, yet complicated homeostatic pathways of biologic systems, such as production of inflammation against non-self and danger signals. The term ‘autoinflammatory disorders. was initially coined to describe the monogenic periodic fever syndromes when it was first proposed over 15 years ago. Today, it has become an encompassing term to include diverse conditions that involve not only the disorders of other aspects of the innate

https://CafePezeshki.IR

immune system (hereditary angioedema [HAE], atypical hemolytic uremic syndrome [aHUS]) but also polygenic (Crohn's disease, Behçet's disease, systemic onset JIA), metabolic (gout, pseudogout) and storage (Gaucher's) disorders. The significant role that innate immunity plays is becoming clearer in conditions previously thought to be solely related to abnormalities in the adaptive immune system such as contact hypersensitivity and autoimmune conditions (rheumatoid arthritis and systemic lupus erythematosus). Finally, significant progress has also been achieved in understanding how environmental factors play a role in variable presentations of a particular condition, such as activation of the NLRP3 inflammasome in macrophagic myofasciitis, the result of immune activation caused by injection of aluminum hydroxide adjuvant vaccines and hence renamed as ASIA (autoimmune/inflammatory syndrome induced by adjuvants).[117] Similarly, monosodium urate crystals, silica and asbestos activate inflammasomes. The genetic bases of many AD are found to be related to mutations in genes encoding proteins that have roles in inflammation, cytokine signaling and processing and apoptosis. Our knowledge of the diverse roles of the innate immune system and its intimate cross-talk with the adaptive immune system has expanded exponentially.

Advances in understanding of inflammation with the discovery of mutations in genes causing many AD have led to the discovery of additional related conditions at a rapid pace since the last edition of this book. In many fields of medicine it has become clear that well-defined disease entities are usually the tip of the iceberg and that the majority of the patients are scattered throughout a spectrum. The important role of techniques in molecular biology, such as next generation sequencing, is anticipated. In short, the more we discover, the more the plot thickens, opening up new avenues of exciting research and application to clinical practice.

15 Immunoglobulin Therapy

HEATHER K. LEHMAN | MARK BALLOW

KEY POINTS

- Replacement immune globulin, administered by intravenous or subcutaneous route, is indicated as replacement therapy in patients with antibody immunodeficiency disorders.
- Dosing intravenous immune globulin (IVIG) to target higher IgG troughs (>700–1,000 mg/dL) may be associated with decreased rate of infections and improved pulmonary outcomes in primary immune deficiency patients.
- IVIG is not a generic drug and IVIG products are not interchangeable. Product differences may lead to differences in tolerability and side-effects for individual patients.
- Minor side-effects of IVIG are common. Serious adverse effects, though relatively rare at standard replacement doses of IVIG, may include hemolysis, thromboembolic events and acute renal failure.
- Many mechanisms for the effects of IVIG on immune modulation have been described. These mechanisms are not mutually exclusive and most likely work in concert, depending on the dose of IVIG administered and the specific inflammatory disease process.

Introduction

At the beginning of World War II, Cohn and colleagues from Harvard University developed an ethanol fractionation method to separate plasma proteins into stable fractions.[1] Fraction II was an antibody rich fraction that could be administered in small amounts intramuscularly and had a protective effect against measles and hepatitis A. In 1952, Bruton described the first case of agammaglobulinemia and showed that replacement with Cohn's fraction II immunoglobulin was effective in the treatment of these patients.[2] However, the replacement could be done only intramuscularly; intravascular administration caused serious side-effects. In the early 1960s the Swiss Red Cross Laboratories developed methods to adapt the Cohn fraction II immunoglobulin for intravenous use. In 1981 the first commercial intravenous immunoglobulin became available in the USA.

Immunoglobulin Replacement Therapy in Primary Immunodeficiency

The goal of immunoglobulin replacement therapy in patients with primary immunodeficiency is to provide adequate antibodies to prevent infections and long-term complications, especially pulmonary disease. Patients with recurrent infections and profound hypogammaglobulinemia and/or defective antibody production may be candidates for immunoglobulin replacement therapy,[3] either with intravenous immune serum globulin (IVIG) or subcutaneous immunoglobulin (SCIG). It is very important to evaluate the ability of the patient to produce specific antibodies to polysaccharide or protein antigens. Immunoglobulin replacement therapy should be considered only in patients with deficiencies in antibody formation; it is not indicated in patients solely having low levels of immunoglobulin or IgG subclasses. The uses approved by the US Food and Drug Administration (FDA) for IVIG as replacement or adjunct therapy in patients with immune deficiency, recurrent infections or autoimmune and inflammatory disorders are shown in Box 15-1.

PREPARATION OF INTRAVENOUS IMMUNOGLOBULIN (Box 15-2)

Most IVIG preparations are derived from plasma by Cohn's ethanol fractionation method or its Cohn-Oncley modification.[4] This fractionation process obtains four fractions. Fraction II is the immunoglobulin-rich fraction containing 95% to 99% IgG. There are small varying amounts of IgM, IgA and other proteins.[5] Unmodified Cohn fraction II can only be given intramuscularly. The side-effects of Cohn fraction II when given intravenously are thought to result from aggregation of the IgG molecules and its complement fixing activity, which can produce a severe systemic reaction. A number of approaches have been used to further purify the IgG fraction including caprylate precipitation, octanoic acid precipitation, anion chromatography or polyethylene glycol (Table 15-1). Other additives after purification, such as amino acids, stabilize the IgG molecules from reaggregation, making it suitable for intravenous use. Almost all products available today in the USA are liquids, either 5% or 10%, and are FDA approved for intravenous and/or subcutaneous administration. One liquid 20% product is only suitable for administration via the subcutaneous route (Table 15-1). Incubation at low pH or treatment with solvent and detergent, pasteurization, depth filtration and nanofiltration are important steps for viral removal and inactivation.

IVIG is made from pooled plasma from at least 10,000 donors, but each pool, by FDA guidelines, may contain up to 60,000 donors, and contains a broad spectrum of antibodies with biologic activities especially for infectious pathogens. It contains at least 90% intact monomeric IgG with a normal ratio of IgG subclasses, and is free of aggregates. The biologic activity of the IgG is maintained, especially for Fc-mediated function, and it contains no infectious agents or other potentially harmful contaminants. Although there is no standardization for the titer

https://CafePezeshki.IR

BOX 15-1 FDA-APPROVED USES OF IVIG THERAPY IN PATIENTS WITH IMMUNODEFICIENCY DISORDERS, INFECTION AND INFLAMMATORY PROCESSES

1. Primary immunodeficiency disease or primary antibody immunodeficiency – replacement therapy to prevent and/or control infection
2. Idiopathic thrombocytopenic purpura (ITP) – indicated to prevent and/or control bleeding
3. Kawasaki disease – indicated for the prevention of coronary artery aneurysms
4. B cell chronic lymphocytic leukemia (CLL) – indicated for patients with hypogammaglobulinemia to reduce and/or prevent recurrent bacterial infections
5. Bone marrow transplantation – to decrease the risk of infection, interstitial pneumonia and acute GVHD
6. Pediatric HIV-1 infection – to decrease the frequency and severity of bacterial infections
7. Chronic inflammatory demyelinating polyneuropathy (CIDP) – to improve neuromuscular impairment and for maintenance therapy to prevent relapse
8. Multifocal motor neuropathy – to improve neuromuscular impairment and for maintenance therapy to prevent relapse

BOX 15-2 FEATURES OF INTRAVENOUS IMMUNE SERUM GLOBULIN (IVIG)

- Cold ethanol fractionation (Cohn fraction II)
- >95% IgG; >90% monomeric IgG
- Traces of other immunoglobulins, e.g. IgA and IgM, and serum proteins
- Addition of an amino acid to stabilize IgG from aggregation
- Intact Fc receptor biological function:
  - opsonization and phagocytosis

of specific antibodies against common organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, each lot must contain adequate levels of antibody to certain pathogens, e.g. measles. Specific antibodies in IVIG products may vary slightly from manufacturer to manufacturer and from lot to lot but they are generally comparable.[6] Some products containing very low amounts of IgA may be beneficial in some IgA-deficient patients with antibodies to IgA to minimize the risk of possible anaphylactic reactions,[7] though the role of anti-IgA antibodies in causing anaphylaxis to IVIG is a subject of controversy.[8]

The half-life of antibodies in the IVIG product varies. It depends on the isotype and the subclass of the antibody. Total IgG has a half-life of approximately 17 to 30 days.[9,10] However, the half-life of IgG3 is much shorter (7.5–9 days)[10,11] compared to IgG1and IgG2 which have a half-life of approximately 27 to 30 days. Generally, it should take about 3 months after beginning monthly IVIG infusions or a dosage change to reach equilibration (steady state).[6] Infusing increased amounts of IVIG results in a more rapid catabolic rate since the catabolism of IgG is concentration dependent.[11] This process is mediated by the Fc receptors on phagocytic cells.[12]

DOSAGE

The recommended dose for IVIG as replacement therapy is generally 400–600 mg/kg/month given every 4 weeks in patients with primary immune deficiency. A higher dose of immunoglobulin can lead to higher peak and trough levels of serum IgG.[13] On average, peak serum IgG levels increase approximately 250 mg/dL[13] and trough levels increase 100 mg/dL[14] for each 100 mg/kg of IVIG infused.

Several trials from the 1980s and 1990s demonstrated improved efficacy of current standard dose IVIG versus low-dose therapy (less than 200 mg/kg). In 1987 Bernatowska et al[15] compared 150 mg/kg with 500 mg/kg, and showed that the higher dose decreased the days of fever and days on antibiotics, and improved pulmonary function. The benefits of the higher dose of IVIG were more significant in children who had severe clinical symptoms. In a randomized cross-over study, Roifman et al[16] administered either 200 mg/kg or 600 mg/kg of IVIG to 12 patients with antibody deficiency and chronic lung disease. Pulmonary function improved on the higher doses of IVIG therapy. In 1992 Liese et al[17] reported outcomes of 29 patients with X-linked agammaglobulinemia who received immunoglobulin replacement therapy between 1965 and 1990. They showed a significant decrease in the incidence of pneumonias and the number of hospitalized days in patients receiving 350–600 mg/kg IVIG every 3 weeks compared with patients receiving less than 200 mg/kg IVIG every 3 weeks or 100 mg/kg of IM gammaglobulin every 3 weeks. The improvements were more evident when the high-dose IVIG was initiated before the age of 5 years. Eijkhout et al[18] studied the effect of two different doses of IVIG on the incidence of recurrent infections in patients with primary immune deficiency in a randomized, double-blinded, multicenter cross-over study. Compared with standard doses of IVIG (300 mg/kg every 4 weeks for adults, and 400 mg/kg every 4 weeks for children) the administration of high IVIG doses (600 mg/kg for adults, and 800 mg/kg for children) significantly reduced the number (3.5 vs 2.5 per patient) and duration (median, 33 days vs 21 days) of infections. Trough levels also increased during high-dose therapy. Importantly, the incidence and type of side-effects did not differ between the standard and high-dose therapies.

Historically, IgG trough levels of >500 mg/dL have been shown to prevent severe bacterial infections. However, Kainulainen et al[19] published data in 1999 on 22 patients with primary hypogammaglobulinemia and pulmonary abnormalities who were treated with IVIG. Despite adequate trough serum IgG levels (>500 mg/dL), silent and asymptomatic pulmonary changes occurred. Quartier and associates[20] performed a retrospective study of the clinical features and outcomes of 31 patients with X-linked agammaglobulinemia (XLA) receiving replacement IVIG therapy between 1982 and 1997. IVIG was given at doses of >250 mg/kg every 3 weeks with a mean serum trough level between 500 and 1,140 mg/dL (median 700 mg/dL). While the incidence of bacterial infections requiring hospitalizations fell from 0.4 to 0.06 per patient per year, complications of sinusitis, bronchiectasis, obstructive pulmonary disease and enteroviral meningoencephalitis still occurred. The authors suggested that more intensive therapy to maintain a higher serum IgG level, e.g. >800 mg/dL, may improve pulmonary outcome in patients with XLA.

Targeting of higher IgG trough levels has since been demonstrated to improve outcomes in hypogammaglobulinemic

TABLE 15-1 Commercial Intravenous Immunoglobulin Preparations

Brand (Manufacturer)	Manufacturing Process/ Antiviral Inactivation	pH	Additives	Parenteral Form and Final Concentrations	IgA Content µg/mL	Approved Method of Administration
Gammagard S/D (Baxter Corp)	Cohn-Oncley cold ethanol fractionation, ion exchange chromatography; solvent detergent treatment	6.4–7.2	2% glucose (5% solution)	Lyophilized powder 5% or 10%	<2.2 (5% solution)	Intravenous
Gammagard Liquid (Baxter Corp)	Cohn-Oncley cold ethanol fractionation, ion exchange chromatography; solvent detergent treatment, nanofiltration, low pH incubation	4.6–5.1	No sugars – stabilized with glycine	10% liquid	37	Intravenous and subcutaneous
Flebogamma DIF (Grifols Therapeutics, Inc.)	Cohn-Oncley cold ethanol fractionation, ion exchange chromatography; PEG precipitation, heat pasteurization; pH 4 treatment, solvent detergent treatment; double nanofiltration	5–6	5% D-sorbitol	5% or 10% liquid	<50 (5% solution <100 (10% solution)	Intravenous
Carimune NF (CLS Behring)	Kistler-Nitschmann fractionation, pH 4.0 plus pepsin, nanofiltration, depth filtration	6.4–6.8	5% sucrose (3% solution)	Lyophilized powder – reconstitute to 3, 6, 9 or 12%	720 (6% solution)	Intravenous
Gamunex-C (Grifols Therapeutics, Inc.)	Cohn-Oncley cold ethanol fractionation, caprylate chromatography, anion exchange chromatography, low pH incubation, double depth filtration	4.0–4.5	No sugars – stabilized with glycine	10% liquid	46	Intravenous and subcutaneous
Gammaplex (Bio Products Laboratory)	Kistler & Nitschmann fractionation, DEAE-Sephadex chromatography, Solvent/detergent treatment, CM-Sepharose chromatography, nanofiltration, low pH incubation	4.8–5.1	5% D-sorbitol	5% liquid	<10	Intravenous
Gammaked (Kedrion Biopharma, Inc.)	Cohn-Oncley cold ethanol fractionation, caprylate chromatography, anion exchange chromatography, low pH incubation, double depth filtration	4.0–4.5	No sugars – stabilized with glycine	10% liquid	46	Intravenous and subcutaneous
BIVIGAM (Biotest Pharmaceuticals Corp.)	Cohn-Oncley cold ethanol fractionation, ultrafiltration, solvent/detergent treatment	4.0–4.6	No sugars – stabilized with glycine	10% liquid	≤200	Intravenous
Octagam (Octapharma USA, Inc.)	Cohn-Oncley cold ethanol fractionation, ion exchange chromatography, ultrafiltration, solvent/ detergent treatment	5.1–6.0	Maltose 100 mg/mL	5% liquid	≤200	Intravenous
Privigen (CLS Behring)	Cold ethanol fractionation, octanoic acid fractionation, anion exchange chromatography; pH 4 treatment, nanofiltration, depth filtration	4.8	No sugars, stabilized with L-proline	10% liquid	≤25	Intravenous
Hizentra (CLS Behring)	Cold ethanol fractionation, octanoic acid fractionation, anion exchange chromatography; pH 4 treatment, nanofiltration	4.6–5.2	No sugar, stabilized with L-proline	20% liquid	≤50	Subcutaneous

patients on IVIG therapy. Orange et al[21] performed a meta-analysis of studies evaluating trough IgG level and pneumonia incidence in primary immune deficient patients with hypogammaglobulinemia. Across all included studies, pneumonia incidence progressively declined with increasing trough IgG, with trough levels of 1,000 mg/dL associated with one fifth the incidence of pneumonia seen with trough levels of 500 mg/dL.[21]

There is emerging evidence that ideal trough levels to prevent infection may vary considerably from patient to patient. Bonagura et al[22] proposed the concept of the biologic IgG level as the minimum serum IgG level that protects an individual immune deficient patient against recurrent bacterial infections and bronchiectasis. This level is anticipated to be somewhere in the age-matched normal reference range, but is unique for the individual patient.[22] This concept of individualized IgG trough was supported by Lucas et al,[23] who showed that patients with common variable immune deficiency (CVID) required a wide range of trough IgG levels, from 500 to 1,700 mg/dL, to prevent recurrent infection. X-linked agammaglobulinemia patients required IgG troughs between 800 and 1,300 mg/dL to prevent infection.[23]

The number of bacterial infections may not be a sufficient indicator of adequate treatment when used alone. Pulmonary abnormalities are among the most important factors associated with morbidity and mortality in patients with humoral primary immunodeficiencies. Periodic pulmonary function testing and judicious use of high-resolution chest computed tomography should be used to monitor for adequate control or prevention of pulmonary complications of humoral immune deficiency.

ADMINISTRATION

In patients with primary immune deficiency the replacement dose of IVIG is generally 400–600 mg/kg. The dose, manufacturer and lot number should be recorded for each infusion in order to perform look-back procedures for adverse events or other consequences. It is crucial to record all side-effects that occur during the infusion. It is also recommended to monitor liver and renal function tests periodically, approximately every 6 months. Antigen detection for hepatitis B and polymerase chain reaction (PCR) for hepatitis C should be performed, if clinically indicated.

There are several routes of administration of immunoglobulin.

Intravenous Administration

The recommended rates of IVIG infusion were determined in early studies using reduced and alkylated IgG.[24] Such preparations caused rate-related side-effects in 50% of patients. Newer preparations are generally more tolerable, but significant side-effects such as thrombosis have been associated with higher rates of infusion. Manufacturers recommend starting rates of 0.5–1 mg/kg/min and increasing incrementally up to rates anywhere between 3.3 and 8 mg/kg/min.[25–29] The FDA recommends that for patients at risk of renal failure, e.g. preexisting renal insufficiency, diabetes, age greater than 65 years, volume depletion, sepsis, paraproteinemia and use of nephrotoxic drugs, or patients at risk of thromboembolic complications, the dose should be gradually increased to a more conservative 3–4 mg/kg/min maximum.

Subcutaneous Immunoglobulin Administration (SCIG)

Berger et al[30] first described the use of the subcutaneous (SC) route for immunoglobulin replacement therapy in 1980. It was reported as safe, well tolerated and effective in achieving adequate serum IgG levels. Although used successfully in several studies,[31,32] it was not very popular because it was time consuming due to the slow rate of infusion (1–2 mL/hr). Home treatment with rapid subcutaneous infusion was studied more extensively in the 1990s and was demonstrated to be well tolerated, efficacious and resulting in fewer systemic side-effects than IVIG.[33–36] A meta-analysis of SCIG vs IVIG efficacy and safety studies demonstrated a trend toward better infection control with SCIG (though not achieving statistical significance), along with improved patient quality of life and decreased systemic adverse events when compared with IVIG therapy.[37] Higher and more stable trough levels have been seen with the subcutaneous administration of immunoglobulin, alleviating the fatigue and general constitutional symptoms patients have on IVIG toward the end of their 3–4 weeks dosing interval. The above qualities have made SCIG a viable alternative to IVIG for many patients, especially those with significant systemic adverse effects with IVIG.

When immunoglobulin is administered via the SC route, the dose is absorbed into the circulation and redistributed to the peripheral tissues more slowly than when given via the IV route.[38] One study showed that SCIG infusions (100 mg/kg of a 16.5% preparation) reach a steady state after 6 months if given weekly, or in one week if patients are first loaded with IVIG or given daily SC infusions for 5 days, prior to their maintenance weekly SCIG.[39]

In the USA a 20% immunoglobulin product for subcutaneous use is available and several 10% liquid products have both intravenous and subcutaneous indications (Table 15-1). The FDA required a dose adjustment in SCIG licensing studies, such that the weekly SCIG dose results in a total serum IgG exposure (area under the curve [AUC] of serum IgG versus time) equivalent to that of previous IVIG treatment.[40] Based on this AUC calculation, SCIG prescribing information recommends product-specific dosage increases of 37% to 53% when transitioning patients from IVIG to SCIG.[25,26,41] However, Berger et al[42] have recently shown that all US-licensed SCIG products have a similar bioavailability: 66.7% ± 1.8% of IVIG. They suggest that decreased bioavailability is a basic property of SCIG rather than the result of any manufacturing process or product concentration, and that dose adjustments are not necessary when switching from one SCIG product to another.[42]

Several studies from the EU, where a 1 : 1 conversion from IVIG to SCIG is standard, suggest that a dose adjustment from IVIG to SCIG may not be necessary to achieve good clinical outcomes.[43,44] In contrast, Haddad et al found that patients receiving SCIG doses that were 1.5 times higher than their previous IVIG doses had significantly lower rates of non-serious infections, hospitalization, antibiotic use and missed work/school activity, compared to patients that received SCIG doses identical to previous IVIG doses.[45] When switching a patient from IVIG to SCIG, making a dosage decision based on trough serum IgG levels and the clinical response to therapy is preferable to only taking pharmacokinetic measures into consideration.[40]

The technique of administering SCIG can be taught to most patients or caregivers to facilitate home self-administration.

https://CafePezeshki.IR

Infusions may be given anywhere from daily to weekly or biweekly via 1 to 6 sites, depending on the total amount infused and the amount that can be accommodated in a single site (a function of body mass index). Infusion sites are usually on the abdominal wall and inner thigh. Other sites may include posterior upper arms, flanks or below the buttocks. Before infusion is started, the lines need to be checked to ensure that there is no blood return. The rate of infusion of the various SCIG products is set initially at 15–20 mL/site/hr and may subsequently be increased up to 25–30 mL/site/hr, if no adverse reactions occur. A general guideline is 0.1–0.25 mL/kg/site/hr.[46]

SIDE-EFFECTS

Rate-related Adverse Reactions

Most adverse reactions of IVIG are related to the administration of IVIG and are rate related. Common adverse events include tachycardia, chest tightness, back pain, arthralgia, myalgia, hypertension or hypotension, headache, pruritus, rash and low-grade fever (Box 15-3). More serious reactions include dyspnea, nausea, vomiting, circulatory collapse and loss of consciousness. Patients with more profound immunodeficiency or patients with active infections have more severe reactions. Some of these reactions have been shown to be related to the complement-fixing activity of IgG aggregates in the IVIG.[47] In addition, the formation of oligomeric or polymeric IgG complexes can interact with Fc receptors and trigger the release of inflammatory mediators.[48] These adverse reactions occurred with lower frequency (10–15%) and with less severity in more recent preparations of IVIG. These reactions most commonly occur in newly diagnosed patients with hypogammaglobulinemia and in those patients who have chronic underlying infections such as sinusitis and bronchitis. One possible etiology is the binding of the infused antibodies to pathogen component antigens of the underlying chronic infection or inflammatory process. In a large prospective study of 459 antibody-deficient patients by Brennan and colleagues[49] of 13,508 infusions, the reaction rate was only 0.8%. There were virtually no severe reactions (0.1%).

Common reactions to IVIG, including fatigue, myalgia and headache, may be delayed and may last several hours after the infusion. Slowing the infusion rate or discontinuing therapy until symptoms subside may diminish the reaction. Pretreatment with a nonsteroidal antiinflammatory agent, e.g. ibuprofen (10 mg/kg/dose), acetaminophen (15 mg/kg/dose), diphenhydramine (1 mg/kg/dose) and/or hydrocortisone (6 mg/kg/dose, maximum 100 mg)[14,47,50] 1 hour before the infusion may prevent adverse reactions. If the patient continues to have adverse effects from IVIG despite pretreatment and rate change, the physician should consider changing the route of administration to subcutaneous.

Aseptic meningitis can occur with large doses, rapid infusions and in the treatment of patients with autoimmune or inflammatory diseases.[51–54] Interestingly, this adverse reaction rarely occurs in immunodeficient subjects.[50] Symptoms, including headache, stiff neck and photophobia, usually develop within 24 hours after completion of the infusion and may last 3 to 5 days. Spinal fluid pleocytosis occurs in most patients.[51,52,54] Long-term complications are minimal.[54] The etiology of aseptic meningitis is unclear but migraine has been reported as a risk factor and may be associated with recurrence despite the use of different IVIG preparations and slower rates of infusion.[51]

Renal Adverse Effects

Acute renal failure is a rare but significant complication of IVIG treatment. Histopathologic findings of acute tubular necrosis, vacuolar degeneration and osmotic nephrosis are suggestive of osmotic injury to the proximal renal tubules. Fifty-five percent of the cases were in patients treated for idiopathic thrombocytopenic purpura (ITP), and less than 5% involved patients with primary immunodeficiency.[55] This complication may relate to the higher doses of IVIG used in ITP. The majority of the cases were treated successfully with conservative treatment, but deaths were reported in 17 patients who had serious underlying conditions. Reports suggest that IVIG products using sucrose as a stabilizer may carry a greater risk for this renal complication. Because of this, the infusion rate for sucrose-containing IVIG should not exceed 3 mg sucrose/kg/minute. Risk factors for this adverse reaction include preexisting renal insufficiency, diabetes mellitus, dehydration, age greater than 65, sepsis, paraproteinemia and concomitant use of nephrotoxic agents. For patients at increased risk, monitoring blood urea nitrogen and creatinine before starting the treatment and periodically thereafter is necessary. If renal function deteriorates, the product

should be changed to a nonsucrose-containing IVIG or to SCIG.

Anaphylactic Reactions

Anaphylactic reactions to IVIG infusions are relatively rare.[49] IgE and IgG antibodies to IgA have been reported to cause severe reactions in IgA-deficient patients receiving intravenous gammaglobulin preparations.[7,56,57] Because of these concerns, the prescribing information for current gammaglobulin products includes either a precaution or contraindication to usage in IgA-deficient patients. Several studies have shown that these patients that have reacted to conventional IVIG preparations could then go on to tolerate IVIG preparations containing very low concentrations of contaminating IgA.[7,58] However, other studies have described patients with anti-IgA antibodies tolerating IgA-containing IVIG preparations without reaction.[59,60] Therefore the clinical significance of anti-IgA antibodies, and the role that these antibodies play in cases of anaphylaxis to IVIG products, remains controversial.

Thromboembolic Events

All human immune globulin products currently licensed in the USA carry an FDA warning of the risk of thrombosis with this class of products.[61] Local thromboses at infusion sites, deep vein thrombosis, pulmonary embolism, myocardial infarctions, transient ischemic attacks and stroke have all been reported following IVIG infusion.[62–65]

Risk factors for the development of IVIG-related thrombosis include advanced age, prolonged immobilization, hypercoagulable conditions, history of thrombosis, supplemental estrogens, indwelling central vascular catheters, hyperviscosity and cardiovascular risk factors.[61,62,65,66]

It has been suspected that these thrombotic complications were due to platelet activation and/or increased serum viscosity in patients receiving large doses of IVIG.[67–69] Recently, one IVIG product's increased risk for thromboembolic events has been shown to be due to high levels of activated Factor XI (FXIa).[70] Concerns over FXIa-related thrombosis have led to changes in manufacturing techniques, removal of Factor XI/XIa using an adsorbent during the manufacturing process, and use of the thrombin generation assay to monitor procoagulant activity of immunoglobulin products.[70]

Hemolytic Adverse Reactions

Because IVIG preparations are prepared from a large number of donors, IgG isohemagglutinins (antibodies against A/B blood group antigens) are present in these preparations. In non-O blood type recipients, anti-A and anti-B antibodies from the IVIG may react with red blood cells to cause asymptomatic Coombs positivity, or less commonly clinically significant hemolytic reactions, especially in those receiving high cumulative doses of immune globulin.[71–73] Clinically significant hemolysis is very rare in licensing studies of IVIG for primary immune deficiency, using doses of 400–800 mg/kg. Currently all immunoglobulin products licensed in the EU and USA are required to contain anti-A and anti-B titers that are less than or equal to 1 : 64 by the direct agglutination test.[74] Despite this, current products meeting these regulations are still implicated in cases of hemolysis, and strategies to address this issue of hemolysis are being pursued by the FDA.[74] Some manufacturers are instituting steps such as the use of adsorbents to lower titers of anti-A and anti-B.[75]

Infectious Complications

Hepatitis C virus (HCV) infection in patients receiving IVIG products was initially reported in experimental lots in Europe and the USA. HCV infection usually occurred in clusters associated with contaminated lots[76,77] and specific manufacturing procedures. The clinical course of HCV infection in patients with immune deficiency is not well defined. Routine screening of plasma donors for hepatitis C RNA by reverse transcriptase polymerase chain reaction (RT-PCR) and the addition of a viral inactivation process in the final manufacturing step, e.g. treatment with solvent/detergent and/or pasteurization, has drastically reduced the risk of transmission of hepatitis C and other viruses. In addition to these approaches in donor and plasma screening and testing, new innovative steps have been incorporated during the manufacturing process that include viral inactivation and viral removal stages. Some of the more common processes include solvent-detergent treatment of the final IVIG product to destroy potential lipid-envelope viruses, incubation at low pH, pasteurization, caprylate treatment and viral removal steps with depth filtration and nanofiltration. In aggregate, all these steps lead to a potential removal of 10–20 $\log_{10}$ reduction values (depending on the virus).[78,79] Thus, today's IVIG products are considered safe from a number of potential viral pathogens that were of concern in the early and mid 1990s. However, one potential group of pathogens that are still of potential concern are prions, which can cause transmissible spongiform encephalopathy, a fatal degenerative disease of the brain.[80] IVIG manufacturers have recognized prion-mediated disease as a potential problem and have initiated testing and IVIG purification and treatment steps (e.g. nanofiltration) to address this issue.[81]

Reactions to Subcutaneous Immunoglobulin

In general, the SCIG route has been remarkably free from severe systemic reactions.[25,26,41,82] In contrast, the majority of patients do experience local site reactions at some point during SCIG therapy, with symptoms of swelling, soreness, warmth, redness, induration, pruritus and/or bruising. Most of these local reactions last for less than 48 hours, and the severity and frequency of local reactions decrease as the patient continues SCIG therapy.[83–85]

IVIG as an Immune Modulating Agent in Patients with Autoimmune or Inflammatory Disorders

Since the first report by Imbach and colleagues[86] on the use of IVIG in childhood ITP, IVIG has been used for the treatment of a variety of inflammatory and autoimmune disorders.[87] A number of mechanisms have been postulated for the immunomodulatory effects of IVIG.[88] The mechanisms of action of Ig therapy can be broadly examined as follows: effects of Ig on Fc receptors, effects on the innate immune system, and effects on the adaptive immune system (Figure 15-1).

IMMUNE MODULATION OF FC RECEPTORS

In ITP the platelet counts rise rapidly following the administration of IVIG 1–2 g/kg.[89] The mechanism for platelet destruction is from FcγR-mediated phagocytic clearance of autoantibody-opsonized platelets in the spleen and liver.[90] Fehr

https://CafePezeshki.IR

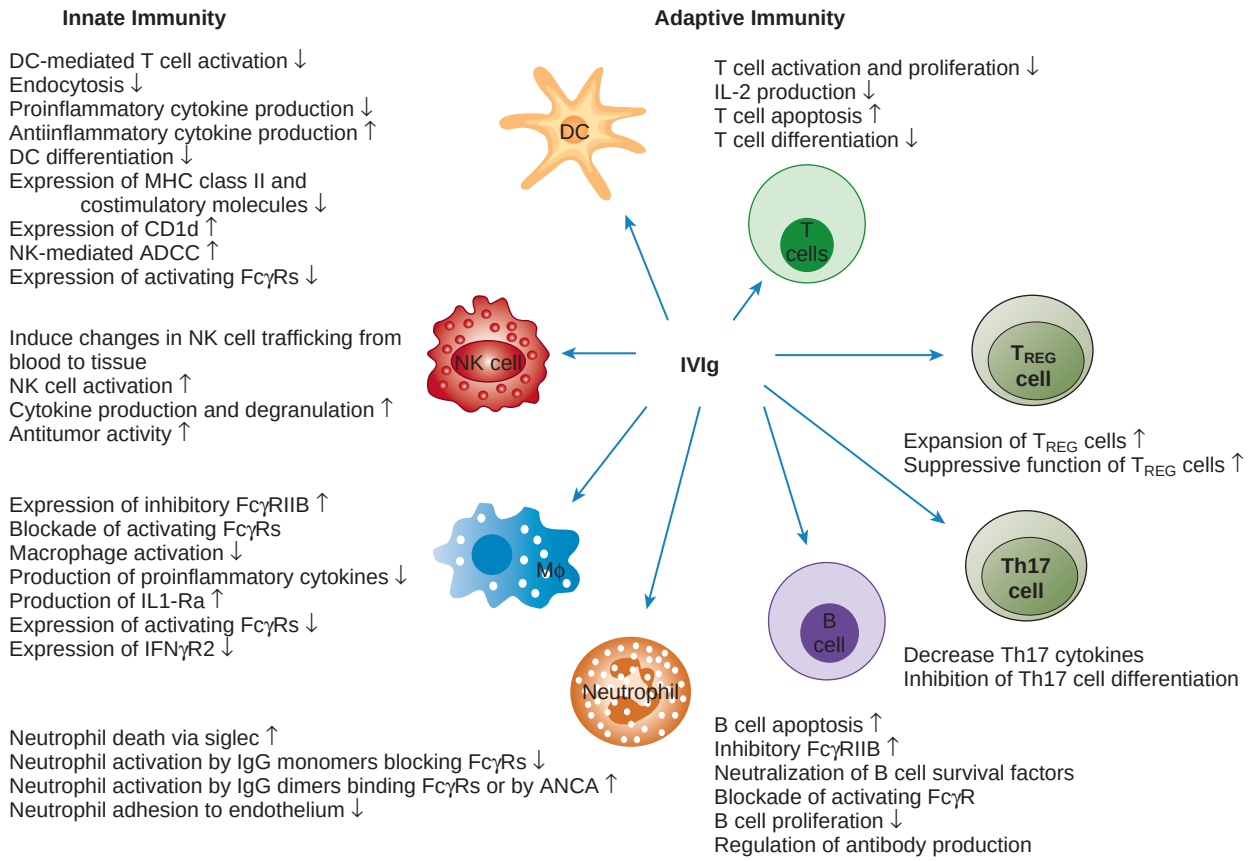

Figure 15-1 Mechanisms of action of IVIG on the immune modulation of various components of the innate and adaptive immune systems. *DC,* Dendritic cell; *Mϕ,* macrophage; *NK,* natural killer; MHC, major histocompatibility complex; ADCC, antibody dependent cellular cytotoxicity; ANCA, antineutrophil cytoplasmic antibody *siglec* – sialic acid-binding immunoglobulin-type lectin. *(Adapted from Tha-In T, et al. M Trends Immunol 2008;29(12):608–15; and Ballow M. The IgG molecule as a biological immune response modifier: mechanisms of action of intravenous immune serum globulin in autoimmune and inflammatory disorders. J Allergy Clin Immunol 127(2):315–23.)*

and colleagues[91] and Bussel[92] suggested that the rapid responses following IVIG treatment in ITP were caused by a blockade of the reticuloendothelial system (RES) by saturating these Fcγ receptors with the exogenous IgG. The observations by Debre and colleagues[93] when children with acute ITP were treated with intravenous Fcγ fragments from a preparation of IVIG supports the hypothesis that Fcγ receptor blockade is an important mechanism of action of IVIG in ITP, although other immune regulatory mechanisms are present.

Another mechanism that involves a specialized Fc receptor is the proposed antiinflammatory effect of IVIG on the clearance of pathogenic autoantibodies by competing with autoantibodies for the neonatal Fc receptor (FcRn).[12] FcRn protects IgG from degradation and is critical for its long half-life in the serum.[94] In mouse models of bullous pemphigoid and arthritis, IVIG treatment results in a reduction in pathogenic antibodies to levels beneath the disease-causing threshold, and this effect is attenuated in FcRn-deficient mice.[95,96] Hansen and Balthasar[97] reported that high-dose IVIG in a rat model of immune thrombocytopenia enhanced the clearance of antiplatelet antibodies by the saturation of the FcRn receptor for IgG. The importance of this mechanism in human diseases is difficult to measure but in an FcRn-deficient rat model it has been estimated that this mechanism may account for approximately 50% of the immune-modulating effects of IVIG in ITP.[97]

Macrophages, B cells and a subpopulation of T cells express a low-affinity inhibitory Fcγ receptor (FcγRIIB).[98,99] This receptor provides an inhibitory signal to cells through a pathway mediated by an immunoregulatory tyrosine-based inhibition motif, e.g. ITIM. Similar inhibitory Fcγ receptors are present on basophils and mast cells. Samuelsson and colleagues[100] investigated a murine model of immune thrombocytopenia. They found that the protective effects of IVIG required the inhibitory Fcγ receptor, e.g. FcγRIIB, since either disruption of the receptor or blocking with a monoclonal antibody reversed the therapeutic effects. In addition, IVIG therapy results in the up-regulation of the inhibitory FcγRIIB on effector macrophages.[100,101] The observations on the effects of IVIG in patients with steroid-dependent asthma[102,103] may be related to similar FcγRIIB regulatory receptors on basophils and mast cells.

Studies by Kaneko and colleagues[101] showed that a component moiety of the IVIG molecule responsible for its antiinflammatory activity is the part of the IgG molecule that contains a sialylation site on the glycan linked to asparagine at position 297 on the Fc fragment (only 1–2% of the total IgG in IVIG). Desialylation of the sialic acid residues with neuraminidase was demonstrated to blunt the protective effect of an IVIG preparation in a mouse model of rheumatoid arthritis. In the same K/BxN arthritis model, sialic acid-enriched fractions of IVIG with the 2,6-sialylated linkage at Asn297 on the Fc portion showed a 10-fold increase in protection against immune-mediated arthritis. Anthony and colleagues[104,105] have demonstrated that greatly reduced doses of a recombinant, sialylated Fc fragment can completely recapitulate the antiinflammatory effects of IVIG in this same mouse model. These investigators have shown that the action of sialylated Fc in the rheumatoid arthritis

https://CafePezeshki.IR

mouse model is mediated through the interaction of sialylated Fc with the SIGN-R1 receptor on macrophages.[105] The authors propose that the interaction between sialylated Fc and SIGN-R1 (CD209) produces an antiinflammatory state that results in an up-regulation of inhibitory FcγRIIB receptors on effector macrophages, making these cells more resistant to triggering by immune complexes. They suggest that DC-SIGN, the human ortholog of SIGN-R1, may have a comparable role in the anti-inflammatory effects of IgG Fcs in human disease. More recently, Anthony et al[106] reported that the modulating effect of sialylated-rich IgG binding to SIGN R1 on marginal zone macrophages in their K/BxN arthritis mouse model was mediated by the production of IL-33 by dendritic cells, which, in turn, induced the expansion of IL-4 producing basophils that promote the increased expression of FcγRIIB receptors on effector macrophages. These new findings may explain some of the observed effects of IVIG and have the potential to tie together several of the proposed antiinflammatory actions into a more cohesive model for the mechanism(s) of IVIG activity in many autoimmune diseases.[107]

EFFECTS OF IMMUNOGLOBULIN ON COMPONENTS OF THE INNATE IMMUNE SYSTEM

IVIG binds to activated C3b and C4b and prevents the tissue deposition of these activated complement proteins.[108] Several diseases and animal models have been reported in which inhibition of complement has been suggested as the mechanism of IVIG's antiinflammatory activity. Frank and his co-workers,[109] using an animal model of Forssman shock, demonstrated that high-dose IVIG prevented the death of guinea pigs by preventing activated C3 and C4 fragments from binding to target cells, resulting in the modulation of acute complement-dependent tissue injury. Basta and colleagues[110] showed that IVIG not only inhibited the uptake of C3 fragments onto antibody-sensitized cells, but also C4, an early complement component.

Dermatomyositis (DM) provides an example of the effects of IVIG on complement-mediated damage in an autoimmune disease. This autoimmune disease is characterized by the subacute onset of muscle weakness, affecting predominantly the proximal muscle groups, is often accompanied or preceded by a characteristic skin rash, and is associated with circulating autoantibodies to endothelial cells and histidyl-tRNA synthetase (Jo-1).[111,112] A humoral immune process directed against the intramuscular capillaries characterizes the immunopathogenesis of DM. This process leads to a complement-mediated endomysial microangiopathy with deposition of the membrane attack complex (MAC) consisting of activated complement components C5b-9 on the intramuscular capillaries.[112] The endomysial capillary damage as a result of MAC deposition leads to microinfarcts within the muscle fascicles, muscle ischemia, inflammation and eventually perifascicular atrophy.[113] The expression of ICAM-1 is increased on the endomysial blood vessels and muscle cells, which further facilitates the infiltration of inflammatory cells, mainly $CD4^+$ T cells and some B cells.[113,114] Dalakas and colleagues[112,115] reported that the muscle biopsies of patients improve after IVIG therapy and histologically the MAC deposits disappear from the endomysial capillaries along with a decrease in ICAM-1 expression in muscle tissues.[112,116]

The acute vaso-occlusive crisis of sickle cell disease (SCD) is another disease in which IVIG may modulate adhesion molecules. In SCD, abnormal sickle red blood cells (RBCs) have an increased propensity to adhere to each other and to vascular endothelial cells, resulting in vascular occlusion. Sickled RBCs have also been shown to adhere to other blood cells, including leukocytes. Chang and colleagues[117] investigated the effect of IVIG on a mouse model of sickle cell acute vaso-occlusive crisis, in which the adhesion of sickle RBCs to leukocytes is known to cause the vaso-occlusive pathology. In this model, high-dose IVIG given after the onset of a crisis resulted in improved blood flow and prolonged survival. The investigators demonstrated that the mechanism of IVIG in this model was a rapid reduction in neutrophil adhesion to vascular endothelium and decreased interaction between RBCs and leukocytes.

EFFECTS OF IMMUNOGLOBULIN THERAPY ON COMPONENTS OF THE ADAPTIVE IMMUNE SYSTEM

Viard and colleagues[118] reported that IVIG could inhibit the apoptotic process, i.e. programmed cell death, in patients with toxic epidermal necrolysis (TEN or Lyell's syndrome), a severe drug-induced bullous skin reaction. In in vitro studies IVIG was demonstrated to protect the keratinocytes from apoptosis by blocking the effects of FasL on the Fas receptor. These investigators also determined that the depletion of anti-Fas antibodies from IVIG abrogated the ability of IVIG to inhibit FasL-mediated apoptosis. In an open, uncontrolled trial of IVIG (0.2–0.75 g/kg/day for 4 consecutive days) in 10 patients with TEN, skin progression was halted within 1 to 2 days and was followed by rapid skin healing and a favorable outcome. This immune-modulating effect of IVIG in patients with TEN represents another unique mechanism by which IVIG can modify the disease process, and may prove to be useful in other Fas-mediated inflammatory or autoimmune diseases.

While IVIG has been shown to have suppressive effects on effector T cells,[119,120] it has been shown to expand and enhance the function of $Foxp3^+$ regulatory T cells (T_{REGS}). In a mouse model of multiple sclerosis, the protective effect of IVIG was lost in mice that were depleted of T_{REGS}.[121] In patients with Kawasaki disease and Guillain-Barré syndrome, clinical improvement with IVIG therapy correlated with increased T_{REG} number and function.[122] De Groot and colleagues[123] proposed that IVIG has a positive effect on T_{REGS} because of the presence of T cell epitopes in the Fab and Fc fragments which, when presented by antigen-presenting cells, specifically activate $CD4^+CD25^+Foxp3^+$ T_{REGS}, and that this expansion of T_{REGS} mediates the immunomodulatory effects of IVIG. Tjon et al[124] reported that high-dose, but not low-dose, IVIG treatment in patients with immunodeficiency and autoimmune disease enhanced the activation of circulating T_{REG} cells, but the numbers of circulating T_{REG} cells remained unchanged. Kaufman et al have extensively studied the effects of IVIG therapy in an ovalbumin-sensitized mouse model of asthma. IVIG markedly attenuated lung inflammation and decreased bronchial hyperresponsiveness to methacholine.[125] IL-13 and TNF-α levels were diminished, Delta-4 (part of the Notch pathway that induces Th1 cells) expression increased, while Jagged-1 (part of the Notch pathway that induces Th2 cells) expression and GATA-3 mRNA decreased, suggesting that Th2 responses were suppressed. The draining pulmonary lymph nodes of IVIG-treated mice showed a significant increase in $CD4^+CD25^+Foxp3^+$ regulatory cells, and IVIG-primed dendritic

BOX 15-4 THERAPEUTIC PRINCIPLES OF IVIG TREATMENT IN PATIENTS WITH PRIMARY IMMUNE DEFICIENCY

- Initial dosage: 400–600 mg/kg every 4 weeks for replacement therapy:
  - some patients may benefit from trough levels of 700–900 mg/dL
  - adjust the dose and/or dosing interval depending on clinical response
  - record manufacturer, lot number and dose with each infusion
- Equilibration takes several months even when dosage changes made:
  - check trough levels if patient continues to have infections or prior to dose change
    - may be useful to determine adherence in patients on SCIG
  - treat the patient and not the 'numbers', e.g. trough level
- For patients with systemic adverse effects or poor venous access, the subcutaneous route may be a better option.
- Ig replacement therapy is indicated as continuous replacement therapy for primary immunodeficiency. Treatment should not be interrupted once a definitive diagnosis has been established.
- Site of care. The decision to infuse IVIG in a hospital, hospital outpatient, community office or home-based setting must be based upon clinical characteristics of the patient.
- IVIG is not a generic drug and IVIG products are not interchangeable. A specific IVIG product needs to be matched to patient characteristics to ensure patient safety. A change of IVIG product should occur only with the active participation of the prescribing physician.

MONITOR

- Complete blood count with differential; liver and renal function tests every 6–12 months
- Nucleotide testing for viral pathogens, e.g. hepatitis C, when indicated
- Pulmonary function testing; diffusion capacity testing as indicated; chest x-ray, high-resolution chest tomography (initially if there is a history of lung disease and thereafter as indicated – may enhance patient's risk of malignancy)

cells on adoptive transfer to ovalbumin-sensitized and -challenged mice abrogated airway hyperresponsiveness and induced T_{REG} cells.[126] In this model system, Massoud et al reported that sialylated IgG bound to a novel C-type lectin receptor, i.e. dendritic cell immunoreceptor (DCIR), induced T_{REG} cells. Thus, a number of studies recently have demonstrated the importance of the induction of $Foxp3^+$ T_{REG} cells by IVIG in modulating the autoimmune/antiinflammatory process, while immunoglobulin therapy may down-regulate the TH-17 pathway.[127]

Conclusion

Immunoglobulin replacement is the mainstay of treatment for patients with primary humoral immune deficiency. The goal of the treatment is to provide a broad spectrum of antibodies to prevent infections and chronic complications. The usual dose is 400–600 mg/kg/month but this may vary individually and higher doses may be required during active infection. A serum trough level above 500 mg/dL has been shown to be effective in the prevention of severe infections. However, recent studies have suggested that even higher doses and achieving IgG trough levels of 700–1,000 mg/dL may be desirable.[21,22] Recently, SCIG has gained acceptance as an alternative route for the administration of replacement therapy in patients with immune deficiency. Generally, IVIG replacement therapy is considered safe in the majority of patients. Side-effects are usually mild and treatable by premedication. Improvements in good manufacturing practices, closer screening of plasma donors, testing of the source plasma with sensitive nucleic acid assays, e.g. PCR, and additional viral inactivation steps have made IVIG a better and safer plasma-derived product. The majority of the utilization of IVIG therapy is in patients with autoimmune disorders. The use of IVIG in these patient groups has not only led to a new treatment modality but has enhanced our understanding of the disease pathogenesis and the mechanisms by which IVIG may modulate the immune and inflammatory processes (Box 15-4).

16 Hematopoietic Stem Cell Therapy

DONALD B. KOHN | LUIGI D. NOTARANGELO

KEY POINTS

- Hematopoietic stem cell transplantation (HSCT) can correct many primary immune deficiencies (PIDs) by providing a normal source that produces functional leukocytes to replace the defective cells.
- Best outcomes are obtained when using matched sibling donor bone marrow, although results using matched unrelated adult or umbilical cord blood donors or haploidentical (parental) donors continue to improve.
- Multiple factors affect outcomes, include the specific PID being treated, the general health of the recipient, presence or absence of intercurrent infections, the choice of pretransplant conditioning regimen used to facilitate engraftment and the source of donor hematopoietic stem cells.
- Several clinical trials of gene therapy – autologous transplantation of genetically corrected hematopoietic stem cells – using murine retroviral vectors showed significant immune reconstitution. However, there was a high incidence of vector-related leukoproliferative complications.
- Current trials mostly use lentiviral vectors, which may be more effective and safer than the murine retroviral vectors, further improving outcomes for gene therapy for PID.

Several forms of primary immune deficiency (PID) result from mutations of genes involved in the production, function or survival of leukocytes. Therefore, these PIDs can be treated by allogeneic hematopoietic stem cell transplantation (HSCT) that provides patients with a new source of genetically normal leukocytes. The first successful clinical allogeneic bone marrow transplant (BMT) was performed in 1968 for a patient with severe combined immune deficiency (SCID), resulting in sustained reconstitution of immunity that has lasted now for several decades.[1] Since that time, allogeneic HSCT has become the standard of care for patients with SCID and is often used for patients with other severe, life-threatening forms of PID. Patients with less severe PIDs, especially those primarily affecting production of antibodies that can be replaced with intravenous gammaglobulin administration, generally are not treated with HSCT.

The major barriers to allogeneic HSCT are immunologic. In solid organ transplantation, a recipient's T cells can reject the organ donor's cells. Graft rejection is less of a problem in severely immune deficient recipients, such as patients with SCID who lack T lymphocytes, and in some cases also B and NK cells. However, in some of the PIDs that retain partial function of the immune system, a significant risk for graft rejection remains. In most cases, transplant recipients need partial or essentially complete ablation of their endogenous immune and hematopoietic systems to achieve enduring engraftment of donor HSCs. Definition of optimal pretransplant conditioning regimens remains one of the major areas of discovery in the field.

The flipside of graft rejection, which is mostly limited to HSCT and only rarely encountered in solid organ transplant, is graft versus host disease (GvHD), where alloreactive T cells from the donor that are given with the allogeneic bone marrow can, in effect, reject the recipient's cells. GvHD can be severe, chronic and even fatal; complications increase in frequency and severity with increasing degree of mismatch between the donor and the recipient. Efforts to prevent or suppress GvHD, by administration of immune suppressive medications or by depleting the donor's mature T lymphocytes from the graft, often result in prolonged immune deficiency that poses high risks for opportunistic infections, especially beyond the infant period when patients may bear latent herpesviruses, BK virus or adenovirus.

Severe Combined Immune Deficiency

Severe combined immune deficiency is the most severe of the PIDs, with inherited absence of T and B cell function (and variable NK activity). In the absence of medical intervention, infants with SCID suffer a high rate of early mortality from infections. SCID is a clinical phenotype which may result from defects in any one of more than 12 genes (Box 16-1). The clinical research associated with the treatment of human SCID has produced many of the major advances in the field of HSCT[1–6] (Box 16-2).

Allogeneic HSCT can be curative for SCID when bone marrow from a human leukocyte antigen (HLA)-matched sibling donor (MSD) is used, with most centers reporting greater than 90% long-term survival. PID patients who receive an allogeneic HSC transplant from an HLA-MSD generally achieve high rates of immune reconstitution and good quality of life. For patients with SCID, HLA-MSD marrow can be infused without chemotherapy or radiation 'conditioning', and will appropriately restore T cell function in most patients. Most other PIDs require full or partial marrow 'conditioning' for proper engraftment of donor cells without rejection.

By contrast, HSCT from HLA-mismatched donors (e.g. a haploidentical/haplodisparate parent) carries a significant risk of severe GvHD, because the donor's T cells contained in the graft would react against the non-shared HLA proteins (such as those inherited from the other parent). To prevent this, methods to deplete T lymphocytes from bone marrow in order to limit GvHD risks were developed in the mid 1970s (Box 16-3). Using

Artemis (*DLCRE1C*)
DNA-dependent protein kinase catalytic subunit (DNA-PKcs)
Cernunnos

METABOLIC DEFECTS

Adenosine deaminase (*ADA*) (10–15%)
Purine nucleotide phosphorylase (*PNP*)
Adenylate kinase 2 (*AK2*)

BOX 16-2 HISTORICAL LANDMARKS FOR THE USE OF HSCT FOR SCID

First successful human BMT (1968)[1]
First use of matched unrelated donor (MUD) bone marrow (1973)[2]
First transplant with haploidentical (parent) bone marrow (1975)[3]
First approach using gene therapy (1990)[4,5]
First 'cure' using gene therapy (2000)[6]

BOX 16-3 METHODS FOR T CELL DEPLETION OF DONOR BONE MARROW

Complement-mediated lysis
Counterflow centrifugation elutriation
Density gradients
Polyclonal antibodies (ALG, ATG)
Monoclonal antibodies (anti-CD2, anti-CD3, anti-CD4, anti-CD5, anti-CD6, anti-CD7, anti-CD8, anti-CD52, TcRαβ, CD45RA)
Soy bean agglutinin/E-rosette with sheep red blood cells
Stem cell enrichment (e.g. anti-CD34)

such approaches to deplete T cells, marrow from parental donors, who are only matched by one HLA haplotype and therefore mismatched for a full HLA haplotype, has been frequently used for SCID patients lacking an HLA-matched donor; 50% to 80% of SCID patients have realized long-term survival.[7–9] The lower success rate with haploidentical transplants may reflect the morbidity and mortality associated with: (1) the increased risks of graft rejection and/or GvHD; (2) the T cell depletion that is utilized to prevent GvHD which slows immune reconstitution and prolongs the period of increased susceptibility to infections; and (3) the adverse effects secondary to the possible use of chemotherapy to make space and eliminate residual immunity.

One of the continuing controversies about the optimal approach to haploidentical HSCT for SCID concerns the necessity, or lack thereof, of pretransplant conditioning with chemotherapy or other immune suppressive medications to facilitate long-term engraftment of donor HSCs. In the absence of conclusive data from randomized clinical trials, there are strong advocates of either of these approaches.

A few very active centers have performed haploidentical transplants for SCID patients for more than three decades, successfully giving T cell-depleted bone marrow from a parent without any preconditioning therapy or immune suppressive medicines to prevent GvHD.[8] Most of these patients have had successful T cell immune reconstitution lasting decades, although it will take longer observation to assess the durability of T cell function. However, more than half of them have had inadequate B cell reconstitution and were reported still to require regular administration of intravenous gammaglobulin, possibly indicating a failure to engraft sufficient numbers of HSCs in the absence of marrow conditioning.

Use of cytoreductive conditioning prior to HSCT for SCID typically leads to donor cell chimerism in all lineages, indicating replacement of the endogenous HSCs with those of the donor. This full donor engraftment may lead to more sustained production of new T cells and may lead to increased numbers and activity of B and NK cells.[10] However, the acute and long-term toxicities of the chemoablative regimens may lead to increased toxicity and mortality in the initial period, especially in patients with preexisting infections, and may cause long-term growth, endocrinologic and neurocognitive abnormalities.[11,12]

Historically, less has been done using matched unrelated donor marrow (MUD) or cord blood for transplantation of SCID patients who do not have an HLA-MSD. HSC transplantation using MUD or cord blood carries increased risks for GvHD, compared to the use of marrow from an MSD.[13] The frequency of severe GvHD in MUD marrow and cord blood HSC transplantation is in the range of 25–50% and 20–40%, respectively. In addition, HSC transplantation with cord blood has a risk for engraftment failure between 10% and 20%. These increased complications are likely to be due to more mismatches for non-HLA (minor) antigens. Generally, full cytoablation and GvHD prophylaxis (i.e. post-transplant immune suppression) are needed to prevent graft rejection or GvHD.[14]

In the past few years, a consortium of investigators from North America involved in the clinical care of patients with severe PIDs has organized as the Primary Immune Deficiency Treatment Consortium (PIDTC) to compile data on treatment and outcomes, mainly focussed on hematopoietic transplants.[15] Results were analyzed retrospectively for transplants performed between 2000 and 2009 in 240 patients with typical or 'classical' SCID.[16] Outcomes for infants treated at less than 3.5 months of age were excellent (94% 5-year survival), independently of the source of HSC used. For patients older than 3.5 months of age at the time of transplant, the presence of ongoing infections, mostly viral, led to poorer survival (50% 5-year survival). Among patients who were infected at the time of HSCT, the outcome was worse in those who received pretransplant conditioning (31.2% 5-year survival) than in those transplanted without conditioning (61.4% 5-year survival). Nevertheless, for surviving infants, T and B cell functions were more frequently better in those who received pretransplant conditioning, which raises a conundrum in defining the best approach (Box 16-4). Importantly, newborn screening for SCID is now available in many States and may permit rapid identification of affected babies, who can be referred to HSCT before developing infections. While this is expected to result in improved outcome, the role (and intensity) of pretransplant conditioning in this group of very young infants remains to be defined.

Because SCID is rare, and may be caused by various genetic defects, few studies have analyzed the outcome of HSCT in

BOX 16-4 POTENTIAL TRANSPLANT DONOR AND APPROACHES FOR SCID INFANTS

MSD when available for all, without conditioning
Infants 3.5 months or less: MSD, MMFD, MUD (adult or cord blood) or autologous/gene therapy; with or without conditioning, per center experience
Infants >3.5 months without resistant viral infection: MSD, MMFD, MUD (adult or cord blood), or autologous/gene therapy; with or without conditioning, per center experience
Infants >3.5 months with resistant infection: MSD, MMFD, MUD (adult or cord blood) or autologous/gene therapy; without conditioning. May develop full or partial T cell immunity, but good B and NK cell function unlikely. Second, conditioned transplant may be considered at time of improved health to improve immunity

MSD, Matched sibling donor; *MMFD,* Mismatched family donor, typically parent; *MUD,* Matched unrelated donor.

specific forms of SCID. An international consortium has reported on the outcome of HSCT in 106 patients with ADA deficiency.[17] Overall survival after HSCT from MSD or matched family donors (86% and 81%, respectively) was better than from MUDs (66%; $P < .05$) or haploidentical donors (43%; $P < .001$). Survival was superior for patients who received unconditioned transplants than for those who received myeloablative conditioning (81% vs 54%, respectively; $P < .003$). However, unconditioned transplantation was associated with a higher risk of non-engraftment. Long-term studies showed that most surviving patients attained durable immune reconstitution.

Defects of V(D)J recombination due to RAG, Artemis, DNA PKcs, or Cernunnos mutations cause $T^-B^-NK^+$ SCID. In addition, Artemis and DNA PKcs deficiency cause increased cellular radiosensitivity, which may lead to additional toxicity when conditioning regimens are used for HSCT. Schuetz et al have reported on the outcome of HSCT in patients with Artemis mutations vs patients with RAG1/2 deficiency.[18] Survival after MSD HSCT was comparable in the two groups. However, patients with Artemis deficiency had an increased rate of late complications, including poor growth and requirement for nutritional support, autoimmune manifestations, growth hormone deficiency, hypothyroidism and dental anomalies.

Wiskott-Aldrich Syndrome

The pathophysiology, presentation, diagnosis and general management of Wiskott-Aldrich syndrome (WAS) are discussed in Chapter 9.

Bach and colleagues performed the first sibling HSCT for WAS.[19] MSD HSCT provides the best outcome for WAS patients and is established as the standard of care when available.[20] In recent years, advances in transplant methods have significantly improved outcome of MUD HSCT also in WAS patients less than 5 years old. In particular, in a recent multicenter international study of 194 patients with WAS who received HSCT in the period 1990–2009, 5-year survival was 84%, and it was 73.3% in those who received MUD HSCT at less than 5 years of age.[21]

With current approaches, the majority (72%) of WAS patients attain full chimerism after HSCT. However, mixed chimerism may be associated with complications. In particular, post-HSCT autoimmune disease is frequently observed. Host WASp-deficient B cells that persist after transplantation due to mixed donor chimerism may not respond fully to regulatory cues and produce autoantibodies.[22,23] Furthermore, low myeloid chimerism is associated with an increased risk of persistent thrombocytopenia.[21] Overall, HLA-MSD HSCT in patients who are less than 5 years of age and achieve full donor chimerism has the best outcome, but if an MSD is unavailable, a matched unrelated donor HSCT is a viable option.

Chronic Granulomatous Disease

The pathophysiology, presentation, diagnosis and general management of chronic granulomatous disease (CGD) are discussed in Chapter 11 (and reference 24). It is estimated that the median lifespan of patients with CGD is 20 to 25 years and the mortality rate is 2% to 5% per year.[25] Since many CGD patients live into adulthood, in contrast to the near certain early mortality of SCID, decisions are more difficult concerning the potential benefits of transplant versus the risks that are associated with a myeloablative HSCT.[26–28] Theoretically, reduced intensity conditioning decreases the toxicity associated with the conditioning regimen and T cell depletion decreases the risks for GvHD.[29] Recently, a multicenter European study using reduced intensity conditioning and matched sibling or matched unrelated donors for CGD reported excellent outcomes for 56 CGD patients; overall survival was reported as 93% with event-free survival (surviving with donor engraftment) at 89%.[30]

Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is a rare disorder that is characterized by highly activated macrophages and lymphocytes. Primary or familial HLH is inherited as an autosomal recessive disease, while secondary HLH is an acquired form that is usually associated with a viral illness. While initially considered to be a malignant disorder of histiocytes, more recent understanding of HLH classifies it as a PID, with defects in genes involved in transport and/or release of cytolytic granules, such as perforin, *MUNC 13-4*, *STX11*, *STXBP2*. Inability to kill activated cells results in persistent stimulation of the immune system with increased production of IFN-γ and uncontrolled activation of macrophages.

The first curative HSCT for HLH was performed in 1986.[31] Currently, standard treatment for the familial type involves induction immunochemotherapy with etoposide, dexamethasone and cyclosporin A, followed by HSCT. An earlier clinical trial, HLH-94, showed that the outcomes with MUD HSCT were equivalent to those with HLA-MSD HSCT (67% vs 68%). Patients who received transplants from mismatched related donors (usually haploidentical) had a survival rate of 43%.[32,33] More recently, significant improvement of outcome has been reported after HSCT for HLH with use of a reduced intensity conditioning (RIC) regimen. In a series of 40 patients who received HSCT for HLH at Cincinnati Children's Hospital, 3-year overall survival was 43% for those who received fully myeloablative conditioning (MAC) vs 92% for those who received RIC.[34] This difference was mostly due to increased risk of early death (<6 months after HSCT) in patients receiving MAC. Although RIC is associated with an increased rate of mixed chimerism, levels of 10–20% donor chimerism apparently suffice to control HLH.

https://CafePezeshki.IR

Other Primary Immune Deficiencies Amenable to Hematopoietic Stem Cell Transplantation

HSCT is the treatment of choice also for severe defects that affect late stages of T cell development (such as ZAP-70 deficiency and MHC class II deficiency), other forms of combined immunodeficiency (X-linked hyper-IgM syndrome, DOCK8 deficiency), immunodeficiency with severe immune dysregulation (IPEX), and X-linked lymphoproliferative disease (XLP). At variance with SCID, these PIDs are characterized by the presence of autologous T cells, requiring use of conditioning in preparation for HSCT. Less severe PIDs, such as X-linked agammaglobulinemia (XLA), common variable immune deficiency, selective antibody defects, etc., have not been routinely subjected to HSCT thus far, since the risks of HSCT may exceed those of the underlying disorder.

Gene Therapy Using Hematopoietic Stem Cells

GENE THERAPY FOR ADA-DEFICIENT SCID

Gene therapy was conceived as an alternative to allogeneic HSCT in which a patient's own HSCs would have a normal copy of the disease-related gene inserted (Figure 16-1). Autologous gene therapy should avoid the immunologic complications of allogeneic HSCT (graft rejection and GvHD) but could yield the same clinical benefits. Based on the known therapeutic effects from non-myeloablated MSD transplants for SCID with only low engraftment of donor HSCs, it was postulated that in SCID there would be selective lymphoid expansion from a small number of gene-corrected HSCs that could amplify the effects of low efficiency gene transfer.

Six clinical trials of gene therapy for ADA-deficient SCID were performed in the 1990s.[4,5,35–40] All of these studies used retroviral vectors to transfer a normal *ADA* cDNA, targeting either mature T lymphocytes that developed after PEG-ADA therapy, or CD34$^+$ HSCs from autologous bone marrow or umbilical cord blood.[41] While there were no serious adverse events from the gene transfer in any of the subjects, there were also no significant clinical benefits. Overall, survival and immune function in these subjects were comparable to those in patients receiving only PEG-ADA therapy.

During the 1990s, incremental progress was made with techniques of gene transfer and stem cell culture.[42–46] Additionally, the use of RIC prior to allogeneic HSCT was shown to allow a moderate degree of engraftment of donor cells, with significantly reduced acute toxicity.[47,48] Such non-myeloablative conditioning was postulated to be beneficial in the autologous gene therapy setting (Figure 16-2). Based on these advances, second-generation clinical trials of gene therapy for SCID were begun in the late 1990s.

The investigators at the San Raffaele Telethon Institute for Gene Therapy in Milan, Italy, made a major advance in the field with their clinical trial of gene therapy for ADA-deficient SCID. Initial results were reported in 2002 on two ADA-SCID infants treated using retroviral-mediated *ADA* gene transfer to bone marrow CD34$^+$ cells.[49] Two important variables were changed, compared to earlier trials. First, the patients were given RIC, using a moderate dosage of busulfan (4 mg/kg, approximately ¼ of 'full dose') to eliminate some of the endogenous HSCs prior to infusion of the gene-corrected bone marrow cells. Second, the patients were *not* given PEG-ADA enzyme replacement therapy, which was expected to allow the maximum selective advantage of gene-corrected T cells to manifest. Indeed, over the first 6 to 9 months, immune function was largely restored, with the development of antigen-specific T cell responses and antibody production. Measurements of gene marking showed that 75–100% of T, B and NK cells contained the transferred gene, consistent with the strong purported selective advantage for ADA-expressing lymphocytes. At the same time, 1–10% of myeloid cells contained the gene, which was a

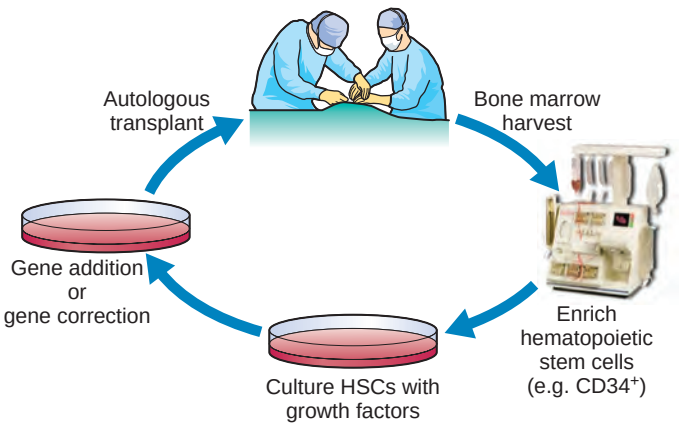

Figure 16-1 Gene therapy using autologous hematopoietic stem cells. Bone marrow is harvested from the PID patient. In the laboratory, the HSCs are enriched by immune affinity with a monoclonal antibody to the CD34 antigen. The CD34 enriched cells are cultured with hematopoietic growth factors to activate the cells and then gene addition or gene correction is performed. The HSCs are then transplanted by intravenous infusion back into the patient.

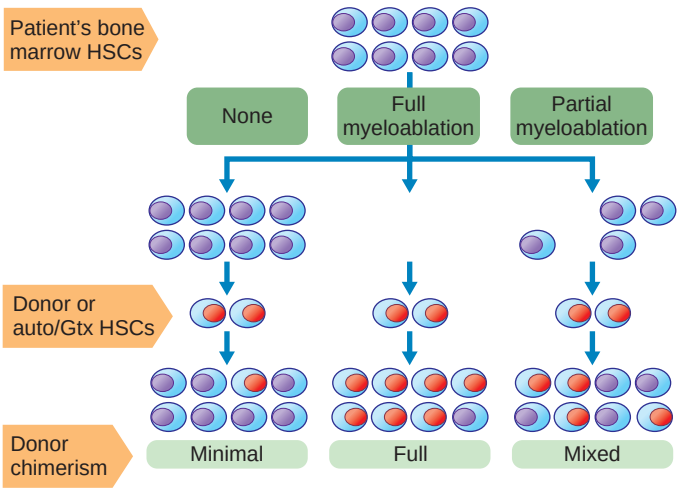

Figure 16-2 Outcome after HSCT with full, partial or no myeloablative conditioning. If HSCs are transplanted from an allogeneic donor or as gene-corrected (*Gtx*) autologous cells with no pretransplant conditioning, only minimal chimerism of donor cells will occur (lower left). If full myeloablation is given, essentially complete donor cell chimerism will be achieved (lower middle). If partial myeloablation is administered, as has been done in some gene therapy clinical trials, mixed chimerism will be achieved with a significant fraction of donor or gene-corrected cells engrafted (lower right).

https://CafePezeshki.IR

level significantly higher than that seen in earlier studies in which cytoreductive chemotherapy was not given.

Further results of this approach have now been reported from Milan, with 8 of 10 subjects realizing excellent and sustained immune reconstitution.[50] Similar studies at University College London/Great Ormond Street Hospital in London, UK, and in the USA at Children's Hospital Los Angeles, the University of California, Los Angeles, and the National Human Genome Research Institute, NIH, have led to similar clinically beneficial results.[51,52] Of at least 40 ADA-SCID patients treated by gene therapy using retroviral vectors and non-myeloablative conditioning in these studies, all are surviving and approximately 75% have sufficient immune restoration to remain well without other treatment, such as enzyme replacement therapy or allogeneic HSCT. No complications from genotoxic effects of the vectors have been observed in any, in contrast to findings in other diseases (see below). Thus, for ADA-deficient SCID patients lacking an HLA-MSD, gene therapy has become a proven therapeutic modality.

GENE THERAPY FOR XSCID

The next PID approached as a candidate for gene therapy was X-linked SCID (XSCID), caused by mutations of the common cytokine receptor γ chain (γc or IL2Rγ). Investigators at the Hopital Necker- Enfants Malades in Paris, France, instituted a clinical trial of retroviral-mediated transfer of a normal human γc cDNA into $CD34^+$ cells from bone marrow of infants with XSCID.[9,53] In this trial, the transduced $CD34^+$ cells were reinfused without any prior cytoreduction, counting on the very potent selective survival advantage of the γc-corrected lymphoid cells to repopulate the immune system from a low level of gene-modified HSCs. No adverse events were noted in the initial years in 9 treated subjects. The γc gene was present and expressed in T, NK and B cells. Over the initial 2 to 5 months, 9 of 10 infants developed normal numbers of T and NK cells, with good immune function. While B cell numbers remained low, protective levels of antibodies were produced and some of the subjects were removed from routine gammaglobulin treatment. The subjects were in good health over the first 1 to 2 years, without opportunistic infections, and were growing and developing without protective isolation. Ten XSCID infants were treated in a similar clinical trial by investigators at the Institute of Child Health, University College London, UK, with similarly good outcome.[54]

Longer-term follow-up of subjects in both the French and British trials was published and reported sustained T cell immunity in those achieving initial reconstitution.[55,56] However, B cell function allowing independence from IVIG replacement therapy was achieved in only 4 of 7 and 5 of 10, respectively, with essentially no gene-corrected B cells detected and a paucity of memory B cells; apparently, gene-corrected T cells are not of adequate help to induce full maturation and function in the non-gene-corrected B cells.

However, 5 subjects from these two trials subsequently developed a leukemia-like complication, with escalating white blood cell counts, 2.5–5 years after the gene therapy procedures. Four of these subjects have been successfully treated for the lymphoproliferative syndrome and have retained the benefits of the gene therapy on immune reconstitution, but one died as a result of this complication. Investigations have implicated the process of insertional oncogenesis, in which the retroviral vector integrates semirandomly into different chromosomal sites in each transduced cell; integrants adjacent to cellular genes that mediate proliferation or survival may be inappropriately *trans*-activated by transcriptional elements of the vector, such as the potent enhancers present in the long terminal repeats (LTRs). It remains uncertain why the complication of insertional oncogenesis with lymphoproliferation was seen in 25% of the XSCID subjects but in none of the more than 40 subjects with ADA-deficient SCID.[57–61]

Faced with these mixed results with life-saving immune reconstitution in the majority of XSCID subjects using gene therapy, but the potential for a severe treatment-related complication, the relative risks and benefits need to be compared to the current therapeutic alternative for these subjects – allogeneic HSCT from a haploidentical or MUD donor. SCID patients with allogeneic donors other than HLA-matched siblings have had survival rates of 50% to 80% with restored T cell immunity, as discussed previously. However, more than half of these patients may fail to produce protective antibodies, and there are risks of GvHD and post-transplant Epstein-Barr virus (EBV)-driven lymphoproliferative disease (LPD). Gene therapy for XSCID using retroviral vectors led to immune restoration in 90% 18 of 20) of patients, but with a 25% incidence of LPD.

Notably, this same approach for gene therapy has been applied to older XSCID subjects, most of whom had undergone prior HSCT from haploidentical donors that resulted in only partial immune reconstitution with ongoing poor health.[62,63] These adolescent subjects showed minimal responses to the gene therapy, suggesting that their older age was associated with inadequate thymic function to support de novo lymphopoiesis; it is uncertain if the prior transplants were associated with GvHD, which is known to impair thymic function.

The way forward for gene therapy for XSCID lies in evaluating new vector designs that lack the strong LTR enhancer elements (so-called 'self-inactivating', or 'SIN' vectors), which have been shown by in vitro and murine transplant studies to have significantly lowered risks for causing insertional oncogenesis.[64] Ideally, these improved vectors will lead to similar levels of immune reconstitution, with minimal or no occurrences of insertional oncogenesis. One such trial with use of a SIN γ-retroviral vector to treat infants with XSCID without conditioning regimen is currently underway at five collaborating institutions in London, Paris, Boston, Cincinnati and Los Angeles. Initial results have shown ability to attain T cell immune reconstitution, and no clonal proliferations have been observed so far, although follow-up is still limited.[9] More recently, De Ravin and colleagues opened a second clinical trial to treat older, partially reconstituted XSCID patients, in the present form using a lentiviral vector and RIC (6 mg/kg busulfan). Initial results indicate some improvements of B cell immunity and overall wellbeing.[65]

GENE THERAPY FOR CGD

Another major PID that has been approached in several gene therapy clinical trials is CGD. The cDNA for the oxidases responsible for the X-linked form (gp91*phox*) and most common autosomal forms (p47 *phox*, p67 *phox* or p22 *phox*) were cloned and placed into retroviral vectors. Preclinical studies using patient-derived cells and murine gene knockout models provided evidence that gene transfer could at least partially restore the defective oxidase function in myeloid cells.[66,67]

https://CafePezeshki.IR

Initial trials in X-linked CGD (the most common form of the disease) used murine leukemia virus (MLV)-based retroviral vectors, targeted G-CSF mobilized $CD34^+$ peripheral blood stem cells (PBSC) and did not administer cytoreductive chemotherapy. Neutrophils were produced in vivo in multiple subjects that had their functional activity restored, based upon sensitive flow cytometric assays, but these were present at very low frequencies and only transiently.[68,69]

A later study performed at the German Cancer Research Center added cytoreductive conditioning with 8 mg/kg of busulfan (approximately two times higher than the dose used in the ADA-deficient SCID studies) and used a retroviral vector derived from the murine spleen focus forming virus (SFFV) which has LTRs that are highly potent in myeloid progenitor cells expressing the normal human gp91*phox*.[70] Two young men in their twenties with X-CGD and lifelong histories of chronic infections poorly responsive to intensive medical therapy were treated. They had clinically beneficial responses to the treatment with resolution of the longstanding infections. The production of gene-corrected, oxidase (+) neutrophils was readily detected; the frequencies of gene-containing neutrophils increased from 20% in the first few months after transplant to levels exceeding 60% over the next few months. Both patients developed monosomy 7 and myelodysplasia. One of these patients died as a result of gastrointestinal infection, at a time when there was loss of expression of oxidase activity in neutrophils, despite the continued presence of gene-containing cells.[71]

The highly dichotomous outcome of clinical benefit followed by severe adverse event in these CGD patients is highly reminiscent of the XSCID studies. For CGD, the use of a vector with a potent myeloid-type LTR promoter led to myeloproliferation, while there was lymphoproliferation in the XSCID studies where the MLV LTR is more active in lymphoid cells. It is known from research on wild-type retroviruses that the virus's LTRs may play a major role in defining the disease tropism.[72] Retroviral vectors used to drive high-level expression of a transgene in a specific lineage may predispose that lineage to insertional oncogenic effects.

The unexpected complications that occurred in these patients treated for PID led to major increases in the understanding of these risks, their underlying mechanisms and potential ways to overcome them. Some of these improved approaches will be discussed below. A lentiviral vector has been developed to express the gp91*phox* cDNA under transcriptional control of a chimeric promoter with expression relatively specific to mature myeloid cells; this vector could be active in granulocytes and monocytic cells but have a reduced potential to transform stem and progenitor cells.[73] A multinational clinical trial using this new vector has recently started in Europe, with a US trial planned.

GENE THERAPY FOR WAS

A clinical trial for WAS performed in Germany using a first-generation retroviral vector led to sustained engraftment and correction of WASp expression in lymphoid and myeloid cells and platelets in 9 out of 10 patients treated, resulting in improved immunologic and hematologic status. However, 7 of these 9 patients developed leukemia due to insertional mutagenesis, which makes this approach unacceptable.[74,75] Initial results from a trial for WAS using a lentiviral vector with the endogenous *WAS* gene promoter at San Raffaele Telethon Institute for Gene Therapy in Milan, Italy, demonstrated good immune reconstitution, significant improvement in platelet numbers (although they remained subnormal) and no safety problems in the initial period of observation.[76] Another multicenter trial using the same vector but a slightly different conditioning regimen is under way in London, Paris and Boston.

PERSPECTIVES FOR GENE THERAPY IN OTHER PRIMARY IMMUNE DEFICIENCIES

Other PIDs that are under extensive study and are subject, or will be subject, to gene therapy clinical trials include SCID due to RAG1, RAG2 or Artemis deficiency, LAD and HLH. Other PIDs that involve defects in cytokine and signaling pathway components, such as the JAK3 kinase and ZAP-70 kinase, CD40 ligand deficiency (X-linked hyper-IgM syndrome), IPEX, IL-7 receptor and XLA will require new approaches to gene therapy to achieve more sophisticated control of the expression of the responsible gene than occurs using constitutive promoters such as viral LTRs.

NEW APPROACHES TO GENE THERAPY USING HEMATOPOIETIC STEM CELLS

Gene therapy for PIDs has progressed from an essentially ineffective method in the 1990s to its present status, where clear-cut efficacy has been achieved for several disorders, albeit with a risk for a significant degree of side-effects. Further advances will be based upon new insights into HSC biology and new methods for gene transfer. New understandings may eventually support efforts for ex vivo expansion of HSCs, which would allow the selective use of HSCs with favorable vector integration sites.

New major alternatives to the murine γ-retroviral vectors are vectors derived from lentiviruses or foamy viruses.[77–79] These latter types of retrovirus are of primate origin (HIV-1 lentiviruses from humans and the simian foamy virus from nonhuman primates) and are more efficient for transferring genes into human cells. These vectors can be made lacking the strong LTR enhancers that are problematic in the γ-retroviral vectors. Lentiviral vectors have entered clinical trials for T cells and $CD34^+$ HSCs and are likely to be applied to several PIDs and other genetic blood disorders in the near future.[66,73,76,80–84] A study in a canine model of LAD showed excellent clinical response using a foamy viral vector to transfer the relevant CD18 cDNA and may also be moving to the clinic.[85] Another important tactic being explored for added safety is the addition to vectors of 'insulator' sequences, which are DNA sequences that act as boundaries to prevent transcriptional cross-talk between adjacent genes in the chromosomes.[86]

GENE CORRECTION

All of the gene therapy efforts discussed so far have involved the use of methods for *adding* a functional copy of a gene to cells (in a nonphysiologic chromosome location). A promising new approach to gene therapy under investigation seeks to *correct* the disease-causing mutation in a patient's own gene. Effective gene correction may have key advantages over gene addition. The corrected therapeutic gene would be in its normal location in the chromosomes, and so should be expressed in the normal developmental and quantitative pattern; this may be essential for safe and effective therapy of diseases due to defects

https://CafePezeshki.IR

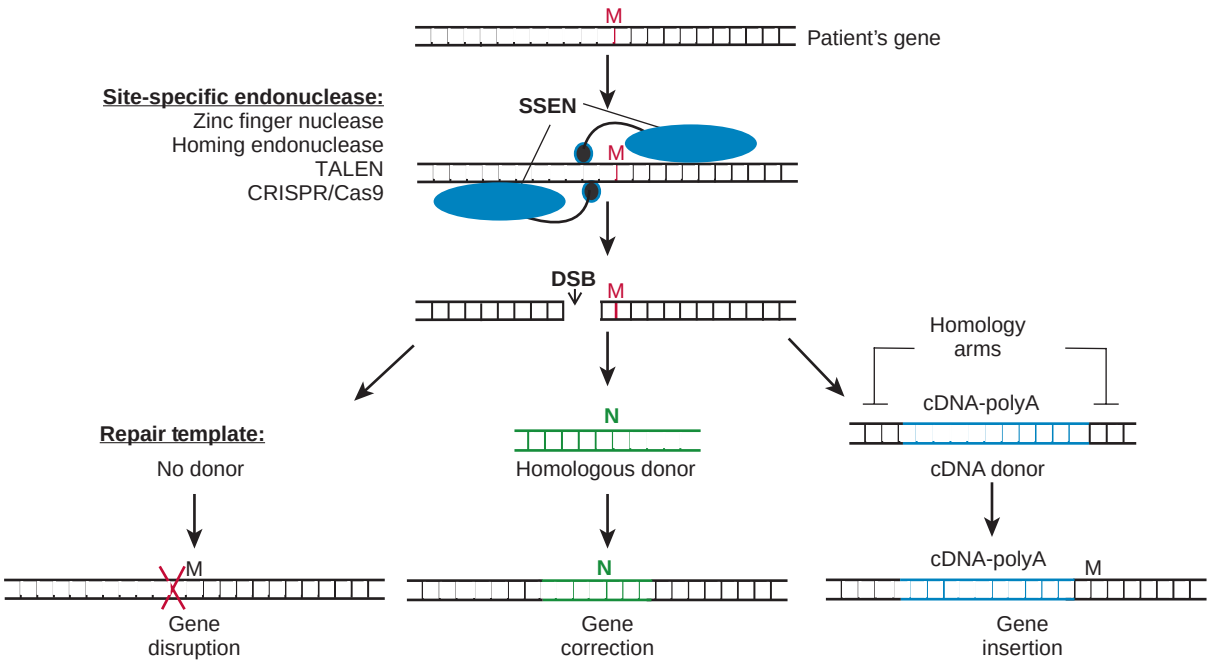

Figure 16-3 Gene modification using site-specific endonucleases. For correcting a genetic mutation (red 'M'), site-specific endonucleases can be used to facilitate the repair process by producing a double-strand break (DSB) in the DNA near the mutation. The DSB may be resolved in several ways. If no donor is provided (left), non-homologous end joining may re-link the cut ends of the DNA, but often creates base-pair insertions or deletions, leading to gene disruption. If a homologous donor is introduced that contains the normal sequence (green 'N'; center), homology-driven repair may use the donor as a template to repair the DSB, copying the normal sequence into the genome for gene correction. If a donor is provided that contains the relevant cDNA with a polyadenylation signal flanked by homology arms to the sequence at the DSB (right), the cDNA-polyA signal may be copied into the DSB, leading to gene insertion.

in signaling proteins, including XLA, X-linked hyper-IgM syndrome and ZAP-70 kinase deficiency, as discussed above. Gene correction should avoid the problems of insertional oncogenesis from gene addition due to random insertion throughout the genome, resulting in activation of nearby genes.

Cells have multiple ways to repair damage to their chromosomal DNA, including homologous recombination (HR) that can lead to the genetic information on one strand being copied into a homologous, but nonidentical sequence (Figure 16-3). Flooding cells with high concentrations of nucleic acid sequences complementary to an endogenous gene sequence can cause the HR pathways to introduce corrective sequences into a cellular gene, for example to correct the single base-pair change in the human β-globin gene responsible for sickle cell disease.[87] However, early efforts to direct gene repair by HR were limited by very low efficiency. More recently, the efficiency of HR has been markedly improved by the use of transiently expressed site-specific endonucleases targeted to introduce double-stranded DNA breaks near the intended site of HR. A succession of such engineered nucleases (zinc-finger nucleases [ZFNs], homing endonucleases, TALENS and CRISPR/Cas9) can be designed to have DNA recognition domains that bind to unique sites in the genome and introduce a double-stranded break to induce HR, guided by a 'donor' oligonucleotide.[88–90] Gene correction by HR may be developed to achieve correction of the genes involved in PIDs.[89,91] It will need to be determined whether the efficacy and safety of gene correction provide a better therapeutic window than gene addition methods.

A future approach to gene therapy for these disorders may make use of the ability to 'reprogram' somatic cells to a pluripotent state (Figure 16-4). These induced pluripotent stem

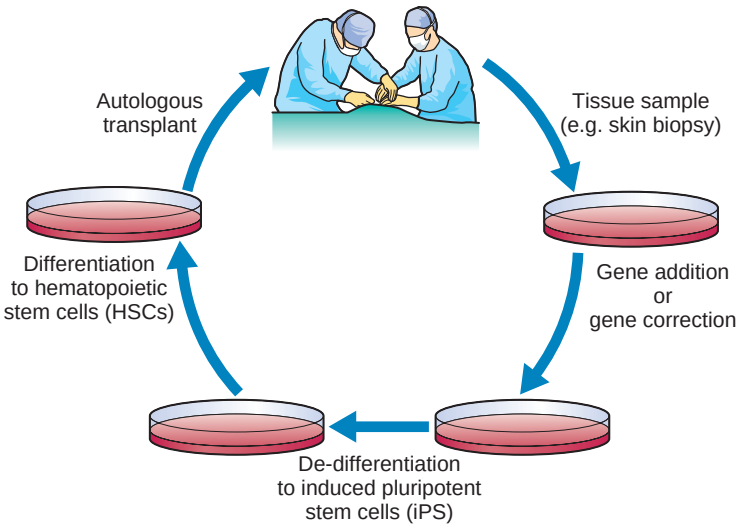

Figure 16-4 Gene therapy using autologous HSCs made from induced pluripotent stem cells. Somatic cells from a PID patient, such as skin fibroblasts or keratinocytes, can be obtained from a skin biopsy. These cells can be cultured and genetically corrected by gene addition or gene correction methods. The cells can then be de-differentiated to produce induced pluripotent stem cells (*iPS*). The iPS can then be directed to differentiate to HSCs that can be used to transplant the PID patient. The gene correction of the cultured somatic cells can be analyzed and selected for clones with complete appropriate gene correction and safe gene integration sites for use in the production of HSCs.

https://CafePezeshki.IR

cells (iPS) could be produced from patient cells that are efficiently gene corrected in vitro. Then, the iPS could be directed to differentiate to HSCs for transplantation. This process has been demonstrated in a murine model of sickle cell disease, although several key steps have not been advanced to sufficient efficacy for human cells.[92]

Conclusions

Although advances in supportive therapy and enzyme therapy have made improvements in the treatment of primary immune deficiencies, they are not curative for these life-threatening illnesses. HSCT and gene therapy provide the only curative options at this time. MSD HSCT remains the gold standard of treatment for many of these patients, but further data and experience have shown that closely matched unrelated bone marrow, peripheral blood stem cell and umbilical cord blood transplantation have satisfactory results in some of these disorders. HSCT carries its own morbidities, some of which may be severe or even fatal, including GvHD, infections, toxicity associated with chemotherapy, and non-engraftment. Gene therapy utilizes autologous cells, so there is no risk for GvHD or graft rejection, and immune suppressive therapies are not needed. In addition, gene therapy may be successful and potentially have less toxicity due to the use of pretransplant conditioning regimens that are less than fully myeloablative and therefore less toxic. However, unexpected genotoxicity has occurred in some patients with the retroviral vectors used in previous trials.

Improvements in gene transfer to HSCs are under development that should increase clinical efficacy and decrease the risks. Furthermore, direct gene correction may offer advantages over gene addition, if sufficient efficiency can be achieved.

17 Biologic Therapies

ROBERT EISENBERG | EDWARD M. BEHRENS

KEY POINTS

- Biologics are mostly large molecules, usually proteins, that serve as therapeutics and are derived from living organisms.
- Biologics produced in vitro by recombinant technology are monoclonal antibodies, soluble receptor constructs, or cytokines. The first two categories are discussed in this chapter.
- Recombinant biologics bind their target with high affinity, and have reduced potential for off-target effects compared to small molecule agents.
- Safety concerns with biologics arise from their effectiveness in targeting physiologic molecules or cells, or from their ability to elicit an immune response against the drug itself.
- The molecular complexity and unavoidable heterogeneity of recombinant biologics make them expensive to produce and impossible to copy exactly in a generic form. In the future, biosimilars will be produced that mimic an existing approved biologic as far as possible.

Biologics are drugs that are derived from living organisms. In the broadest sense, this category encompasses any agent made by biological processes, including recombinant therapeutic proteins, as well as blood, blood products, proteins or other molecules purified from living material, such as IVIG (see Chapter 15), cells and gene therapies (Chapter 16), allergens (Chapter 23) and vaccines. We discuss in this chapter therapeutic proteins that are monoclonal antibodies or soluble receptor constructs. They have all been developed by genetic engineering, and they are produced in vitro in large cultures of prokaryotic or eukaryotic cells. Therapeutic cytokines manufactured by recombinant technology comprise another increasingly important subset of biologics. They are listed in Table 17-1 but will not be further described here.

The fundamental therapeutic rationale underlying the biologics discussed in this chapter relates to the exquisite specificity of the humoral immune system's antibodies or of certain physiologic receptor-ligand interactions, coupled with the identification of molecules or cells that are critical to the pathologic processes of disease. This permits the development of agents that will target selected steps in a disease pathway with very high affinity yet have little propensity to have 'off-target' interactions that could lead to serious side-effects. In addition to their specificity, many of the biologics closely resemble physiologic molecules, and as such, they may be administered in large quantities to achieve the substantial levels (hundreds of micrograms per mL) that can potentially block all of their targets in vivo. This pharmacodynamic efficiency of the biologics certainly accounts for their impressive efficacy in many uses. It also implies that the failure of a particular biologic to provide therapeutic benefit in a given situation makes it unlikely that the targeted molecule plays a non-redundant role in the disease process.

The complex nature of biologics in part accounts for their high cost, which limits their general use, particularly in developing countries. It also presents several other potential problems particular to this group of drugs. Their molecular complexity makes them relatively difficult to develop and often entails a degree of structural heterogeneity that may have unintended consequences.[15] Any change in the manufacturing process must be assumed to change the final product to some extent. This makes the generation of generic forms of biologics essentially impossible. So-called 'biosimilars' can have the same amino acid sequence as the first-approved biologic, but the post-translational modifications will not be identical.[16,17] This variability demands that the regulatory requirements for approval must go beyond any demonstration of chemical identity and should include some biological measures of equivalence in pharmacokinetics, pharmacodynamics, clinical efficacy and safety. Such requirements would need to be less stringent than those applied to a new compound, or the potential financial benefit of the biosimilar (i.e. lower patient cost) would be abrogated. Biosimilar mimics of the compounds discussed in detail in this chapter have not yet appeared in the US market, and the path to approval will have to be developed individually in each case. Compounds that have the same targets but are independently developed (e.g. adalimumab and infliximab), are of course not biosimilars, and each has to undergo its own extensive developmental process. Nevertheless, the success and failures of a given compound will help guide the clinical development of others with the same target. In addition, the safety concerns that the US Food and Drug Administration (FDA) requires in the package inserts may reflect analogies with other compounds with the same target, even in the absence of adverse event data that are directly relevant.

Another general concern about biologics is immunogenicity. As large protein molecules, these drugs are potentially good immunogens. Most of the receptor constructs, such as rilonacept, are different from any autologous protein in the overall structure (anakinra is the exception), although they are made up of faithful portions of individual physiologic molecules. The monoclonal antibodies are more physiologic, but they also can provoke immune responses. Muromonab-CD3, the first monoclonal antibody approved in the USA in 1986, was derived from a mouse immunized with human T cells.[18,19] It recognizes the CD3ε subunit of the T cell receptor-CD3 complex, and it is effective in treating allograft rejection. However, it frequently induces anti-mouse IgG antibodies (termed HAMA, or human

TABLE 17-1 Biologics Approved in Children, Recombinant Cytokines

Compound	Brand Name, Manufacturer	Pediatric Indications	Age Restriction
C1 esterase inhibitor	Cinryze®	Hereditary angioedema[1,2]	Adolescents
Epoetin alfa	Epogen®	Anemia[3]	None
Filgrastim (G-CSF)	Neupogen®	Neutropenia[4,5]	None
Interferon alfa-2b	Intron® A	Chronic hepatitis B[6]	≥ 1 yr
Interferon gamma	Actimmune®	Chronic granulomatous disease, osteopetrosis[7,8]	None
Peginterferon alfa-2a	Pegasys®	Chronic hepatitis C[9–11]	≥ 5 yr
Peginterferon alfa-2b	Pegintron®	Chronic hepatitis C[12,13]	≥ 3 yr
Sargramostim	Leukine®	Bone marrow transplantation, chemotherapy[14]	None

*These compounds are not discussed in detail in the text.

anti-mouse antibodies), which is part of the reason it was withdrawn from the market in 2010. Some murine monoclonal antibodies are still used clinically (e.g. ibritumomab in adults)[20] for short courses of therapy, but in general, further genetic modifications are undertaken to render the monoclonal more human and thus, less immunogenic.

A monoclonal antibody is usually selected from a mouse immunized with the appropriate human cells or protein. The variable regions of both the light and heavy chains are then joined, respectively, to the constant region domains of human κ or λ, and IgG (IgG1, IgG2 or IgG4) to a make a chimeric molecule that is about two thirds of human origin. Infliximab is an example. Such proteins can still not infrequently induce antibody responses, termed HACA, or human anti-chimera antibodies. Further humanization can be obtained by substituting the framework regions in the variable domains with human framework sequences. This leaves only the complementarity determining regions (hypervariable regions) from the original mouse monoclonal. These are the sequences that determine the antigen-binding site, so the specificity of the engineered monoclonal remains the same, but it now has only about 10% mouse sequences. An example of such a humanized monoclonal is eculizumab.

A fully human monoclonal antibody can be produced in two ways. In one approach, a mouse is used in which the immunoglobulin genes have been replaced with human genes. This mouse then makes antibody responses that use human antibody sequences. Canakinumab was produced in this way. A second approach uses a bacteriophage display library of human variable region sequences and selects for antigen binding in vitro. The selected genes are then combined with human constant region genes to reconstitute a complete IgG antibody. Adalimumab was derived in this manner. Notwithstanding, these human monoclonals can provoke immune responses (termed HAHA, or human anti-human antibody), probably largely akin to anti-idiotype responses that are themselves specific for the reagents' complementarity determining regions. Table 17-2 describes how the mouse/human composition of the monoclonal antibody produced is reflected in the spelling of the penultimate and antepenultimate syllables of its common name.

The immune responses to biologic agents that are often seen in a significant minority of patients may hasten the clearance of the drug, decrease its effectiveness or result in adverse reactions such as hypersensitivity. In many cases, however, they do not seem to have apparent clinical significance, and their presence is not assayed in routine clinical care. In the early studies with infliximab, it was found that higher doses of drug, or giving it along with methotrexate, decreased the incidence of HACA formation.[21] It is not known how well this paradigm may extend to other compounds.

TABLE 17-2 Nomenclature of the Biologics, Based on Structure

1. Ultimate syllable:
   '**-mab**' = monoclonal antibody, e.g. basilixi**mab**
   '**-cept**' = receptor fusion protein, e.g. alefa**cept**
2. Penultimate syllable before '**mab**':
   '**-xi-**' = chimeric (mouse or rat origin immunoglobulin variable regions; human constant regions)
   '**-zu-**' = humanized (chimeric monoclonal antibody genetically engineered, so that the variable region sequences outside the complementarity determining regions [i.e. combining site] are human)
   '**-u-**' = fully human (selected from an in vitro human phage display library or from a mouse engineered to have human immunoglobulin genes)
   '**-mo-**' = murine
3. Antepenultimate syllable:
   '**-li-**' or '**-lim-**' = immune system (not consistently used)

Thus:
chimeric human/mouse antibodies are **xi**mabs, e.g. infliximab
humanized antibodies are **zu**mabs, e.g. alemtuzumab
fully human antibodies are **u**mabs, e.g. adalimumab
murine antibodies are **mo**mabs, e.g. ibritumomab

Another class of adverse reactions to the biologics comes from their therapeutic potency. Although they are unlikely to have 'off-target' side-effects, they are often so thorough in inhibiting their target that the normal physiologic functions of that target are blocked. Thus, the anti-TNF agents can reactivate latent mycobacterial infections in a characteristic way,[22] or eculizumab (anti-C5) can put patients at risk for serious infections with Gram-negative cocci by blocking the terminal complement cascade.[23]

The compounds discussed below are biologic monoclonal antibodies or receptor constructs that have an FDA-indicated use in the pediatric population as of mid-2014 (see Table 17-3). Other biologics approved only for adults have found common use in children. Some of them are listed in Table 17-4, but they will not be further discussed here.

https://CafePezeshki.IR

TABLE 17-3 Biologics Approved for Children: Monoclonal Antibodies and Soluble Receptor Constructs

Compound	Target	Pediatric Indications	Age Restrictions	FDA Approval‡
Abatacept	CD80, CD86	Juvenile idiopathic arthritis	≥ 6 yr	2008
Adalimumab	TNF-α	Juvenile idiopathic arthritis	≥ 4 yr	2008
Anakinra	IL-1R	Neonatal onset multisystem inflammatory disease	None	2014
Basiliximab	CD25	Renal transplantation	None	2001
Canakinumab	IL-1β	Familial cold autoinflammatory syndrome, Muckle-Wells syndrome, SJIA	CAPS ≥ 4 yr; SJIA ≥ 2 yr	2009
Denosumab	RANKL	Giant cell tumor	Bone-mature adolescents	2013
Ecallantide	Kallikrein	Hereditary angioedema	≥ 12 yr	2009
Eculizumab	C5	Atypical hemolytic uremic syndrome	None	2009
Etanercept	TNF-α, TNF-β	Juvenile idiopathic arthritis	> 2 yr	1999
Infliximab	TNF-α	Inflammatory bowel disease	≥ 6 yr	2006
Omalizumab	IgE	Asthma, chronic idiopathic urticaria	≥ 12 yr	2003
Palivizumab	RSV F protein	RSV prevention	≤ 24 months	1998
Raxibacumab	Anthrax toxin	Anthrax	None	2012
Rilonacept	IL-1β	Familial cold autoinflammatory syndrome, Muckle-Wells syndrome	≥ 12 yr	2008
Tocilizumab	IL-6R	Polyarticular and systemic juvenile idiopathic arthritis	≥ 2 yr	2011

*These compounds are discussed in more detail in the text.
‡Year that FDA approval was first granted for a pediatric indication.
SJIA – Systemic juvenile idiopathic arthritis, *CAPS* – cryopyrin-associated periodic syndromes, *RANKL* – receptor activator of nuclear factor κ B ligand, *RSV* – respiratory syncytial virus.

TABLE 17-4 Biologics not Approved in Children, but Commonly Used Off-Label

Compound	Brand Name	Target	Pediatric Uses
Abciximab	ReoPro®	GpIIb/IIIa receptor	Kawasaki disease[24,25]
Alemtuzumab	Campath®	CD52	Hemophagocytic lymphohistiocytosis[26,27]
Belimumab	Benlysta®	BLyS	SLE[28]
Bevacizumab	Avastin®	VEGF-A	Retinopathy of prematurity, malignancies[29,30]
Golimumab	Simponi®	TNF-α	Juvenile idiopathic arthritis, uveitis[31,32]
Natalizumab	Tysabri®	α4 integrin subunit	Multiple sclerosis[33]
Rituximab	Rituxan®	CD20	SLE, transplant, lymphoma/leukemia, others[34,35]
Ustekinumab	Stelara®	IL-12, IL-23	Psoriasis[36]

*These compounds are not discussed in detail in the text. They are all the subject of ongoing (2014) clinical trials in children for the indicated uses, except abciximab, which is listed as being studied only for sickle cell crisis in children (http://www.clinicaltrials.gov).
BLyS – B lymphocyte stimulator, *SLE* – systemic lupus erythematosus, *VEGF-A* – vascular endothelial growth factor A.

Biologics Approved for Pediatric Therapeutic Use

Abatacept (Orencia®). Abatacept is a soluble receptor mimic that consists of the extracellular domain of CTLA-4 (cytotoxic T lymphocyte antigen-4) linked to the Fc fragment of human IgG1.[37] It is produced in vitro from a chimeric gene construct. CTLA-4 is found on activated CD4 and CD8 T cells, and it mediates an inhibitory signal through ligation to CD80 or CD86.[38] However, the mechanism of action of abatacept results from its high-affinity binding to CD80 and CD86, which thereby prevents their interaction with the costimulatory molecule CD28, which is in turn constitutively expressed on CD4 and CD8 T cells. It was initially approved for use in adult rheumatoid arthritis in 2005. The pediatric indication for children 6 to 17 years old with juvenile idiopathic arthritis was added in 2008 on the basis of a 6-month withdrawal trial using 122 patients with polyarticular disease.[39] These patients were also found to benefit in a longer-term open-label follow-up.[40] Abatacept is administered intravenously once a month, either as monotherapy or in conjunction with methotrexate. A preparation for subcutaneous self-administration is available only for adult use. Infections are a potential complication with abatacept therapy, although in general the risk may be less than with other biologics used for inflammatory arthritis.[41–43] Hepatitis B reactivation, however, may be a particular concern.[44,45]

Adalimumab (Humira®). Adalimumab is a fully human recombinant monoclonal antibody that binds the soluble and cell-bound forms of TNF-α. It was initially approved for adult rheumatoid arthritis in 2002.[46] An indication for juvenile idiopathic arthritis in children at least 4 years old was added in 2008 on the basis of a 32-week withdrawal study of 128 patients with polyarticular disease.[47] It is administered in weekly or biweekly subcutaneous doses, either as monotherapy or in combination with methotrexate. In adults (18 years and older), it is also

https://CafePezeshki.IR

approved for use in ankylosing spondylitis, inflammatory bowel disease and psoriasis. Safety concerns for adalimumab are similar to those for the other biologics that target TNF-α and include bacterial, fungal and viral infections, malignancies, heart failure and the development of lupus- or multiple sclerosis-like syndromes.[48,49] In adults with rheumatoid arthritis, the presence of anti-adalimumab antibodies, found in about one quarter of treated patients, was associated with decreased efficacy and possibly increased adverse events.[50,51]

Anakinra (Kineret®). Anakinra is a recombinant form of the physiologic human protein interleukin-1 receptor antagonist (IL-1Ra).[52] It is structurally modified from the natural molecule, in that it lacks glycosylation and it has a methionine residue added to the amino terminus. It binds the IL-1 type 1 receptor without causing signaling and thereby prevents activation by the agonistic ligands IL-1α and IL-1β. In 2001, it was approved for treatment of adults with rheumatoid arthritis.[53] Subsequently, based on the remarkable levels of serum IL-1 found in cryopyrin-associated autoinflammatory syndromes (CAPS), anakinra was tested in an open-label uncontrolled trial of 43 neonatal-onset multisystem inflammatory disease (NOMID) patients of varying ages.[54–56] All patients improved, and a subset relapsed upon withdrawal of the medication. Both the acute attacks and the progression of irreversible organ damage were inhibited. These findings led to the approval of NOMID as an additional indication for anakinra in 2014. Although anakinra has shown some evidence for efficacy in systemic juvenile idiopathic arthritis (SJIA), and is used in practice for this condition, it does not have FDA approval for this indication.[57–58] Anakinra has a relatively short in vivo half-life (4–6 hours), and must be given daily by subcutaneous injection. The main safety concern has been an increased susceptibility to infection.

Basiliximab (Simulect®). Basiliximab is a mouse/human chimeric monoclonal antibody specific for the α chain of the high-affinity IL-2 receptor (CD25).[59] By blocking the cytokine IL-2 from binding to its receptor, basiliximab inhibits the activation of T lymphocytes. It is therefore effective for the prevention of acute rejection after renal transplantation. It was approved for this use in adults in 1998.[60–61] Although only open-label studies have been documented in pediatric patients, an explicit indication for use in this population was added by the FDA in 2001.[62–63] It is approved for use with an immunosuppressive regimen including cyclosporine and corticosteroids. It is administered as a single intravenous dose 2 hours before transplantation, and a second dose 4 days later. Infections are a prominent complication in this highly immunosuppressed patient group; however, the contribution of basiliximab per se to these adverse events is not clear.[61,64] Anaphylaxis-like immediate hypersensitivity reactions have been reported in post-marketing surveillance.[65,66]

Canakinumab (Ilaris®). Canakinumab is a fully human recombinant monoclonal antibody specific for IL-1β. It therefore blocks the binding of this cytokine to its receptor. It received a priority review approval in 2009 for use in two CAPS – familial cold autoinflammatory syndrome (FCAS) and Muckle-Wells syndrome (MWS) – in patients ≥ 4 years of age. Supporting data came from an international double-blind, placebo controlled 24-week withdrawal study of 35 patients,[67] and from uncontrolled experience with an additional 69 patients (including 23 pediatric patients overall). Strikingly, 97% of patients in the controlled study had a complete response by day 29 of the open-label treatment phase. During the withdrawal period, none of the active drug-treated patients relapsed, while 81% in the placebo arm had a disease flare. In 2013, canakinumab received approval for the additional indication of SJIA in children ≥ 2 years of age, based on a 29-day double-blind, placebo-controlled trial of 84 patients, and a double-blind, placebo-controlled withdrawal trial of 100 patients over up to two years of treatment.[68] Although these trials indicated clinical efficacy, the magnitude of the effect was not nearly as impressive as for the CAPS trials. Canakinumab is administered subcutaneously every 8 weeks for CAPS and every 4 weeks for SJIA. The most important safety concern has been serious infections.

Denosumab (Xgeva®). Denosumab is a fully human recombinant monoclonal antibody specific for RANKL (receptor activator of NF-κB ligand). It blocks the binding of this ligand with RANK on pre-osteoclasts and thereby prevents their maturation into osteoclasts.[69–72] It thus favors bone formation over bone resorption. Animal studies have indicated that denosumab can interfere with bone development, so its pediatric use, approved in 2013, has been restricted to skeletally mature adolescents with giant cell tumors of the bone.[72] Two open-label, uncontrolled trials provided evidence of efficacy. In the first trial in 37 adults, 30 were considered to have responded by either histologic or radiologic criteria.[73] In a second trial of 282 patients, including 10 adolescents (13–17 years old), almost no disease progression was seen with a median follow-up of 9 to 13 months, and about half the patients were considered to have a complete or partial tumor response (an exploratory outcome in this phase II study).[74,75] However, an independent review of the data in the two trials concluded that only 25% of patients, including two of the six evaluable adolescents, showed a partial response (Xgeva® package insert). For treatment of giant cell tumors, denosumab is administered subcutaneously on days 1, 8, 15 and 30, and then monthly. The major safety concerns have been hypocalcemia and osteonecrosis. Note that denosumab is also marketed for treatment of osteopenia/osteoporosis under a separate brand name (Prolia®), without a pediatric indication.

Ecallantide (Kalbitor®). Ecallantide is a 7,000 kDa protein that binds to the active site of kallikrein and thereby blocks the conversion of high molecular weight kininogen to bradykinin. Its structure is based on the first Kunitz domain (active site) of human tissue factor inhibitor (also known as lipoprotein associate coagulation inhibitor). It was selected by phage display to bind kallikrein with high affinity, and it is produced in yeast by recombinant technology.[76,77] It was approved in 2009 for the treatment of acute episodes of hereditary angioedema (HAE) due to C1 esterase deficiency or dysfunction, based on two randomized, double-blind controlled trials in a total of 143 HAE patients ≥ 10 years old.[78-82] Not surprisingly, most of the enrolled patients in these trials were adults, and the pediatric population was skewed toward the older ages. Thus, the original labeling was for patients ≥ 16 years old; in 2014, the FDA extended the labeling to include adolescents ≥ 12 years old. The pivotal studies, which were single dose, did not report drug-related serious adverse events, but the package labeling, which includes experience in retreated patients, cites a 4% incidence of anaphylaxis.[83,84] This complication has not been specifically

https://CafePezeshki.IR

seen in the published pediatric experience, but the number of individuals < 18 years old analyzed is relatively small ($N = 29$).[82]

Eculizumab (Soliris®). Eculizumab is a humanized recombinant monoclonal antibody that binds the C5 complement component and prevents its activation by cleavage.[85] This blocks the release of the inflammatory C5a fragment and prevents the subsequent initiation of the terminal complement cascade (C5b–C9). It was approved in 2007 for the treatment of adults with paroxysmal nocturnal hemoglobinuria (PNH).[86] In 2009, eculizumab received an accelerated approval for treatment of atypical hemolytic uremic syndrome (aHUS) on the basis of two prospective, open-label, uncontrolled trials with a total of 37 treated patients, of which 6 were adolescents,[87] and a retrospective experience with 17 pediatric patients age 2 months to 17 years (unpublished, summarized in the package insert). Most patients in all the studies showed improvement in blood counts and renal function, and freedom from need for plasma therapy. It is not known if eculizumab will be effective in infection-induced HUS.[88] Treatment is by intravenous administration, initially every week and then every 2 weeks, continued indefinitely. Whether therapy can be stopped successfully in some patients is subject to further investigation,[89] as is the potential use of eculizumab in children with PNH.[90] In analogy with the congenital terminal component complement deficiencies,[91] eculizumab therapy is associated with increased susceptibility to infections with Gram-negative organisms, including *Neisseria meningitidis*.[92]

Etanercept (Enbrel®). Etanercept is a soluble form of the p75 receptor for TNF. It is a recombinant chimeric homodimer consisting of two polypeptide chains that splice the TNF receptor subunit to the Fc portion of IgG1. It binds both TNF-α and TNF-β (also known as lymphotoxin alpha, LTα) in both the soluble and transmembrane forms. It was first approved for the treatment of adult rheumatoid arthritis in 1998.[93] In 1999, the indication for polyarticular JIA in patients ≥ 4 years old was added on the basis of an open-label study of 69 patients, followed by a controlled, double-blind 4-month withdrawal study on the 51 patients who initially responded.[94] In 2007, the age indication was lowered to ≥ 2 years on the basis of open-label unpublished experience (mentioned in the package insert). Etanercept is administered by subcutaneous injection 1 to 2 times per week. Safety concerns listed in the package insert include infections, malignancies (particularly lymphomas)[22] and the development of autoimmune disease such as multiple sclerosis or lupus. Etanercept therapy may have a lower risk for activation of tuberculosis, compared to monoclonal antibodies against TNF.[95] In addition, the association of malignancies with etanercept and other anti-TNF agents has been questioned in recent analyses.[96–99] Etanercept also has adult indications for ankylosing spondylitis, psoriasis and psoriatic arthritis.[100–102] It does not have the same effectiveness in inflammatory bowel disease as the monoclonal antibody anti-TNF agents.[103]

Infliximab (Remicade®). Infliximab was the first anti-TNF monoclonal antibody to be approved, starting in 1998 with the indication for Crohn's disease in adults.[104–105] Adult rheumatoid arthritis was included in 1999[106] and adult ulcerative colitis in 2005.[107] Treatment of children (≥ 6 years old) with Crohn's disease was added to the label in 2006, based on an open-label trial of an initial 10-week treatment period, followed by randomization of responding patients to maintenance treatment every 8 weeks or every 12 weeks.[108] Pediatric ulcerative colitis received approval in 2011 based on a very similar open-label study.[109] A phase III trial of 122 children (ages 4–17) with polyarticular JIA failed to meet its primary outcome for statistically significant efficacy at 14 weeks, so this indication does not appear on the label.[110] Nevertheless, the general anecdotal experience has been positive, and infliximab is included among the TNF inhibitors recommended by the American College of Rheumatology for treatment of JIA.[111–113] Childhood autoimmune uveitis is another relatively common off-label usage.[114,115] Safety issues with infliximab include infections, especially tuberculosis. A relatively high incidence of immune responses to infliximab (HACA) has been seen in children, as have serious infusion reactions.[104] Infliximab is administered intravenously at weeks 0, 2 and 6, and then every 8 weeks.

Omalizumab (Xolair®). Omalizumab is a recombinant humanized monoclonal antibody that binds the constant region of free IgE.[116] It thus blocks the binding of IgE to cell surface receptors on basophils and mast cells, but it does not cross-link IgE that is already cell bound. It causes a large increase in serum IgE, in the form of omalizumab-IgE complexes. It was approved in 2003 for the treatment of severe to moderate chronic allergic asthma in patients ≥ 12 years old who are not controlled with inhaled corticosteroids.[117–119] It is not used in the setting of acute exacerbations. Two other trials evaluated omalizumab in children between 6 and 12 years old. Although the one efficacy trial met its primary endpoint (rate of asthma exacerbations), other efficacy outcomes did not show statistical superiority over placebo. Based on safety concerns (see below), it was decided that it was not appropriate to extend the label indication to children < 12 years old. In 2014, the indication for chronic idiopathic urticaria was added with the same age limitation.[120] Data to support this label change came from two phase III studies with a total of 640 patients treated over 12 or 24 weeks. The major safety issues with omalizumab have been anaphylaxis, serum sickness, parasitic infestations and malignancy. Omalizumab is administered subcutaneously every 2 to 4 weeks.

Palivizumab (Synagis®). Palivizumab is a humanized monoclonal antibody specific for the envelope fusion protein (RSV-F) of respiratory syncytial virus.[121] It thus prevents cell entry by the virus and cell-to-cell fusion of RSV-infected cells. Its approval in 1998 was based on demonstration of its efficacy in preventing serious RSV infection in two double-blind, randomized, placebo-controlled trials with 2,789 children ≤ 2 years of age who were considered to be at high risk because of congenital heart disease, bronchopulmonary dysplasia or prematurity.[122,123] Palivizumab was given intramuscularly in five monthly injections beginning prior to the RSV season. The incidence of hospitalization with proven RSV infection was decreased about 50% in both studies. Children who were hospitalized for RSV infection despite having received the active drug did not show a milder course of disease. The package insert states that palivizumab is indicated for prophylaxis against serious lower respiratory tract RSV in high-risk children. The major safety concern has been anaphylaxis (rare) and other hypersensitivity reactions. Palivizumab is not indicated for the treatment of RSV infection.[124]

Raxibacumab. Raxibacumab is a fully human monoclonal antibody that is directed at the protective antigen (PA) moiety of the anthrax toxin (from *Bacillus anthracis*) and that prevents

https://CafePezeshki.IR

the toxin from entering cells. It is indicated for the treatment of inhalation anthrax, in combination with appropriate antibiotics. It is also indicated for anthrax prophylaxis if alternatives are not feasible. It is administered as a single intravenous dose. Its approval in 2012 was based on its low toxicity profile in over 500 normal (adult) volunteers, and therapeutic efficacy in monkey and rabbit models of anthrax.[125–127] For evident ethical and logistical issues, it has never been tested in humans for its approved indication. It is available only from the Centers for Disease Control and Prevention(CDC).

Rilonacept (Arcalyst®). Rilonacept is a genetically engineered cytokine 'trap' that binds IL-1β with very high affinity.[128–130] With lower affinity, it also binds IL-1α and IL-1Ra. Rilonacept was approved in 2008 for treatment in patients ≥ 12 years old with CAPS. Approval was based on two sequential randomized controlled trials with the same 47 adult patients (44 with FCAS; 3 with MWS): part A consisted of a 6-week placebo-controlled treatment period; this was immediately followed by part B, which began with 9 weeks of patient-blinded active treatment, followed by 9 weeks of placebo-controlled randomized withdrawal.[131] The institution of rilonacept produced a rapid and sustained reduction in patient-reported symptoms (the primary outcome) in the great majority of subjects, while the group withdrawn to placebo experienced a return in symptoms beginning at around 3 weeks. Treatment also normalized serum markers of inflammation, including CRP and serum amyloid protein. Pediatric data were not required with the initial approval, as rilonacept was given an orphan drug designation. Clinical responses were maintained over a subsequent 72-week open-label extension study of 44 subjects from the pivotal trial plus 57 new patients.[132] The additional patients included eight children, age 12 to 17. Two deaths in adult patients were caused by pneumococcal meningitis and coronary artery disease, respectively, but were not considered to be drug related. The most common drug-related adverse event has been injection site reactions. About one quarter of treated patients have been found to develop anti-rilonacept antibodies, usually in low titer.[132] In two patients this was associated with pharmacokinetic changes, but the clinical significance of these findings is not yet apparent. Rilonacept is administered by weekly subcutaneous injections.

Tocilizumab (Actemra®). Tocilizumab is a recombinant humanized monoclonal antibody that binds the soluble and membrane-bound forms of the IL-6 receptor and prevents its interaction with IL-6. It was approved for the treatment of adult rheumatoid arthritis in 2010.[133] An indication for systemic JIA was added in 2011, and for polyarticular JIA in 2013. Supporting data for the SJIA label came from a 12-week randomized, placebo-controlled trial of 112 children ages 2 to 17, in which the tocilizumab-treated patients showed substantially more improvement than the placebo group (e.g. ACR70 of 71% vs 8%). Improvement was maintained over a 40-week open-label extension study.[134] Supporting data for the polyarticular JIA label came from a three-phase study of 188 patients ages 2 to 17. An active 16-week lead-in period resulted in 166 patients achieving an ACR30 and progressing to the 40-week randomized, placebo-controlled withdrawal period with disease flare as a primary outcome measure.[135] Twenty-six percent of tocilizumab-treated patients experienced a flare, compared to 48% of placebo-treated patients. Responses were maintained over a further 48-week open-label extension. Significant adverse events have included neutropenia, elevated cholesterol and liver function tests, and serious infections.[136,137] Macrophage activation syndrome was seen in some of the clinical trials, with an overall incidence of one to two per 100 patient years, which was not felt to represent an increased risk.[138] Tocilizumab is administered to children in the intravenous preparation, every 4 weeks for polyarticular JIA and every 2 weeks for systemic JIA.

Conclusions

Targeted recombinant biologicals have been developed over the last three decades. They generally take advantage of the exquisite specificity and avidity of binding of the antibody response or physiologic receptor-ligand interactions. We have discussed here 15 compounds that have received FDA approval since 1998 for use in pediatric populations, mostly for inflammatory conditions but also for malignancy, transplant rejection, hypersensitivity and certain infections. More than half of these agents were licensed after 2005 (see Table 17-3). Ongoing trials of new agents in children are currently exploring novel targets such as IL-5,[139] CD22,[140] EGFR (epidermal growth factor receptor),[141] IGF-1R (insulin-like growth factor-1 receptor),[142] IFN-γ,[143] and GD2 (disialoganglioside, expressed on neuroblastoma and some other malignancies).[144] Many more targets are being explored in adult populations, and undoubtedly some successful compounds will find their use extended to younger patients.[145] Biological targeting mechanisms other than recombinant proteins, including those using genetically modified living cells, have shown early promise, such as the use of CAR (chimeric antigen receptor)-modified T cells.[146] Gene therapy approaches with nucleic acid constructs of DNA or RNA have great appeal in principle, but are still far from realizing their potential.[147] Undoubtedly, further genetic and molecular understanding of the complexities of in vivo pathways will uncover additional therapeutic options using the targeting specificity of biologics. This field can be expected to change rapidly in the coming years.

18 Laboratory Diagnosis of Human Allergic Disease

ROBERT G. HAMILTON

KEY POINTS

- Allergen-specific IgE antibody is a marker of allergic sensitization and a risk factor for allergic disease but, alone, it does not make the definitive diagnosis of allergic disease. Confirmation of allergic sensitization with a positive IgE anti-allergen analysis increases the likelihood that the patient's symptoms may be a result of an immediate-type hypersensitivity response.
- Quantitative IgE antibody levels to selected foods (milk, egg, fish and peanut) if above a predefined IgE antibody threshold may eliminate the need for tedious and expensive food challenges (DBPCFC). Caution, however, needs to be exercised as the predictive threshold levels vary among clinical studies, due to differences in study populations, protocols and statistical analyses employed.
- Food antigen-specific IgG and IgG4 antibody levels are not diagnostically useful as they do not correlate with the results of oral food challenges.
- Clinically successful aeroallergen immunotherapy is almost always accompanied by high (micrograms/mL) levels of allergen-specific IgG antibody in serum.
- Mast cell tryptase is a serine esterase that is used as a marker of mast cell activation during anaphylaxis. Immunoreactive tryptase levels in serum of healthy adults are typically <5 µg/L. Elevated mature tryptase levels (>10 µg/L) are detectable 1 to 4 hours after the onset of systemic anaphylaxis with hypotension.

The diagnosis of human allergic disease begins and ends with the patient's clinical history and physical examination.[1] When the clinical history identifies allergic symptoms that are in temporal relationship to a definable and relevant allergen exposure, immunoglobulin E (IgE) antibody sensitization is then confirmed with in vivo skin tests (puncture/intradermal, see Chapter 19) or in vitro blood tests (allergen-specific IgE antibody serological assays). If there is a mismatch between the history and these primary diagnostic tests for sensitization, then a secondary provocation test (open or placebo-controlled food challenge, nasal challenge, bronchial challenge) may adjudicate the veracity of the history-driven diagnosis.[2] This chapter discusses the laboratory's contribution to the diagnostic algorithm and analytes that serve as *diagnostic confirmatory tests* when there is high suspicion of allergic disease based on a clinical history.

Immediate (Type 1) Hypersensitivity Response

Prausnitz and Kustner first described the immediate-type hypersensitivity allergic reaction using an in vivo test in which serum from Kustner, who was allergic to fish, was injected into the skin of Prausnitz.[3] An immediate wheal and flare reaction in the skin was then induced when extracted fish antigen was injected into the same skin site. A serum factor or atopic reagin was later shown to be a novel immunoglobulin (IgE).[4,5]

Box 18-1 summarizes the immune system components that are involved in the induction of IgE antibody and elicitation of the effector mechanisms of type 1 hypersensitivity. Inhalation, skin or parenteral exposure to *allergens* is the initiating event, during which these foreign molecules are presented to antigen-presenting cells on mucosal surfaces. Antigen-presenting cells process antigenic epitopes to *T helper cells* that secrete *cytokines* (IL-4, IL-10, IL-13) which induce *B cell* lymphocyte proliferation. As allergen-specific IgE antibody is produced, it circulates and binds onto FcεR1 receptors on *mast cells* and *basophils*. Upon re-exposure, allergen cross-links receptor bound IgE, causing an influx in calcium, which triggers preformed *mediator release* (*histamine, proteases*) and newly synthesized mediators (*leukotrienes, prostaglandins*). The pharmacological effects of these mediators on blood vessels and airways produce a spectrum of clinical symptoms including hay fever, asthma, eczema and anaphylaxis. Released *cytokines* (IL-4, IL-5, IL-6) from degranulating mast cells serve to enhance the inflammatory response and IgE production.

An investigation that employed engineered antibodies and allergens showed that the concentration, specific activity (specific IgE to total IgE ratio), affinity (tightness of binding) and clonality (epitope specificity) of the IgE antibody response independently impact on effector cell activation.[6] The study concluded that higher levels of basophil activation occur with higher overall total serum IgE levels, higher Derp2-specific IgE to total IgE ratios, broader clonality and higher IgE antibody affinities. Future serological assays for IgE antibody need to monitor more effectively these four important humoral immune response parameters.[7]

Allergens

Allergens are substances, usually glycoproteins, that are released from weeds, grasses, trees, animal danders, molds, house dust mites, parasites, insect venoms, occupational substances, drugs and foods. They are capable of inducing IgE antibody (sensitization) in atopic or genetically predisposed individuals. Each of

https://CafePezeshki.IR

BOX 18-1 PRINCIPAL IMMUNE SYSTEM COMPONENTS INVOLVED IN THE INDUCTION OF IgE ANTIBODY AND EFFECTOR MECHANISMS OF TYPE I HYPERSENSITIVITY*

ANTIGEN PRESENTATION

Allergen (exposure, entry at mucosal surfaces or local lymph nodes)
Antigen presenting cells (processing and presentation)
T_H2 lymphocytes
Cytokines (promoters of IgE production: IL4, IL-10, IL-13; inhibitors of IgE production: IFγ)
B cell lymphocytes

IgE PRODUCTION AND SENSITIZATION

IgE (allergen-specific IgE antibody)
Connective tissue fixed and mucosal mast cells with FcεRI receptors
Circulating basophils with FcεRI receptors

MAST CELL ACTIVATION AND MEDIATOR RELEASE

Re-exposure to *allergen* induces calcium ion influx into mast cells
Mast cell releases preformed and newly synthesized mediators
Release of *trypase*
Exocytosis of preformed *histamine*
Synthesis of newly formed lipid mediators from arachidonic acid
Prostaglandin D_2
Leukotriene B_4, C_4, D_4

HUMORAL IMMUNE RESPONSE

Chronic antigenic challenge (inadvertent or intentional [immunotherapy]) induces antigen-specific IgG and IgA antibodies in blood and secretions)

*Analytes in italics are routinely measured in the clinical diagnostic allergy laboratory and thus they are discussed in the text. Analytes that are underlined are considered research analytes and they are not routinely measured in the clinical immunology laboratory.

these source materials may be extracted with a physiological buffer to produce a final product (extract) that contains a complex mixture of allergenic and nonallergenic material. With the advent of molecular cloning techniques in the late twentieth century, many clinically important allergenic components have been identified and purified out of these complex allergen extracts. A systematic allergen nomenclature for allergenic extracts and components has been adopted that involves the first three letters of the genus and first letter of the species and, for the allergen component, a number. This scheme has been established to identify each unique allergen extract and component specificity. For instance, Ara h 1 signifies the group 1 allergen in peanut (*Arachis hypogaea*) which is a carbohydrate-bearing 7S vicilin-like globulin.

Allergenic components are adopted into the World Health Organization/International Union of Immunological Societies (WHO/IUIS) Nomenclature committee database once they have an established purity to homogeneity, physical-chemical characterization by molecular weight, isoelectric point and glycosylation pattern, nucleotide and/or amino acid sequence and immunoreactivity to IgE antibody.[8] Allergenic molecules are further classified into protein families according to their structure and function. Different allergenic molecules often share common epitopes which can result in immunological cross-reactivity. Other allergenic molecules can serve as unique markers for a particular allergen specificity. Examination of the combined protein family (PFAM) database and structural database of allergenic proteins (SDAP) identified approximately 12 000 protein families, of which only approximately 2% or 236 PFAMs are known to contain allergenic proteins. Of these families, 31 protein families contain multiple allergenic proteins (homologs, orthologs). Thus, allergens comprise a small fraction of the total number of protein families and they possess particular biological structures and functions. They tend to be pervasive or abundant in nature and stable to processing (e.g. heat and digestion) as a result of multiple cysteine linkages. They tend to form aggregates or polymers and many tend to be plant defense related. Importantly, not every member of a protein family is allergenic or cross-reactive. Box 18-2 lists the nine principal allergen families that manifest cross-reactivity due to structural similarity. In addition, it presents their principal biological function in nature and illustrative members of these allergen families.

Since 1968, complex physiological extracts of allergenic materials have been used as reagents in serological assays for IgE antibody quantification in serum as they in theory contain all the principal allergenic components for that specificity. There has been increasing interest in the use of native and recombinant component allergens as serological reagents because component resolved diagnosis may better resolve genuine sensitization from cross-reactivity in polysensitized patients. In food allergy, components can be particularly useful for certain foods such as peanut as they can facilitate the assessment of risk for a severe versus more mild allergic reaction and thus reduce the need for an oral food challenge. By identifying the specific components to which an individual is sensitized, more targeted immunotherapy may also be conducted. Thus, instead of measuring IgE antibody to crude cat dander extract, clinically used singleplex and multiplex microarray assays can measure IgE antibody specific to component allergens produced by cats, namely Fel d 1 (uteroglobin), Fel d 2 (cat albumin), Fel d 3 (cystatin), Fel d 4 (lipocalin), Fel d 5 (cat IgA), Fel d 6 (cat IgM) and Fel d 7 (cat IgG). Use of component allergens allows one to dissect more effectively the IgE antibody response into allergen families that share structural homologies and thus cross-react with each other.

Possibly the most well-studied family of cross-reactive allergens is the pathogenesis related proteins (PR10 family) which are present in pollens, pomaceous and stone fruits, vegetables and nuts. These 17 kDa proteins function as ribonucleases and carriers of steroids. Most PR10 proteins are sensitive to heat and digestion. The group 1 allergen from birch tree pollen, Bet v1, has a number of homologs. These include allergenic proteins from alder tree pollen (Aln g 1), hazelnut pollen (Cor a 1), apple (Mal d 1), peach (Pru p 1), soybean (Gly m 4), peanut (Ara h 8), celery (Apr g 1), carrot (Dau c 1) and kiwi (Act d 8). A primary sensitivity to Bet v 1 may result in oral allergy symptoms after exposure to any of these structurally similar allergenic molecules. The chip-based microarray system discussed below is a comprehensive tool for identifying IgE antibodies in a given patient's serum that cross-react with components from seemingly disparate allergen sources.

Diagnosis of Type 1 Hypersensitivity

The diagnostic algorithm for human allergic disease begins with a thorough clinical history and physical examination. A

BOX 18-2 PRINCIPAL CROSS-REACTIVE FOOD-AEROALLERGEN FAMILIES

Profilin: An actin-binding protein in tree/grass/weed pollen and foods of plant origin that is involved in the dynamic turnover and restructuring of the actin cytoskeleton (12–15 kDa); sensitive to heat and digestion

Birch (*Betula verrucosa*)	Bet v 2
Natural rubber latex (*Hevea brasiliensis*)	Hev b 8
Mercury (*Mercurialis annua*)	Mer a 1
Timothy grass (*Phleum pratense*)	Phl p 12

Serum albumin: Protein in milk, blood and epithelia of animals that functions to transport hemin and fatty acids to muscle tissue and maintains oncotic pressure; sensitive to heat and digestion

Cow (*Bos domesticus*)	Bos d 6
Dog (*Canis familiaris*)	Can f 3
Horse (*Equus caballus*)	Equ c 3
Cat (*Felis domesticus*)	Fel d 2
Chicken (*Gallus domesticus*)	Gal d 5

Pathogenesis related proteins: PR10 Family (Bet v 1 homologs)-present in pollens, pomaceous and stone fruits, vegetables and nuts which functions as a ribonuclease and carrier of steroids (17 kDa); most PR10 proteins are sensitive to heat and digestion

Birch (*Betula verrucosa*)	Bet v 1–
Hazel pollen (*Corylus avellana*)	Cor a 1.010–
Hazelnut (*Corylus avellana*)	Cor a 1.040
Apple (*Malus domesticus*)	Mal d 1
Peach (*Prunus persica*)	Pru p 1
Soybean (*Glycine max*)	Gly m 4
Peanut (*Arachis hypogaea*)	Ara h 8
Kiwi (*Actinidia deliciosa*)	Act d 8
Celery (*Apium graveolens*)	Api g 1

Procalcin: present in weed/grass/tree pollens but not foods that functions to bind calcium and regulate calcium levels; moderately stable

Birch (*Betula verrucosa*)	Bet v 4–
Timothy grass (*Phleum pratense*)	Phl p 7

Nonspecific lipid transfer proteins: present in fruits, vegetables, nuts and pollen which functions to shuttle phospholipids and other fatty acids between cell membranes; stable to heat and digestion (7–9 kDa)

Peanut (*Arachis hypogaea*)	Ara h 9
Hazelnut (*Corylus avellana*)	Cor a 8
Walnut (*Juglans spp*)	Jug r 3
Peach (*Prunus persica*)	Pru p 3
Mugwort (*Artemisia vulgaris*)	Art v 3
Olive pollen (*Olea europaea*)	Ole e 7
Plane tree (*Platanus acerifolia*)	Pla a 3

Lipocalin: present in furry animals; functions to transport small hydrophobic molecules such as steroids, bilins, retinoids and lipids; stable protein

Cat (*Felis domesticus*)	Fel d 4, 7
Dog (*Canis familiaris*)	Can f 1, 2, 4, 6

Parvalbumin: present in fish and amphibians; binds calcium and is involved in calcium signaling in fast-contracting muscles; stable to heat and digestion

Cod fish (*Gadus morhua*)	Gad c 1
Shrimp (*Crangon crangon*)	Cra c 4, 6

Tropomyosin: Present in crustaceans, mites, cockroaches and nematodes and functions as an actin-binding muscle protein that regulates actin mechanics in muscle contraction; stable to heat and digestion

Anisakis – herring worm (*Anisakis simplex*)	Ani s 3
German cockroach (*Blattella germanica*)	Bla g 7
Dust mite (*Dermatophagoides pteronyssinus*)	Der p 10
Shrimp (*Penaeus monodon*)	Pen m 1

Storage proteins: present in seeds and nuts; function as nutrient storage (e.g. 2 S albumin) and are stable to heat and digestion

Peanut (*Arachis hypogaea*)	Ara h 1, 2, 3, 6
Hazelnut (*Corylus avellana*)	Cor a 9
Walnut (*Juglans spp*)	Jug r 1, 2
Soybean (*Glycine max*)	Gly m 5, 6

suggestive history is followed by in vivo skin testing, in vitro serological assays and/or provocation challenge tests as confirmatory measures for the detection of IgE antibodies (Box 18-3). The inter-relationship between each of these components of the diagnostic plan is illustrated in this chapter using natural rubber latex as a model allergen system.

CLINICAL HISTORY

Latex allergy diagnosis begins with a comprehensive clinical history.[9] A child may present with complaints of hives, rhinoconjunctivitis, asthma or anaphylaxis that are temporally associated with exposure to a product that contains natural rubber. The allergist probes the child's general atopic and specific latex allergy history using questions designed to identify predisposing risk factors such as an atopic state (seasonal rhinitis, early-onset asthma, eczema, food allergy), the frequency, consistency and magnitude of latex exposure, the presence of concomitant food allergy and hand dermatitis.[10,11] Exposure to rubber-containing products provides clues which strengthen the clinical suspicion of latex allergy. The rapid onset of allergic symptoms around toy balloons, dental dams or other dipped rubber products (latex gloves, rubber toys) that contain high levels of allergen is supportive.[12] In contrast, respiratory or upper airway symptoms around latex paint that does not contain natural rubber diminish the likelihood of latex allergy. The type of exposure, time of onset, and duration and severity of the symptoms can help differentiate between an immediate type 1 (protein-allergen induced) and delayed type 4 (rubber chemical induced) hypersensitivity. Finally, a genetic predisposition for atopic disease or parental history of allergy, chronic infectious or acute viral illness, relative contribution of Th1/Th2 cells to the immune response and the nutritional status of the individual are other potential risk factors.

DIAGNOSTIC LABORATORY METHODS

Analytes that are measured in the clinical immunology laboratory to support the diagnosis and management of patients suspected of having allergic disease are summarized in Box 18-4. Historically, total serum IgE was used as a diagnostic marker for allergic disease.[13] However, the wide overlap in the total serum

https://CafePezeshki.IR

BOX 18-3 KEY CONCEPTS

Diagnosis

- Allergen-specific IgE antibody is a marker of allergic sensitization and a risk factor for allergic disease but, alone, it does not make the diagnosis of allergic disease. It is performed as a confirmatory test in support of a clinical history that strongly suggests an allergic disorder.
- Allergen-specific IgE antibody is measured by non-isotopic autoanalyzers that employ a two-stage noncompetitive immunoassay format. In the assay, allergen-specific antibodies are bound to a solid phase allergosorbent and bound IgE antibodies are detected with labeled anti-human IgE. A heterologous total serum IgE calibration curve is used to interpolate response levels into quantitative estimates of allergen-specific IgE.
- Quantitative IgE antibody results are reported in kU_A/L, traceable to the World Health Organization IgE Reference Preparation (1 U = 2.4 nanograms of IgE).
- The multi-allergen screen is a qualitative assay that measures allergen-specific IgE antibody to multiple aeroallergens and/or food allergens in a single test. The multi-allergen screening assay produces qualitative (positive or negative) results that lead to subsequent investigation of the patient's serum or skin for IgE antibodies specific for individual clinically defined allergen specificities.
- A competitive inhibition format of IgE antibody assays is used to define the relative potency of allergen extracts used in skin testing, to identify the extent of cross-reactivity of human IgE antibody for structurally similar allergens (e.g. vespid vs Polistes wasp venom allergens) and in *Hymenoptera* venom allergy to select appropriate venoms for immunotherapy.
- Quantitative IgE antibody levels to selected foods (milk, egg, fish and peanut) if above a predefined IgE antibody threshold may eliminate the need for tedious and expensive food challenges (DBPCFC). Caution, however, needs to be exercised as the predictive threshold levels vary among clinical studies, due to differences in study populations, protocols and statistical analyses employed.
- Food antigen-specific IgG and IgG4 antibody levels are not diagnostically useful as they do not correlate with the results of oral food challenges.

BOX 18-4 ANALYTES MEASURED IN THE CLINICAL IMMUNOLOGY LABORATORY

DIAGNOSIS

- Allergen-specific IgE
  - Multi-allergen-specific IgE screen (adult and pediatric forms)
  - Individual allergen specificities (extracts and component allergens)
- Total serum IgE[1]
- Precipitating antibodies specific for proteins in organic dusts
- Tryptase (total and mature) (mast cell protease and used as a marker for mast cell-mediated anaphylaxis)
- Other tests: complete blood count (CBC), sputum examination for eosinophils and neutrophils

MANAGEMENT

- Allergen-specific IgG (Hymenoptera)
- Indoor aeroallergen quantitation in surface dust
  - Der p 1/Der f 1 (Dust mite, *Dermatophagoides*)
  - Fel d 1 (Cat, *Felis domesticus*)
  - Can f 1 (Dog, *Canis familiaris*)
  - Bla g 1/Bla g 2 (Cockroach: *Blattella germanica*)
  - Mus m 1 (Mouse: *Mus musculus*)
  - Rat n 1 (Rat: *Rattus norvegicus*)
- Cotinine (metabolite of nicotine measured in serum, urine and sputum and used as a marker of smoke exposure)

RESEARCH ANALYTES

- IgE specific autoantibodies
- Eosinophil cationic protein
- Mediators[2,3]
  - Preformed biogenic amine: histamine
  - Newly formed
    - leukotriene C_4 (LTC_4)
    - prostaglandin D_2 (PGD_2)
- Proteoglycans[2]
  - Heparin
  - Chondroitin sulfate E
- Proteases[2]
  - Mast cell chymase
  - Mast cell carboxypeptidase
  - Cathepsin G
- Fibroblast growth factor (bFGF)[2]
- Cytokines
  - Tumor necrosis factor (TNF)-alpha
  - Interleukins (ILs) 4, 5, 6, 13[3]

[1]Total serum IgE is the only one of these tests listed that is regulated under the CLIA 88. [2]Primarily released from mast cells. [3]Primarily released from basophils.

IgE levels between atopic and nonatopic populations[14] caused it to be superseded by allergen-specific IgE as the single most important laboratory analyte in the diagnostic work-up for allergic disease. Since 2003, all patients receiving anti-IgE therapy (Xolair) must first have a total serum IgE to determine whether or not they are a candidate for the treatment. According to the Xolair indication, if the patient's total IgE falls between 30 and 700 kIU/L, (IU – international unit of IgE which is equivalent to approximately 2.4 nanograms of IgE) then the clinician can use the total serum IgE level to compute the starting Xolair dose using package insert criteria.

The radioallergosorbent test (RAST) was the first assay developed in 1968 for the detection of allergen-specific IgE antibodies in human serum.[15] The RAST is a noncompetitive, heterogeneous (separation step included), solid-phase immunoradiometric (radiolabeled antibody) assay in which allergen is covalently coupled to a solid phase (e.g. cellulose paper disc). In an initial incubation, human serum is added to the allergosorbent, during which time antibodies of all human isotypes, if present, bind to immobilized antigens. Following a buffer wash, bound IgE is detected with ^{125}I-labeled anti-human IgE Fc. After a second buffer wash to remove unbound radiolabeled anti-human IgE, bound radioactivity is measured in a gamma counter. The counts per minute level associated with the solid phase is proportional to the amount of allergen-specific IgE in the initial serum specimen.

The basic RAST chemistry has remained essentially unchanged for approximately 50 years. However, there have been major advances in assay automation and reagent quality. For instance, the number and quality of allergen extracts and especially component allergens used in preparing allergosorbents have increased as a result of extensive research using new methods of extraction and quality control. The paper disc solid phase in the one current assay (Aligent-Hycor, IgE Turbo-MP) is being replaced by newer matrix materials such as the cellulose sponge (Phadia ImmunoCAP) and biotinylated allergens (Siemens Immulite) that bind to avidin-coated beads. These advances have enhanced the binding capacity and reduced the

https://CafePezeshki.IR

nonspecific binding levels of allergosorbents. Various polyclonal and monoclonal anti-IgE detection antibody combinations insure maximal assay sensitivity while maintaining their required specificity for human IgE. Microprocessor-driven automation has improved intra-assay precision and inter-assay reproducibility. Nonisotopic labels have lengthened the shelf-life of immunochemical reagents and have made the assays more user-friendly. The various assays now use a common calibration system in which a (heterologous[16]) total serum IgE curve is used to convert allergen-specific IgE assay response data into quantitative dose estimates of IgE antibody in kU_A/L units. All these modifications have resulted in assays with superior analytical sensitivity and specificity. They are more quantitative, reproducible and automated than their earlier counterparts. These improvements have made the serological assay for IgE antibody diagnostically competitive with its in vivo puncture skin test counterpart. The intradermal skin test still appears to possess an inherent advantage in terms of analytical sensitivity and a major disadvantage involving the loss of diagnostic specificity.[1,17]

A consensus guideline (I/LA20-A3) on allergen-specific IgE assays has been established by an international body of scientists from academia, industry and government regulatory agencies.[18] This effort has led to a more uniform strategy among the various assay manufacturers in reporting IgE antibody results using a common unit (kU_A/L) with a calibration system that is linked to the World Health Organization IgE reference preparation. In spite of the use of a common calibration scheme, the clinically used assays measure different populations of IgE antibody.[19,20] This observed inter-assay difference is believed to stem from the use of extracts containing different compositions of allergens. The consequence is that published IgE antibody data generated with one assay cannot be directly extrapolated to published predictive outcomes that are based on IgE antibody levels from a second assay method. Specific IgE antibody levels measured in different commercial assays are currently not interchangeable or equivalent.[18]

Until recently, all allergen preparations used in clinical IgE antibody assays have been mixtures of proteins derived from biological extracts of raw material that varies in its composition (molecular weight, charge [isoelectric point], relative content) and allergenic potency as a function of a number of factors. These factors include the season in which the raw material is collected, the degree of difficulty in identifying a pure source of raw material, the presence of morphologically similar raw materials that may cross-contaminate and differences in the allergen extraction process used by different manufacturers. Once prepared, allergen extracts undergo extensive quality control involving isoelectrofocusing, SDS-polyacrylamide gel electrophoresis, crossed immunoelectrophoresis and immunoblotting. Issues of stability during storage, heterogeneity of the human IgE antibody containing quality control sera and different acceptance criteria for extract-based allergen-containing reagents also contribute to inter-method variability. Thus, allergosorbents from different manufacturers can be expected to bind different distributions of IgE antibodies for any given allergen specificity.

Some allergen extracts used in IgE antibody assays have been supplemented with recombinant allergens that are either in low quantity or missing. One successful supplementation involves the crude latex extract in which recombinant Hev b 5 has been added since it is labile and does not survive the extraction from natural rubber products. The addition of recombinant Hev b 5 by one manufacturer to the latex reagent has increased the diagnostic sensitivity of their latex-specific IgE antibody assay by 10%, with no apparent loss of specificity.[21] However, problems can arise when recombinant protein supplementation of an allergen extract is performed without the knowledge of the clinician who ultimately uses the results in patient management. When hazelnut extract that is used on an allergosorbent was supplemented with recombinant Cor a 1, it caused enhanced detection of IgE antibody to its structurally similar birch pollen homolog Bet v 1.[22] This led to exceptionally high levels of IgE anti-hazelnut in patients with a concomitant birch pollen sensitivity which were challenging to interpret by clinicians.

In 2002, microarray chip technology emerged.[23] Its commercialized version, the ImmunoCAP ISAC or immuno-solid phase allergen chip (Thermofisher Scientific/Phadia), has 112 native/recombinant component allergens that are spotted in triplicate onto glass slides. Thirty microliters of serum are pipetted onto the chip and antibodies specific for the allergens attached to the chip bind during a 2-hour incubation period. Following a buffer wash, bound IgE is detected with a fluorescently labeled antihuman IgE conjugate. The chip is read in a fluorometer and fluorescent signal units are interpolated into ISU or immuno-solid phase allergen chip (ISAC) units as semi-quantitative estimates of specific IgE antibody in the original serum. The analytical sensitivity of the ISAC varies as a function of the allergen specificity. It is generally less than the ImmunoCAP singleplex system when the same component allergen is coupled to the sponge. The strength of the microarray system is its ability to identify cross-reactivity among structurally similar allergens from different biological substances as noted in Box 18-2. Knowledge of the extent of IgE cross-reactivity must be factored into the diagnostic process within the context of the patient's clinical history.

A point-of-care IgE antibody lateral flow test is a novel alternative IgE antibody assay technology that is used in Europe but has failed to obtain acceptance in North America. In this assay, a drop of whole blood from a finger prick is inserted into the sample well of the cassette. A current commercialized device (ImmunoCAP Rapid, Phadia) allows serum proteins to flow with the fluid front across a nitrocellulose strip that has been impregnated with 10 lines of extract-based aeroallergens (cat dander, *D. farinae, D. pteronyssinus*, Bermuda grass, short ragweed, oak tree, *Alternaria*, timothy grass, elm tree and dog dander). If IgE antibody is bound, it is detected with anti-IgE colloidal gold that subsequently migrates up the same nitrocellulose strip following the addition of developing solution to a second well in the cassette. This device is intended for use by primary care physicians who would then refer their IgE-positive patients to an allergist for a comprehensive diagnostic work-up.

PERFORMANCE OF IgE ANTIBODY CONFIRMATORY TESTS USING A DEFINED POSITIVE CUT-OFF POINT

The practicing medical professional needs to know how well the available IgE antibody confirmatory assays perform analytically and diagnostically. The analytical performance of the available clinical assays is readily defined since they are all calibrated using the same WHO total serum IgE reference preparation. In general, available clinically-used assays detect allergen-specific

https://CafePezeshki.IR

IgE antibody down to 0.1 kU_A/L (≈0.24 ng of IgE) and false positive nonspecific binding typically occurs only with extremely high total IgE levels (e.g. >20 000 IU/mL).[18] Analytical specificity is a function of the quality of the allergen component and anti-IgE used in the assay.

The allergen-specific IgE antibody analysis is a test for allergic sensitization and not for making the definitive diagnosis of allergic disease. Confirmation of allergic sensitization with a positive IgE anti-allergen analysis increases the likelihood that the patient's symptoms may be a result of an immediate type hypersensitivity response. Thus, it is difficult to define the relative 'diagnostic' sensitivity and specificity of IgE antibody assays because these parameters require, first, differentiating individuals who have allergic disease from those who do not have allergic disease. There exists no perfect 'gold standard' method for defining the presence of human allergic disease. The diagnostic algorithm indicates, however, that the clinical history should be the primary decision criterion in making the final diagnosis of allergic disease. Unfortunately, a patient's history is not infallible.

Gendo and Larson have proposed three strategies for defining the presence of human allergic disease, with the expressed purpose of judging the performance of confirmatory IgE antibody tests.[24] The 'clinical criteria gold standard' correlates the patient's symptoms and signs with clinical criteria that have been established by expert opinion. It is easy to use and applicable to most patients but, unfortunately, it is prone to recall bias. Box 18-5 lists the principal patient and medical care professional factors that can influence the accuracy of the clinical criteria based gold standard approach. The 'composite gold standard' combines the clinical history and physical examination information with one or more IgE antibody confirmatory test results (skin tests or serological tests). This approach is generally more robust than just using the history alone, however it tends to overestimate the index test's diagnostic sensitivity and specificity if the index test is a part of the composite gold standard. Box 18-5 lists variables that influence the accuracy of skin test and serological test results. The third and possibly most rigorous strategy for defining the presence of allergic disease is the 'challenge gold standard'. Use of a challenge test to verify the presence of an allergic disease process on the surface sounds ideal. However, it too can be problematic due to differences in threshold of organ sensitivity, a lack of standardization of methods and outcome measures, and the use of a higher allergen dose than is found in nature to elicit a clinically measurable response. Because skin and serological tests and provocation testing are analytical methods, they are inherently variable.[10,18,19,25] Thus, the validity of their results must always be critiqued, especially if inconsistent with the history-based diagnosis.

A number of clinical studies have used one of these three gold standard approaches to define the presence of aeroallergen-related allergic disease.[17,26,27] With the cases defined, the investigators computed the diagnostic sensitivity and specificity of puncture skin tests and/or serological tests for IgE antibody to a limited number of aeroallergen specificities. Since the patient population studied, positive cut-off criteria, reagent sources used and statistical methods varied among the studies, generalized conclusions from the data in these studies are not possible. Within the limits of these studies, the performance of the puncture skin test ranged from 55% to 98% (diagnostic sensitivity) and 70% to 90% (diagnostic specificity) using the clinical or composite gold standard to identify allergic disease. In the same studies, the performance of the serological tests for IgE antibody with the same allergen specificities ranged from 55% to 80% (diagnostic sensitivity) and 82% to 99% (diagnostic specificity) using the clinical or composite gold standard. Performance improved slightly for both the skin test and serology when a challenge-based gold standard was used to define the presence of clinical disease. In a 2014 comparative study,[26] substantial

BOX 18-5 VARIABLES THAT INFLUENCE THE ACCURACY OF THE ALLERGY DIAGNOSIS

The allergen-specific IgE antibody analysis is a test for allergic sensitization and not for making the definitive diagnosis of allergic disease. Multiple factors also influence the translation of allergen exposure into an allergic symptom.

PATIENT FACTORS

- Recognition of symptoms: recall bias related missing data, lack of knowledge or ability to accurately describe symptoms
- Environment: rural, suburban, urban, pet ownership, smoking
- Extent of allergen exposure: time between exposure and symptom recognition, exposure route (ingestion, inhalation, injection, adsorption)
- Demographics: age (adult vs child-parent), gender, social economic status, language, race, family history of atopy
- Prevalence of allergic disease in question in the population

MEDICAL CARE PROFESSIONAL FACTORS

- Extent of education, training and experience
- Physical examination skills
- Questionnaire tools/skills: sensitivity and specificity
- Differential interpretation of diagnostic test results

SKIN TEST FACTORS

- Allergen extracts: potency, stability, standardization or characterization, concentration used, irritant in allergen extract, contaminant allergen in extract
- Technique: puncture, intradermal, skin test device, number of skin tests, reporting scale [0 to 4+] vs mm of wheal/erythema, comparison to saline control or histamine control, skin test spacing application, insufficient penetration of the needle, testing in the week after anaphylaxis
- Technologist and physician: education, training, experience in grading and interpretation of results
- Quality control: negative control, positive control
- Patient: dermagraphism, interfering premedication (antihistamines, tricyclic antidepressants, long-term oral steroids, topical steroids)
- System factors: quality assurance practices, records, office procedures, level of documentation of results

SEROLOGICAL TEST FACTORS

- IgE antibody assay method: analytical sensitivity, degree of automation, method of standardization and quality control, reproducibility, linearity, units
- Reagents: allergen containing reagent, anti-IgE detection reagent, buffers, protein matrix effects, recombinant allergen supplementation
- Specimen/allergen specificity factors: specific to total IgE ratio, cross-reactive carbohydrate reactivity, high IgE nonspecific binding levels, allergen heterogeneity (analytical specificity)
- Technical staff: education, training and experience
- System factors: laboratory quality control practices, records, office procedures, level of documentation of results, laboratory certification

https://CafePezeshki.IR

discordance was demonstrated between IgE antibody serology and skin testing results performed on the same individuals. The two methods of IgE antibody detection appeared to complement each other and ideally they should not be interpreted interchangeably.[26] Importantly, using the IgE antibody results from either serology or skin testing alone can lead to a misdiagnosis of every fourth allergically sensitized patient as nonsensitized.

For food allergy diagnosis where the skin testing food extracts are highly variable, serological IgE antibody assays may be more reliable and reproducible. If the confirmatory test result is inconsistent with the history-based diagnosis, it should be repeated with the same or an alternative confirmatory test for verification. Both skin and serological tests for IgE antibody are analytical methods with their inherent variability, and thus repetitive confirmation is often needed to minimize error associated with random or systematic bias.

PERFORMANCE OF IgE ANTIBODY CONFIRMATORY TESTS USING A PROBABILITY OF CLINICAL DISEASE

Current assay technology produces quantitative estimates of IgE antibody in serum as international units per mL that are traceable to the WHO International Reference Preparation for human IgE. Rather than examine the dichotomized IgE antibody data as a positive or negative result using a positive cut-off value, the alternative has been to examine the risk of clinical allergy associated with different IgE antibody levels as a series of probabilities. A 1997 study retrospectively investigated sera from 196 children and adolescents (mean age 5.2 years, 60% male) with atopic dermatitis who were evaluated for food allergy over a 10-year period.[28] Levels of IgE antibodies specific for cow's milk, chicken egg, peanut, wheat, soy and fish were correlated with a diagnosis of food allergy as defined by positive double-blind, placebo-controlled food challenges or a convincing history of food-induced anaphylaxis. They were able to identify IgE antibody levels using the Phadia FEIA CAP system that could predict clinical reactivity (positive food challenges) with >95% certainty for egg (6 kU_A/L), milk (32 kU_A/L), peanut (15 kU_A/L), and fish (20 kU_A/L). The significance of this report rests in its potential for identifying truly food allergic individuals and thus eliminating the need for food challenges in children suspected of having IgE-mediated food allergy. In a 2001 report,[29] a prospective study was performed with sera from 100 children and adolescents (mean age: 3.8 years, 62% male) who had been referred for evaluation of food allergy. This prospective study verified the retrospective study based on 95% predictive decision points for egg, milk, peanut and fish allergy. The study also confirmed that use of the positive criteria correctly diagnosed food allergy in >95% of children using the serum IgE antibody level. The study showed that quantitative food-specific IgE antibody measurements can be judiciously used to define the probability or risk of symptomatic allergies related to egg, milk, peanut and fish in the pediatric population. The important conclusion of these studies is that careful use of quantitative serological IgE antibody test results may eliminate the need for food challenges in some children.

For inhalant allergies, quantitative cat allergen-specific IgE antibody measurements have been shown to be equivalent to puncture skin tests and superior in performance to intradermal skin tests in the diagnosis of clinical reactivity to cat allergen.[17] When compared to a positive cat inhalation challenge outcome, IgE antibody levels by the ImmunoCAP system displayed a diagnostic sensitivity of 69%, specificity of 100%, positive predictive value of 100% and negative predictive value of 73%. In the dust mite system, a significant correlation was observed between the concentration of dust mite specific IgE and the concentration of sensitizing mite allergen in the individual's mattress dust ($P = .001$).[30] The authors reported a 77% probability of being exposed to high dust mite allergen (>10 μg per g of dust) when the serum IgE anti-mite levels were greater than 2 kU_A/L and vice versa. Finally, using specific IgE as a continuous variable, the risk of current wheeze and reduced lung function in children increases significantly with increasing summed measurements of dust mite, cat and dog specific IgE antibody.[31] These data indicate that quantitative estimates of serum IgE antibody can identify individuals who are not only sensitized but also who are in need of avoidance practices which they accomplish through environmental control measures. Other illustrations of the importance of quantitative allergen-specific IgE to respiratory allergy are reviewed elsewhere.[32] As a general rule for inhalant allergen specificities, the skin test and quantitative IgE antibody immunoassay can be viewed as interchangeable. One exception is in the monitoring of patients on immunotherapy where a decrease in the positivity of the puncture skin test titration alone has been shown to predict continued remission after cessation of allergen immunotherapy.[33]

Multi-Allergen IgE Antibody Screening Assays

When a patient provides an equivocal history for allergic disease, it can be difficult to pinpoint with reasonable certainty the appropriate IgE antibody specificities for further diagnostic investigation. A multi-allergen screen is a single IgE antibody analysis that has the highest negative predictive value for atopic disease of any single laboratory test currently available. Multiple companies have multi-allergen screens which cover a broad number of specificities (e.g. 10–15 common indoor and outdoor aeroallergens that induce most upper and lower airway related allergic disease). Other multi-allergen screens are specifically targeted at a limited number of specific allergens in a group such as the foods (e.g. chicken egg, cow's milk, peanut, soybean, wheat). A negative multi-allergen screen reduces the likelihood that allergic disease is the cause of the child's clinical problems. Multi-allergen screen results are particularly useful in the diagnosis of pediatric allergic diseases where there is a need to detect allergen-specific IgE antibody in serum as a marker for sensitization. For this reason, the biomarkers committee of a National Institute of Health organized workshop on asthma outcomes has recommended that the multi-allergen screen be performed on all participants in asthma clinical trials to define their atopic status.[34]

In one illustrative study,[35] 143 children and adolescent patients were assigned an allergy status (103 positive, 40 negative) based on a combined history, skin prick test and specific IgE antibody (UniCAP, Thermofisher Scientific/Phadia) to six common inhalants (mite, oak, ragweed, grass, dog, cat and *Alternaria*). The multi-allergen screen (Phadiatop, Thermofisher Scientific/Phadia) run on these same sera correctly identified the allergy status of all subjects, verifying the diagnostic sensitivity and specificity of Phadiatop in differentiating sensitized individuals from those who are not sensitized to common inhalant allergens.

Mast Cell Tryptase

Serum levels of tryptase can be useful as a marker of mast cell activation in making the definitive diagnosis of anaphylaxis. Tryptase is a 134 000 Da serine esterase with four subunits, each containing an enzymatically active site.[36] When tryptase becomes dissociated from heparin, it spontaneously degrades into enzymatically inactive monomeric subunits. It is released from activated mast cells in parallel with pre-stored histamine and other newly generated vasoactive mediators. The total protryptase concentration in blood is considered a measure of the mast cell number and it is estimated by subtracting the mature tryptase from the total tryptase concentration. In contrast, mature tryptase levels in blood are considered a measure of mast cell activation.

An enzyme immunoassay is available to measure total tryptase levels in human serum. It uses a capture monoclonal antibody that binds both protryptase and mature tryptase.[37] Mature tryptase is measured with a solid phase noncompetitive immunoassay that uses a mature tryptase specific capture monoclonal antibody. Prior to analysis, tryptase in the blood is converted into an enzymatically inactive form. Total serum tryptase concentrations in healthy (nondiseased) individuals range from 1 to 10 ng/mL (average 5 ng/mL). If baseline total serum tryptase levels exceed 20 ng/mL, systemic mastocytosis should be suspected. A mature tryptase <1 ng/mL is observed in nondiseased individuals and mature tryptase levels >1 ng/mL indicate mast cell activation. For optimal results, blood samples should be collected from 0.5 to 4 hours following the initiation of a suspected mast cell mediated systemic reaction.[38] A peak mature tryptase >10 ng/mL in a postmortem serum suggests systemic anaphylaxis as one probable cause of death. Systemic anaphylaxis induced by an insect sting can produce mature tryptase levels that peak at >5 ng/mL by 30 to 60 minutes after the sting and then decline with a biological half-life of ≈2 hours.[39]

Serum Markers of Hypersensitivity Pneumonitis

Extrinsic allergic alveolitis or hypersensitivity pneumonitis is an inflammatory reaction involving the lung interstitium and terminal bronchioles.[40] A heavy exposure to antigenic organic dusts (e.g. molds, bird droppings) can induce chills, fever, malaise, cough and shortness of breath within hours of exposure. While histology of the lung lesions indicates that a cell-mediated pathology is involved in hypersensitivity pneumonitis, most individuals have high levels of IgG antibody in their serum to the offending antigen that is used as a marker of the disease. Precipitating IgG antibody specific for antigens in organic dusts has been measured in human serum to support the differential diagnosis of this condition. The classical double diffusion (Ouchterlony) analysis is routinely performed to detect precipitating antibodies in the diagnosis of this disease. In this assay, crude antigen extract and antibody (control or patient's serum) are delivered into closely spaced wells in a porous agarose gel. Visible white precipitin lines confirmed by lines of identity with known human antibody controls are considered a positive test. Precipitating antibodies or precipitins were detected in the serum of nearly all ill patients in one study, but also in the serum of 50% of asymptomatic individuals exposed to the relevant organic dusts.[40,41] More recently, enzyme immunoassays for IgG antibody to selected organic dust antigens have been reported.[42] In many cases, however, the enzyme immunoassay appears to be too analytically sensitive and diagnostically nonspecific. Thus, the classical precipitin assays continue to be widely used for detecting IgG precipitins to antigens in pigeon serum, *Aureobasidium pullulans*, thermophilic actinomyces, *Aspergillus fumigatus* and extractable proteins from fecal material produced by parakeets and a variety of exotic household birds.

Management of Type 1 Hypersensitivity

The management of individuals with allergic disease involves the combined use of pharmacotherapy, immunotherapy, anti-IgE therapy and avoidance therapy. A number of analytical measurements performed by the clinical immunology laboratory can aid the clinician in optimizing an immunotherapy regimen by monitoring the humoral (IgG antibody) immune responses in patients on venom immunotherapy (Box 18-6). Anti-IgE therapy begins with a total serum IgE to determine proper dosing. Assays to monitor the level of free (non-anti-IgE bound) IgE in circulation of patients on omalizumab have remained research assays[43] as there is currently no documented clinical indication for their use. Finally, indoor aeroallergen levels may be measured in surface reservoir dust before remediation to document the need for and monitor the extent of allergen avoidance measures and after remediation to verify that the environment has been cleaned of allergen sources.

OPTIMIZING VENOM IMMUNOTHERAPY

When considering the medically important *Hymenoptera*, cross-reactivity has been known to exist between the vespid venoms (yellow jacket, white faced hornet and yellow hornet) and *Polistes* wasp venom proteins. Results from a competitive inhibition format of the *Polistes* wasp venom-specific IgE antibody serology have allowed allergists to select the venom specificities more effectively and to minimize the number of venoms that must be administered during immunotherapy.[44] This targeted venom therapy is especially important for children where unnecessary administration of *Polistes* wasp venom may lead to de novo sensitization to *Polistes* allergens. More recently, component resolved diagnosis using recombinant venom allergens permits more effective identification of cross-sensitization that results from dual sensitization to honeybee and vespid venoms. This allows venom immunotherapy to be performed with the relevant single venom rather than multiple venoms.[45]

AEROALLERGEN MEASUREMENTS OF INDOOR ENVIRONMENTS TO FACILITATE AVOIDANCE THERAPY

Dust mite (*Dermatophagoides pteronyssinus*, *D. farinae*), cat epithelium/dander (*Felis domesticus*), dog epithelium/dander (*Canis familiaris*), German cockroach (*Blattella germanica*), mouse (*Mus musculus*), rat (*Rattus norvegicus*) and molds are known sources of potent indoor aeroallergens.[46] Allergic proteins from each of these biosources are being used as 'indicator' allergens for relative levels in surface reservoir dust in the home, workplace or school (Box 18-6).

A surface dust specimen is collected from air ducts, floors or other horizontal surfaces (bed, upholstered furniture) using an

https://CafePezeshki.IR

BOX 18-6 KEY CONCEPTS

Management

- Clinically successful aeroallergen immunotherapy is almost always accompanied by high (µg/mL) levels of allergen-specific IgG antibody in serum.
- Quantitative venom-specific IgG antibody levels can be useful in individualizing venom doses and injection frequencies for patients on maintenance venom immunotherapy for up to 4 years.
- Mast cell tryptase is a serine esterase that is used as a marker of mast cell activation during anaphylaxis. Immunoreactive tryptase levels in serum of healthy adults are typically <5 µg/L. Elevated levels (>10 µg/L) are detectable 1 to 4 hours after the onset of systemic anaphylaxis with hypotension.
- Indoor allergens from dust mites, animals (cat, dog, mouse, rat), cockroaches and a limited number of molds are quantified in processed house dust to investigate individual risk for allergic symptoms or sensitization and to monitor effects of environmental control.

inexpensive dust collector that is attached to a standard household vacuum cleaner. Crude dust is sent to a clinical immunology laboratory where it is sieved, extracted and quantified using a monoclonal antibody-based immunoenzymetric assay in plates (ELISA) or on fluorescent beads (BioPlex). A high level of one or more indoor aeroallergens identifies an allergen source that can sensitize or induce an allergic reaction in a sensitized individual. Levels of Der p 1/f 1 allergen >2000 ng/g of fine dust have been associated with an increased risk for allergic symptoms in sensitized individuals. In contrast, cat allergen levels >8000 ng/g of Fel d 1 in fine dust have been suggested as the threshold for sensitization. Comparable risk targets have also been used for dog (Can f 1) allergen levels in indoor environments. For cockroach, mouse and/or rat urinary allergen, any detectable allergen in the indoor environment places cockroach, mouse or rat allergic individuals at risk for symptoms and further sensitization.[47]

MOLD/FUNGUS EVALUATION IN INDOOR ENVIRONMENTS

Accurate quantitation of the mold content of an environment is a challenge. *Alternaria, Aspergillus, Cladosporium* and *Penicillium* comprise the majority of indoor molds.[47] The total spore counts (nonviable and viable) can be determined by collecting particulate from an air impactor or suction device and then assessing the spore's morphology for the purpose of speciating the mold. Viable fungal spores that grow when environmental conditions are favorable are considered by some allergists as more clinically important since they can colonize indoor environments and, in some cases, the respiratory tract. In one clinical laboratory, a qualitative viable mold spore analysis is performed on 5 mg of fine dust that is distributed over a microbiological culture plate containing Sabouraud's dextrose agar. Visual inspection of the plate at 24 and 48 hours allows the total number of mold colonies to be quantified. The colony count at 24 hours is an estimate of the mold burden of the environment. Repetitive subculturing and morphological identification allows speciation of the predominant molds; however, this is infrequently performed. Rather, once a mold contamination has been identified, remediation by cleaning with bleach and reducing humidity is generally instituted.

There are no established mold spore contamination ranges that can be considered safe, partly because mold is ever present, different individuals have different relative sensitivities and the target airborne mold allergens are difficult to sample and verify. Thus, it is not possible to identify an environment that will place a mold-allergic person at risk for symptoms. Multiple variables associated with mold spore heterogeneity, differential growth based on nutrients and environmental conditions, the degree of aerosolization, and variable specificity of the patient's IgE antibody complicate the interpretation of a mold spore measurement when attempting to predict a clinical outcome from any environmental exposure. Sometimes the indoor mold levels are compared to the outdoor mold levels collected at the same time to judge if airborne mold spores are significantly higher and thus playing a more significant role in the allergy and asthma symptoms experienced indoors. Mold spore levels above 25 000 colonies per gram of fine dust have been identified in one study as a level that places a home in the 75th percentile for random homes monitored across the USA. When this proposed threshold level is exceeded, the allergic individual is encouraged to remediate their environment, which often involves replacing air duct filters, removing plants and decreasing indoor humidity and removing carpeted floors, upholstered furniture and stuffed toys.

Conclusions

The diagnostic allergy laboratory exists to provide serological testing that supports the clinician in the diagnosis and management of patients suspected of type 1 hypersensitivity reactions. To this end, the most important analyte measured in the clinical laboratory is allergen-specific IgE antibody. Selection of the laboratory and the IgE antibody assay methods and standards that it employs to insure quality are the ultimate responsibility of the referring physician.[48] Performance on national diagnostic allergy proficiency surveys and successful inspections leading to federal licensure under the Clinical Laboratory Improvement Act of 1988 are benchmarks that can be used by the healthcare professional to insure that the clinical laboratory provides quality diagnostic allergy testing.

In Vivo Testing for Immunoglobulin E-Mediated Sensitivity

HAROLD S. NELSON

KEY POINTS

- Skin testing is the preferred method for in vivo detection of IgE-mediated sensitivity due to its objective end-point and the ability to test for multiple sensitivities in one session.
- Positive skin tests are present in most patients with asthma and allergic rhinitis but are also common in subjects without symptoms. Therefore the presence of a positive skin test is not sufficient to make a clinical diagnosis of allergy.
- Some patients have typical symptoms of allergic rhinitis but negative skin and in vitro tests for the relevant allergens. This local nasal allergy can be confirmed by the presence of a positive nasal challenge with the allergen.
- Positive skin tests are most common and largest in subjects in the third decade. They are considerably less common and smaller in young children and older adults.
- Prick/puncture skin tests are less sensitive than intradermal tests with the same concentration of extract but they correlate better with clinical symptoms caused by inhalant allergens.

Introduction

In the USA, in vivo testing for the diagnosis of allergy is virtually synonymous with skin testing. The preference for skin testing over allergen challenges to the conjunctiva, nose or lungs is attributable to skin testing being less time consuming and more comfortable for the patient. It provides an objective end-point, rather than the subjective end-points typical with conjunctival and nasal challenges. Finally, many allergens can be tested for in a single session, compared to the limitation to a single allergen with mucosal challenges. There is little to suggest that the information gained from mucosal testing is different from that obtained by skin testing. Results of nasal challenges have been shown to correlate closely with skin tests,[1] as do the results of bronchial challenges, when the additional factor of nonspecific airway responsiveness to histamine is included.[2] A joint committee of the American Academy of Allergy, Asthma and Immunology and the American College of Allergy Asthma and Immunology has developed a Practice Parameter for Allergy Diagnostic Testing which is comprehensive and based on the most current published literature on this topic.[3]

Prevalence of Positive Skin Tests

Reaction of the skin to extracts of environmental allergens is common, but not invariable, in patients with the so-called 'atopic diseases' – perennial and seasonal rhinitis, bronchial asthma and atopic eczema. Of 656 asthmatic patients referred for an allergy evaluation in London, 544 (84%) had at least one positive immediate reaction to prick skin testing with 22 common allergens.[4] Skin test reactivity was more common in those with onset of asthma prior to 10 years of age, whereas those with onset after the age of 30 years were more commonly skin test negative. A similar percentage with positive skin tests has been reported in patients evaluated for rhinitis[5] and eczema.[6]

Positive reactions on skin testing are also common in studies of unselected residents in westernized societies and there is a suggestion that the prevalence is increasing, including in the USA.[7] Allergy skin testing was administered in the second and third National Health and Nutrition Examination Survey (NHANES) from 1976 to 1980 and 1988 to 1994. In NHANES III, 10 allergens were tested in all subjects aged 6 to 19 years and a random half-sample of subjects aged 20 to 59 years. In NHANES III, 54.3% had a positive prick skin test to one or more allergens. Among those with positives, the median number was 3.0. For the six allergens common to NHANES II and III, prevalences were 2.1 to 5.5 times higher in NHANES III and the percentage of sensitized subjects increased in all age groups. Although the extracts were not identical, it is likely that the pollen extracts, at least, were of comparable strength.

It is clear that these positive reactions are not limited to persons with clinical allergy. A study was conducted in 200 young and middle-aged adults, employing a battery of 13 extracts (10 pollens, 2 mites and cat).[8] Three groups were recruited for prick skin testing. In those with a personal history of rhinitis or asthma, 90% had at least one positive prick skin test. In those with no personal history of rhinitis or asthma, but a close relative with one of these conditions, 46% had at least one positive prick skin test. Even in those who denied rhinitis or asthma personally, or in close relatives, 29% had at least one positive prick skin test.

Factors Affecting the Size and Prevalence of Positive Skin Tests

AGE

Epidemiological studies in Tucson demonstrated the varying prevalence of positive immediate prick skin test reactions with age in their population.[9] When tested with a battery of five allergens or mixes, only 22% of those who were 3 and 4 years

https://CafePezeshki.IR

old had at least one positive test. The peak prevalence of reactivity was seen in the first half of the third decade, when 52% reacted to at least one test. The prevalence of a positive skin test then declined slowly until the age of 50 years, following which there was a more rapid fall-off, reaching a low of 16% in the subjects over 75 years of age. Further studies in this population related the presence of prick skin test reactivity to the reactivity of the skin to histamine and to the serum total immunoglobulin E (IgE) levels.[10] Dividing the population studied into four age groups, they found that total IgE was highest in those who were 9 to 19 years of age and declined progressively in the other three groups (20 to 34, 35 to 50, and over 50 years). Histamine reactivity in the skin was lowest in the 9- to 19-year-old group, however, and was higher in the three older groups. The prevalence of positive skin tests, reflecting in part the interaction of specific IgE and reactivity of the skin to histamine, was highest in the 20- to 34-year-old group.

The evolution of skin prick test reactivity was followed in a birth cohort on the Isle of Wight.[11] The prevalence of a positive prick skin test to any allergen was 19.7% at age 4 years, 26.9% at age 10 years and 41.3% at age 18 years. In Sweden, 664 adults (age 20 to 60 years) were prick skin tested.[12] The highest prevalence of positive prick skin tests was 55% in those 20–29 years of age and the lowest prevalence was 26% in those 50 to 60 years of age. When they repeated the prick skin tests 10 years later, the yearly incidence of any newly positive prick skin test was 0.5% while the rate of conversion of prick skin tests from positive to negative was 3.2% per year.

Supporting data for the above observations come from separate studies of levels of specific IgE and cutaneous reactivity to histamine by age.[13,14] A retrospective review was conducted of results in 326 patients whose serum was analyzed for total and specific IgE.[13] The highest levels for grass and house dust mite-specific IgE were observed in those who were 10 to 15 years of age. A prospective study of cutaneous reactivity to histamine was conducted in 365 subjects from 1 to 85 years of age.[14] The size of the prick skin test to histamine increased progressively, peaking in those who were 21 to 30 years of age. There was then very little difference until the age of 50 years. Following this, there was a decline in the mean reaction size. Representative values with the 27 mg/mL concentration of histamine were: age 0 to 3 years, 3.8 mm; age 21 to 30 years, 6.2 mm; and age 61 to 70 years, 4.5 mm.

Reactivity of the skin to histamine and codeine was examined in children from infancy to the age of 2 years.[15] Prick skin tests with both histamine and codeine (a nonimmunologic mast cell degranulating agent) were particularly small up to the age of 6 months, although after 1 month of age there was usually some reactivity to both reagents. Due to the reduced reactivity to histamine in children under 2 years, adjustment of the interpretation for the size of the positive histamine control is important.

Varying reactivity to histamine can have a significant effect on skin test reactions, even in adults.[16] In an epidemiological study, 893 adult subjects were prick skin tested with 14 allergens and 10-fold dilutions of histamine, ranging from 1 mg/mL to 0.001 mg/mL. In those positive only to the highest concentration of histamine, 56% had all negative skin tests to allergens and only 15% had six or more positive skin tests. By comparison, of those responding to 0.01 and 0.001 mg/mL histamine concentrations, only 11% had all negative skin tests to allergens and 60% had six or more positive tests.

PHYSIOLOGIC FACTORS

The size of the reaction of the skin has been reported to vary with the time of day, the season of the year, the menstrual cycle, the subject's handedness and with the part of the body used for testing. Although it had been reported that there was a circadian pattern to skin reactivity, a study of 20 children and 20 adults did not find any significant variation during the normal clinic hours.[17] Subjects were tested in duplicate with serial dilutions of short ragweed and histamine at 8 a.m. and 4 p.m. No significant differences between the two sessions were observed at any dilution of either test material. The size of the skin reactions to histamine and allergens was examined over the course of a year.[18] It was found that reactions to both allergens and histamine were greater in October and February than in July and August.

Fifteen allergic women with seasonal rhinitis and/or asthma and 15 nonallergic female controls were skin tested three times during their menstrual cycle.[19] There were significantly greater reactions to histamine and morphine in both allergic and nonallergic women and to *Parietaria* extract in allergic women on days 12 to 16 of the cycle, corresponding to ovulation and peak estrogen levels. The size of the reaction to histamine on the forearms was compared with handedness in 176 subjects.[20] Significant differences between the size of the wheal and flare on the two forearms were observed. Subjects who were right-handed, with only right-handed relatives, had significantly larger reactions on the left arm. Subjects who were either left-handed or ambidextrous had significantly larger reactions on the right arm.

REACTIVITY OF THE SKIN IN DIFFERENT AREAS OF THE BODY

The back is commonly used for percutaneous testing, since it provides a large surface that can accommodate many tests. Although it may be acceptable to consider the back as homogenous for clinical purposes, there is a significant gradient of reactivity, with the upper back being less reactive than the middle, which in turn is less reactive than the lower third. The wheal diameter with allergens was 30% less and with histamine 19% less on the upper compared with the lower back.[21] Often the forearm is employed as an alternative site for percutaneous testing because there is no need for the patient to disrobe and testing may be done with the patient sitting in a chair rather than lying down. It has been long recognized that the forearm is not as reactive as the back. In one study, allergen-induced wheal diameter was 27% smaller and flare diameter 14% smaller.[22] While the difference is not great, it is estimated that 2.3% of tests positive on the back would be negative if performed on the forearm.[22]

VIRAL INFECTIONS

Skin testing with inhalant allergens was performed in 16 adults before and up to 21 days following experimental inoculation with respiratory syncytial virus (RSV).[23] Even subjects with no measurable skin test reactions at baseline showed increased wheal and flare areas in response to histamine and allergen skin tests after RSV infection. The altered skin test response persisted for up to 21 days after RSV inoculation. It was suggested that up-regulation of pathways relating to neurogenic inflammation may have played a role.

MEDICATION (see Table 19-1)

Histamine is a major mediator of the immediate skin test, so drugs that have antihistaminic properties suppress skin test reactions. Studies have assessed the duration of this suppression after the medication is discontinued, since this is often an important consideration for diagnostic allergy skin testing. Persisting suppression after multiple doses of first generation antihistamines was studied.[24] The mean time for skin reactivity to return to normal after stopping the drug was 3 days for chlorpheniramine and tripelennamine and 5 days for hydroxyzine. However, some patients remained suppressed for 6 to 8 days. After a single dose of the second-generation antihistamine, fexofenadine, skin reactivity had returned to normal after 24 hours.[25] Single 25 mg doses of the tricyclic antidepressants, desipramine and doxepin, produced suppression which lasted an average of 2 and 6 days respectively.[26] It was recommended that doxepin be withheld at least 7 days before skin testing. Multiple dosing of the H_2 antagonist, ranitidine, produced significant suppression of both the wheal and flare of the histamine skin test.[27] Suppression was only 18% of the mean diameter, so withholding the drug on the day of testing should be adequate.

In 15 subjects, the leukotriene receptor antagonist, montelukast, significantly reduced the flare reaction to histamine, codeine and allergen.[28] There was a nonsignificant trend toward reduction in wheal size with all three agents. Other investigators found nonsignificant reductions in both wheal (9.6%) and flare (7.3%) following administration of montelukast.[29]

There is no consensus regarding the effect of corticosteroids on allergy skin tests. In a prospective study, topical application of corticosteroids for 4 weeks reduced the area of the allergen-induced wheal by 72% and the flare by 62%.[30] The reduction could at least, in part, be explained by an 85% reduction in the number of detectable skin mast cells in the treated skin. A prospective study of 1 week of oral corticosteroids, 24 mg daily of methylprednisolone, found no effect on reactivity to ragweed.[31] A retrospective analysis of 25 patients who had been on oral steroids for longer, but varying periods, suggested that they had diminished skin reactivity to codeine, a nonimmunologic mast cell degranulating agent.[32] However, a prospective study of 33 patients who received oral steroids for at least 1 year (median dose 20 mg of prednisone per day, median duration of 2 years) revealed no suppression of skin reactions to either codeine or allergen.[33]

The monoclonal antibody against IgE, omalizumab, has been reported to reduce skin test reactions.[34] In 19 subjects with perennial allergic rhinitis, 3 months of treatment with omalizumab 0.030 mg/kg/IU/mL reduced free IgE levels >98% and the cumulative whealing response to titrated prick skin tests (150–10 000 AU/mL of house dust mite extract) by 78–83%.

Allergy immunotherapy has been observed to reduce the immediate reaction to allergen skin testing.[35] The reductions in the immediate skin test are accompanied by reductions in nasal and conjunctival sensitivity.[35] Allergen immunotherapy reduces the late cutaneous reaction even more than the immediate.[36]

QUANTITY AND QUALITY OF EXTRACTS

The size of the reaction is a function of the patient's sensitivity and the amount of the relevant allergen injected. The relationship between dose and response is best expressed as a log : log relationship.[37] The slope is steeper when the size of the reaction is expressed as the log of the area, as opposed to the log of the diameter. When log-linear dose responses are calculated, the resulting curve is S-shaped, but linear in the midrange.[38] A 10-fold increase in the concentration of allergen or histamine will produce approximately a 1.5-fold increase in mean diameter[37] or a doubling of the area of the wheal.[37]

In the USA, standardized extracts are available for several grasses, ragweed, *Dermatophagoides pteronyssinus* and *farinae*, and cat. In general, other pollen extracts, although not standardized, are of good potency. Most extracts of dog dander,[39] probably most or all fungi[40] and all extracts of cockroach[41] are relatively weak. In the case of fungi and cockroach, proteases in the extracts may degrade susceptible proteins within the extract.[42] One exception to the low potency of most dog extracts is the acetone-precipitated dog extract manufactured by Holister-Steir (Spokane, WA). This extract contains 30 to 40 times as much major allergen as the other commercially available dog extracts. The increased allergen content has been shown to result in an increased number of positive prick skin tests in comparative skin testing.[39]

A unique problem appears to exist with extracts of some foods. Many patients with documented food sensitivity will fail to react to commercial extracts or in vitro tests prepared from these extracts but will react to testing with fresh extracts of the foods.[43–46] Reactions to fresh foods, but not commercial food

TABLE 19-1 Inhibitory Effect of Various Treatments on Skin Prick Tests

Treatment	Degree	Duration	Clinical Significance
H_1 antihistamine	++++	2–7 days	Yes
H_2 antihistamine			None
H_1 antihistamine	0–+		None
Imipramines	++++	Up to 21 days	Yes

https://CafePezeshki.IR

extracts, have been reported with fruits and celery,[44,45] with shellfish and fish,[44,46] and even with peanuts and walnuts.[44] This report notwithstanding, peanut extracts have been reported to be reliable in other studies.[45,47] In 76 children aged 5 months to 15 years, there were 31 positive blinded food challenges out of 96 foods which yielded positive prick skin tests.[47] All the positive challenges were to peanuts, eggs, milk or soy. There were no positive open feeding challenges to foods that had not been positive on prick skin testing.

Methods of Skin Testing

PRICK VERSUS INTRADERMAL TESTING

There are two approaches to allergen skin testing. One is percutaneous introduction of the allergen through a break in the skin by pricking, puncturing or scratching.[48] In the last of these, a linear scratch is made without drawing blood. The scratch may be performed first with the extract then dropped on the abraded skin, or the scratch may be made through a drop of extract. The scratch test has now largely been abandoned due to greater discomfort, poorer reproducibility and the possibility of leaving multiple linear depigmented areas for some time afterward.[49] The prick test is performed by introducing the tip of the device into the epidermis at approximately a 45-degree angle through a drop of extract; the tip is then lifted, creating a small, transient break in the epidermis. Prick testing can be performed with either solid needles or hollow hypodermic needles. Puncture testing is performed by pressing the tip of the device at a 90-degree angle to the skin. Usually the device employed has a sharp point approximately 1 mm long, with a widening above to limit penetration into the skin.

The alternative to percutaneous testing is intracutaneous testing. A hypodermic syringe and needle is employed. The needle is threaded into the dermis where, typically, 0.01 to 0.02 mL of extract is injected. Intradermal testing is more sensitive than prick/puncture. For equivalent reactions at threshold-sized reactions, the extract for prick/puncture testing must be 1000-fold more concentrated.[48] Also, direct comparisons indicate that intradermal testing is more reproducible than percutaneous testing.[48] Nevertheless, there are many arguments in favor of the percutaneous test as the routine for allergy testing. These include economy of time, patient comfort and safety. These apply to percutaneous versus intracutaneous, no matter what relative concentrations of extract are employed. If, in addition, the intradermal test is performed with a concentration greater than 1:1000 that of the percutaneous test, in order to increase its sensitivity, additional considerations arise as to whether this increased sensitivity is clinically necessary or useful.

DIAGNOSTIC USEFULNESS OF THE PERCUTANEOUS TEST

The prick skin test has served well in epidemiological studies. Prick skin test reactivity to indoor allergens, but not pollens, has been shown to be a risk factor for asthma in children[50,51] and adolescents and adults.[52] Prick skin test reactivity in asymptomatic freshmen in college carried an increased risk for development of allergic rhinitis.[53,54] Three-year follow-up revealed that 18.2% of those with positive prick skin tests had developed allergic rhinitis compared to 1.8% of those with negative prick skin tests.[53] At 7-year follow-up, 31.9% of those with positive prick skin tests and 7.7% of those with negative skin tests had developed allergic rhinitis.[54] The larger the prick skin test as a freshman, the more likely the development of allergic rhinitis. Furthermore, after 7 years, new-onset asthma had developed in 5% of the prick skin test positive group, versus 1.5% in the skin test negative group.[54]

DIAGNOSTIC USEFULNESS OF THE INTRACUTANEOUS TEST

Although the intracutaneous test, at the strength customarily performed, is more sensitive, it may be questioned whether this increased sensitivity is clinically necessary. The prick skin test, performed with good quality extracts, is positive in many subjects who do not have a personal or even a family history of allergy.[8] A number of studies have addressed the clinical usefulness of intracutaneous testing. In the Tucson epidemiological study, 311 subjects had prick skin testing followed, if negative, by intracutaneous testing with 1:1000 w/v extract to 14 common allergens.[55] Subjects were divided, by history, into allergic and nonallergic groups. Prick test reactivity correlated with the presence of allergy symptoms. Conversely, positive reactions to intracutaneous testing, which followed a negative prick test for that allergen, showed no correlation with either the patient's clinical allergic status or the level of total serum IgE. Studies in smaller groups of patients have supported these epidemiological data.

Two studies examined the intracutaneous test as a predictor of symptoms with natural exposure to the allergen.[56,57] In a study of the clinical usefulness of intradermal skin tests to grass, four groups were compared: three of the groups had a history of seasonal allergic rhinitis, one with positive prick skin tests to timothy, one with negative prick but a positive intradermal test to timothy, and one with both prick and intracutaneous tests to timothy negative. The fourth group was a nonallergic control.[56] On the basis of nasal challenge with timothy, grass pollen allergic reactions were present in 68% of those with positive prick skin tests to timothy and none of the nonallergic controls. In both the group with positive and those with negative intracutaneous tests to timothy, 11% were positive. Subjects were then followed through the grass pollen season. Their symptom scores, recorded in a diary, were examined for a correlation with grass pollen counts. A positive correlation was present in 64% of those with positive skin prick tests and none of the nonallergic controls. A positive correlation of symptoms and pollen count was present in 22% of those with a positive intracutaneous test and 21% of those with a negative intracutaneous test to timothy. Both criteria for allergy to timothy, a positive nasal challenge and a correlation between symptoms and grass pollen counts, were met in 46% of those with positive prick skin tests, but in none in the other three groups. Thus, under the conditions of this study, the presence of a positive intradermal skin test response to timothy in the presence of a negative prick skin test response to timothy did not indicate the presence of clinically significant sensitivity to timothy grass.[56]

In the second study, subjects were challenged with cat exposure for 1 hour.[57] Both positive prick skin tests and RASTs to cat were highly predictive of development of symptoms on exposure to the cat room. Subjects with a negative prick skin test were just as likely to have a positive challenge result if they had a negative (31%) as if they had a positive intracutaneous skin test to cat (24%). The authors concluded that, at least with regard to cat allergy, these results strongly suggest that major

https://CafePezeshki.IR

therapeutic decisions such as environmental control or immunotherapy should never be based on a positive intracutaneous skin test result alone.[57]

It is clear from these studies that the intradermal skin test adds little to the diagnostic evaluation of allergy when allergy extracts of reasonable quality are available for skin testing. This probably includes almost all pollen extracts, house dust mite, cat and acetone-precipitated dog extracts. What of the extracts of poorer quality, particularly cockroach, fungi and some dander extracts? A study of the diagnosis of allergy to mouse extract is informative in this regard.[58] In this study, 49 workers reported symptoms on mouse exposure. The mouse extract contained only 2.37 μg of Mus m 1 per mL, about 6% the major allergen content in cat extract. Using a nasal challenge as the gold standard, sensitivity was only 47% for measurement of mouse IgE (mIgE), 67% for the prick skin test, and 100% for an intradermal test at a 1:100 dilution of the extract. On the other hand, specificity was 91% for mIgE, 94% for prick skin test, but only 65% for intradermal testing. The prick skin test performed best, but with this weak extract, intradermal testing was required to identify some clinically sensitized workers.

EXPRESSING THE RESULTS OF SKIN TESTING

The results of both percutaneous and intracutaneous skin tests are often reported in only semi-quantitative terms. Results may be recorded only as positive or negative, or graded 0 to 4+ without any indication of what size reactions these numbers represent.[59] At the very least, a record of skin testing should indicate certain information that will allow another physician to interpret the results. In addition to the concentration of extract employed, the form should indicate whether the tests are percutaneous or intracutaneous and, if the former, which device was employed for testing, whether testing was performed on the back or the arm, and the size of the positive and negative reactions. Finally, if an arbitrary grading system is employed, the range of reaction for each grade should be clearly indicated on the form (see Table 19-2).

A superior method of expressing results is to measure and record actual size of the reaction. This need not be excessively time consuming. Although the area of the wheal is the most accurate, measurements of the product of the orthogonal diameters, the sum of the orthogonal diameters and even the longest diameter correlate very well with area, with *r* values greater than 0.9.[60] In fact, the longest diameter has been reported to correlate better with the wheal area than the mean of two perpendicular diameters.[61] An additional advantage of measuring the diameter of the wheal is the observation that, with 17 of 18 standardized extracts, the risk of having allergic symptoms increased significantly with larger wheal diameter.[62]

The Scandinavian Society of Allergology recommended that skin test results be standardized in relation to the size of the reaction to histamine, employing 0.1 mg/mL of histamine for intradermal testing and 1 mg/mL of histamine for prick skin testing.[63] If the diameter of the reaction to allergen was the same size as the histamine reaction, the grade was 3+, if half that size 2+, and if twice as large 4+. A subsequent study suggested that the histamine control should be 10 mg/mL, because of the small reactions with high coefficient of variation with the 1 mg/mL histamine prick skin test.[64] Even the 20–30% coefficient of variation for reactions to 10 mg/mL raises questions regarding the desirability of basing grading on a histamine control, which, if used for this purpose, should be performed at least in duplicate.[65]

TABLE 19-2 Semiquantitative Reporting of Skin Test Results

CRITERIA TO READ PRICK/PUNCTURE SKIN TESTS		
Negative	0	No reaction or no different from control
One plus	+	Erythema < a nickel in diameter
Two plus	++	Erythema > a nickel in diameter
Three plus	+++	Wheal with surrounding erythema
Four plus	++++	Wheal with pseudopods and surrounding erythema
CRITERIA TO READ INTRACUTANEOUS TESTS WHEN CONTROL ≥2 MM		
Negative	0	No different from control
One plus	+	Wheal 1½ to 2 times control or definite erythema > a nickel in size
Two plus	++	Wheal 2–3 times control
Three plus	+++	Wheal >3 times control
Four plus	++++	Wheal with pseudopods
CRITERIA TO READ INTRACUTANEOUS TESTS WHEN CONTROL <2 MM		
Negative	0	No difference from control
One plus	+	3–4 mm wheal with erythema or erythema > a nickel in size
Two plus	++	4–8 mm wheal without pseudopods
Three plus	+++	>8 mm wheal without pseudopods
Four plus	++++	Wheal with pseudopods and erythema

Modified from Vanselow NA. In: Sheldon JM, et al, editors. A Manual of Clinical Allergy. 2nd ed. WB Saunders; 1967.

The reliability of different means of expressing the results of prick skin testing was compared in patients sensitive to dogs.[66] A determination of sensitivity to dog was made in 202 children based on a composite score from history, RAST and bronchial or conjunctival allergen challenges. The results with the three common means of expressing results (wheal diameter, wheal diameter compared to the histamine control and titrated prick skin tests) were compared for sensitivity, specificity and overall efficacy. Although the overall efficacy of the histamine reference was greatest in this study, most allergists would prefer to have the maximum sensitivity, which was provided by a wheal ≥3 mm diameter, in order not to miss any truly sensitive patients. Other methods, or clinical judgment, should then be used to distinguish between those who are only sensitized and those who are clinically allergic.[66]

DEVICES FOR PERCUTANEOUS SKIN TESTING

Intracutaneous skin tests are performed using a hypodermic syringe and needle. Percutaneous tests are performed with an ever-increasing variety of devices.[19,67–72] Some devices have a single stylus with a single or several points and are used either to prick or puncture through a drop of extract or to carry a drop of extract from the extract bottle, so that application of extract and the puncture occur in one step. The puncture technique may be combined with twisting, which generally results in more pain and a greater chance of a false positive test.[73,74] Increasingly, devices are being introduced which have multiple heads, so that up to 10 tests can be accomplished with one

https://CafePezeshki.IR

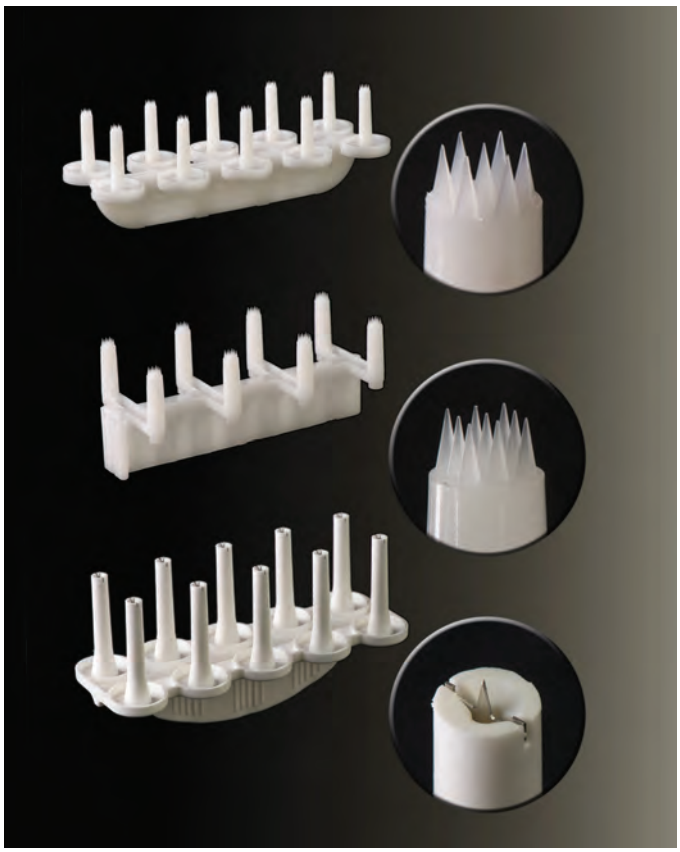

Figure 19-1 Examples of multi-headed devices for prick/puncture skin testing. From top to bottom: Skintestor OMNI (Greer Laboratories, LeNoir, NC), MultiTest II (Lincoln Diagnostics, Decatur, IL) and ComforTen (HollisterStier Spokane, WA).

application (Figure 19-1). Generally the multiple-headed skin test devices are designed to first be dipped into the extract bottles, then applied to the skin so that testing is accomplished in one step. Both the single and multiple test devices for percutaneous testing vary in the degree of trauma that they impart to the skin, therefore they vary in the size of positive reactions and also in the likelihood of producing a reaction at the site of the negative control. Thus, different devices require different criteria for what is the minimum wheal diameter that constitutes a positive reaction.

Before selecting a device for clinical use, it is prudent to test the device at multiple sites on multiple subjects with histamine to rule out false negative tests and with saline to assess the maximum wheal size resulting from the trauma induced by the device.

PLACEMENT OF ADJACENT TESTS

There are two reports, both describing intracutaneous testing with hymenoptera venom, which indicate that false positive tests can result from an adjacent positive histamine control.[75,76] The influence of large positive reactions to histamine or to inhalant allergen on adjacent prick skin tests was prospectively studied.[22] There was no evidence of falsely positive prick skin tests attributable to the large adjacent reactions, even when the test sites were only separated by 2 cm. Thus, it appears that the augmentation that has been observed may be limited to intracutaneous testing, and perhaps also to testing with the active constituents in the hymenoptera venom.

Special Considerations

SAFETY OF SKIN TESTING

Deaths have been reported with skin testing.[77,78] For the most part these were reactions to testing with horse serum or other potent allergens and, almost without exception, they were associated with intradermal testing.[77] Severe reactions can occur, however, even with prick skin testing in very sensitive patients treated with undiluted commercial or fresh food extracts.[79] A fatal reaction was reported in a young woman with moderate asthma, probably poorly controlled, following application of 90 food allergens employing the Dermapik (Greer Laboratories, Lenoir, NC) skin testing device.[78] In a private practice, 10 400 patients were skin tested first by prick, followed, if negative, by intradermal testing.[80] Two systemic reactions occurred, both with intradermal testing. One was in a patient who had had a negative prick skin test, and the other in a patient who did not have preliminary prick skin testing. The experience with allergy skin testing at the Mayo Clinic between 1992 and 1997 was reviewed.[77] Puncture skin testing was performed in 16 505 patients, while 1806 received puncture tests followed by intracutaneous tests for selected allergens (hymenoptera venom, penicillin and other drugs). Five patients experienced systemic reactions following puncture tests, while one patient experienced a systemic reaction to an intracutaneous test following a negative puncture test. Two of the five patients who experienced systemic reactions to puncture testing had positive reactions to latex. One patient reacted to both latex and aeroallergens, while two reacted only to aeroallergens. Thus, for prick/puncture testing to aeroallergens, systemic reactions, none of which were life threatening, occurred with an incidence of about 0.02%. Another university allergy clinic reported an incidence of systemic symptoms with prick skin testing of 0.4%, but none were associated with severe asthma or hypotension.[81]

LOCAL ALLERGY

Patients sometimes present with what sounds like a convincing clinical history for an allergic respiratory condition, but they have negative skin tests to the suspected allergen and sometimes to all allergens. There are several studies that report that patients may be sensitive to an allergen and have IgE antibodies to that allergen in their nasal secretions, even though prick skin tests and serum in vitro tests for that same allergen are negative. The question of local nasal allergy has been extensively studied by a group from Malaga, Spain. Fifty adult subjects with persistent rhinitis who had negative prick skin tests and no specific IgE for perennial allergens and who had negative intradermal skin tests for house dust mites (PNAR) were compared to 30 subjects with persistent allergic rhinitis (PAR) and 30 nonallergic controls.[82] Subjects with PNAR and PAR did not differ in symptoms or nasal cytology. All of the PAR, 54% of the PNAR and none of the normal controls had a positive nasal challenge with house dust mite allergen *Dermatophagoides pteronyssinus* (DP). Nasal DP-specific IgE was found in 23/30 with PAR and 6/50 with PNAR, all of whom had positive nasal challenges with DP. Subsequently they studied 32 patients with apparent nonallergic spring symptoms. Positive nasal challenges to grass or olive

https://CafePezeshki.IR

pollen extracts or both were found in 63%.[83] They also reported an increase in specific IgE in the nasal secretions 24 hours after the positive nasal challenges.[84] A 5-year follow-up of 194 patients with local nasal allergy diagnosed by this group revealed that very few had developed systemic sensitization.[85] In their experience local nasal allergy constituted 25.7% of the rhinitis population and more than 47% of patients previously diagnosed with nonallergic rhinitis.[85]

DELAYED REACTIONS TO SKIN TESTS

Immediate skin reactions to histamine typically peak at 8 minutes, while those to allergen peak at 15 minutes. Large allergen induced immediate skin tests may be followed by a late cutaneous reaction. Progressive erythema and induration occur at the site of the immediate reaction, peaking at 4 to 6 hours. These reactions can be triggered by mast cell mediators released by a variety of mechanisms including allergens, anti-IgE and nonimmunologic mast cell degranulating agents, but not by histamine alone.[86] There appears to be a threshold size of the immediate reaction below which the late phase reaction does not occur. Beyond that size, there is a rough correlation between the size of the immediate reaction and the size of the resulting late phase reaction in the same individual[86] and in unselected patients.[87] The IgE-mediated late cutaneous reaction has not been described in the absence of the immediate reaction. The late phase cutaneous reaction is not suppressed by antihistamines but is reduced by corticosteroids. Furthermore, it is markedly reduced by allergen immunotherapy, more so than the immediate reactions.[36]

Isolated, delayed reactions to allergy skin testing have been described.[88] Furthermore, when looked for, they appear to fairly commonly follow intracutaneous testing.[88] Two hundred and ninety two adult patients who had received a total of 2700 intracutaneous tests were examined after 20 minutes for immediate reactions and again after 48 hours for evidence of delayed reactions.[88] Immediate reactions were observed in 17% of the skin tests in allergic and 5% of the skin tests in nonallergic patients. At 48 hours, delayed reactions were present at 7% of the skin test sites in the allergic and 5% in the nonallergic patients. Delayed reactions were over twice as common at sites of positive immediate as negative immediate skin reactions. Those occurring at the site of negative immediate skin tests had the histology of a delayed-type hypersensitivity reaction. There was no suggestion that the late or delayed cutaneous reactions had clinical relevance.

RELATION OF SKIN TESTS TO IN VITRO MEASUREMENTS OF SPECIFIC IgE

For at least some aeroallergens, the in vitro tests are somewhat less sensitive than percutaneous tests,[89] and both are much less sensitive than intracutaneous tests at the concentrations of allergen extracts that are commonly employed. Even though they are less sensitive than the intracutaneous test, the prick/puncture and in vitro tests still are often positive in patients without clinical symptoms. This has led to attempts to increase the diagnostic precision of these tests by defining cut-offs that enhance specificity without too great a loss in sensitivity. An ambitious study recruited 267 patients who were prick skin test positive and had a clear history of respiratory symptoms in relation to the allergen producing the positive skin test.[90] They were compared to 232 subjects with similar positive prick skin tests but negative histories of respiratory symptoms caused by the aeroallergens producing the positive prick skin tests. Finally, there were 243 nonallergic controls. Patients also had in vitro testing for the allergens that produced the positive prick skin tests. The investigators constructed receiver operating characteristic curves for sensitivity versus specificity for both in vitro and prick skin tests. They found maximum diagnostic accuracy at cut-offs of 11.7 kU/L in the Pharmacia CAP system (where threshold for sensitivity is 0.35 kU/L). The maximum diagnostic accuracy of prick skin testing was a wheal area of 32.2 mm (roughly 6 mm diameter). They also reported that the diagnostic accuracy of in vitro testing exceeded that of the prick skin test.

Despite similar sensitivity and performances by the in vitro and percutaneous tests, the quantitative relationship between them in individuals is relatively weak. Reactivity on intracutaneous skin testing and in vitro testing was measured in 43 patients with rhinitis and/or asthma employing five purified major allergens.[91] The overall correlation for skin testing versus serum IgE was only 0.68. For the same level of specific IgE, the amount of the allergen required in different subjects for a positive prick skin test varied by as much as 100-fold. Skin reactivity was adversely affected by total IgE and correlated positively with reactivity of the skin to histamine. Skin testing correlated better than in vitro testing with histamine release, suggesting that 'releasability' as well as differences in reactivity of the skin to released mediators might account for part of the residual variation in the correlation between skin test results and levels of IgE antibodies.

An additional factor may be the affinity for IgE-allergen binding.[92] Reactions on prick skin testing to ragweed and *Dermatophagoides pteronyssinus* were compared to serum Amb a 1- and Der p 1-specific IgE levels in 165 members from families with histories of clinical atopy. Those donors with positive skin test reactions tended to have higher concentrations of specific IgE than those donors with negative skin tests. However, there was considerable overlap between the skin test positive and skin test negative groups, without a clear demarcation between them, and mean values between prick skin test positive and prick skin test negative groups were not statistically significant. Donors with positive skin test reactions had, on average, higher binding affinities than those with negative skin test results. These values differed significantly for the two groups ($P < .001$). The product of affinity and concentration, termed the antibody capacity, provided a much clearer demarcation between donors who were skin test positive and those who were skin test negative.

RELATION OF SKIN TESTS TO NASAL ALLERGEN CHALLENGE AND IN VITRO ASSESSMENT OF SPECIFIC IgE

Nasal allergen challenges with 3-fold increasing numbers of grass pollen grains, prick skin tests with 3-fold increasing concentrations of grass pollen extract and in vitro tests utilizing the same grass pollen extract were compared in 44 subjects with rhinitis and 10 nonallergic controls during the grass pollen season.[1] The nasal challenge method, which employs a total symptom score of 5 as an end-point, has been validated by demonstration of release of PGD_2 into nasal secretion at end-point and by correlation of threshold scores with symptoms on

https://CafePezeshki.IR

seasonal exposure to grass pollen. Nasal challenges were positive in 41 of 43 patients and 0 of 10 controls. There was a significant correlation (R_s = .54, P < .005) between threshold for nasal challenge and threshold for prick skin testing. There was no significant correlation between nasal threshold and levels of specific IgE, suggesting that releasability of mast cells and basophils and reactivity to the released mediators may be an important parameter in determining symptoms. In a related study, the correlation between threshold for nasal allergen challenge and titrated prick skin test was confirmed and both were shown to correlate with symptoms during natural pollen exposure.[93]

RELATION OF SKIN TESTS TO BRONCHIAL ALLERGEN CHALLENGE

There is a relatively poor correlation between the results of allergen skin testing and bronchial allergen challenge. The reason is the presence of a second variable, nonspecific bronchial hyperresponsiveness as measured by histamine or methacholine inhalation challenge. It was observed that positive bronchial allergen challenges occurred almost exclusively in subjects with positive prick skin tests,[94] but that the correlation between skin testing and bronchial allergen challenge could be improved considerably by incorporating the threshold of nonspecific bronchial responsiveness.[95,96] A prospective study confirmed these retrospective observations.[2] The early bronchoconstrictor response to allergen challenge could be predicted within an 8-fold range by a formula employing skin test reactivity and bronchial sensitivity to histamine. It was pointed out that this degree of prediction was better than the reproducibility of bronchial allergen challenge achieved by some investigators (Box 19-1).

The complete reference list can be found on the companion Expert Consult website at http://www.expertconsult.inkling.com.

BOX 19-1 KEY CONCEPTS

- Skin testing with allergenic extracts is the favored method of in vivo testing for IgE-mediated sensitivity.
- The preferred method of skin testing is percutaneous (prick or puncture), with intracutaneous (intradermal) testing generally reserved for weak allergenic extracts such as hymenoptera venom or agents used for testing for drug allergy.
- Advantages of percutaneous (prick or puncture) testing over intracutaneous (intradermal) include: (1) they are safer, less technically demanding, less painful, more rapidly performed, and many tests can be performed in one session; (2) the extracts are more stable and positive and negative reactions are more easily differentiated; most importantly, (3) positive reactions correlate better with clinical sensitivity than is the case with intracutaneous tests.
- Advantages of the intracutaneous tests are a somewhat better reproducibility and greater sensitivity. The latter, however, has not been found to be useful for detecting clinically relevant sensitivity in several studies.
- The results of skin testing correlate only weakly with those from in vitro studies with the same allergen in the same patient. The size of the skin test reactions depends, in addition to the amount of specific IgE, on the binding affinity of the IgE antibody, the releasability of the patient's mast cells, and the reactivity of their skin to released mediators.
- In a particular individual, the size of the skin test will also depend on the area of the body used for testing, with the back being more reactive than the arm.
- Devices for percutaneous skin testing vary greatly in the size of reaction and the likelihood of a false positive reaction. Thus different threshold values for a positive reaction must be used with different devices.

20 Outdoor Allergens

RICHARD W. WEBER

KEY POINTS

- Sources of airborne allergens vary from microscopic to large fauna.
- Outdoor aeroallergenic particles include intact pollen grains or spores, as well as cell fragments and submicronic particles.
- Preferred samplers measure a calculable volume of air to determine the density of aeroallergens and have capture efficacy of particles down to 3–5 micron.
- Meteorological parameters of temperature and precipitation have the greatest impact on timing and intensity of airborne pollen concentration.
- Increased atmospheric temperature and CO_2 concentration act to increase allergenic plant biomass and pollen production.

Aerobiology is the science of airborne emanations of organic or biologic origin. Aeroallergens may be dispersed on a variety of particle sizes and come from various sources and settings (see Table 20-1).[1] The origin may be: microscopic such as bacteria or protozoa; at the limits of visual detection such as dust mites; or easily seen such as mushrooms, bracket fungi or animals such as cats, dogs or horses. The airborne particle may be: a cell, intact pollen grain or cytoplasmic component thereof; fungal spore or mycelial fragment; or protein adhering to epidermal scales or dust particles, or dissolved in water droplets. Outdoor sources are frequently of plant origin, while animal allergens are greater problems indoors; fungal spores may be troublesome both indoors and outdoors. Once entrained into airstreams, aeroallergens may be deposited on conjunctival or nasal membranes, or inhaled into the lungs.

General Principles of Allergen Aerobiology

POLLEN

Vascular plants propagate through extension, trunk or root shoots, rhizomes or stolons, or by seed. Sexual reproduction is accomplished by transport of the male gamete, the pollen or spore, to the female gamete, the ovary. Pollen dispersal mechanisms are via the wind, anemophily or with a vector such as an insect, entomophily. Insect pollinated plants are less frequently inducers of hay fever. Some amphiphilous plants utilize both mechanisms.

FUNGI

Fungi comprise one of the seven kingdoms of living organisms, more closely related to the animal kingdom than to the plant kingdom. Fungi are eukaryotic organisms with chromosomes within membrane-bound nuclei, dividing through mitosis. Fungi have chitin-containing cell walls, a polysaccharide found also in insect exoskeletons. Fungi may be unicellular, syncytial (many nuclei not separated into different cells) and multicellular (nuclei separated by septa). Complex life cycles have multiple life stages, with both sexual and asexual reproduction. 'Holomorph' refers to the fungus throughout its entire life cycle, with 'anamorph' referring to the asexual reproductive stage and 'teleomorph' to the sexual reproductive stage. Sometimes the alternate life stage is not known, with only the anamorph or the teleomorph identified. Anamorphs without a known teleomorph stage are frequently classified as Deuteromycota, or Fungi Imperfecta: an artificial taxon, a paraphyletic group united only by asexual propagation.[2]

ANIMALS

While primarily indoors, animal sources may be significant outdoor allergens as well. Heavy hatches of caddis flies or mayflies, or miller moth infestations have been reported to induce allergic symptoms.[3] Occupational exposures to tussock moths in pine trees may bother lumberjacks, and sewer flies municipal sanitation workers.[4] Outdoor horse dander allergen can be sampled down wind of stables.[5]

SUBMICRONIC ALLERGENIC PARTICLES

The finding that ragweed hay fever symptoms may persist after intact pollen is no longer seen spurred studies demonstrating airborne allergens in submicronic particles.[6,7] Airborne birch antigenic activity has been demonstrated in particles smaller than 2.4 micron. Cytoplasmic starch granules are prominent in grass (Poaceae) and dock (*Rumex*, Polygonaceae) pollen.[8] Grass starch granules have heavy concentrations of groups 1, 5 and 13 allergens.[9–11] While the force of storm-driven raindrops may disrupt grass pollen grains, releasing large amounts of respirable allergen-laden starch granules, Schäppi and colleagues demonstrated that a moisture-drying cycle will result in starch granules emanating through the grass pollen aperture.[9,12]

CHARACTERISTICS OF WIND-POLLINATED PLANTS

Although wind pollination may appear to be a simpler process than vector-facilitated pollination, it is the later evolutionary mechanism.[13] Its characteristics are summarized in Box 20-1. Anemophilous plants have incomplete flowers, with separate

TABLE 20-1 Aeroallergen Sources and Types

Allergen Source	Particle Type
Bacteria	Cells, fragments, metabolites
Thermophilic actinomycetes	Spores, metabolites
Algae	Cells, fragments, metabolites
Protozoa	Metabolites
Fungi	Spores, mycelial fragments, metabolites
Ferns and mosses	Spores
Grasses, weeds and trees	Pollens, cytoplasmic particles
Arthropods	Feces, saliva, body parts
Birds	Feces, serum proteins, epidermal debris
Mammals	Dander, saliva, urine

*Modified from Burge.[1]

BOX 20-1 CHARACTERISTICS OF WIND-POLLINATED PLANTS

- Incomplete flowers (spatially separate male and female)
- Male flowers exposed to wind
- Petals and sepals insignificant or absent
- Absent attractants (color, aroma, nectar)
- Pollen grains small and dry, reduced ornamentation

BOX 20-2 THOMMEN'S POSTULATES*

- Pollen must contain excitant of hay fever
- Pollen must be anemophilous
- Pollen must be produced in sufficiently large amounts
- Pollen must be buoyant to carry long distances
- Plant must be widely and abundantly distributed

*From Thommen.[15]

male and female structures. The male pollen-producing flowers are exposed to the wind. On trees, dangling structures called catkins have hundreds of small individual flowers. On weeds or grasses the inflorescences are thrust up into the air from the higher portions of the plant. Female flowers are lower, at the axils of leaves or at stem junctions. Attractants such as color of petals and sepals, fragrance, or nectar are absent. The pollen grains tend to be small and dry, with reduced ornamentation to minimize turbulence, and with little sticky resin (pollenkitt).

Wind-pollinated trees produce extraordinary amounts of pollen. Erdtman reported a single birch catkin produced about 6 million pollen grains, and an alder catkin 4.5 million. An English oak catkin released 1.25 million grains.[14] By tabulating the number of catkins on such trees, Erdtman calculated the pollen produced in a single year. A birch tree released over 5.5 billion grains over a single year, an alder 7.2 billion and an oak 0.6 billion. Spruce, like birch, produced about 5.5 billion grains in a year. Cereal rye grass produced 4.25 million pollen grains per inflorescence.[14]

Eighty years ago, August Thommen set out five principles necessary for a plant to be an important inducer of pollinosis (Box 20-2). Thommen's Postulates have remained correct, with some caveats.[15] That the pollen must contain an excitant of hay fever is self-evident, and such are proteins or glycoproteins that are easily elutable or coat the surface of expelled respirable cytoplasmic particles. While the majority of pollinosis inducers are wind pollinated, some primarily insect-pollinated plants will release sufficient airborne pollen to cause sensitization in the proper setting. A single point source could lead to sensitization, such as a tree or shrub situated at a bedroom window. Although most pollen grains come to rest within meters of their source, grains may be transported for hundreds of miles.[14]

FLORISTIC ZONES

The distribution of individual plant species is dependent on a multitude of factors. Foremost is 'climate': average high and low temperatures, ambient humidity and average precipitation. Soil factors such as mineral content, pH, and density also impact on plant adaptation and selection.[16] Certain plants are cosmopolitan, adapting to diverse circumstances; others are limited to a niche, adapting to extremes of moisture or temperature. The range of native indigenous species may be limited by niche selectivity. The extent an introduced plant will spread is determined by its adaptability, its aggressiveness and the length of time from introduction. Which plants may be found in different locations may be deduced from several sources. Numerous gardening texts contain 'hardiness zone' maps defined by the United States Department of Agriculture (USDA). There are ten climatic zones in the North American continent based on the average annual minimum temperature: beginning with zone 1 at −50°F, and progressing by about 10° increments to zone 10 at 30–40°F. These isotherms generally define the northern limits of species, determined by ability to survive the winter cold. Exceptions may occur in protected sites with extraneous sources of heat. The USDA maps also consider other factors like rainfall or maximum temperature. A more exact 24-climate zone classification system has been described for the western half of the USA, determined by the interplay of six factors: latitude, elevation, Pacific Ocean influence, continental air mass influence, mountains and hills, and local terrain.[17] However, 24 zones are cumbersome to consider. Solomon popularized ten floristic zones which are a cross between the USDA hardiness zones and additional factors, and offer a useful compromise.[18,19] While the zone boundaries are purposely ill-defined, they are descriptive of the territories they encompass. The zones are: Northern Forest, Eastern Agricultural, Southeastern Coastal Plain, Florida Subtropical, Central Plains, Rocky Mountain, Arid Southwest, Great Basin, Northwest Coastal, and California Lowland. A useful reference giving the distribution maps of many native allergenic plants is *Airborne and Allergenic Pollen of North America*.[20] However, numbers of introduced major allergenic plants do not have distribution maps.

CHARACTERIZED ALLERGENS

Numerous allergens have now been characterized, and a list of those that have been fully sequenced is maintained and updated on-line by the International Union of Immunological Societies (IUIS).[21] Allergen nomenclature, by convention, is the first three letters of the genus and the first letter of the species, followed by a number; e.g. the major allergen of short ragweed is Amb a 1, initially known as Antigen E. The number may signify importance or chronology of discovery. Allergens may be renumbered to conform to the function and number of a related allergen. Variations in the molecular weight or charge of an allergen due

https://CafePezeshki.IR

to amino acid substitutions or glycosylation are called isoallergens and are designated by a decimal point followed by four digits (e.g. Phl p 5.0102 and Phl p 5.0201).

AEROALLERGEN SAMPLING

In order to assess the type and intensity of the aeroallergen exposure, it is necessary to monitor the environment. Table 20-2 lists the types of samplers that are useful in assessing outdoor and indoor air. The earliest samplers relied on gravity. The Durham sampler is a greased microscope slide mounted horizontally on a stand, with a roof or rain shield above. Petrie dishes containing the appropriate agar medium have been used indoors for mold studies, with the advantage that the growth medium allows identification of viable spores from the distinctive colony characteristics. Disadvantages of gravimetric samplers are that they can only be quantified in terms of surface area (cm^2) and do not give an estimate of particle burden in a volume of air. Capture is skewed to larger particles, with smaller mold spores underrepresented as air currents may carry them over the top of the surface. Gravimetric samplers are no longer considered adequate for meaningful study.

Volumetric devices sample volumes of air over a given time interval and report in particles/m^3/24 hours (Table 20-2). The Rotorod seen in Figure 20-1A is a rotary impaction device that spins two small plastic rods at fixed time intervals, usually for 1 minute in every 10 (total of 144 minutes in 24 hours). The rods are lowered into the ambient air from the spinning armature by centripetal force. The silicone-greased leading side of the rod has a fixed surface area (length and width) that sweeps a given length of air (circumference of the circle) for a given length of time. An advantage is that it is not affected by wind direction. A disadvantage is that it loses capture efficiency as the surface becomes loaded with impacted particles, explaining the necessity of not running it continually over 24 hours. Suction devices use vacuum pumps to move air through an aperture to impact on tape on a rotating drum (with the Burkard) or an advancing microscope slide (Kramer-Collins). The Burkard (Figure 20-1B) can be configured for a 24-hour or 7-day sample. Capture efficacy is best when the aperture is facing into the wind, and when the wind velocity matches the intake flow. The Burkard has a large weather vane to orient the aperture into the wind. Another either indoor or outdoor suction device is the Andersen cascade impactor, which can segregate particles by size over several stages. Figures 20-1C and D show the Andersen intact and disassembled to show the individual stages. Agar plates can be used to identify fungi from culture characteristics. Small personal-sized samplers can be worn or carried and have been useful in risk assessment, especially in indoor occupational settings. High volume suction devices are fitted with fiberglass filters that can be scanned microscopically, or eluted and stained with specific monoclonal antibodies. The subtleties of outdoor sampling and interpretation as well as the importance of pauci-micronic particles carrying allergen has been described.[22] Immunochemical techniques to measure outdoor allergen have come into vogue.[23,24] Unfortunately, the number of pollen or fungal-related allergens contributing to the aeroallergen atmospheric burden exceeds by several orders of magnitude the number of monoclonal specific allergen immunochemical assays.

Outdoor aeroallergen sampling has been based on microscopic examination with identification based on morphologic pattern recognition, which is labor intensive and requires an experienced counter.[25] The National Allergy Bureau is the American Academy of Allergy, Asthma & Immunology (AAAAI) sponsored pollen-and-mold counting stations scattered primarily around the contiguous USA (with additional stations in Alaska, Hawaii, Puerto Rico, Canada and Argentina). The majority of over 85 stations have only a single qualified counter. Therefore, the prospect of automated systems is highly tantalizing. Conceptually elegant automated counters evaluated by Delaunay and associates have significant drawbacks.[26] The inability to discern ice particles from pollen by one sampler, and the relatively high particle detection threshold (above that necessary to induce symptoms in the majority of patients) are major problems. Work is progressing on computerized pattern recognition programs.

TABLE 20-2 Types of Aeroallergen Samplers

Type	Example	Comment
Gravimetric	Durham Petrie dish	Large particles overrepresented Particles per surface area (p/cm^2)
Volumetric		Particles per air volume (p/m^3)
Impaction		
intermittent rotary suction drum	Rotorod Burkard	Easily overloaded Wind orientation necessary
cascade	Anderson	Indoor or outdoor use
Filtration	Accu-Vol	Microscopic or immunoassay
Personal sampler		Clinically relevant exposure
Automatic counter	NTT-Shinyei KH300	Misreading likely Lack of sensitivity

Representative Pollens

GRASSES

The huge grass family, Poaceae, has several subfamilies and numerous tribes. The Fescue subfamily, including the temperate climate pasture grasses and most cereal grains, is the most prominent in pollinosis. These grasses have wide range throughout the USA and Europe. With only minor exceptions, members of the Fescue subfamily have strongly cross-reactive major allergens.[27] Representative members include Kentucky bluegrass, timothy, and cereal rye (Figure 20-2A). Bermuda (*Cynodon dactylon*) is the most important southern grass, found south of the 38° parallel, with extension north along the coasts. Johnson (*Sorghum halepense*) is a southern grass, but is found throughout the Eastern Agricultural zone and across the Arid Southwest. Buffalo grass and grama grass are two native prairie grasses related to Bermuda grass.

CONIFERS

The most important member of the order Coniferales is the cedar family (Cupressaceae), containing cedars, junipers (*Juniperus spp*, *Thuja spp*) and cypresses (*Cupressus spp*). Exposure is from forest stands, but also the ubiquitous use of junipers in home landscaping. In Texas and parts of Oklahoma,

https://CafePezeshki.IR

Figure 20-1 Aeroallergen samplers. A – Rotorod; B – Burkard spore trap; C – Andersen cascade impactor; D – Andersen sampler showing inner layers.

mountain cedar (*Juniperus ashei*) counts may be >20,000 grains/m^3. Members of this family are strongly cross-reactive.[27] A subfamily includes bald cypress, redwoods, sequoias and the foremost producer of pollinosis in Japan, Japanese cedar (*Cryptomeria japonica*). The pine family consists of pines (*Pinus spp*), spruces (*Picea spp*), hemlocks (*Tsuga spp*) and firs (*Abies spp, Pseudotsuga*). This family produces copious amounts of pollen, but they are weak allergens and induce little hay fever.

OTHER TREES

Deciduous trees are scattered throughout a great number of botanical orders and families. With few exceptions, there is little cross-reactivity between these diverse plants. Cottonwoods, aspens, poplars and willows are within the same family. Aspens are prevalent in the Rocky Mountains and throughout the Northern Forest. Poplars and cottonwoods are common throughout the eastern states and Great Plains. Willows, although primarily insect pollinated, may release significant amounts of airborne pollen. Several birch species (*Betula*) and alder (*Alnus*) are found throughout the Northern Forest, Northwest Coastal, California Lowlands and Great Basin. Alder is especially prevalent in the Northern Forest and Pacific Northwest zones. Red and white oaks (*Quercus spp*) have a wide range from the entire east through the Central Plains. Live oaks are evergreen and found throughout the Southern Tier. The

https://CafePezeshki.IR

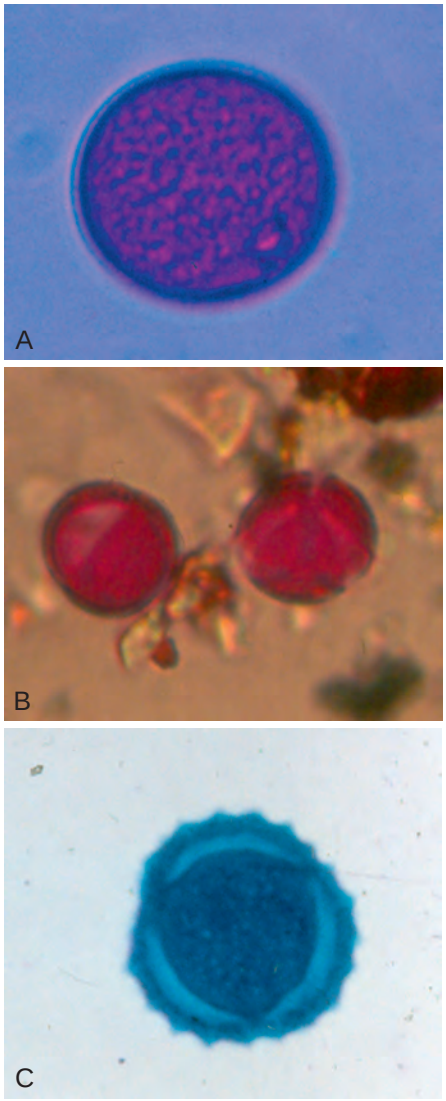

Figure 20-2 Representative pollens. A – grass; B – maple; C – Ragweed.

American elm (*Ulmus americana*) has been decimated by disease, and the Siberian and Chinese elms (*U. pumila* and *U. parvifolia*) are now more common, with a similar wide range. Numerous maples (*Acer spp*) are found across the USA, with box elder (*A. negundo*) having a wide range in the Eastern zones, Central Plains, Rocky Mountain, Southwest and California Lowlands (Figure 20-2B). Box elder is an entirely wind-pollinated, prodigious pollen producer, while other maples are amphiphilous. Ash trees are found across the continent and have strong cross-reactivity with European olive. Linden, or basswood (*Tilia spp.*), is another amphiphilous tree that produces large amounts of airborne pollen in summer, causing significant sensitization. Russian olive (*Elaeagnus angustifolia*) has been widely planted across the Great Plains as a drought-resistant windbreak. It is both wind and insect pollinated.

WEEDS

Numerous annual or perennial weeds are significant inducers of hay fever. The sorrels and docks pollinate earlier than many weeds, coinciding with the grass pollen season. Sheep sorrel (*Rumex acetosella*) is considered a moderate hay fever inducer; curly or yellow dock (*R. crispus*), is a lower pollen producer but a common plant. Excepting the Florida and Southeast Coastal zones, nettle (*Urtica spp*) is common. Pellitory (*Parietaria spp*) is found throughout the zones. Under-appreciated as a source of hay fever, nettle produces large amounts of small, pale pollen. Pellitory is a major inducer of pollinosis in the Mediterranean basin. The closely related chenopod and amaranth weeds of Amaranthaceae are major inducers of hay fever in the later summer. Their pollen grains are very similar and difficult to discriminate by species. Pigweeds such as *Amaranthus retroflexus* are ubiquitous. The two major tumbleweeds found in the Central Plains, Russian thistle (*Salsola kali*) and burning bush (*Kochia scoparia*), are introduced and have expanded throughout the central states to the gulf and California coasts. Lamb's quarter (*Chenopodium album*), a modest pollen producer, has a worldwide distribution. Plantains (*Plantago spp*) are common weeds, which, while moderate pollen producers, have a long season, from spring into fall.

Short (*Ambrosia artemisiifolia*) and giant (*A. trifida*) ragweeds predominate in the eastern states through the Central Plains, with false (*A. acanthicarpa*) and western (*A. psilostachya*) ragweed common in the Rocky Mountain, Great Basin, Arid Southwest and California Lowlands (Figure 20-2C). These four major ragweed plants strongly cross-react.[27] Cocklebur (*Xanthium commune*) and the marshelders (*Iva spp*) are related to ragweed, but are of lesser significance. Mugwort (*Artemisia vulgaris*) in the east and several western sages (*Artemisia spp*) are important pollen producers in the late summer, rivaling the importance of ragweed in the western states. Goldenrod, *Solidago spp*, is a showy late summer flower which has been blamed for much of the misery caused by the less conspicuous ragweed. Although goldenrod and sunflower are primarily insect pollinated, they can release moderate amounts of pollen, which may persist at higher levels as ragweed pollen is waning.

Representative Fungi

Long and Kramer demonstrated than airborne fungal spora should be classified as those facilitated by dry windy conditions, and those with greater spore release with increased humidity or precipitation.[28] In the Central Plains, fungi such as *Alternaria*, *Cladosporium* and *Epicoccum* grow on grasses and grains, and spores are released through wind turbulence. These mold spores are present in greatest concentrations on dry windy afternoons (Figure 20-3). Many Basidomycetes and Ascomycetes have spore release dependent on increased humidity, and puffballs release spores when hit by raindrops. Such fungi will then be present in greatest concentrations during or after rainfall and during the damper hours of darkness.[28] Although *Alternaria* is recovered on samplers at an order of magnitude less than *Cladosporium*, it is a more potent allergenic source and has been incriminated in severe asthma and life-threatening events.[29,30] *Epicoccum* and basidiospores have also been linked with decreases in pulmonary function and asthma admissions.[31,32]

Meteorological Variables

While the prevalent weather conditions help define climate, individual factors such as rain, humidity, wind speed and

https://CafePezeshki.IR

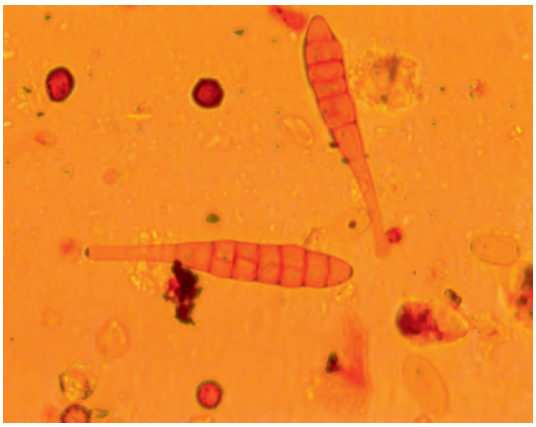

Figure 20-3 *Alternaria*. Two club-shaped *Alternaria*; four clear cigar-shaped *Cladosporium* in lower right quadrant; two pairs of dark brown Basidiomycete smut spores in upper and lower left quadrants.

direction, temperature or amount of sunshine may all have effects on bioaerosols.[33] Effects may be immediate or cumulative. Precipitation and humidity decrease particle air burden acutely, while sufficient moisture preseasonally is necessary to assure proper growth of flower buds on perennials and trees, and growth of annuals in general. Ambient temperature rise is necessary for pollen anthesis in many plants, and cumulative heat above a threshold value has been linked to onset and intensity of pollination in grasses, weeds and trees.

Wind speed may factor in re-entrainment of settled particles or act to scour the air. Thunderstorms provide a sum of factors that may greatly increase aeroallergen burden due to outflows from storm cells as well as disruption of pollen grains with increase in airborne submicronic particles.[34,35]

Dispersal of mold spores is intimately linked to precipitation and humidity. However, effects may be diametrically opposed, depending on the type of fungi. Certain ascospores and basidiospores require active rainfall for release of spores, while other Deuteromycota will be suppressed by precipitation.

Impact of Climate Change on Aeroallergens

Pollen anthesis has been used as a monitor of anthropogenic climate change. Over a 16-year period, oak pollen onset in Poland advanced by 9 days, correlating with temperature increase.[36] Researchers have reported increased short ragweed (*A. artemisiifolia*) biomass and pollen production of 61–90% with increased ambient CO_2.[37,38] Rogers and co-workers increased temperature to simulate early spring and found increased inflorescences and pollen in earlier compared to later blooming ragweed plants.[39] Increasing CO_2 also resulted in greater biomass and pollen production, more so in later growing cohorts. Since the content of Amb a 1 will vary in ragweed plants from site to site and from year to year, the question was raised whether increased pollen production necessarily implies an increase in airborne allergenic load.[40,41] Ziska and associates collected ragweed pollen along an urban transect in Maryland, using the urban environment as a surrogate for climate change.[42] The urban site averaged 2°C higher and the CO_2 level was 30% higher than in the rural site. The urban ragweed grew faster with a greater above-ground biomass, flowered earlier and produced more pollen than plants in the rural site. There was about a 2-fold greater concentration of Amb a 1 per microgram of protein in the rural versus the other sites. However, there was a >7-fold production of pollen from the urban sites compared to the rural site, documenting an increased airborne allergenic burden. The northern expansion of invasive ragweed in Europe has been linked to climate change.[43]

There is now a wealth of evidence that climate change has had, and will have further impact on a variety of allergenic plants.[44,45] Increased CO_2 increases plant biomass and pollen production. It is conceivable that increases in airborne pollen numbers will increase the efficiency of wind-borne pollination, thereby increasing propagation of such plants. The expectation then is that there will be increasing amounts of robust allergenic plants and an increasing aeroallergen burden for inhalant allergy sufferers. The rise of other pollutants in association with CO_2 may have a potentiating effect. Increased allergenicity of birch pollen has been linked with increased ozone levels.[46]

21 Indoor Allergens

WILLIAM J. SHEEHAN | WANDA PHIPATANAKUL

KEY POINTS

- Studies in both inner city and suburban locations indicate that more than 80% of school age children with asthma are sensitized to at least one indoor allergen.
- The level of early life environmental exposure to a specific indoor allergen influences the development of sensitization to that allergen and subsequent atopic conditions.
- Humidity levels greater than 50% promote house dust mite growth and house dust mite allergy has been associated with asthma development, severity and morbidity.
- Given the lack of scientific evidence, it is standard for current guidelines to state that hypoallergenic cats and dogs should not be recommended for individuals who are sensitized.
- In urban environments, several important studies have demonstrated the relationship between cockroach exposure and poor asthma outcomes in children.

Introduction

Allergens found in house dust have been associated with asthma since the 1920s, when Kern[1] and Cooke[2] independently reported a high prevalence of immediate skin tests to house dust extracts among patients with asthma. Van Leeuwen[3] showed that asthmatics who were admitted to a modified hospital room free of 'climate allergens' (thought to be bacteria and molds) showed clinical improvement. Allergists sought to explain how a heterogenous material such as house dust could contain a potent allergen that appeared to be ubiquitous. The puzzle was finally resolved in 1967, when Voorhorst and Spieksma[4] showed that the origin of house dust allergen was biologic. Extracts of mite cultures gave positive skin tests, and asthma symptoms correlated with seasonal variation in mite numbers. Exposure to 100 mites per gram of dust was associated with sensitization, and 500 mites per gram was associated with symptom exacerbation.

Over the past few decades, the investigation of the important role of indoor allergens in the pathogenesis of allergic disease has included the identification of the most important allergens, the evaluation of the effect of allergen exposure on allergic disease, and the development of techniques to accurately monitor allergen exposure. The primary indoor allergens include allergens from house dust mite, pets such as dogs and cats, molds, and pests such as cockroach and rodents. This chapter reviews the structure and biologic function of indoor allergens, the clinical significance of the primary indoor allergens and the methods for assessing environmental exposure.

Allergen Structure and Function

Allergens are proteins or glycoproteins of 10 to 50 kDa that are readily soluble and able to penetrate the nasal and respiratory mucosae. A systematic allergen nomenclature has been developed by the International Union of Immunological Societies' (IUIS) Allergen Nomenclature Subcommittee: the first three letters of the source genus followed by a single letter for the species and a number denoting the chronologic order of allergen identification. For example, the abbreviated nomenclature for the house dust mite allergen, *Dermatophagoides pteronyssinus* allergen 1, is Der p 1 (see http://www.allergen.org). To be included in the IUIS nomenclature, the allergen must have been purified to homogeneity and/or cloned, and the prevalence of IgE antibody must have been established in an appropriate allergic population by skin testing or in vitro IgE antibody assays.[5] Molecular cloning has determined the primary amino acid sequences of more than 500 allergens and most common allergens can be manufactured as recombinant proteins. There are over 50 three-dimensional structures of allergens in the Protein Database (PDB) and allergens are found in protein families in the Pfam protein family database (http://www.sanger.ac.uk/software/Pfam).[5–10]

The x-ray crystal structures of Der p 1 and Der f 1 (*Dermatophagoides farinae* 1) are shown in Figure 21-1.[11] It is noted that only a small percentage of the more than 10,000 protein families in Pfam are allergens. This implies that only a limited group of proteins (with certain structural features) have the potential to become allergens;[6,12] however, detailed structural analyses have not revealed any common features or motifs that are associated with the induction of IgE responses.

Allergens belong to protein families with diverse biologic functions including enzymes, enzyme inhibitors, lipid-binding proteins, ligand-binding proteins, structural proteins or regulatory proteins (Box 21-1).[5] Some dust mite allergens are digestive enzymes excreted with the feces, such as Der p 1 (cysteine protease), Der p 3 (serine protease) and Der p 6 (chymotrypsin). Enzymatic activity of mite allergens promotes IgE synthesis and local inflammatory responses via cleavage of CD23 and CD25 receptors on B cells and by causing the release of proinflammatory cytokines (interleukin [IL]-8, IL-6, monocyte chemotactic protein-1 [MCP-1] and granulocyte-monocyte colony-stimulating factor [GM-CSF]) from bronchial epithelial cells.[13] Mite protease allergens cause detachment of bronchial epithelial cells in vitro and disrupt intercellular tight junctions. Activation of mite proteases could damage lung epithelia and allow access of other nonenzymatic allergens, such as Der p 2, to antigen-presenting cells. Der p 2 has structural homology to MD-2, the lipopolysaccharide (LPS) binding component of the Toll-like receptor 4 (TLR4) complex. Recent studies have shown that Der p 2 can drive signaling of the TLR4 complex and may enhance the expression of TLR4 on the airway

https://CafePezeshki.IR

epithelium and have intrinsic adjuvant activity.[14] Mite feces contain other elements, including endotoxin, bacterial DNA, mite DNA and chitin that could also influence IgE responses and inflammation.[15,16]

With the exception of cat allergen Fel d 1 (*Felis domesticus* 1), most animal allergens are ligand-binding proteins (lipocalins) or albumins. Lipocalins are 20–25kDa proteins with a conserved, eight-stranded, antiparallel β-barrel structure that bind and transport small hydrophobic chemicals. In contrast, Fel d 1 is a calcium-binding, steroid-inducible, uteroglobin-like molecule – a tetrameric 35 kDa glycoprotein, comprising two subunits which are heterodimers of two chains comprising eight α-helices.[17] Fel d 1 has two amphipathic water-filled cavities which may bind biologically important ligands. Rat and mouse urinary allergens are pheromone- or odorant-binding

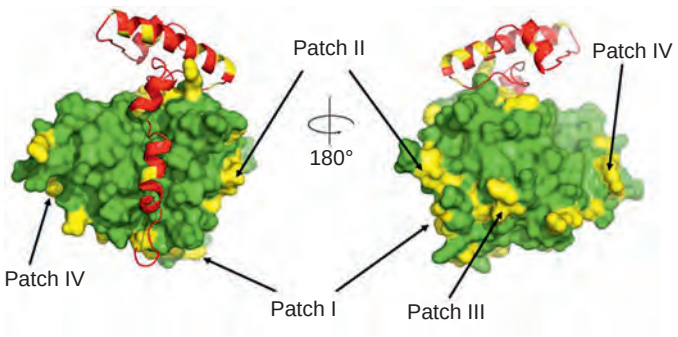

Figure 21-1 X-ray crystal structures of the mite cysteine protease allergens, Der p 1 and Der f 1. Residues that differ between the two allergens are shown in yellow and labeled as patches I, II, III and IV. The conserved Cys35 active site residue is shown in orange. *(From Chruszcz M, Chapman M, Vailes L, et al. J Mol Biol 2009;386:520–30.)*

BOX 21-1 KEY CONCEPTS

Indoor Allergens: Structure and Function

- Allergens are soluble proteins or glycoproteins of molecular weights of 10 to 50 kDa.
- More than 500 allergen sequences are deposited in protein databases (GenBank, PDB), and more than 50 tertiary structures have been resolved by x-ray crystallography.
- Allergens have diverse biologic functions and may be enzymes, enzyme inhibitors, lipid-binding proteins, lipocalins or regulatory or structural proteins.
- Allergens promote T cells to differentiate along the Th2 pathway to produce IL-4 and IL-13 and to initiate isotype switching to IgE.
- Biologic functions of allergens, such as proteolytic enzyme activity or other adjuvant-like effects, can enhance IgE responses, damage lung epithelium and cause allergic inflammation.

proteins. The cockroach allergen Bla g 4 (*Blattella germanica* 4) is a lipocalin that is produced in utricles and conglobate glands of male cockroaches and may have a reproductive function. Other important cockroach allergens include: Bla g 1, a gut-associated allergen; Bla g 2, an inactive aspartic proteinase; Bla g 5 (glutathione transferase family); and the Group 7 tropomyosin allergens.[18]

Clinical Significance of Indoor Allergens

Exposure data collected in epidemiologic studies, population surveys and birth cohort studies have strengthened the association between indoor allergen exposure and the pathogenesis of allergic respiratory diseases including asthma and allergic rhinitis. The measurement of indoor allergen levels in dust and air samples has allowed for the determination of risk levels for allergen exposure leading to both sensitization and symptom exacerbation. International workshop reports recommend that allergen exposure be expressed as μg allergen/gram dust (μg/g) for dust samples or ng/m^3 for air samples.[8] Childhood asthma is more closely linked to allergic sensitization and allergen exposure than adult asthma. Sensitization to indoor allergens likely occurs earliest in life as young children have been shown to have higher rates of sensitization to indoor allergens as compared to outdoor allergens.[9] Studies in both inner city and suburban children with asthma indicated that more than 80% of school age children with asthma are sensitized to at least one indoor allergen and that allergic sensitization is a strong predictor of disease persistence in later life.[10,19,20] In one large inner city study, 94% of the study population of severe asthmatics was sensitized to at least one allergen and the number of sensitivities correlated with asthma severity.[21] Furthermore, European cohorts have demonstrated that high-level allergen exposure in early life is associated with chronic asthma in children.[10,20] Epidemiologic studies have demonstrated risk of allergic sensitization to be attributable to certain levels of allergen exposure among different populations of atopic individuals (Table 21-1).

DUST MITES

The two principal mite species, *D. pteronyssinus* (Der p) and *D. farinae* (Der f), account for more than 90% of the mite fauna in US house dust samples. Other allergenic mites include *Euroglyphus maynei* and *Blomia tropicalis* (found in subtropical regions such as Florida, southern California, Texas and Puerto Rico). Storage mites, such as *Lepidoglyphus destructor, Tyrophagus putrescentiae* and *Acarus siro,* cause occupational asthma among farmers, farm workers and grain handlers.

TABLE 21-1 Allergen Exposure Thresholds for Sensitization

	ALLERGEN LEVEL IN DUST SAMPLE				
Risk for Sensitization*	Mite Group 1 (μg/g)	Fel d 1 (μg/g)	Can f 1 (μg/g)	Bla g 1 (U/g)	Bla g 2 (μg/g)
Low	<0.3†	<0.5 or >20	<0.5 or >20?	<0.6	<0.08
Medium	2–10	8–20	8–20	1–8	0.08–0.4
High	>10	1–8	1–8	>8	>1

*For atopic children.
†Levels found in 'allergen-free' hospital rooms or in houses/apartments maintained for at least 6 months at less than 45% relative humidity.

https://CafePezeshki.IR

House dust mites (Der p and Der f) are found in dust and products with woven material or stuffing such as mattresses, pillows, stuffed animals and bedding. Warmth and humidity greater than 50% are the major factors that promote dust mite growth. Rabito et al found that, in New Orleans, asthmatic children living indoors with average humidity greater than 50% were three times more likely to be exposed to elevated levels of house dust mites.[22] In contrast, house dust mite levels are generally low or undetectable in areas of high altitude or low humidity. In fact, maintaining an indoor humidity below 50% is one of the recommended components of interventions to reduce dust mite exposure.[23]

More than 50% of children and adolescents with asthma are sensitized to house dust mites.[24] There is strong evidence for a dose-response relationship of exposure to house dust mites and sensitization in both cross-sectional[25–27] and prospective studies.[20,28–30] Mite allergen levels at high altitude or in 'allergen-free' rooms are generally <0.3 μg/g and <10% of atopic individuals are likely to become sensitized at this low level of mite exposure. Persistent exposure of atopic individuals to ≈2 μg of mite allergen is likely to result in sensitization in a majority of atopic individuals, increasing as mite allergen levels exceed 2 μg/g (Table 21-1). A prospective study of German schoolchildren demonstrated a 7-fold increase in sensitization to dust mites between children exposed to dust mite allergen levels in the first quartile (<0.3 μg/g) as compared to those exposed in the highest quartile (1–240 μg/g).[30] Exposure to dust mite allergen levels greater than 10 μg/g is considered high risk for sensitization, and findings from the National Survey of Lead and Allergens in Housing (NSLAH) indicate that these levels are found in ≈23% of US homes (22 million housing units).[31]

Asthma development,[32–35] severity[36] and morbidity[24,26] have been strongly associated with house dust mite allergy. Dust mite exposure influences the development of asthma by exposure leading to sensitization and subsequent asthma symptoms. Sporik et al demonstrated dust mite exposure to be an important factor in the development of childhood asthma, particularly if there was exposure to high levels in the first year of life.[20] The relative risk of asthma was almost five times greater in the subjects who were exposed to high levels of dust mite allergen (>10 μg/g). Tovey et al showed a nonlinear relationship between levels of dust mites in homes and the development of asthma at 5 years of age in a high risk cohort of children.[29] The trends showed increasing prevalence of sensitization and asthma correlating with dust mite exposure up to a critical point and then sharply dropping at the highest level of exposure (>23.40 μg/g for Der p 1). The explanation of attenuated disease development with very high levels of dust mite exposure is unclear but may indicate that high concentrations of nonallergenic immune modifiers such as endotoxin are accompanying the house dust mites. Celedon et al found a dose response relationship between levels of dust mite exposure in high risk infants at age 2–3 months and asthma at school age.[28] In this study, the high allergen threshold was ≥10 μg/g, much lower than the critical threshold found in Tovey's evaluation. A survey of middle school children in Virginia showed that dust mite sensitization was independently associated with asthma (OR 6.6, $P < .0001$) and that dust from 81% of homes contained more than 2 μg/g mite group 1 allergen.[33] In addition to the implications for developing asthma, sensitization to dust mites predicts worse lung function as compared to those not sensitized.[24]

PETS (CAT AND DOG)

The major cat allergen, *Felis domesticus* 1 (Fel d 1), is primarily found in cat skin and hair follicles and is produced in sebaceous, anal and salivary glands. The major dog allergen, *Canis familiaris* 1 (Can f 1), is found in hair, dander and saliva. What distinguishes pet allergen exposure from other indoor allergens is the wide range of exposure levels (from <0.5 to >3000 μg/g) and the ubiquitous allergen distribution. The small particles of cat and dog allergen can scatter easily in the air and adhere to clothing for further dispersal.[37,38] As such, these allergens are found in non-pet homes, schools and public places.[38–46]

Data on cat and dog allergen exposure in relation to sensitization are more difficult to interpret as there is a nonlinear relationship.[25] This nonlinear relationship of pet allergen exposure and risk of sensitization is seen in Table 21-1. Exposure to Fel d 1 of <0.5 μg/g is considered to be low and is a low risk for sensitization.[27] Paradoxically, the prevalence of sensitization is also reduced among atopic individuals who are continuously exposed to high levels of Fel d 1 (>20 μg/g).[25,47,48] This high level of exposure appears to reduce the prevalence of sensitization by ≈50%. High exposure to Fel d 1 (>20 μg/g) gives rise to a modified Th2 response – a form of tolerance that results in a lower prevalence of IgE antibody responses. Studies have demonstrated that infants exposed to the highest levels of cat allergen had decreased cat-specific IgE levels and high allergen-specific IgG levels corresponding to a low risk phenotype for atopy.[49,50] This helps to explain why early exposure to cat has been found protective for asthma and other atopic conditions.[51,52] The nonlinear dose response may also explain why, in population surveys, sensitization to cats is often lower than that to dust mites. In countries such as New Zealand, where 78% of the population owns cats and high levels of allergen occur in houses, the prevalence of sensitization to cat is only 10% and cat is not as important a cause of asthma as dust mites.[53] Most houses that contain cats or dogs have Fel d 1 or Can f 1 levels of greater than 10 μg/g, whereas homes that do not contain these pets usually have allergen levels of 1 to 10 μg/g, placing those inhabitants at the highest risk for sensitization.[39,43,44]

In addition to risk of sensitization, studies have demonstrated that cat allergen exposure early in life is associated with the development of asthma.[35,54,55] In geographic areas where dust mite levels are low, dog and cat have been found to be the primary allergens associated with asthma.[43] Increased exposure in sensitized individuals may lead to higher rates of asthma; however, a Norwegian study reported that cat exposure led to an increased risk of asthma independent of cat sensitization.[56] This result indicates a possible nonallergic mechanism. Regardless, an already sensitized child who lives in a home without a cat can become symptomatic by visiting homes or attending schools where cat allergen is present, even if those locations do not physically have any cats. Schools are the best example of this phenomenon. A Swedish study showed a 9-fold increased risk of asthma exacerbations at school among elementary schoolchildren who attended classes with other students from cat homes as compared to children who attended classes with fewer than 18% cat owners.[57] Thus, passive exposure of schoolchildren to animal allergens can exacerbate asthma, even among asthmatic children who are purposely avoiding pets.

Similar to cat allergen, dog allergen has a nonlinear dose-response relationship between exposure and development of sensitization. A medium-dose exposure of Fel d 1 (1–8 μg/g) is

https://CafePezeshki.IR

most strongly associated with the development of sensitization as seen in Table 21-1. Dog exposure and asthma is less studied. A recent meta-analysis noted a slightly increased, statistically significant, relative risk of asthma in pet owners, not taking into account allergic sensitization.[52] Other birth cohort studies have not been suggestive of an association.[58]

Recently, issues regarding so-called 'hypoallergenic' pets have arisen. Many pet companies have aggressively marketed the benefits of these pets. It is important to stress that there is no scientific evidence to support the existence of 'hypoallergenic' pets.[59–61] In fact, Vredegoor et al actually found higher levels of Can f 1 in hair and fur samples of 'hypoallergenic' dog breeds as compared to non-hypoallergenic breeds.[61] In the homes of these pets, the same study found that there were not any differences in Can f 1 levels in settled floor dust or air samples between the two groups. Currently, it is standard for guidelines to state that hypoallergenic cats and dogs should not be recommended for individuals who are sensitized.[59]

COCKROACH

The German (*Blattella germanica*) and American (*Periplaneta americana*) cockroaches are the most common species to cause allergies. The major allergens, Bla g 1, Bla g 2 and Per a 1, are found in saliva, fecal material, secretions, cast skins and debris. Urban environments, low socioeconomic status, multifamily homes and old buildings are risk factors for cockroach infestation and higher levels of cockroach allergen.[62,63] The National Cooperative Inner-City Asthma Study (NCICAS) found that 85% of collected dust samples had detectable levels of cockroach allergen.[64] In public housing residences of New York City, 77% were found to have evidence of cockroaches.[65] Cockroach allergen exposure is typically assessed by measuring Bla g 1 and Bla g 2, which cause sensitization in 30% and 60% of cockroach-allergic patients, respectively.[66] Most dust samples from cockroach-infested homes contain both allergens, and there is a modest, but significant, correlation between levels of the two allergens.[67]

Increased cockroach exposure leads to increased risk of sensitization. Although the highest levels of cockroach allergen are typically found in kitchens, Eggleston et al demonstrated that the bedroom concentration of cockroach allergen was most associated with cockroach sensitization.[19] More recent work by Chew et al showed this relationship to be dose responsive between inner city home cockroach level and cockroach sensitization in children.[68] Cockroach allergens appear to be particularly potent. Atopic individuals develop IgE-specific responses after exposure to 10-fold to 100-fold lower levels of cockroach allergen as compared to dust mite or cat.[27]

Several important studies have demonstrated the relationship between cockroach exposure and poor asthma outcomes in children.[21,64] Most notably, Rosenstreich et al demonstrated that asthmatic children living in inner cities who were sensitized to cockroach and exposed to high levels of cockroach allergen (>8 U/g) had significantly more frequent hospitalizations, more days with wheezing, more unscheduled medical visits for asthma, more missed school days and more nights with lost sleep.[64] This study demonstrates the important principle of allergic disease – that sensitization plus exposure leads to symptoms. In that inner city study, similar patterns were not found for the combination of sensitization to dust mites or cat and exposure to higher levels. A follow-up study confirmed these findings with cockroach allergen having a greater effect on asthma morbidity in the inner city as compared to dust mite or pet allergens.[21] These findings underscore the importance of cockroach allergen as a major factor in asthma control for children living in urban environments. Additionally, cockroach allergen exposure has been shown to increase the risk of development of childhood wheeze in longitudinal studies.[69–71]

MOUSE

The major mouse allergens are *Mus musculus* 1 and 2 (Mus m 1 and Mus m 2). These allergens are found in mouse urine, dander and hair.[72] The allergen can be found in homes with and without mice infestation as the allergens easily migrate on dust particles.[73] Factors that increase mouse infestation are high population density (high rise apartments and multifamily dwellings), clutter and integrity of the residence. It is one of the few allergens to span environments from inner city to suburban areas, affecting both homes and schools.[45,46,74,75] Phipatanakul et al found that 95% of inner city homes in multiple US cities had detectable mouse allergen levels and the highest levels in those homes were found in the kitchens.[75] Similar rates of detectable mouse allergen have been discovered in urban schools and the levels of mouse allergen found in those schools can be higher than the surrounding homes.[45,46]

Data from inner city studies have shown that subjects living in homes with higher mouse allergen concentrations had significantly higher rates of mouse sensitization.[76] In sensitized individuals, exposure to mouse allergen affects clinical asthma outcomes, leading to increased asthma morbidity.[77,78] Furthermore, exposure to mouse allergen may lead directly to asthma development. Early life mouse exposure was shown to be associated with increased risk of wheezing in early life.[79] Likewise, current mouse exposure was associated with current wheeze through 7 years of age; however, early mouse exposure in infancy did not predict later wheeze or asthma at 7 years of age.[79] Mouse allergen may lead to current wheeze by acting as a direct irritant, as seen in laboratory workers.[80] Additionally, mouse allergen exposure may lead to sensitization, which has been significantly associated with wheezing in the early years of life.[70]

Evaluation of Allergen Exposure

Allergens are typically measured in dust samples that are collected by either vacuuming settled dust (on the floor or furniture) or gathering airborne dust from filtered air within a room. Samples may be collected from multiple sites within a home, including mattresses, bedding, bedroom or living room carpet, soft furnishings or kitchen floors. After dust collection, fine dust can then be extracted for further testing and analysis. For dust mite evaluation, collection of dust in bedding and mattresses provides the best marker of exposure.[81] Cat and dog allergens are widely distributed throughout the house. Not surprisingly, the highest concentrations of cockroach and mouse allergens are usually found in kitchens, although in heavily infested homes allergen accumulates throughout the home.

The decision to sample dust or air has to account for the aerodynamic properties of allergens.[44,82,83] Dust mite and cockroach allergens occur on large particles (10–40 μm in diameter) and cannot be detected in rooms under undisturbed conditions. After a disturbance, such as using a vacuum cleaner without a filter, these particles remain airborne for only a short time of approximately 20 to 40 minutes. In contrast, cat and

https://CafePezeshki.IR

dog allergens can be carried on small airborne particles (1–20 μm in diameter) allowing for easier detection in air samples under undisturbed conditions and persistence in the air for several hours.[84] While airborne, pet allergens are easily able to adhere to clothing for further dispersal.

After collection, filtered dust is sent to accredited labs for extraction, analysis and evaluation of the concentrations of specific allergens within the specific dust sample. Since the 1980s, measurement of major allergens within the dust samples has been made by using monoclonal antibody (mAb)-based ELISA (enzyme-linked immunosorbent assays). ELISA methods have defined specificity and high sensitivity (≈1 ng/mL) and provide accurate and reproducible measurements.[8,85] A growing number of academic and commercial laboratories in the USA and in Europe offer ELISA testing services. While ELISA provides reliable quantitative exposure assessment, it does require a separate test for each allergen. More recently, innovative fluorescent multiplex array technology has been developed that allows the most common indoor allergens to be detected at once in a single test using a multiplex array for indoor allergens (MARIA).[86,87] The multiplex test occurs within a single microtiter well and the assay conditions are the same for each allergen, resulting in improved standardization and reproducibility. The other advantage of MARIA compared to ELISA is the time savings achieved by analyzing multiple allergens at once. For allergen exposure assessment, nine indoor allergens can be measured by MARIA: Der p 1, Der f 1, mite group 2, Fel d 1, Can f 1, Mus m 1, Rat n 1, Bla g 2 and Alt a 1.

Monitoring Allergen Exposure as Part of Asthma Management

The most recent National Asthma Education and Prevention Program (NAEPP) Expert Panel Report 3 (EPR-3) significantly strengthened guidelines recommending allergen avoidance as an important goal of asthma management (Box 21-2). Targeted interventions in the homes of allergic individuals can significantly improve health and should be part of the management of children with asthma. Studies of inner city asthma demonstrated that reduction of indoor allergen exposure leads to improvement of asthma symptoms, associated with a reduced use of medication and also a reduction in lost work or school time due to asthma.[88] The guidelines recommend using patient histories and allergic sensitization as evidence of allergen exposure but do not include any environmental assessment. Targeted indoor allergen avoidance strategies must account for geographical considerations and living conditions to attempt to identify the specific troublesome exposures for that patient.

BOX 21-2 THERAPEUTIC PRINCIPLES

Control of Environmental Factors that Affect Asthma (NAEPP EPR-3)

- For patients who have persistent asthma, the clinician should evaluate the potential role of indoor allergens.
- Use the patient's medical history, skin testing or in vitro testing to identify allergen exposures that may worsen the patient's asthma.
- Patients who have asthma at any level of severity should reduce, if possible, exposure to allergens to which the patient is sensitized and exposed.
- Know that effective allergen avoidance requires a multifaceted, comprehensive approach.
- Consider allergen immunotherapy when there is clear evidence of a relationship between symptoms and exposure to an allergen to which the patient is sensitive.

Conclusions

Indoor allergens are a risk factor for the development of asthma as well as other allergic diseases. Indoor allergens have diverse biologic functions and may be enzymes, lipid-binding proteins, ligand-binding proteins, structural proteins or regulatory proteins. The biologic function of allergens may enhance IgE responses and play a direct role in causing allergic inflammation. The level of environmental exposure to allergen as well as the atopic predisposition of the individual also influences the development of IgE responses and Th2 responses. The NAEPP-EPR 3 guidelines for the management of asthma recommend that for any patient with persistent asthma, the clinician should: (1) identify allergen exposures; (2) use skin testing or in vitro testing to assess specific sensitivities to indoor allergens; and (3) implement environmental controls to reduce exposure to relevant allergens. Avoidance procedures that can help to reduce exposure to indoor allergens have been developed and can reduce symptoms and medication requirements.

22 Environmental Control

ROBERT A. WOOD

KEY POINTS

- The major indoor allergens include dust mite, animal danders, cockroach, rodents and mold.
- Indoor allergen exposure and sensitivity should be considered for all patients with chronic allergic symptoms, including asthma, allergic rhinitis and atopic dermatitis.
- Allergen avoidance should be considered the first line of therapy for patients with indoor allergen sensitivities.
- Allergen avoidance should be approached with a comprehensive specific environmental control strategy based on the patient's sensitivities and exposures.

There is no doubt that aeroallergens play a major role in the pathogenesis of allergic disease, including asthma, allergic rhinitis and atopic dermatitis. Among these, the indoor allergens are of particular importance. These principally include the allergens of house dust mites, domestic pets, molds and pests such as cockroaches and rodents. The relative importance of these different allergens varies in different environments depending on a variety of geographic, climatic and socioeconomic factors. All studies agree, however, that children with asthma have a high likelihood of becoming sensitized to whichever of these allergens are prominent in their local environments. This chapter focusses on the possible role that allergen avoidance may play in the management of allergic disease.

As a general concept, it is important to recognize that allergen avoidance should be based on knowledge of the patient's specific allergic sensitivities as well as their environmental exposures. Based on this information, it is important to recommend a comprehensive strategy to reduce exposure to as many relevant allergens as possible. In fact, most of the studies in which environmental control has been proven effective are those that utilize a multifaceted approach tailored to the patient's sensitivities and environment,[1–6] which requires both thoughtful consideration and detailed patient education.

Dust Mites

Dust mites are arachnids that live in the dust that accumulates in most homes, particularly the dust contained within fabrics. Favorite habitats include carpets, upholstered furniture, mattresses, pillows and bedding materials. Their major food source is shed human skin scales, which are present in high numbers in most of these items. The major dust mite species known to be associated with allergic disease are *Dermatophagoides pteronyssinus* and *Dermatophagoides farinae.*[1,7–9] Other mites, including *Euroglyphus maynei* and *Blomia tropicalis,* are also important in some areas, although their distribution is considerably more limited. Dust mites grow optimally in areas that are both warm and humid, and they grow very poorly when the relative humidity remains below 40%.[10] Dust mites grow from eggs to adults over the course of about 4 weeks and adult dust mites live for about 6 weeks, during which time females produce 40 to 80 eggs.[11]

Assessment of dust mite exposure has been accomplished largely through the analysis of settled dust samples. Although some studies have not been able to show a relationship between dust mite levels and allergic sensitization or disease activity, there is now general agreement that dust mite levels of greater than 2 μg of group 1 allergen per gram of dust should be considered a risk factor for sensitization and that levels greater than 10 μg/g of dust are a risk factor for increased asthma morbidity.[9,11–15] Airborne sampling for dust mite allergen has not proven useful in assessing exposure.[16]

The prevalence of dust mite sensitivity in patients with asthma or allergic rhinitis varies considerably from one geographic area to another. For example, studies have demonstrated sensitization rates ranging from 5% in asthmatic children in Los Alamos, New Mexico, to 66% in Atlanta, Georgia, to 91% in Papua, New Guinea.[17,18] These differences are roughly proportional to differences in mite exposure in these areas of the world.

In addition to the relationship between mite exposure and mite sensitization, there is also evidence that mite exposure contributes to the development of asthma.[1] In a prospective trial, Sporik and colleagues[14] demonstrated a significant increase in asthma, as well as mite sensitivity, in 11-year-old children who had experienced high mite exposure during infancy. Other studies have demonstrated a striking association between asthma development and mite sensitivity,[17,19–21] although these studies lacked a prospective evaluation of mite exposure. While these studies suggest that mite avoidance early in life could potentially prevent the development of asthma, studies of prevention have yielded inconsistent and mostly disappointing results.[22–29]

Extensive evidence also exists to support a relationship between ongoing mite exposure and disease activity.[1,30–33] With regard to chronic symptoms, Vervloet and colleagues[32] demonstrated a significant correlation between medication requirements and current mite exposure in a group of mite-sensitive adult asthma patients. Custovic and colleagues[30] also demonstrated a relationship between mite exposure and asthma severity as evidenced by bronchial hyperreactivity (BHR), peak expiratory flow rate variability and forced expiratory volume in 1 second (FEV_1). Several studies have also demonstrated mite exposure to be a risk factor for acute asthma and emergency room visits.[15,33] The most compelling evidence for the role of dust mites in asthma comes from studies of allergen avoidance,[1]

https://CafePezeshki.IR

either through environmental control in the home or the removal of mite-allergic patients from their homes. Two classic studies from the early 1980s provided dramatic evidence for the potential benefits of dust mite avoidance. Platts-Mills and colleagues[34] investigated the effects of mite avoidance by placing nine young adults with mite-induced asthma in a hospital setting for a minimum of 2 months. All patients experienced reduced symptoms, seven had reduced medication requirements, and five showed at least an 8-fold reduction in bronchial reactivity. In the second study Murray and Ferguson[35] studied 20 mite-allergic asthmatic children in a controlled trial of mite avoidance in the patients' homes. They found significant reductions in asthma symptoms, days on which wheezing was observed, days with low peak flow rates, and BHR in the group using active mite control measures.

Most subsequent trials of mite avoidance have yielded similar results.[36–40] Ehnert and colleagues[38] studied 24 children with asthma and mite sensitivity in a 1-year trial of mite avoidance. The patients were divided into three groups. The first had their mattresses, pillows and comforters covered with impermeable encasements; the second had their mattresses and carpets treated with an acaricide (benzyl benzoate); and the third had their mattresses and carpets treated with placebo. Significant reductions in dust mite allergen levels were found only in the group with mattress and pillow encasements. Similarly, a highly significant reduction in BHR was noted in that group compared with the other two. In another study, Peroni and colleagues[40] studied mite avoidance by moving asthmatic children to a high-altitude environment and demonstrated significant reductions in total immunoglobulin E (IgE) levels, dust mite-specific IgE levels, methacholine reactivity and response to dust mite bronchoprovocation.

However, it is also important to recognize that there have been several important negative studies of mite avoidance, especially when using a single intervention such as bedding encasements,[41–43] and that meta-analyses on the efficacy of mite avoidance have yielded conflicting results.[44–49] For example, in one study Woodcock and colleagues studied the efficacy of impermeable bed covers in over 1,100 adults with asthma and dust mite sensitivity.[47] While the impermeable covers resulted in significant decreases in mite allergen in mattress dust, asthma symptoms were not significantly reduced. These studies again point to the need for a comprehensive allergen reduction plan rather than relying on single interventions.

DUST MITE CONTROL MEASURES

Although a variety of approaches to dust mite control have been studied, there is still some controversy as to the specific measures that are necessary to reduce mite exposure sufficiently to control disease. This controversy arises for three major reasons. First, some environmental control measures have not been adequately studied to make any firm conclusions. Second, for some measures, studies of their efficacy have yielded conflicting results. Third, in many studies a combination of environmental control measures was used, making it difficult to determine which measures actually led to the benefit that was observed. Specific environmental control measures will therefore be reviewed individually. They are summarized in Box 22-1.

It is very clear that allergen-proof encasements for mattresses and pillows significantly reduce dust mite exposure.[1,38,48–50] In the study by Ehnert and colleagues,[38] polyurethane mattress encasements produced a 91% decrease in mite allergen by day 14 of treatment, which rose to 98% by month 12 of the study. Encasements of the mattress, pillows and box springs should therefore be recommended for all patients with mite sensitivity. In addition, although encasements had been constructed of impermeable plastic or vinyl materials that were very uncomfortable, they are now also available in tightly woven fabrics that are considerably more comfortable.[51]

The effects of vacuum cleaning on mite exposure have been studied. Live mites are difficult to remove from carpeting, and it is clear that vacuum cleaning in the absence of other measures will provide only limited benefit.[1] However, regular vacuum cleaning does remove significant amounts of dust from carpets, which will at least help to reduce the allergen reservoir. Patients should also be warned that vacuuming creates considerable disturbance, with transient increases in airborne mite levels. Vacuum cleaners equipped with special bags or HEPA filters help prevent this problem and may be of some added benefit.[52] There is some evidence that wet vacuum cleaning or steam cleaning may provide additional benefit,[53,54] although one study showed that wet vacuum cleaning led to a subsequent increase in mite numbers.[55]

A variety of carpet treatments, including acaricides such as benzyl benzoate and denaturing agents such as tannic acid, have also been developed in an effort to control dust mite allergen exposure. At best, both approaches provide only modest, short-lived effects and should not be recommended for routine use.[1,37,56,57]

Because of the limitations of both vacuuming and chemically treating carpets, carpet removal is always best when feasible, especially from the bedroom of the allergic person. Bed linens, stuffed animals and other soft furnishings also provide excellent environments for dust mite growth. Objects such as stuffed animals should be removed whenever possible. The mite content of bedding materials and other objects that cannot be removed can be reduced by washing. Washing in hot water (greater than 55°C) is ideal in that it both removes allergen and kills dust mites.[58] These water temperatures, however, may not be available in many homes due to safety concerns. It is important to note, therefore, that washing in cooler water does not kill mites but does remove most live mites as well as mite

BOX 22-1 ENVIRONMENTAL CONTROL OF HOUSE DUST MITES

FIRST LINE (NECESSARY AND COST EFFECTIVE)

- Encase mattresses and pillows
- Wash bed linens every 1 to 2 weeks, preferably in hot water
- Remove stuffed toys
- Regularly vacuum carpeted surfaces
- Regularly dust hard surfaces
- Reduce indoor relative humidity (dehumidify and do not add humidity)

SECOND LINE (HELPFUL BUT MORE EXPENSIVE)

- Remove carpets, especially in the bedroom
- Remove upholstered furniture
- Avoid living in basements

THIRD LINE (LIMITED OR UNPROVEN BENEFIT)

- Acaricides
- Tannic acid
- Air cleaners

https://CafePezeshki.IR

allergens very effectively. Weekly washing of all bed linens in a hot cycle is therefore recommended for all mite-allergic patients. Dry cleaning also kills dust mites,[59,60] as does tumble drying at temperatures greater than 55°C for at least 20 minutes.[48]

Dust mites are susceptible to the effects of low as well as high temperatures. Freezing in a typical household freezer for 24 hours will kill most dust mites, although the mite allergen in the object will not necessarily be reduced.[61] Exposing carpets to direct sunlight for several hours will also kill dust mites because of the high temperature, the low humidity or both.[62] It has also been shown that electric blankets will reduce mite growth.[4,63] None of these methods have been established in clinical trials.

Because of the reliance of dust mites on humidity for growth, it has been suggested that methods capable of reducing relative humidity would be useful in the control of mite exposure. Korsgaard and Iversen[64] demonstrated that dust mite growth could be significantly reduced by keeping indoor humidity below 7 g/kg by ventilation, whereas Arlian[65] demonstrated that mite growth could be prevented by maintaining relative humidity below 35% for at least 22 hours a day. Air conditioning and dehumidification may also help to deter mite growth and should be used whenever possible; humidifiers should be avoided.[66] It is clear, however, that achieving low humidity will be difficult or impossible in very humid environments. A prime example of this fact is the difficulty in eliminating dust mites from carpets over cement slab floors in basements.

Finally, air filtration devices are frequently purchased by patients for the control of their dust mite allergies; however, there is little evidence to support their use.[67–70] One would logically not anticipate much effect because of the fact that dust mite allergens do not remain airborne for extended periods and would therefore not be available for filtration in most instances.

In summary, effective dust mite control can be accomplished in most homes with a combination of mattress and pillow covers, hot washing of bed linens, removal of stuffed animals and other soft furnishings, and carpet removal.[1] Because of the convincing benefits provided through dust mite avoidance in mite-sensitive asthmatic patients, these measures should be routinely recommended, and compliance with these recommendations should be reassessed at each subsequent visit.

Animal Allergens

Animal allergens are also potent causes of both acute and chronic asthma and allergy symptoms.[4,71] Cat and dog allergens are the most important, although significant exposure to a wide variety of other furred animals is not uncommon. Sensitivity to cat and dog allergens is very common in asthmatic children, and in some settings these are clearly the dominant indoor allergens.[18,72,73] This fact was best demonstrated in a study conducted in Los Alamos, New Mexico.[18] In this environment, where cat and dog allergens are common but exposure to dust mite and cockroach allergens is rare, IgE antibody to cat and dog allergens was detected in 62% and 67% of asthmatic children, respectively. The presence of this IgE antibody was highly associated with asthma, whereas sensitivity to mite or cockroach allergen was not associated with asthma in this setting.

A number of studies have investigated the distribution of cat and dog allergens in the home and other environments.[4,18,73–76] Using settled dust analysis, it has been shown that levels of cat and dog allergens are clearly highest in homes housing these animals. However, it is also clear from a number of studies that the vast majority of homes contain cat and dog allergen even if a pet has never lived there. This widespread distribution of cat and dog allergens has also been documented in a variety of other settings, including office buildings and schools. Whereas most of the environments with no animals have relatively low allergen levels compared to those with a cat or dog, it is not uncommon to find rather high levels in some of these homes. This widespread distribution is presumed to occur primarily through passive transfer of allergen from one environment to another. The particles carrying animal allergens appear to be very sticky and, unlike dust mite allergens, can be found in high levels on walls and other surfaces within homes.[77]

The characteristics of airborne cat allergen have also been extensively studied. Cat allergen has been shown to be carried on particles that range from less than 1 μm to greater than 20 μm in mean aerodynamic diameter.[78,79] Although estimates have varied, studies agree that at least 15% of airborne cat allergen is carried on particles less than 5 μm. Dog allergen is distributed very much like cat allergen, with about 20% of airborne dog allergen being carried on particles less than 5 μm in diameter.[80]

Cat allergen can also be detected in air samples from all homes with cats and from many homes without cats.[81] In an attempt to determine the clinical significance of this unsuspected cat exposure, patients were challenged in an experimental cat exposure facility to varying levels of cat allergen.[81] It was found that allergen levels of less than 100 ng/m^3 were capable of inducing upper and lower respiratory symptoms as well as significant pulmonary function changes. These levels are similar to those found in homes with cats as well as a subset of homes without cats, suggesting that even patients without known cat exposure may be exposed to clinically significant concentrations of airborne cat allergen on a regular basis.

CONTROL OF ANIMAL ALLERGENS

At the present time much less is known about the control of animal allergens than about the control of dust mite allergens.[82] In particular, there are still very few studies on the clinical benefit of environmental control measures for animal allergens. Although it is assumed that removing an animal from the home will lead to clinical improvement in patients who have disease related to their pets, even this simple concept has undergone little investigation. One prospective study did evaluate patients with asthma who were sensitized to furry animals, with some choosing to find their pet a new home and others electing to keep it. After 1 year, there was a significant improvement in airway hyperresponsiveness and a reduction in inhaled corticosteroid use in the pet removal group compared with the pet keeping group.[83] Even fewer data are available regarding the potential benefits of methods that might be used in lieu of animal removal. The overall approach to the control of animal allergens is summarized in Box 22-2.

To begin, it should be stated that in any asthmatic patient who is known to be cat or dog sensitive and whose asthma is believed to be related to a significant degree to the pet, the most appropriate recommendation is to remove the pet from the home. This is clearly the correct advice from a medical standpoint, and it should be recommended strenuously. A number of potential alternative measures will also be discussed, however, because of the high proportion of patients who are either reluctant or completely unwilling to remove a household pet.

https://CafePezeshki.IR

BOX 22-2 ENVIRONMENTAL CONTROL OF ANIMAL ALLERGENS

Remove source (e.g. find a new home for the pet):
- Allergen levels fall slowly – benefit would not be expected for weeks to months.
- Follow by aggressive cleaning to remove reservoirs of allergen.
- Possible role for tannic acid to augment allergen removal.

If the pet is not removed:
- Install air cleaners, especially in the bedroom.
- Remove carpeting, especially in the bedroom.
- Encase mattresses and pillows.
- Wash animals (not likely to help unless done at least twice a week).
- These measures may not reduce allergen levels enough to help highly allergic patients.

Once a cat has been removed from the home, it is important to recognize that the clinical benefit may not be seen for a period of at least several months because allergen levels fall quite slowly after cat removal.[76] In most homes, levels of settled dust will have fallen to those seen in homes without cats within 4 to 6 months of cat removal. Levels may fall much more quickly if extensive environmental control measures are undertaken, such as removal of carpets, upholstered furniture and other reservoirs from the home, whereas in other homes the process may be considerably slower. This information points to the fact that thorough and repeated cleaning will be required once the animal has been removed. It has also been shown that cat allergen may persist in mattresses for years after a cat has been removed from a home,[84] so new bedding or impermeable encasements must therefore also be recommended.

A number of studies have investigated other measures that might help to reduce cat allergen exposure without removing the animal from the home. De Blay and colleagues[85] demonstrated significant reductions in airborne Fel d 1 with a combination of air filtration, cat washing, vacuum cleaning and removal of furnishings, although these results were based on a small sample size and did not include any measure of clinical effect. When cat washing was evaluated separately in that study, dramatic reductions in airborne Fel d 1 were seen afterward. Subsequent studies, however, have presented conflicting results. Klucka and colleagues[86] studied both cat washing and Allerpet/c (Allerpet, Inc., New York, New York) and found no benefit from either treatment. In addition, Avner and colleagues[87] studied three different methods of cat washing and found transient reductions in airborne cat allergens after each. There was no sustained benefit, however, with levels returning to baseline within 1 week of washing. Results regarding dog allergen are very similar to those with cat, suggesting the need to wash dogs at least twice a week to achieve any meaningful reduction in allergen exposure.[88]

Information is very limited as to the clinical benefits of these environmental control measures if one or more pets is allowed to remain in the home. Studies have evaluated different combinations of control measures, and although all have shown reductions in allergen levels, clinical effect was less consistent.[89–92] Two studies showed a clear benefit, one showed benefit only in the group in which environmental control was performed along with intranasal steroid treatment, and the fourth showed no clinical benefit whatsoever. It therefore still remains to be seen whether allergen exposure can be sufficiently reduced to produce a clinical effect in the absence of animal removal.

While the notion of hypoallergenic cats and dogs is increasingly popular, there are no studies confirming that any specific breeds are predictably less allergenic. Further, there is no evidence that the size, hair length, hair type or degree of shedding have any effects on indoor allergen levels or allergenicity.[4,93]

In families who insist on keeping their pets, the following should be recommended pending more definitive studies.[4] The animals should be restricted to one area of the home and certainly kept out of the patient's bedroom. HEPA or electrostatic air cleaners should be used, especially in the patient's bedroom. Carpets and other reservoirs for allergen collection should be removed whenever possible, again focussing on the patient's bedroom. Finally, mattress and pillow covers should be routinely used. Although tannic acid has been shown to reduce cat allergen levels, the effects are modest and short-lived when a cat is present, so this treatment should not be routinely recommended. Similarly, cat and dog washing appears to be of such transient benefit that it is only likely to add significantly to the other avoidance measures if it is done at least twice a week.

Cockroach Allergen

The importance of cockroach allergen in asthma and allergy has been recognized only over the past 30 years.[94,95] It is now clear that cockroach allergens play a major role in asthma, particularly in urban areas.[2,96] Significant cockroach exposure has been demonstrated in a number of cities, and the prevalence of cockroach sensitivity in urban patients with asthma has been shown to range from 23% to 60%.[15,97,98] In addition, cockroach exposure has been associated with higher rates of sensitization.[99] The combination of cockroach exposure and cockroach sensitization has been shown to be a risk factor for increased asthma morbidity and acute asthma exacerbations.[15,33,74]

In the first comprehensive study on the problem of asthma in inner city children, 1,528 children with asthma from eight major inner city areas were extensively investigated with regard to the factors, both allergic and otherwise, that contributed to their disease.[74] Although sensitivity to cockroaches, dust mites and cats were all common (36.8%, 36.9% and 22.7%, respectively), exposure to cockroach allergen was much more common than exposure to either dust mite or cat (50.2%, 9.7% and 12.8%, respectively). The combination of cockroach sensitivity and high cockroach exposure was associated with significantly more hospitalizations, unscheduled medical visits for asthma, days of wheezing, missed days from school, and nights with sleep loss because of asthma. Such a correlation was not seen for dust mite or cat allergens. These data argue persuasively that cockroach allergen is a major factor, if not *the* major factor, in the high degree of morbidity seen in this patient population.

Although there are at least 50 cockroach species in the USA, only four or five are domiciliary.[2,96] Two species, the German cockroach (*Blattella germanica*) and the American cockroach (*Periplaneta americana*), are the most common causes of both household infestation and allergic sensitization. Several allergens from each species have been identified and characterized.[100,101] The most important among these are Bla g 1, Bla g 2 and Per a 1. There is significant cross-reactivity between *B. germanica* and *P. americana,* although most patients in the USA are primarily sensitized to *B. germanica.* The source of the major cockroach allergens is still not completely clear, although

https://CafePezeshki.IR

they do appear to be secreted or excreted, suggesting that they may also be digestive proteins.

The distribution of cockroach allergens has been studied in a number of settings. The highest levels tend to be found in kitchens, although the allergen is widely distributed through the home, including the bedroom.[2,74,101] In fact, in the inner city asthma study noted above, the 50.2% exposure rate was found in bedroom dust samples.[74] It has been suggested that cockroach allergen levels of greater than 2 units per gram are associated with sensitization and levels greater than 8 units per gram are associated with disease activity.[74] Cockroach allergen has also been detected at significant concentrations in schools in urban Baltimore.[102] Finally, studies have shown that cockroach allergen is very much like dust mite allergen, with little or no measurable airborne allergen in the absence of significant disturbance.[96]

COCKROACH ALLERGEN CONTROL

Extensive study has been performed on the chemical control of cockroach infestation, and a variety of pesticides and traps are readily available. These include chlorpyrifos, diazinon, boric acid powder and bait stations that contain hydramethylnon. All of these agents, with the exception of boric acid, can reduce cockroach numbers by 90% or more, whereas boric acid reduces numbers by 40% to 50%. Several studies have shown that cockroach extermination is possible in most homes and that a combination of extermination and thorough cleaning can reduce cockroach allergen levels by 80% to 90%,[103–105] although studies to date have not convincingly demonstrated that cockroach eradication alone is capable of significantly reducing disease activity.[106–108]

In addition to these measures, integrated pest management also includes other strategies that help to reduce cockroach infestation including eliminating food sources and hiding and entry points (Box 22-3).[2,109] All foods should be stored in sealed containers and the kitchen should be cleaned regularly. Finally, extensive cleaning should be performed after extermination to remove the cockroach debris as completely as possible. Even with the most aggressive measures, however, it may be difficult to reduce cockroach exposure adequately in some environments. This is particularly true of the older, multiple dwelling units that house a preponderance of inner city residents. A more encouraging study related to inner city asthma did demonstrate a convincing benefit from a multifaceted, allergen-specific environmental control program in asthmatic children living in urban areas.[5] In that study, cockroach extermination was part of a global environmental treatment that also included education, a HEPA filtered vacuum cleaner, allergen-proof bedding encasings and a HEPA filter in the child's bedroom. Bla g 1 in floor dust was reduced by 53% compared to 19% in the control group but, more importantly, symptoms were also significantly reduced in the treated group. This trial supports the concept that integrated environmental avoidance strategies have the highest likelihood of producing beneficial clinical effects.

BOX 22-3 ENVIRONMENTAL CONTROL OF COCKROACH ALLERGEN

Regular and thorough extermination
Thorough cleaning after extermination
Extermination of neighboring dwellings
Roach traps
Repair leaky faucets and pipes
Repair holes in walls and other entry points
Behavioral changes to reduce food sources
- Clean immediately after cooking
- Clean dirty dishes immediately
- Avoid open food containers
- Avoid uncovered trash cans

Rodent Allergens

Mice and rats produce allergens, primarily urinary proteins, that have been shown to cause sensitization and disease in both occupational and home environments.[3] The widespread distribution of mouse allergen in home environments and its potential importance in asthma, especially in those living in inner cities, has recently been demonstrated in a number of studies.[110–116] In fact, mouse allergens are measurable in nearly all inner city homes and as many as 75% of suburban homes.[117–119] However, the levels in inner city homes are far higher, in fact 100 to 1,000-fold higher, in comparison to suburban homes.[120] With regard to effects on disease, mouse exposure has been associated with increased sensitization, poorer asthma control and increased healthcare utilization.[3,111–116] Even in adults, sensitization to mouse allergens has been shown to be associated with asthma and asthma morbidity.[121]

Although there are a number of ongoing trials, to date relatively little has been published on the effectiveness of environmental control for mouse allergen. Phipatanakul and colleagues did demonstrate a >75% reduction in mouse allergen exposure using an integrated pest management strategy that included filling holes with copper mesh, vacuuming, cleaning and baiting of traps with low-toxicity pesticides.[122] In another study, an integrated pest management intervention that was performed by study participants had less overall success because mouse allergen levels were only reduced by approximately 27%.[123] However, the subset of children whose homes had at least a 50% reduction in mouse allergen had fewer missed school days, reduced sleep disruption and reduced caretaker burden.

Based on these studies and general information about pest management, recommendations for mouse allergen control include professional extermination, thorough cleaning after extermination, keeping food and trash in covered containers, cleaning food scraps from the floor and countertops, and sealing cracks in the walls, doors and floors (Box 22-4).[3]

Mold Allergens

A wide variety of mold species can be present in both indoor and outdoor environments. *Aspergillus* and *Penicillium* species are generally regarded as the most numerous indoor molds,[60,101] whereas *Alternaria* is important in both indoor and outdoor environments. Several mold allergens, including Alt n 1 and Asp

BOX 22-4 ENVIRONMENTAL CONTROL OF RODENT ALLERGENS

Regular and thorough extermination
Thorough cleaning after extermination
Keep food and trash in covered containers
Seal cracks in walls, door and floors

https://CafePezeshki.IR

f 1, have been identified and characterized. Mold exposure has been associated with chronic asthma symptoms as well as with asthma exacerbations.[124–126]

Molds tend to grow best in warm, moist environments and mold exposure is therefore roughly correlated with these conditions. Basements, window sills, shower stalls and bathroom carpets are common sites of mold infestation. Air conditioners and humidifiers have also been shown to be sources of significant mold exposure.[127,128] The assessment of mold exposure has been improved by the development of immunoassays to measure major allergens, although for most molds one must still rely on culture and microscopic examination of air or dust samples. Airborne mold allergens have been shown to be carried on particles ranging in size from less than 2 μm to greater than 100 μm.[129]

The control of mold allergens requires a concerted approach combining fungicides, measures to reduce humidity and the removal of mold-infested items whenever possible[124] (Box 22-5). With more severe infestation, such as after flooding has occurred, professional remediation may be required. A variety of fungicides are commercially available that are highly effective as long as the sites of mold growth are carefully investigated. Any measures that can then be taken to reduce humidity should be recommended, including dehumidification, air conditioning, increased ventilation and a ban on the use of humidifiers and vaporizers. Moldy items, such as a basement carpet that has suffered water damage, should be removed altogether. Although no specific data are available, air filtration devices may also assist in reducing mold exposure; no clinical studies on the efficacy of mold avoidance measures have been undertaken.

Indoor Air Pollution

Although a detailed discussion of indoor air pollution is beyond the scope of this chapter, it should be emphasized that effective environmental control cannot be achieved without attention to a variety nonspecific irritants. The deleterious effects of passive cigarette smoke on pediatric asthma have been well documented in a number of studies.[130,131] No studies to date have assessed the clinical benefit of removal from a smoke-containing environment, but one would predict that this would have highly beneficial effects. In addition to passive cigarette smoke, a variety of other indoor pollutants, such as nitrous oxide, have been documented to exacerbate pediatric asthma, especially in inner city environments.[132,133] All patients must therefore be queried about these exposures and counseled about their control. Parents who are smokers and who have asthmatic children need to be reminded at each visit about the ongoing damage that they are causing.

BOX 22-5 ENVIRONMENTAL CONTROL OF MOLD ALLERGENS

- Identify sites/sources of mold growth
- Clean moldy areas with a fungicide
- If cleaning is not possible, discard moldy items (e.g. carpets, furniture)
- Dehumidify
- Repair leaks and maximize drainage
- Run vent in bathroom and kitchen
- Clean refrigerator, dehumidifier and humidifier with fungicide

Outdoor Allergens

There is far less ability to control exposure to outdoor allergens than indoor allergens. Source control is rarely an option because the airborne pollens and molds travel so widely. Local mold control may be accomplished by ensuring good drainage, removing leaves and other debris as they accumulate, and limiting the use of mulch and other ground cover that might support mold growth. Otherwise, exposure may be reduced by staying indoors when pollen and mold counts are high, as long as windows and doors are kept closed. An air filter may help to reduce exposure, especially if windows are being left open; some activities, such as lawn mowing or plowing, may need to be avoided altogether. After being outside, it is important that allergic individuals wash their hands and faces immediately and that they wash their hair daily. When outside, masks and goggles can be very effective but very few children and adolescents are willing to wear them.

Conclusions

Indoor allergens are of tremendous importance to pediatric allergic disease. Exposure is a risk factor for the development of asthma as well as for more severe disease. Thankfully, there are measures that can help to reduce exposure to most allergens, significantly reducing symptoms and medication requirements. The guidelines for the management of asthma that were originally published in 1997 and most recently revised in 2007[134] have consistently stressed the importance of indoor allergens and environmental control, stating that for any patient with persistent asthma the clinician should: (1) identify allergen exposures; (2) use skin testing or in vitro testing to assess specific sensitivities to indoor allergens; and (3) implement environmental controls to reduce exposure to relevant allergens. With all the time, effort and money put forth for the use of medications and immunotherapy for asthma and allergic rhinitis, it is very important that we do not lose sight of this logical and important recommendation.

23 Immunotherapy for Allergic Disease

ELIZABETH C. MATSUI | PEYTON A. EGGLESTON

KEY POINTS

- Subcutaneous immunotherapy is an effective treatment for pediatric patients with allergic rhinitis and stinging insect hypersensitivity, and selected pediatric patients with allergic asthma.
- Sublingual immunotherapy is an approved and effective treatment for seasonal allergic rhinitis due to grass and ragweed pollen allergy.
- There is a small but real risk of systemic allergic reactions with immunotherapy, and the risk associated with subcutaneous immunotherapy appears to be greater than that for sublingual immunotherapy.
- Immunotherapy is associated with changes in humoral and cellular immune responses as well as effector cell responsiveness.
- Oral immunotherapy for food allergy is an active area of investigation.

In 1911, Noon[1] found that by administering increasing doses of grass pollen extract, he could induce a marked decrease in conjunctival sensitivity to grass pollen. It was this observation that eventually led to the widespread use of immunotherapy for the treatment of allergic disease.[1] *Immunotherapy* is the term used to describe a prolonged process of repeated administration of extracts of pollens or other allergen sources to patients with diseases with a demonstrable allergic etiology for the purpose of reducing symptoms. It has also been called *desensitization* or *allergy injection therapy.* It is recommended in most discussions of the treatment of allergic airway disease, along with allergen avoidance and symptomatic drug therapy.

Principles of Immunotherapy

In allergic rhinitis (AR), the effectiveness of immunotherapy has been demonstrated in many carefully conducted placebo-controlled trials. The results of a typical clinical trial are shown in Figure 23-1.[2] Three groups of patients matched on the basis of their allergic sensitivity to ragweed allergen were treated with injections of whole ragweed pollen extracts, purified Antigen E (Amb a 1) or placebo. Although everyone became symptomatic during the ragweed pollen season, it is obvious that those receiving placebo injections were more symptomatic than those receiving pollen extracts. These trials have been reviewed in detail elsewhere[3] and are addressed here only to review the principles learned for the safe and effective use of immunotherapy.

The first principle is that clinical effectiveness is dose dependent; that is, a certain minimal dose of allergen extract must be administered to produce effective symptomatic control.[4] These extracts are prepared by suspending source material (pollen, fungal cultures, dust mites or animal pelts) in buffers to extract the water-soluble components into the buffer, and they are now available commercially under license by the US Food and Drug Administration (FDA). Extracts are complex mixtures of dozens of proteins, of which only a few are major allergens. Clinical trials that compare treatment with purified allergens or with partially purified extracts containing high concentrations of allergens with treatment with currently available crude extracts have shown them to be equally effective. For instance, symptoms are reduced to a similar extent with immunotherapy with purified ragweed allergen Amb a 1 and with whole ragweed extract in the study illustrated in Figure 23-1.

Another lesson from these studies is that therapeutic effectiveness of conventional immunotherapy increases with time. Significant improvement is generally not seen before 3 months or more of therapy.[5] It is not clear why such a long time is needed, but in part it reflects the time required to increase the injected dose from the very small dose that can be tolerated initially to the 10,000-fold higher dose that produces immunologic and clinical effects. It is also obvious that immunologic effects must be taking place very early in this process to allow the patient to tolerate increasing doses without anaphylaxis. Clinical benefit increases for several years after the maximal doses of antigens are achieved. Although the reason for the delayed effect of immunotherapy is not clear, it is important to discuss with patients so that their expectations will be realistic. It is important to note, however, that single dose sublingual immunotherapy, which has recently been approved in the United States for grass and ragweed allergy, has a more rapid onset of action, likely because no build-up phase is required, and is efficacious when given only part of the year, prior to and during the relevant pollen season.

In clinical trials when symptom scores are compared with those in untreated patients, a placebo effect is consistently seen. This placebo effect is especially easy to see in the asthma trials, in which most placebo-treated patients improve and 25–30% improve significantly.[5] For clinical investigators, this fact has made it absolutely essential to include a placebo group in any immunotherapy trial. For clinicians, it is important to recognize that there is a significant and powerful placebo effect associated with the repeated injections and frequent visits with sympathetic physicians and nurses. Only by administering concentrated antigen preparations to carefully selected patients are the benefits greater than those seen with sympathetic support.

For most patients, symptomatic improvement is partial and immunotherapy serves to decrease the severity of symptoms without totally eliminating them. In addition, a significant number of allergic patients, perhaps as many as 25%, do not benefit from IT regardless of the potency of the antigen or the length of therapy. The reasons why certain patients are 'nonresponders' are unclear, but the point is an important one to bear in mind when discussing immunotherapy with patients.

In clinical trials, systemic anaphylactic reactions are common. Although these are usually mild and not life threatening, they

https://CafePezeshki.IR

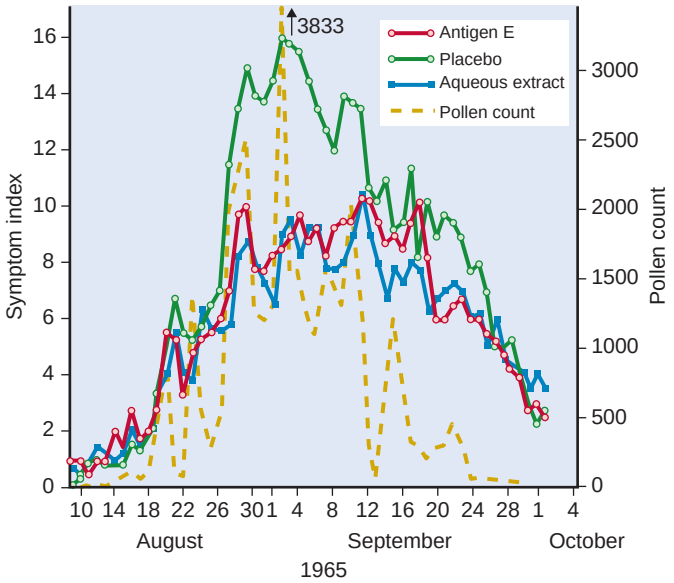

Figure 23-1 Typical result of an immunotherapy trial in patients allergic to ragweed pollen. *(From Norman PS, Winkenwerder WL, Lichtenstein LM, et al. J Allergy Clin Immunol 1968;42:93–108.)*

may require epinephrine therapy and may be fatal. Such reactions are not surprising because patients are selected who are clearly allergic on the basis of skin tests and/or specific immunoglobulin E (IgE) tests and history of severe symptoms on allergen exposure. In a recent large clinical survey, one fatality out of 23.3 million injection visits was identified, approximately one out of every 1 million injections resulted in a very severe, near-fatal reaction, and one out of every 1000 injections resulted in a systemic reaction.[6]

Research in immunotherapy continues in several directions. Standardization of allergen extracts to make available products with consistent potency has dramatically increased the reliability of commercially available extracts. Studies have demonstrated the safety and efficacy of shortening the dose escalation phase with schedules for rush and ultrarush immunotherapy. Investigators have also been studying adjuvants to improve efficacy of immunotherapy as well as modified allergens to reduce the risk of serious reactions to immunotherapy. Other routes of administering allergen extracts are also being studied, as well as the use of immunotherapy for other allergic diseases such as eczema[7] and food allergy.[8] Finally, immunomodulatory therapies are currently in clinical trials; these include agents such as anti-IgE and anticytokine therapies.

Mechanisms of Action

Many observations about patients' immunologic and cellular responses to immunotherapy have been made, but the precise mechanism of action of immunotherapy remains unknown. What is generally recognized is that skin test sensitivity decreases and allergen-specific IgG increases with immunotherapy.[9] It is not until after several years of immunotherapy that allergen-specific IgE decreases.[10] There has also been much speculation that immunotherapy acts on the T helper cell type 1 (Th1)/Th2 axis to shift the T cell phenotype away from the allergic Th2 phenotype. More recently, a growing body of evidence suggests that immunotherapy may promote regulatory T cells which may play a role in attenuating allergic symptoms.[11]

ANTIBODY RESPONSE AND IMMUNOTHERAPY

Studies have consistently demonstrated an increase in allergen-specific IgG and IgE within months of starting immunotherapy. One trial of ragweed immunotherapy in adults that examined allergen-specific antibody responses can be seen in Figure 23-2. Subjects demonstrated significant dose-dependent increases in ragweed-specific IgG long before symptom relief was seen. Ragweed-specific IgE initially increased and did not decrease until years into therapy.[10] Similar observations have been made by other investigators for both venom immunotherapy and inhalant allergen immunotherapy. It has been suggested that allergen-specific IgG acts as blocking antibody either by blocking antigen binding by IgE or by preventing aggregation of the high-affinity IgE receptor (FcεRI) at the cell surface. Although allergen-specific IgG levels do not correlate with clinical efficacy, the functional blocking activity of allergen-specific IgG does appear to correlate with clinical efficacy.[11]

Effects on T Cells

Because a Th2 phenotype has been associated with allergic disease and a Th1 phenotype with protection against allergic disease, it has been hypothesized that immunotherapy exerts its effects through modulation of the T helper phenotype. This modulation may result in either a shift from the Th2 to Th1 phenotype or through induction of $CD8^+$ suppressor activity. Indeed, evidence has been published in support of both of these hypotheses. Rocklin and colleagues[12] demonstrated the generation of allergen-specific suppressor cells during immunotherapy and provided evidence that the suppressor cells decrease IgE synthesis. Other studies have examined the cytokine profile of peripheral blood Th2 cells and demonstrated decreases in interleukin (IL)-4 production and, in some cases, concomitant increases in interferon (IFN)-γ production,[11,13] suggesting a modulation of the T helper phenotype from Th2 to Th1. The mechanism of these changes has recently advanced with the recognition of $CD4^+CD25^+$ regulatory T cells that are capable of directing the Th1:Th2 balance and are activated by effective immunotherapy, as well as the more recent recognition of a role for regulatory B cells.[11,14]

EFFECTS ON INFLAMMATORY CELLS

There also is evidence that immunotherapy affects mast cells, basophils and eosinophils. In the first few weeks of immunotherapy, it has been shown that the in vitro basophil response to allergen decreases sharply, just as it does during rapid desensitization regimens for patients with drug allergy.[14] One study demonstrated a significant decrease in metachromatic cells (mast cells and basophils) in nasal scrapings after dust mite immunotherapy.[15] Allergen-specific immunotherapy has also been demonstrated to decrease peripheral blood basophil histamine release.[16] In addition, successful immunotherapy has been associated with a decrease in the numbers of eosinophils from nasal and bronchial specimens.[17–19]

Specific disease indications

ALLERGIC RHINITIS

Immunotherapy has been demonstrated to be quite effective in both seasonal and perennial AR. Many well-designed studies have examined the efficacy of immunotherapy for pollen-

https://CafePezeshki.IR

J Allergy Clin Immunol 1984;73:94–104.)*

allergic patients with seasonal AR.[11,20,21] These randomized, controlled trials have been the subject of a meta-analysis which demonstrated significant symptom relief and reduction of medication requirements.[22] Immunotherapy has also been shown to be effective for mite-induced perennial AR[23] and may also be effective in mold-induced rhinitis.[24] The duration of treatment is generally 3 to 5 years, and symptomatic improvement continues for years after discontinuation.

ASTHMA

Many studies in the past decade have examined the efficacy of immunotherapy for allergic asthma.[9,25–28] Certainly, allergic sensitization and subsequent allergen exposure contribute significantly to asthma morbidity in children, making immunotherapy an appealing option for children with allergic asthma. However, IgE-mediated mechanisms are only part of the underlying pathophysiology of asthma, making the rationale for immunotherapy as a treatment option in allergic asthma less straightforward.

Results of clinical trials examining the efficacy of immunotherapy in allergic asthma have been conflicting. To complicate matters further, many studies have not included placebo arms, making it difficult to draw any conclusions about efficacy from those studies. Abramson and colleagues[29] conducted a meta-analysis of randomized, controlled trials for immunotherapy in asthma. Eighty-eight trials met inclusion criteria of being double blind, randomized and placebo controlled. After analysis of the combined results from these trials, immunotherapy was found to reduce bronchial hyperreactivity and medication use and to improve asthma symptoms. There was no clear effect of immunotherapy on pulmonary function.

A comprehensive review also concluded that immunotherapy is effective in the treatment of asthma but in carefully selected circumstances.[30] The authors concluded that immunotherapy is effective in grass pollen asthma but that results from studies for ragweed asthma were inconclusive. In addition, mite immunotherapy with standardized extracts was effective in reducing symptoms and increasing the threshold dose of mite extract needed to induce bronchial obstruction in bronchial challenges. The authors also make the point that children receiving mite immunotherapy benefited to a greater extent than adults, and a recent study demonstrated that mite immunotherapy had a steroid-sparing effect in children with asthma.[31]

Immunotherapy for animal-induced asthma has been more controversial. Some proponents of immunotherapy believe that there is a role for animal immunotherapy in the treatment of asthmatic patients who live with pets, but consensus statements from respected international organizations maintain that allergen avoidance is first-line therapy for these patients.[32] There have been carefully conducted, placebo-controlled trials demonstrating the efficacy of specific immunotherapy for cat asthma.[27,33] Studies have demonstrated a decrease in the quantitative airway responsiveness to cat allergen and decreased skin test reactivity in those treated with cat immunotherapy, but studies examining improvement in clinical symptoms have been inconclusive.

Clinical trials evaluating mold immunotherapy for asthma have been published for *Alternaria* and *Cladosporium*. One of the *Cladosporium* trials was conducted in children and demonstrated a decrease in allergen sensitivity on inhalation challenge, but did not provide good evidence of a decrease in symptoms or medication use.[24] Some studies evaluating *Alternaria* immunotherapy have demonstrated an improvement in asthma symptoms and a decrease in medication use.[34] Although there is evidence to support the addition of certain mold extracts to an immunotherapy prescription, more data are needed before any firm conclusions can be made about immunotherapy in mold asthma.

Although many studies support a role for immunotherapy in the treatment of allergic asthma, there have been some studies that have not demonstrated the efficacy of immunotherapy for asthma. One of these was a well-conducted, placebo-controlled trial of immunotherapy for children with allergic asthma, and the investigators found little evidence to support the efficacy of polyvalent (i.e. a mixture of extracts of various allergens) immunotherapy.[9] Both the active treatment and placebo groups had a reduction in medication use and improvement in PD_{20} FEV_1, and the outcomes in the treatment group were not statistically significantly better than those in the

https://CafePezeshki.IR

placebo group. Despite the negative results of this well-conducted study, many other published studies have demonstrated the efficacy of immunotherapy for allergic asthma. One of the major differences in this trial is that multiple allergen extracts were included in the injections. Although this is the usual approach to immunotherapy for allergic asthma in the USA, European standards require therapy with a single allergen extract (e.g. dust mite, cat, *Alternaria*), and this trial is the only one dealing with polyvalent immunotherapy. It is possible that this approach differs in some important way from immunotherapy with single-allergen extracts.

STINGING INSECT

Immunotherapy for venom allergy is highly efficacious, affording protection for more than 95% of individuals undergoing treatment.[35] Although venom immunotherapy is indicated in adults with evidence of IgE to Hymenoptera venom and a history of a systemic reaction to Hymenoptera, the indications in children are somewhat different. Studies of the natural history of venom allergy in children indicate that the risk of a serious reaction from a subsequent sting for a child with a history of a cutaneous systemic reaction is small. There is an approximately 10% incidence of subsequent systemic reactions in this patient population and a 0.4% incidence of more severe reactions involving the respiratory and cardiovascular systems.[36] In light of these findings, venom immunotherapy has been reserved for those children who have had 'life-threatening' reactions to Hymenoptera as well as evidence of IgE to Hymenoptera venom (see also Chapter 57).

FOOD

Although oral and sublingual immunotherapy are not currently recommended treatments for food allergy, they are being actively investigated. Subcutaneous immunotherapy for foods has proved far too risky to pursue as a treatment option. More recently, several randomized controlled trials of oral immunotherapy (OIT) for several foods, including egg, milk, and peanut have been completed, and although their results have indicated that OIT is a promising treatment for IgE-mediated food allergy, there are some significant limitations that must be addressed before it can be recommended as a treatment.[8] First, reactions are common and unpredictable, so methods for reducing and predicting risk are needed. Second, only approximately 30% of children on active treatment achieve sustained unresponsiveness, meaning that they can tolerate a full serving of the food after stopping OIT for a period of time, typically 1–6 weeks. The remaining children have therefore lost their desensitization, indicating that it was dependent on continued doses of OIT. A more detailed discussion of immunotherapy for food allergy can be found in Chapter 49.

Practical Considerations

PATIENT SELECTION

Allergic Rhinitis

Immunotherapy should be considered for patients with clear evidence of IgE-mediated symptoms who have not been adequately controlled with first-line medical therapy, including antihistamines, nasal corticosteroids and ocular antihistamines or antiinflammatory medications. Other aspects of the patient's history should be taken into consideration. For example, successful immunotherapy requires that a patient be able to visit a physician's office weekly and spend a minimum of 30 minutes there. Certain medications, such as beta blockers, put a patient at higher risk for systemic reactions to immunotherapy.

Asthma

Although some of the same principles of patient selection apply, immunotherapy for asthma deserves separate commentary. As in AR, patients must have demonstrable IgE to allergens to which they are exposed and the clinical history should be consistent with exacerbation of asthma symptoms with exposure to the allergens. A patient's ability to visit a medical facility weekly, as well as his or her medications and age, should be taken into consideration. Immunotherapy may be appropriate for treating asthma that has been difficult to control, but it should not be prescribed for patients with unstable asthma and an FEV_1 less than 70% of predicted, so it may be least appropriate for patients who continue to have clinical symptoms of asthma despite maximal medical therapy.

ALLERGEN EXTRACTS

Allergen Extracts for Immunotherapy

Allergen extracts are prepared by extracting bulk source materials (e.g. pollens, mite cultures, fungal cultures) in aqueous buffers; typically the potency of these extracts is expressed in a ratio of the weight of source material extracted to the extraction volume, such as 1:10 wt/v. Variations in the bulk sources and in the manufacturing process have led to vast differences in the quantity of active allergens in these extracts.[37] A second approach to labeling is based on the total protein content of the extract and is expressed in protein nitrogen units (PNUs); this method has little relationship to allergenic potency but is still commonly used in the USA. Efforts to standardize extracts in Europe and the USA have produced fundamentally different approaches. One approach measures the content of the major allergen or allergens in the mixture using crossed immunoelectrophoresis, immunodiffusion, RAST inhibition or enzyme-linked immunosorbent assay. Another approach compares the biologic activity of the material with the diameter of a control intradermal injection of histamine and expresses this as a BU (biologic unit). The FDA uses a slightly different approach to establish a BU, in which the flare diameter of reference extract in a select group of allergic volunteers is compared with a reference extract, and expresses the result in allergen units (AU) or bioequivalent allergen units (BAU). The results are somewhat confusing, and most commercially available extracts are labeled with more than one method to try to simplify administration of the materials. Studies that have established guidelines for effective maintenance doses for particular allergens report these doses in micrograms of major allergen, but translating wt/v, PNU, BU, AU or BAU into microgram doses can be difficult. Fortunately, some products have also been standardized by the major allergen concentration expressed as micrograms per milliliter (μg/mL). There are also some data translating allergen content into micrograms of major allergen; this information may be helpful in guiding dosing decisions. Table 23-1 is adapted from a recent comparison of labeling methods.[38] Where they are available, standardized extracts should always be used for therapy.

https://CafePezeshki.IR

TABLE 23-1 Major Allergen Content of Extracts

Source	Label	Allergen	N	Mean (μg)	Maximum (μg)	Minimum (μg)
Orchard grass	100,000 BAU/mL	Dac g 5	14	918	2414	294
Short ragweed	1 : 10 wt/v	Amb a 1	13	268	458	87
D. farinae	10,000 AU/mL	Der f 1	18	44	72	30

Modified from Nelson HS. J Allergy Clin Immunol 2000;106:41–5.

Storage

Some loss of potency is usual over time; therefore, manufactured extracts are supplied with expiration dates. These expiration dates are based on the assumption that the extracts will be refrigerated because loss of activity is more rapid at temperatures above 5°C. Loss of potency is faster in more diluted solutions, but it can be decreased by the addition of 50% glycerol or 0.03% human serum albumin. Because glycerol is irritating, most allergen solutions are diluted in albumin-containing buffers. Fungal, dust mite and cockroach extracts have been found to have significant protease activity[39] and therefore may accelerate the deterioration of allergen solutions. Some experts recommend that when making up immunotherapy solutions, dust mite, cockroach and fungal extracts should be placed in vials separate from other allergen extracts that do not contain protease activity.

Injection Regimens

A prescription for immunotherapy should reflect the patient's demonstrated specific IgE-mediated sensitization, as well as the clinical history of symptoms on exposure and other medical illnesses. The decision is a complex one and should be made by a trained allergist rather than a manufacturer or testing service. Typically, a prescription is written for a treatment set, with one vial containing a 1:10 dilution of concentrated material from a manufacturer and three or four other vials containing 10-fold dilutions (i.e. 1:100, 1:1000, etc.). Each vial of the set should be clearly labeled with the patient's name, the allergens contained in the vial, the dilution and an expiration date.

Administration and Dosing

Dosing instructions are shown in Table 23-2, modified from Nelson. The principle is that a dose is administered that is 10-fold smaller than the dose that will induce a positive skin test; then increasing doses are administered weekly until a dose 1000 to 10,000 times greater is tolerated (Table 23-2). Once the maximum dose is reached (0.5 mL of the 1:10 dilution in Table 23-2), the patient continues to receive this dose every other week for the first year. Generally, it takes 6 months of weekly doses to reach the maintenance dose. Alternative dosing schedules have been proposed in which the build-up doses are administered every 20 to 30 minutes (rush immunotherapy) or 2 or 3 times a week (cluster immunotherapy). These regimens allow a patient to reach the maintenance dose in a shorter period of time, but each has a greater risk of allergic reactions to the injections.

Duration of Immunotherapy

Once maintenance doses have been reached, these are generally continued for 3 years or longer. If a patient is able to tolerate two sequential pollen seasons with minimal symptoms or none at all, they are able to stop immunotherapy without a relapse for up to 3 years. Although this has been shown in adult clinical trials,[11] it is likely to be true for children as well. Duration of treatment for asthma is less clear.

TABLE 23-2 Allergen Extract Prescription

Begin with vial A and progress to vial D, which is the most concentrated, or 'maintenance', solution. Injections should be administered subcutaneously every week until the highest maintenance dose is administered, 0.5 mL of vial D. Then repeat this dose every other week for the next year. After the first year, maintenance doses can be given every 3 to 4 weeks.

- Call the center before resuming treatment if the treatment has lapsed by 4 weeks or more.
- During the build-up phase, repeat a dose if the last dose produced local swelling of more than 3 cm in diameter (the size of a silver dollar) or if treatment lapses for 1 to 2 weeks.
- Drop back 2-fold (i.e. from 0.4 to 0.2 mL) if the previous dose has produced local swelling of 5 cm or more in diameter, if a mild systemic reaction occurs, or if treatment lapses for more than 2 weeks.
- Drop back 4-fold (i.e. from 0.4 to 0.1 mL) if a systemic reaction occurs.
- The patient should remain for observation for 30 minutes after each injection.

Vial A (1 : 10,000)	Vial B (1 : 1000)	Vial C (1 : 100)	Vial D (1 : 10)
0.05 mL	0.05 mL	0.05 mL	0.05 mL
0.10 mL	0.10 mL	0.10 mL	0.07 mL
0.20 mL	0.20 mL	0.20 mL	0.10 mL
0.40 mL	0.40 mL	0.40 mL	0.15 mL 0.20 mL 0.30 mL 0.50 mL

Modified from Nelson HS. Immunotherapy for inhalant allergens. In: Adkinson NF Jr, Busse WW, Bochner BS, editors. Middleton's allergy: principles and practice. 7th ed. St Louis: Mosby; 2008.

Reactions to Immunotherapy

The risks of immunotherapy are not trivial. Clinical surveys from the 1980s reported that 3% to 7% of patients experience systemic reactions and that one reaction occurs for every 250 to 1600 injections.[40] The American Academy of Asthma, Allergy, and Immunology and the American College of Asthma, Allergy, and Immunology initiated a surveillance program of immunotherapy reactions in 2008, and the most recent results indicate a rate of 1 in 1 million injections for near-fatal reactions and 1 in 1000 injections for systemic reactions.[6] Reactions may be limited to urticaria, but 40% to 73% include respiratory reactions and almost 10% include hypotension; fatal reactions occur in 1 per 2 to 3 million injections.[41] From 70% to 90% of

Injectable and oral diphenhydramine
Intravenous corticosteroids
Injectable vasopressor

reactions begin within the first 30 minutes of an injection. The risk of reactions is greater during the build-up phase, but about half of the reactions occur during maintenance therapy. Reactions are more common in adolescents and young adults and possibly during pollen or mold seasons. Other risk factors for serious systemic reactions include severe asthma, age of less than 5 years and use of a beta blocker.[42] For these reasons, injections should be given in a medical facility and by personnel who know how to recognize and treat a local and systemic reaction to allergenic extract and who are trained in basic cardiopulmonary resuscitation. Resuscitation equipment should be available (minimal equipment is summarized in Box 23-1). Patients should remain in the facility for 30 minutes after an injection and should report immediately if a reaction begins. Injections should not be administered at home.

Future Directions

ALLERGOIDS AND ADJUVANTS

Allergoids are produced by chemically modifying or denaturing native allergens. The goal is to retain the ability of the allergen to elicit an immunologic response (specifically a T cell response) while decreasing the risk of anaphylaxis (the IgE-mediated response). Various chemical agents have been used, including urea, glutaraldehyde and polyethylene glycol. Although some of these agents have appeared promising, the inability to standardize the process of chemical modification has made this approach impractical. Adjuvants are used with the allergen extract to boost immunologic response to immunotherapy in hopes of increasing its efficacy. Substances such as alum, tyrosine absorbate and Freund's adjuvant have been used with the rationale that they have the ability to boost Th1-type immune responses, and more recently there has been interest in using innate immune stimulants such as TLR2, TLR4 and TLR9 ligands as adjuvants.

PEPTIDES AND RECOMBINANT ALLERGENS

As more is discovered about T cell epitopes, peptides of major allergens can be produced and used as a means of decreasing the risk of IgE-mediated reactions while retaining immunologic potency. In fact, fragments of both the dust mite allergens Der p 1 and Der f 1 and the cat allergen Fel d 1 were found to contain epitopes that were capable of inducing tolerance in mice.[43] This led to clinical trials that showed that injections of mixtures of small synthetic peptides containing the Fel d 1 epitope modified T cell responsiveness in allergic patients and decreased symptoms on exposure to cats.[44] The effects were modest, but other groups have improved on some of the immunologic and technical limitations of this prototype peptide vaccine and have begun to study the effect of the new formulation on cat allergy.[45]

IMMUNE MODULATORS

Many immune modulators are being actively investigated as therapeutic strategies for allergic disease; these include treatment strategies aimed at IgE as well as those aimed at cytokines. Two such therapies that have made it to human trials are an anti-IgE humanized monoclonal antibody and a humanized monoclonal antibody to IL-5. Anti-IgE was evaluated as a treatment for allergic asthma and AR starting in the 1990s. Milgrom and colleagues[46] conducted a randomized, placebo-controlled trial of anti-IgE in adolescent and adult patients with moderate to severe allergic asthma. Symptom scores in the active treatment groups were improved compared with the placebo arm, but perhaps the most striking result was the steroid-sparing effect of anti-IgE. Anti-IgE has also been shown to be effective in reducing the symptoms of seasonal AR in adolescents and adults with ragweed allergy.[47] One randomized, double-blinded study in children and adolescents examined its therapeutic value in seasonal AR when added to immunotherapy. Those subjects receiving anti-IgE in addition to specific immunotherapy had significant reduction in symptoms compared with those receiving immunotherapy alone.[48] The currently available anti-IgE medication, omalizumab, is approved for use in patients 12 years and older with sensitization to a perennial aeroallergen and moderate to severe persistent asthma.

Monoclonal anti-IL-5 has been demonstrated in a placebo-controlled trial to significantly reduce peripheral and sputum eosinophilia without affecting the early- or late-phase responses with inhaled allergen challenges.[49] Despite serious methodologic concerns regarding this study,[50] it has tempered enthusiasm for anti-IL-5 therapy. Recent studies in a rare form of adult-onset asthma characterized by persistent eosinophilia, despite systemic corticosteroid therapy, have demonstrated significant benefit in terms of reduced exacerbations and steroid requirement.[51] Antagonists to IL-4, IL-13, thymic stromal lymphopoietin (TSLP), TNF-α, and IL-17 are also in various stages of development.[52,53]

ALTERNATIVE ROUTES OF ADMINISTRATION

Interest in sublingual swallow immunotherapy (SLIT) began in Europe as a method to reduce the risk of serious allergic reactions to therapy. Since then, many clinical trials have examined efficacy and safety, and the results of these trials have been examined in recent meta-analyses. In adults with allergic rhinitis, 49 high quality randomized clinical trials were identified and demonstrated a significant reduction in symptoms ($P < .0001$) and medication requirements ($P = .0001$).[54] In children with asthma, nine high quality trials were examined and the reduction in symptoms and medication requirements was significant, although less consistent than that seen in adults.[55,56] Dose requirements of relevant aeroallergens are now better defined and an order of magnitude larger than those used for injection immunotherapy. Successful studies using these doses produce symptomatic changes and immunologic changes

https://CafePezeshki.IR

similar to those seen with injection immunotherapy. Systemic reactions are uncommon, but local (oral and gastrointestinal) reactions are common. SLIT for grass pollen and ragweed for patients with allergic rhinitis has been approved by the FDA for use in the US and data on perennial allergen SLIT are emerging. The ragweed formulation is only approved for adults and the two grass pollen formulations are approved down to ages 5 and 10 years, respectively. SLIT products generally contain either a single dose of allergen or two doses of allergen, so there is little to no build-up phase, and they can be used prior to and during the relevant pollen season. Contraindications include severe, unstable or uncontrolled asthma, eosinophilic esophagitis, a history of a severe allergic reaction or any severe local reaction to sublingual allergen immunotherapy, and hypersensitivity to any of the inactive ingredients. Patients should take the first dose in a medical setting and be observed for 30 minutes and have auto-injectable epinephrine available for subsequent home doses. Other routes under study include intralymphatic and epicutaneous immunotherapy.

IMMUNOTHERAPY AS PREVENTION

Immunotherapy has traditionally been used as a therapeutic intervention rather than a preventive one. However, some evidence suggests that specific immunotherapy may have a future role in the secondary prevention of allergic diseases. The Preventative Allergy Treatment Study is a European multicenter, randomized trial of specific immunotherapy for seasonal AR. Among those children without asthma, those who had received 3 years of immunotherapy had significantly fewer asthma symptoms than those in the open control group.[57] The children who had received immunotherapy continued to be at lower risk for asthma 10 years after initiation of treatment.[58] In addition, a study evaluating dust mite immunotherapy in monosensitized children demonstrated a decreased risk of the development of additional sensitizations in the active treatment group compared with the control group.[59] The evidence is preliminary, but there is a suggestion that immunologic intervention at an early stage of immune development may alter the natural progression of the allergic phenotype.

Conclusions

Immunotherapy is an effective treatment option for pediatric patients with stinging insect hypersensitivity and AR (Box 23-2). It is also effective in selected patients with asthma. There is a small but definite risk of systemic allergic reactions; therefore facilities administering immunotherapy should be adequately prepared to handle such an event and patients should remain in the medical facility for 30 minutes after receiving the injection (Box 23-3).

Immunotherapy may act to suppress allergic symptoms through modification of antibody responses, lymphocyte responses or target cell responses to allergen. Studies are under way to determine whether modifications of immunotherapy reagents or dosing route will improve its efficacy or reduce side-effects. Immunotherapy is also being pursued as a treatment option for food allergy, and there is some evidence to suggest that immunotherapy may alter the natural progression of sensitization.

BOX 23-2 KEY CONCEPTS

Principles of Immunotherapy

- Efficacy is dose dependent.
- Clinical effectiveness occurs after maintenance doses are reached.
- There is a significant placebo effect.
- Approximately 75% of patients respond.
- A major risk is systemic reaction.

BOX 23-3 THERAPEUTIC PRINCIPLES

Clinical Principles of Allergen Immunotherapy

- Immunotherapy is effective only in IgE-mediated diseases such as stinging insect anaphylaxis, allergic rhinitis and asthma.
- Patients should be selected who have demonstrated specific IgE and in whom medical management has not adequately controlled disease.
- Successful therapy requires that maximal tolerated doses of allergen extracts be given and requires months to years to reach maximal benefit.
- Because of the risk of anaphylaxis during therapy, injections should be administered in a physician's office or other medical facility that can support cardiorespiratory resuscitation. Patients should be observed for 30 minutes after an injection is administered.

24 Allergic Rhinitis

DEBORAH A. GENTILE | NICOLE PLESKOVIC | ASHTON BARTHOLOW | DAVID P. SKONER

KEY POINTS

- There are many different causes of rhinitis in children and 50% of all cases of rhinitis are caused by allergy.
- On the basis of timing and duration of allergen exposure, allergic rhinitis is classified as seasonal, perennial or mixed (perennial with seasonal exacerbation).
- A careful history and physical examination are the most effective diagnostic tools for the identification of allergic rhinitis in children.
- Diagnostic tests for allergic rhinitis include in vivo skin testing and in vitro serum IgE antibody immunoassay.
- Specific treatment options for allergic rhinitis include environmental control for allergen avoidance, pharmacotherapy and immunotherapy.

Rhinitis is defined as inflammation of the membranes lining the nose and is characterized by one or more of the following nasal symptoms: sneezing, itching, rhinorrhea and nasal congestion. Rhinitis is frequently accompanied by symptoms that involve the eyes, ears and throat.[1,2] Approximately 50% of all cases of rhinitis are caused by allergy. In allergic rhinitis, symptoms arise as a result of inflammation induced by an immunoglobulin E (IgE)-mediated immune response to specific allergens that involves the release of inflammatory mediators and the activation and recruitment of cells to the nasal mucosa.[1,2] A careful history and physical examination are the most effective tools for diagnosing allergic rhinitis, and specific diagnostic testing should be pursued when indicated. Management options for allergic rhinitis include treatment with pharmacologic agents and preventative measures such as environmental controls and immunotherapy.

Epidemiology

There are several limitations regarding epidemiologic studies of allergic rhinitis. First, most data regarding the true prevalence of allergic rhinitis are difficult to interpret because the majority of studies use either a physician diagnosis of disease or results from patient-administered surveys and/or phone interviews. Results of both types of studies are likely to under-report the actual prevalence of allergic rhinitis.[2–7] Additionally, most epidemiologic studies focus on seasonal allergic rhinitis because of the easy identification of symptoms association with pollen exposure. Perennial allergic rhinitis is more difficult to identify because its symptom complex often overlaps with chronic sinusitis, recurrent upper respiratory tract infections and vasomotor rhinitis.

The current prevalence of allergic rhinitis in the USA is reported to be approximately 30% for adults and 42% for children.[5] In 2013, allergic rhinitis was reported to affect about 60 million people in the USA, with about 40% of those affected being children. The Allergies, Immunotherapy, and RhinoconjunctivitiS (AIRS) surveys reported seasonal symptoms in 78% of subjects with the most common triggers being pollen (53%), dust (26%) and grass (26%), and nasal congestion being the most bothersome symptom.[2,3] The frequency of allergic rhinitis in the general population has risen in parallel with that of all IgE-mediated diseases during the past decade. The International Study of Asthma and Allergies in Childhood (ISAAC) showed that the prevalence of allergic rhinitis in US children rose from 13.4% in 1994 to 19.1% in 2003.[8]

SEX

At ages 6 to 7, boys with allergic rhinitis outnumber girls; however, at ages 13 to 14, girls outnumber boys.[9] In general, equal numbers are affected during adulthood.

AGE

Symptoms of allergic rhinitis develop before the age of 20 years in approximately 80% of cases. Children in families with a bilateral family history of allergy generally have symptoms before puberty; those with a unilateral family history tend to have symptoms later in life or not at all.[5–7]

RISK FACTORS

The frequency of allergic rhinitis increases with age and positive allergy skin tests have been identified as a significant risk factor for disease development. Disease prevalence is higher in more affluent socioeconomic classes, minorities, areas with heavy outdoor air pollution, individuals with a family history of allergy, firstborn children and individuals born during pollen season.[10] Childhood studies have confirmed that disease risk is increased in those with early introduction of food or formula, maternal tobacco smoking, indoor allergen exposure, elevated serum IgE levels, positive allergy skin tests and parental allergic disorders.[5] Recent studies demonstrated associations between obesity, nutrition, vitamin D deficiency, stress/anxiety, poor housing and allergic predisposition.[11–13] Maternal diets high in antioxidants and omega-3 fatty acids, and pediatric diets high in antioxidants and food diversity are associated with decreased risks of atopy.[14,15] Additionally, probiotics have been found to be effective in treating pediatric atopy.[11,13]

https://CafePezeshki.IR

SOCIOECONOMIC IMPACT

Because of the high prevalence of allergic rhinitis, impaired quality of life, costs of treatment and the presence of co-morbidities such as asthma, sinusitis and otitis media, it has a tremendous impact on society. The severity of allergic rhinitis ranges from mild to seriously debilitating. The cost of treating allergic rhinitis and indirect costs related to loss of workplace productivity resulting from the disease are significant and substantial. Allergic rhinitis was noted as the illness that caused the greatest loss of productivity in the workplace. The estimated cost of allergic rhinitis, based on direct and indirect costs, was approximately $11 billion for 2005, exclusive of costs for associated medical problems such as sinusitis and asthma.[16] In children with allergic rhinitis, the quality of life of both the parents and the child, including the ability to learn, may be affected.

Pathophysiology

Under normal conditions, the nasal mucosa quite efficiently humidifies and cleans inspired air. This is the result of orchestrated interactions of local and humoral mediators of defense.[17] In allergic rhinitis, these mechanisms do not function appropriately and contribute to signs and symptoms of the disorder.[18]

COMPONENTS OF THE ALLERGIC RESPONSE

The tendency to develop IgE, mast cell and T helper cell type 2 (Th2) lymphocyte immune responses is inherited by atopic individuals. Exposure to threshold concentrations of allergens for prolonged periods of time leads to the presentation of the allergen by antigen-presenting cells to $CD4^+$ T lymphocytes, which then release interleukin (IL)-3, -4 and -5 and other Th2 cytokines. These cytokines drive proinflammatory processes, such as IgE production, against these allergens through the mucosal infiltration and actions of plasma cells, mast cells and eosinophils. Once an individual becomes sensitized, subsequent exposures trigger a cascade of events that result in the symptoms of allergic rhinitis. The response in allergic rhinitis can be divided into two phases: the *early-phase* response and the *late-phase* response.

Early Phase

During periods of continuous allergen exposure, increasing numbers of IgE-coated mast cells traverse the epithelium, recognize the mucosally deposited allergen, and degranulate.[19] Products of this degranulation include preformed mediators such as histamine, tryptase (mast cell-specific marker), chymase (connective tissue mast cells only), kininogenase (generates bradykinin), heparin and other enzymes. In addition, mast cells secrete several inflammatory mediators de novo, including prostaglandin D_2 and sulfidopeptidyl leukotrienes C_4, D_4 and E_4. These mediators cause blood vessels to leak and produce the mucosal edema and watery rhinorrhea that are characteristic of allergic rhinitis. Glands secrete mucoglycoconjugates and antimicrobial compounds and dilate blood vessels to cause sinusoidal filling and thus occlusion and congestion of nasal air passages. These mediators also stimulate sensory nerves, which convey the sensation of nasal itch and congestion, and recruit systemic reflexes such as sneezing. These responses develop within minutes of allergen exposure and thus constitute the early-phase allergic response.[20] Sneezing, itching and copious, clear rhinorrhea are characteristic symptoms during early-phase allergic responses, although some degree of nasal congestion can also occur.

Late Phase

The mast cell-derived mediators released during early-phase responses are hypothesized to act on postcapillary endothelial cells to promote the expression of vascular adhesion molecule and E-selectin, which facilitate the adhesion of circulating leukocytes to the endothelial cells. Chemoattractant cytokines such as IL-5 promote the infiltration of the mucosa with eosinophils, neutrophils and basophils, T lymphocytes and macrophages.[21,22] During the 4- to 8-hour period after allergen exposure, these cells become activated and release inflammatory mediators, which in turn reactivate many of the proinflammatory reactions of the immediate response. This cellular-driven, late inflammatory reaction is termed the late-phase response. This reaction may be clinically indistinguishable from the early phase, but congestion tends to predominate.[22] Eosinophil-derived mediators such as major basic protein, eosinophil cationic protein and leukotrienes have been shown to damage the epithelium, leading ultimately to the clinical and histologic pictures of chronic allergic disease.

Subsets of the T helper lymphocytes are the likely orchestrators of the chronic inflammatory response to allergens. Th2 lymphocytes promote the allergic response by releasing IL-3, IL-4, IL-5 and other cytokines that promote IgE production, eosinophil chemoattraction and survival in tissues and mast cell recruitment.[23] Cytokines released from Th2 lymphocytes and other cells may circulate to the hypothalamus and result in fatigue, malaise, irritability and neurocognitive deficits that are commonly noted in patients with allergic rhinitis. Cytokines produced during late-phase allergic responses can be reduced by glucocorticoids.[24]

Role of Th17 Cells

Recently, Th17 cells have been identified as an important regulator of immune responses in allergic rhinitis. These cells produce IL-17A which increases the production of proinflammatory cytokines.[25] After an allergic subject is challenged intranasally with a relevant allergen repeatedly, the amount of allergen required to produce an immediate response decreases.[26] This effect is termed *priming* and is hypothesized to be a result of the influx of inflammatory cells that occurs during late-phase allergic responses, with IL-17A having a role in priming toward the development of immune responses against new allergens. This response is clinically significant because exposure to one relevant allergen may promote an exaggerated response to other allergens in a susceptible individual. The priming phenomenon highlights the need to fully identify the spectrum of allergens to which an individual patient reacts. Additionally, it emphasizes the need to intervene in the allergic cascade at an early time point via the prompt initiation of preseasonal, prophylactic, antiinflammatory therapy.

CLASSIFICATION

Allergic rhinitis is classified as seasonal or perennial based on the timing and duration of allergen exposure. Overall, approximately 20% of all cases are strictly seasonal, 40% are perennial, and 40% are mixed (perennial with seasonal exacerbation).

https://CafePezeshki.IR

Seasonal Allergic Rhinitis

Tree, grass and weed pollens and outdoor mold spores are common seasonal allergens. The symptoms typically appear during a defined season in which aeroallergens are abundant. The length of seasonal exposure to these allergens is dependent on geographic location. Therefore, familiarity with the pollinating season of the major trees, grasses and weeds of the locale makes the syndrome easier to diagnose.[27] Certain outdoor mold spores also display seasonal variation with the highest levels in the summer and fall months.[28]

Typical symptoms during pollen exposure include the explosive onset of profuse, watery rhinorrhea; nasal congestion and itching; and sneezing; along with frequent allergic symptoms of the eye. The onset and offset of symptoms usually track the seasonal pollen counts. However, hyperresponsiveness to irritant triggers, which develops from the inflammatory reaction of the late phase and priming responses, often persists after cessation of the pollen season. Such triggers include tobacco smoke, noxious odors, changes in temperature, and exercise.

Perennial Allergic Rhinitis

Year-round exposure to dust mites, cockroaches, indoor molds and cat, dog and other danders leads to persistent tissue edema and infiltration with eosinophils, mast cells, Th2 lymphocytes and macrophages.[29] Perennial allergic rhinitis can also be caused by pollen in areas where pollen is prevalent perennially.

A universally accepted definition of perennial rhinitis does not exist. Most often, it is defined as persisting for longer than 9 months each year and producing two or more of the following symptoms: serous or seromucus hypersecretion, nasal blockage caused by a swollen nasal mucosa, and sneezing paroxysms. Nasal congestion and mucus production (postnasal drip) symptoms predominate in most patients, and sneezing, itching and watery rhinorrhea may be minimal.[2] Because late-phase reactivity is commonly ongoing, it becomes difficult to distinguish early- from late-phase reactions, therefore the history of trigger factor exposure is often difficult to decipher.

Perennial Allergic Rhinitis with Seasonal Exacerbation

Symptoms of allergic rhinitis may also be perennial with seasonal exacerbation, depending on the spectrum of allergen sensitivities.

Differential Diagnosis

The causes of rhinitis are summarized in Box 24-1.[2] The most common form of nonallergic rhinitis in children is infectious rhinitis. The symptoms of allergic rhinitis are frequently confused with those of infectious rhinitis when patients complain of a constant cold. Symptoms persisting longer than 2 weeks should prompt a search for a cause other than acute viral infection. If tests for atopy are negative, foreign body rhinitis should be considered in the differential diagnosis. In such cases, symptoms may be acute or chronic and unilateral or bilateral, and the nasal discharge may be bloodstained or foul smelling. Exacerbation of rhinitis symptoms with predominant, clear rhinorrhea in patients with a known history of allergic rhinitis may be difficult to diagnose. The difference between active infection and allergy should be noted. When the history or physical examination is not diagnostic, a nasal smear may be obtained to aid in differentiation. The presence of more than 5% eosinophils suggests allergic disease, whereas a predominance of neutrophils suggests infection.

Allergy, mucociliary disturbance and immune deficiency may predispose certain individuals to the development of chronic infection.[30,31] Mucociliary abnormalities may be congenital, as in primary ciliary dyskinesia, Young syndrome or cystic fibrosis, or they may be secondary to infection.[32,33] Similarly, immune deficiency may be congenital or acquired.

Tumors or nasal polyps (Figure 24-1) as well as other conditions (e.g. nasal septal deviation, adenoidal or nasal turbinate

hypertrophy) can produce nasal airway obstruction.[34,35] Nasal polyps are common in children with cystic fibrosis but not in children with allergic rhinitis. Nasal septal deviation and nasal turbinate or adenoidal hypertrophy may block the flow of nasal secretions, leading to rhinorrhea or postnasal drip as well as causing nasal blockage. Reduced airflow through the nasal passages in infants may be caused by congenital choanal atresia. Refractory, clear rhinorrhea may be caused by cerebrospinal fluid leak, even in the absence of trauma or recent surgery.

Evaluation and Management

HISTORY AND PHYSICAL EXAMINATION

A careful history and physical examination are the most effective diagnostic tools for the identification of allergic rhinitis.[2] The key to accurate and timely diagnosis is a heightened awareness of the condition and its potential co-morbidities. Allergic rhinitis in children is often undiagnosed or misdiagnosed as other disorders such as recurrent colds. To make an accurate and efficient diagnosis, the clinician must be knowledgeable about and attentive to the symptoms and signs of rhinitis, ask specific questions directed at the presence and cause of rhinitis symptoms at each well-child visit, and understand the differential diagnosis of allergic rhinitis in children[2,36] (see Box 24-1). The clinician must be aware of the co-morbidities of allergic rhinitis (asthma, sinusitis, otitis media), pursue specific diagnostic tests when indicated, and often administer therapeutic trials of antiinflammatory medications.[37,38]

The signs and symptoms of allergic rhinitis are summarized in Box 24-2. Typical symptoms of allergic rhinitis include sneezing, itching, clear rhinorrhea and congestion. Congestion may

BOX 24-2 SIGNS AND SYMPTOMS OF ALLERGIC RHINITIS

Itching of the nose, ears, palate or throat
Sneezing episodes
Thin, clear rhinorrhea
Nasal congestion
Sinus headache
Eustachian tube dysfunction
Mouth breathing or snoring
Chronic postnasal drip
Chronic, nonproductive cough
Frequent throat clearing
Sleep disturbance
Daytime fatigue

be bilateral or unilateral and may alternate from side to side. It is generally more pronounced at night. With nasal obstruction, the patient is likely to be a mouth breather, and snoring can be a nocturnal symptom. As such, sleep disturbances and daytime tiredness or concentration problems may indicate the presence of an allergic disorder. With chronic disease, abnormalities of facial development, dental malocclusion and the allergic facies may ensue, with an open mouth and gaping habitus.

Older children blow their noses frequently, whereas younger children do not. Instead, they sniff, snort and repetitively clear their throats. Their voices may be abnormally hyponasal. Nasal pruritus may stimulate grimacing and twitching and picking of the nose. The latter may result in epistaxis. Children often have the allergic salute, an upward rubbing of the nose with the palm of the hand. This often produces an allergic nasal crease, which is an accentuated, horizontal skin fold over the lower third of the nose. Children with allergic rhinitis may also have recurrent sinusitis or otitis media, eczema or asthma. Patients may also complain of red, itchy eyes, along with itchy throat and ears. They may also lose their senses of smell and taste. Increased symptoms are frequently noted with increased exposure to the responsible allergen.

With development of the allergic reaction, clear nasal secretions will be evident and the nasal mucous membranes will become edematous without much erythema. The mucosa appears boggy and blue-gray. With continued exposure to the allergen, the turbinates will appear swollen and can obstruct the nasal airway. Conjunctival edema, itching, tearing and hyperemia are frequent findings in patients with associated allergic conjunctivitis. Allergic rhinitis patients, particularly children with significant nasal obstruction and venous congestion, may also demonstrate edema and darkening of the tissues beneath the eyes. These 'shiners' are not pathognomonic for allergic rhinitis; they can also be seen in patients with chronic rhinitis and/or sinusitis.

In severe cases, especially during the peak pollen season, mucous membranes of the eyes, Eustachian tube, middle ear and paranasal sinuses may be involved. This produces conjunctival irritation (itchy, watery eyes), redness and tearing, ear fullness and popping, itchy throat and pressure over the cheeks and forehead. Malaise, weakness and fatigue may also be present. The coincidence of other allergic syndromes, such as atopic eczema or asthma, and a positive family history of atopy point toward an allergic pathology. Approximately 20% of cases are accompanied by symptoms of asthma.[4]

https://CafePezeshki.IR

DIAGNOSTIC TESTS

Laboratory confirmation of the presence of IgE antibodies to specific allergens such as dust mites, pollens and animal dander is helpful in establishing a specific allergic diagnosis, especially if the history of specific allergen exposure is not clear cut. Although skin testing can be performed on any child of any age, children younger than 1 year may not display a positive reaction. Often the child with seasonal respiratory allergy will not have a positive test until after two seasons of exposure. Clinicians should be selective in the use of allergens for skin testing and should use only common allergens of potential clinical importance. The most useful allergens for testing in the child with perennial inhalant allergy are dust mite, animal dander and fungi. Allergens important in the diagnosis of seasonal allergic rhinitis are weed, grass and tree pollen. Because there is a significant geographic specificity with regard to pollens, the importance of these seasonal allergens varies not only by season of the year but also by geographic distribution. Therefore allergens used for skin testing must be individualized and should be selected on the basis of prevalence in the patient's geographic area, as well as home and school environments.

There are two methods for specific IgE antibody testing: in vivo skin testing and in vitro serum testing. Each has advantages and disadvantages[39] (Table 24-1). At the present time, properly performed skin tests are the best available method for detecting the presence of allergen-specific IgE. The skin prick, which is also called the *puncture* or *epicutaneous skin test*, is the preferred method of IgE antibody testing. In vitro tests are acceptable substitutes for skin tests in the following circumstances: (1) the patient has abnormal skin conditions such as dermatographism or extensive dermatitis; (2) the patient cannot or did not discontinue antihistamines or other interfering medications; (3) the patient is very allergic by history and anaphylaxis is a possible risk; and (4) the patient is noncompliant for skin testing. To avoid false-negative tests, most antihistamine medications should be withheld for 72 hours because antihistamines suppress the skin results.

Physicians must remember that positive tests for allergen-specific IgE are not by themselves sufficient for a diagnosis of allergic disease. These tests only indicate the presence of IgE molecules with a particular immunologic specificity. A decision about whether the specific IgE antibodies are responsible for clinically apparent disease must be based on the physician's assessment of the entire clinical picture. The current standard for the diagnosis of allergic disease remains the combination of (1) positive history, (2) the presence of specific IgE antibodies, and (3) demonstration that the symptoms are the result of IgE-mediated inflammation.

Advances in diagnostic testing are currently evolving with the development of microarrayed recombinant allergens as well as molecular or component-resolved diagnostics. The availability of these technologies is likely to change the future diagnostic landscape for allergic rhinitis. The major advantage of microarray testing is potential incorporation of thousands of allergens that could be assayed in parallel with a very small amount of serum. Additionally, there is potential for greater resolution between clinical reactivity and asymptomatic sensitization with this platform. The major advantage of molecular or component-resolved diagnostics is the use of individual allergen molecules instead of complex whole allergen extracts to specifically characterize IgE specificity. These technologies are in their infancy and large studies will be needed to critically evaluate their diagnostic and prognostic value as compared to current testing modalities.

TABLE 24-1 Comparison of In Vivo Skin Tests and In Vitro Serum IgE Antibody Immunoassay in Allergic Diagnosis

Skin Test	Serum Immunoassay
Less expensive	No patient risk
Greater sensitivity	Patient-doctor convenience
Wide allergen selection	Not suppressed by antihistamines
Results available immediately	Results are quantitative
	Preferable to skin testing in: Dermatographism, Widespread dermatitis, Uncooperative children

From Skoner DP. J Allergy Clin Immunol 2001;108:S2–S8.

GUIDELINES FOR DIAGNOSIS AND MANAGEMENT

Strategies for the evaluation and management of allergic rhinitis are summarized in an algorithm compiled by the Joint Task Force on Practice Parameters in Allergy, Asthma and Immunology[1] (Figure 24-2). As outlined, the initial evaluation of a patient with rhinitis symptoms (e.g. rhinorrhea, nasal congestion, sneezing, nasal pruritus, postnasal drainage and conjunctivitis) should be performed by a primary care physician. The primary care physician should institute an appropriate therapeutic trial. Upon follow-up, the primary care physician should determine if the patient has responded to treatment and/or meets the criteria for consultation with an allergist as summarized in Box 24-3. One of the primary purposes of a consultation with an allergist is the differential diagnosis of allergic rhinitis based on the combined results of a detailed medical history, physical examination of the airway, and ancillary tests, particularly skin tests.

Effective management of allergic rhinitis may require a combination of aggressive avoidance measures, patient education regarding allergen avoidance and the administration of pharmacologic therapy, allergen immunotherapy, management of co-existing conditions and adjustments in pharmacologic therapy. Cooperative follow-up is an essential part of the

BOX 24-3 INDICATIONS FOR REFERRAL TO AN ALLERGIST/IMMUNOLOGIST

- Prolonged history of rhinitis
- Presence of complications or co-morbid conditions including asthma, otitis media, sinusitis and/or nasal polyposis
- Prior systemic corticosteroid for the treatment of rhinitis
- Treatment that is either ineffective or produces adverse events
- Symptoms that significantly interfere with the patient's functional ability or reduce the quality of life
- Diagnosis of rhinitis medicamentosa
- Need to further define allergic/environmental triggers of rhinitis
- Need for more education

https://CafePezeshki.IR

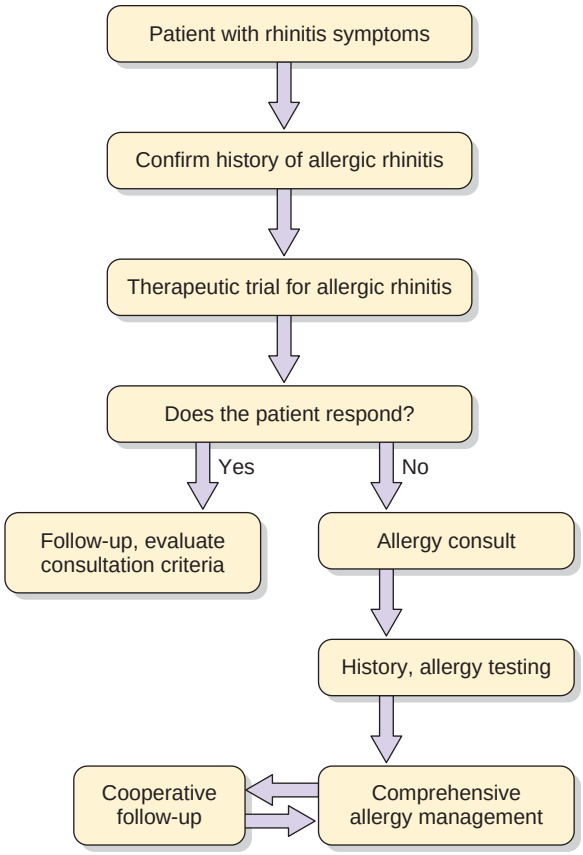

Figure 24-2 Algorithm for diagnosis and management of rhinitis. *(Modified from Wallace DV, Dykewicz MS, Bernstein DI, et al. J Allergy Clin Immunol 2008;122:S1–S84.)*

successful management of allergic rhinitis and ideally includes the patient, the family and all healthcare providers. With the common goal of reducing symptoms and improving functional ability, all involved would cooperatively manage exacerbations and complications through the optimal use of environmental avoidance measures, medications and immunotherapy in appropriately selected patients. Periodic assessments and continued patient education should also be included in the follow-up protocol.

MANAGEMENT

Specific treatment options include environmental controls for allergen avoidance, pharmacotherapy and immunotherapy. In all cases, the primary goal of treatment is to control the symptoms and to improve the quality of life without altering the patient's ability to function. A second but equally important goal is to prevent the development of sequelae of allergic rhinitis, including sinusitis, otitis media and asthma exacerbations.[1,38]

Environmental Control for Allergen Avoidance

Educating families about avoiding exposure to allergens is an essential part of the treatment of allergic rhinitis (Table 24-2). Unfortunately, the specific measures are often highly impractical; moreover, they may have negative psychosocial ramifications for children that should not be ignored. Avoiding outdoor sports in the springtime and banishing furred pets from the home, for example, may have adverse effects on children that range beyond allergen control. Nevertheless, families should be taught about the importance of environmental control measures and advised to adhere to them to the extent possible.[1]

TABLE 24-2 Environmental Control of Allergen Exposure

Allergens	Control Measures
Dust mites	Encase bedding in airtight covers Wash bedding in water at temperatures >130°F Remove wall-to-wall carpeting Remove upholstered furniture
Animal dander	Avoid furred pets Keep animals out of patient's bedroom
Cockroaches	Control available food supply Keep kitchen/bathroom surfaces dry and free of standing water Professionally exterminate
Mold	Destroy moisture-prone areas Avoid high humidity in patient's bedroom Repair water leaks Check basements, attics and crawl spaces for standing water and mold
Pollen	Keep automobile and house windows closed Control timing of outdoor exposure Restrict camping, hiking and raking leaves Drive in air-conditioned automobile Air-condition the home Install portable, high-efficiency particulate air filters

Antihistamines

The Joint Task Force on Practice Parameters in Allergy, Asthma and Immunology previously published guidelines on the diagnosis and management of allergic rhinitis, and more recently the Allergic Rhinitis and its Impact on Asthma Guidelines were updated.[40] Antihistamines are available in both oral and nasal formulations. The decision in choosing between an oral or nasal formulation is driven by a variety of factors including insurance coverage, side-effects and patient preference.

Three generations of oral antihistamines are available: the first-generation (sedating) antihistamines, which are available without prescription; the second-generation (hyposedating or nonsedating) agents, which are available without a prescription; and the third-generation (nonsedating metabolites of second-generation agents), all of which require a prescription in the USA at this time (Table 24-3). Oral antihistamines act primarily by blocking the H_1 receptor. The second- and third-generation agents have several advantages over the first-generation agents, including preferential binding to peripheral H_1 receptors, which results in minimal penetration of the central nervous system; minimal antiserotonergic, anticholinergic and α-adrenergic blocking activities; and minimal sedative and performance-impairing effects.[41,42]

As a general rule, oral antihistamines reduce symptoms of sneezing, pruritus and rhinorrhea but have little or no effect on nasal congestion. Consequently, a topical or oral decongestant may have to be added. Many antihistamine/decongestant formulations are available. The major advantage of these combinations is their convenience. Disadvantages are intolerance of the fixed dose of decongestant in certain patients and an inability to titrate each agent independently.[41,42]

https://CafePezeshki.IR

TABLE 24-3 Second- and Third-Generation Antihistamines

Medication	Formulations	Recommended Dosage
Azelastine	Nasal spray	≥12 yr: 2 sprays per nostril bid 5–11 yr: 1 spray per nostril bid
Cetirizine	Tablets 5, 10 mg Syrup 5 mg/5 mL	≥12 yr: 10 mg qd 6–11 yr: 5–10 mg qd 6 mo–5 yr: 5 mg qd
Desloratadine	Tablets 5 mg Syrup 2.5 mg/5 mL	≥12 yr: 5 mg qd 6–11 yr: 2.5 mg qd 1–5 yr: 1.25 mg qd 6–11 mo: 1 mg qd
Fexofenadine	Capsules/tablets 30, 60, 180 mg Syrup 30 mg/5 mL	≥12 yr: 60 mg bid or 180 mg qd 2–11 yr: 30 mg bid
Levocetirizine	Tablets 5 mg Syrup 2.5 mg/5 mL	≥12 yr: 5 mg qd 6–11 yr: 2.5 mg qd
Loratadine	Tablets 10 mg Syrup 5 mg/5 mL	≥12 yr: 10 mg qd 6–11 yr: 5–10 mg qd 2–5 yr: 5 mg qd
Olopatadine	Nasal spray	≥12 yr: 2 sprays per nostril bid

TABLE 24-4 Intranasal Corticosteroid Sprays

Corticosteroid	Dose per Actuation (μg)	Recommended Dosage
Beclomethasone	42	≥6 yr: 168–336 μg/day bid
Budesonide	32	≥12 yr: 64–256 μg/day qd 6–11 yr: 64–128 μg/day qd
Ciclesonide	50	≥6 yr: 200 μg/day qd
Flunisolide	25	≥14 yr: 200–400 μg/day bid 6–14 yr: 100–200 μg/day bid
Fluticasone furoate	27.5	>12 yr: 110 μg/day qd 2–11 yr: 55 μg/day qd
Fluticasone propionate	50	≥4 yr: 100–200 μg/day qd
Mometasone furoate	50	≥12 yr: 100–200 μg/day qd 2–11 yr: 100 μg/day qd
Triamcinolone acetonide	55	≥12 yr: 110–220 μg/day qd 6–11 yr: 110 μg/day qd

Tran NP, Vickery J, Blaiss MS. Management of rhinitis: allergic and non-allergic. Allergy Asthma Immunol Res 2011;3:148–156.

Patients should be educated about the appropriate use of oral antihistamines. For optimal results, oral antihistamines should be administered prophylactically (2–5 hours before allergen exposure) or on a regular basis if needed chronically. Although oral antihistamines are effective on an as-needed basis, these agents work best when they are administered in a maintenance fashion.[41,42]

Nasal antihistamines relieve sneezing, nasal itching, congestion and postnasal drip. Additionally, they have some efficacy against nasal and sinus congestion. There are currently two second-generation formulations available in the USA including olopatadine, which is available by prescription only as a brand name product, and azelastine which is available by prescription only in brand name and generic products. Onset of action is within minutes and these are often administered on an as-needed basis. Side-effects of these products include a bitter taste, drowsiness and fatigue.[41]

Decongestants

Decongestants produce vasoconstriction within the nasal mucosa through α-adrenergic receptor activation and therefore are effective in relieving the symptoms of nasal obstruction. However, these agents have no effect on other symptoms such as rhinorrhea, pruritus or sneezing and may be most effective when used in combination with other agents, such as antihistamines.[41,42]

A number of decongestants are available for oral use, but the most commonly used decongestant is pseudoephedrine. The most common side-effects of oral decongestants are central nervous system (nervousness, insomnia, irritability, headache) and cardiovascular (palpitations, tachycardia) effects. In addition, these drugs may elevate blood pressure, raise intraocular pressure and aggravate urinary obstruction.[41,42]

Topical intranasal decongestants are sometimes used by patients with allergic rhinitis. However, when these agents are used for longer than 3 to 5 days, many patients experience rebound congestion after withdrawal of the drug. If patients continue to use these medications over several months, a form of rhinitis, rhinitis medicamentosa, will develop, which can be difficult to treat effectively.[41,42]

Intranasal Corticosteroids

Topical intranasal corticosteroids represent the most efficacious agents for the treatment of allergic rhinitis and are useful in relieving symptoms of nasal pruritus, rhinorrhea, sneezing and congestion. These drugs exert their effects through multiple mechanisms, including vasoconstriction and reduction of edema, suppression of cytokine production and inhibition of inflammatory cell influx. Physiologically, prophylactic treatment before nasal allergen challenge reduces both the early- and late-phase allergic responses.[43]

These agents work best when taken regularly on a daily basis or prophylactically in anticipation of an imminent pollen season. However, because of their rapid onset of action (within 12–24 hours for many agents), there is increasing evidence that they may also be effective when used intermittently. A number of glucocorticoid compounds are available for intranasal use in both aerosol and aqueous formulations (Table 24-4). Although the topical potency of these agents varies widely, clinical trials have been unable to demonstrate significant differences in efficacy.[44,45]

The most important pharmacologic characteristic differentiating these agents is systemic bioavailability. After intranasal administration, the majority of the dose is swallowed. Most of the available compounds, including beclomethasone dipropionate, budesonide, flunisolide and triamcinolone acetonide, are absorbed readily from the gastrointestinal tract into the systemic circulation and subsequently undergo significant first-pass hepatic metabolism. The resulting bioavailabilities can be as high as 50%. However, fluticasone propionate, fluticasone furoate and mometasone furoate are not well absorbed through the gastrointestinal tract, and the small amount of drug that reaches the portal circulation is rapidly and thoroughly metabolized. The newest agent, ciclesonide, is administered as a

https://CafePezeshki.IR

prodrug and metabolized to a bioactive metabolite by esterases in the nasal mucosa. Ciclesonide has low oral bioavailability due to low gastrointestinal absorption and high first-pass metabolism. The lower systemic availabilities of these newer agents may be most important in growing children and in patients who are already using inhaled corticosteroids for asthma. Nevertheless, there are no studies to document the comparative effects of nasal corticosteroids on growth and development at this time.[46–49]

Patients who use intranasal corticosteroids experience dryness and irritation of the nasal mucous membranes in 5% to 10% of mild cases and mild epistaxis in approximately 5%. For mild adverse events, the dose of intranasal corticosteroid may be reduced if tolerated, and/or saline nasal spray should be instilled before the drug is sprayed. Some patients who do not tolerate the administration of wet spray formulations may benefit by switching to newer dry aerosol formulations including beclomethasone and ciclesonide.[50]

Combination Nasal Products

Recently, a combination product containing azelastine and fluticasone has been approved by the FDA for use in children older than 12 years.[51] It has the advantage of delivering both an antihistamine and nasal steroid in one product and may subsequently improve compliance. This combination nasal product has been shown to improve symptoms of nasal congestion, rhinorrhea, itchy nose and sneezing when compared to treatment with placebo or treatment with either an antihistamine or a nasal steroid. Adverse effects are similar to those listed for the individual drug components. In addition to azelastine/fluticasone, several other combination products are currently under development.

Mast Cell Stabilizers

Mast cell stabilizers, such as cromolyn sodium, can be useful in relieving nasal pruritus, rhinorrhea and sneezing; however, they have minimal effects on congestion. Cromolyn sodium is generally well tolerated and is most efficacious when taken prophylactically, well in advance of allergen exposure. In addition, because of its short duration of action, it should be taken 4 times a day; as a result, compliance is difficult for many patients.

Ipratropium Bromide

Topical intranasal ipratropium bromide 0.03% and 0.06% solution reduces the volume of watery secretions but has little or no effect on other symptoms. Therefore this agent is most helpful in allergic rhinitis, when rhinorrhea is refractory to topical intranasal corticosteroids and/or antihistamines. The most common side-effects include nasal irritation, crusting and mild epistaxis. This drug can be helpful for blocking reflex-mediated rhinitis, profuse rhinorrhea that occurs after the ingestion of spicy foods or cold air exposure.[1] It has not been well researched in the pediatric population.

Leukotriene Receptor Antagonists

These agents are effective in the treatment of seasonal and perennial allergic rhinitis.[52–55] Because allergic rhinitis often co-exists with asthma, and montelukast is approved for both of these diagnoses, montelukast may be considered in such patients. It should also be considered in patients who are unresponsive or noncompliant with intranasal corticosteroids. Montelukast has an excellent safety profile, is approved down to 6 months of age, and recently became available in generic formulations. An attractive attribute of this drug is that it is available as a once-daily oral formulation. Dosing is one 10 mg tablet daily for patients ≥14 years, one 5 mg chewable tablet daily for patients aged 6 to 13 years, and 4 mg daily (chewable tablet or granules) for children of 6 months to 5 years of age. Adverse effects are rare, with the most common complaints being headache or stomachache shortly after dosing.

Saline

Saline is of benefit in reducing symptoms and improving quality of life in some patients with allergic rhinitis. A recent study demonstrated that hypertonic saline was more effective than isotonic saline in improving outcomes.[56] Various mechanisms of action, including improvement in mucociliary clearance, removal of allergen and inflammatory mediators and a protective effect on nasal mucosa, have been proposed but not confirmed. Side-effects are minimal and include local burning and irritation as well as nausea. Optimal delivery techniques, volumes, concentrations and dose frequency have not been established.

Allergen Immunotherapy

Specific allergen immunotherapy continues to be a useful and important treatment for many patients with severe allergic rhinitis.[57,58] Specific allergen immunotherapy has traditionally been administered via the subcutaneous route. In making the decision to prescribe subcutaneous immunotherapy, the clinician should consider the positive and potentially negative effects of regular office visits for the administration of injections. If the decision is made to prescribe subcutaneous immunotherapy, it must be administered by a physician who is experienced in its use and whose office is set up to deal with the management of adverse allergic reactions, including anaphylaxis should this rare, untoward event occur.

Recently, several sublingual formulations for the treatment of grass and ragweed pollen allergy have received US Food and Drug Administration (FDA) approval.[59–61] Other sublingual formulations, including but not limited to dust mite and cat, are currently under development in the USA. In controlled trials, this route of delivery appears to be safer with side-effects usually restricted to the upper airways and gastrointestinal tract. However, there are currently neither enough data nor experience with this delivery route to be certain of its safety. This is particularly true in patients with a history of anaphylaxis, eosinophilic esophagitis or uncontrolled asthma. When prescribing sublingual immunotherapy, the first dose must be administered in an allergy specialist's office and the patient must be instructed on the signs and symptoms of anaphylaxis and the use of an epinephrine autoinjector and they must be discharged with an anaphylaxis action plan.

When administered to appropriately selected patients, either formulation of immunotherapy is effective in most cases. In addition to short-term benefits, recently published data suggest that the improvement in rhinitis symptoms persists for several years after the treatment is discontinued.[62] Research performed during the past decade has demonstrated that allergen immunotherapy induces a state of allergen-specific T lymphocyte tolerance with a subsequent reduction in mediator release and tissue inflammation.[63] Immunotherapy should be considered in patients who (1) do not respond to a combination of environmental control measures and medications,

https://CafePezeshki.IR

(2) experience substantial side-effects with medications, (3) have symptoms for a significant portion of the year that require daily therapy, or (4) prefer long-term modulation of their allergic symptoms.

Conclusions

Despite the high prevalence of allergic rhinitis in the pediatric population, this disease is often overlooked or undertreated. Untreated allergic rhinitis impairs the quality of life of the child and his or her parents. Accurate and timely diagnosis of allergic rhinitis in children relies on awareness of the symptoms and signs of the disease and its co-morbidities, including asthma, sinusitis and otitis media. Clinicians should understand the differential diagnosis of allergic rhinitis in children and pursue specific diagnostic testing when indicated. Treatment options include environmental controls and the use of intranasal corticosteroids, nonsedating antihistamines and immunotherapy. The key concepts of allergic rhinitis in children are summarized in Box 24-4.

BOX 24-4 KEY CONCEPTS

Allergic Rhinitis

- Allergic rhinitis is one of the most common chronic disorders of childhood.
- Allergic rhinitis in children is an inflammatory airway disease.
- The distinction between allergic and nonallergic forms of rhinitis is important in children.
- Treatment should be individualized, aggressive and targeted toward decreasing inflammation.
- Attention should be given to decreasing environmental exposures (e.g. allergens, tobacco smoke) and the use of intranasal corticosteroids and nonsedating antihistamines.
- Intranasal steroids constitute very effective therapy for allergic rhinitis and are safe despite a potential small drug-specific effect on growth rates.
- Allergic rhinitis in children may predispose to the development of otitis media, sinusitis and asthma.

25 Otitis Media

BRUCE D. MAZER

KEY POINTS

- Otitis media remains an extremely common disorder; vaccination strategies are decreasing its incidence.
- Recent guidelines highlight the need for more careful diagnostic criteria.
- Initial treatment can include either initiation of antibiotics or a period of observation, depending on patient age and severity of presentation.
- Frequent otitis media is a key feature of primary immune deficiency.
- Respiratory allergy contributes to chronic otitis media with effusion (OME), but more study is needed to fully define the impact of allergy on this common condition.

Introduction

Acute otitis media (AOM), and the related otitis media with effusion (OME), are the most common diseases requiring pediatric care in the first decade of life, except for viral upper respiratory infections. The costs of primary and specialty care, as well as the indirect costs incurred by the family, are enormous. In 2013, estimates for the direct cost of treating otitis media (OM) in the USA totaled $ 2.88 billion, not including indirect costs.[1] Indirect costs incurred by families (such as hours of work lost, transportation, etc.) may equal the direct costs, doubling the financial burden.[2] There have been significant advances in the past 40 years in understanding of the pathogenesis, pathophysiology and immunopathology of OM, leading to a decrease in physician visits and antibiotic prescriptions for this illness.[3,4] Improved recognition, a willingness to observe the evolution of less severe cases and widespread pneumococcal vaccination likely have contributed to this improvement. This chapter provides a review of the epidemiology, pathogenesis, Eustachian tube (ET) physiology and immunology of OM as well as medical and surgical therapies employed to treat it. It also provides information on the potential role of allergy in the pathogenesis of this prevalent condition.[3]

Definitions

OM is characterized by acute or chronic inflammation of the middle ear (ME).[5] AOM is typically preceded by or associated with viral upper respiratory tract infections (URTI); up to 37% of viral URTIs may be complicated by OM.[6] Persistent OM is defined as persistence of symptoms and signs of ME infection despite antimicrobial therapy (i.e. treatment failure) and/or a relapse of AOM within 1 month of completion of antibiotic therapy. When two episodes of OM occur within 1 month, it may be difficult to distinguish recurrence of AOM from persistent otitis media (relapse). Recurrent AOM is defined as having 3 or more episodes of AOM in 6 months or 4 episodes in 12 months (Box 25-1).[7]

AOM often evolves into OME, chronic middle ear effusion (MEE) without signs or symptoms of acute infection. After an episode of AOM, 60% to 70% of children have OME at 2 weeks, decreasing to 40% at 1 month and 10% to 25% at 3 months.[8] Chronic OME is defined as OM lasting for 12 weeks. Children with certain sensory, physical, cognitive and behavioral conditions are particularly vulnerable to the hearing loss, speech, language and learning problems associated with OME.[9]

Epidemiology

The peak incidence for AOM is during the first 2 years of life, and most initial cases occur between 6 and 12 months of age.[7] By 1 year of age almost 50% of children have had at least one episode of AOM,[10] and two thirds by 3 years. Three or more episodes of OM occur in 10% of children by 1 year of age and in 33% by 3 years of age. Tos and colleagues reported a point prevalence of OME of 13% during the first 2 years of life. In 4- to 6-year-old children, point prevalence decreased to 7% and then further decreased to 2% to 4% in 8- to 10-year-old children.[11–13] Whereas population-based studies in the USA and Finland suggested that OM was increasing toward the end of the 20th century,[14,15] changes in healthcare systems, access to care, patterns of using services and awareness of OM may be partially responsible for these increases.[16] The widespread use of pneumococcal vaccination appears to play a positive role in reducing the overall incidence of acute OM and subsequent complications, although the effect appears to be restricted to early infancy.[3,17]

Multiple factors increase the risk of OM in children. The best-defined risk factor in the development of AOM is a preceding viral URTI. A prospective cohort study by Wald and colleagues reported that 25% to 40% of URTIs in children from birth to 3 years of age were accompanied by an episode of AOM,[18] most commonly under 1 year of age.

Universally, males are affected more than females. Indigenous populations, such as North American Indians, native Canadians and Polynesian children, have a much higher incidence than white children.[19] Compared with bottle-feeding, breastfeeding for at least 6 months is associated with a decreased risk of acute otitis or recurrent otitis during the first year of life.[20] This protective effect on both the frequency of URTIs and the resultant AOM may not be seen with shorter durations of breastfeeding.[21–23] Cigarette smoking by the parents, especially the mother, is a significant risk factor for AOM during the first year of life.[24] Children whose parents or siblings have had a history of chronic otitis have a higher incidence than those with

BOX 25-1 CLASSIFICATION OF OTITIS MEDIA

Acute otitis media
Recurrent acute otitis media
Persistent acute otitis media
Otitis media with effusion
Chronic otitis media with effusion

BOX 25-2 RISK FACTORS FOR OTITIS MEDIA

ENVIRONMENTAL FACTORS

Viral upper respiratory tract infection
Daycare attendance
Cigarette smoke (passive)
Low socioeconomic status
Environmental pollution

HOST FACTORS

Male gender
Genetic predisposition
Premature birth
Not breastfed
Supine bottle-feeding
Immune deficiency (primary and secondary)
Craniofacial abnormalities
Eustachian tube dysfunction
Cilia dysfunction
Allergic rhinitis

no family history.[10] A cohort study of 2,512 children in Finland concluded that, while family size, low socioeconomic status and cigarette smoking were all individually correlated with an increased risk of recurrent AOM, they were all interdependent variables. The association of these factors with AOM was best accounted for by the strong correlation with attendance at large (≥20 children) daycare centers as well as short duration of breastfeeding.[25] A study of 175 sets of twins and triplets followed from birth indicated a genetic component to susceptibility to AOM. The estimate of discordance of AOM in monozygotic twins was 0.04 compared with 0.49 in dizygotic twins ($P < .005$).[26] Numerous studies confirm an augmented risk of AOM, recurrent otitis media (ROM) and OME as the number of children in the childcare setting increases.[27] Other factors such as preterm birth and greater number of siblings in the household also increased a child's risk of AOM.[7] Specific conditions such as Down's syndrome, craniofacial anomalies,[28,29] ciliary dyskinesia syndromes and primary and secondary immune deficiency syndromes[30–32] are associated with increased risks of AOM (Box 25-2).

Using tympanometry, Mandel and Casselbrant found that asymptomatic OME is relatively frequent in daycare settings, especially in the winter months. Repeated evaluations indicated that many cases resolved spontaneously without therapy and effusions could persist for up to 6 months without overt symptoms.[33]

Whether allergy predisposes children to AOM and OME is an area of controversy.[34] Scandinavian and US studies have shown that, during the first 3 years of life, there is no association between AOM and allergic disease.[35] Allergy is cited as a potential risk factor for OME, especially in children needing surgical intervention. Early clinical studies suffered from significant methodologic limitations such as lack of control groups or unclear definitions of allergy. For example, one study of children with chronic OM referred for placement of ventilation tubes found that approximately half the children had positive allergy skin tests or increased serum immunoglobulin E (IgE) antibodies to specific allergens. However, there was no comparison to normal controls, nor was it clear whether these children had clinical allergies or asymptomatic sensitization.[36–38] More recent studies have used prospective birth cohorts to examine the risk of OME in children with allergic disease. The COPASC cohort from Copenhagen found little effect of allergic rhinitis on OME in early life, but a strong correlation at age 6.[39] This was not only due to obstruction, but potentially to effects of Th2 inflammation. The LISA cohort from Germany found similar associations at age 6. They also examined if early OM predicted onset of allergic disease; they found positive correlations for late-onset atopic eczema and asthma, but not for allergic rhinitis.[40] Several in vitro studies substantiate a pathophysiologic link between allergy and OME.[34]

No association between OM and food ingestion has been found. A large unblinded trial showed some efficacy of elimination diets in OME.[41] One study suggested a link between IgE-mediated cow's milk allergy and recurrent otitis media, however the effect could be completely accounted for by the presence of respiratory allergies in these children.[42] There has been little progress and no significant peer-reviewed studies in this area in the past decade.

Pathophysiology

STRUCTURE AND FUNCTION

Otitis media is a disease of the upper respiratory tract. Ventilation of the ME is accomplished via the ET from the posterior nasopharynx. Middle ear effusions in children are most often related to abnormal ET function. The ET provides an anatomic communication between the nasopharynx and the ME. Like mucosa elsewhere in the respiratory tract, the ET lining contains mucus-producing cells, ciliated cells, plasma cells and mast cells.[43] Unlike the bronchial tree, the ET is usually collapsed and thus closed to the nasopharynx and its contents. The ET, like the bronchi, serves several physiologic functions. It protects the ME from nasopharyngeal secretions, drains secretions produced within the ME into the nasopharynx, ventilates the ME to equilibrate pressures and replenishes oxygen in the ME. In normal tubal function, intermittent opening of the ET maintains near-ambient pressure in the ME cavity. It is suspected that in cases in which active swallowing is inadequate to overcome tubal resistance, the tube remains persistently collapsed, resulting in progressively negative ME pressure. This abnormal pressure appears to be common in children. Periodic or persistently high negative pressure may be pathologic and associated with abnormal ET function and may lead to AOM.

EUSTACHIAN TUBE OBSTRUCTION

Two types of ET obstruction, mechanical and functional, could result in acute or chronic OME (Box 25-3). Intrinsic mechanical obstruction may result from inflammation of infection or allergy, whereas extrinsic obstruction may result from enlarged adenoids or, in rare instances, nasopharyngeal tumors. Experimentally, allergic rhinitis provoked in patients with a history of allergy has been associated with the development of ET

https://CafePezeshki.IR

BOX 25-3 TYPES OF EUSTACHIAN TUBE OBSTRUCTION

- Mechanical obstruction
  - Intrinsic
    - Infectious inflammation
    - Allergic inflammation
  - Extrinsic (peritubular)
    - Adenoidal hypertrophy
    - Nasopharyngeal tumor
- Functional obstruction
  - Poor tensor veli palatini muscle function
  - Increased tubal compliance

obstruction.[44] A persistent collapse of the ET during swallowing may result in functional obstruction, which appears to be related to increased tubal compliance, an inefficient, active opening mechanism by the tensor veli palatine muscle, or both. The angulation of the craniofacial base changes with age, improving the tensor veli palatine muscle after puberty. Additionally, in infants and younger children the cartilaginous support of the ET is less robust.[19,45]

Pathogenesis

A role for ET dysfunction in the pathogenesis of AOM during a viral URTI is supported by multiple clinical and experimental studies. Studies reported tubal dysfunction in children and adults with natural viral URTI,[46] experimental infection[47] and animal models.[48]

Rhinovirus infection results in significant increases in nasal inflammation, impaired tubal function and abnormal ME pressures in more than 40% of subjects, and asymptomatic OM in approximately 2% of subjects.[47] These events occurred sequentially and in descending frequency, supporting a causal pathway. This pattern occurred in infection with rhinovirus, influenza A virus, and coxsackievirus A and influenza.[49,50] In the majority, OM was asymptomatic with experimental infection and the recovered effusion was negative by culture for viruses and bacteria but positive for influenza A and *Streptococcus pneumoniae* by polymerase chain reaction (PCR).[51] The inflammatory response to acute infection is a key part of the pathophysiology of the disease. Using a murine model of ME and *H. influenzae* infection, Ryan and colleagues documented that ME mucosa rapidly undergoes hypertrophy and within 24 hours exhibits edema, mucosal thickening and lymphocytic infiltrate.[52] This progressed over a 5- to 7-day period and resolved. Similar pathology was noted in larger animal models of AOM, including rats, guinea pigs and chinchillas.[48] Middle ear effusions were accompanied by inflammatory cytokines, including TNF-α, IL-1, IL-8, IL-10 and IL-6, which diminished over 48 to 72 hours.[53,54] The inflammatory infiltrate was potentiated by chemokines produced in the infectious response. What is lacking in the animal models of acute OM are experiments mimicking both early viral infection and subsequent bacterial superinfection characteristic in humans. Most models induce OM via introduction of bacteria to the ME via the tympanic membrane (TM) or the bulla (i.e. the ME in mice). While this duplicates the pathogens found within ME fluid in AOM, it does not completely mimic AOM pathogenesis. A small number of models have employed co-exposure to viruses and bacteria, primarily to assess therapeutic approaches.[55–59] A novel, potentially highly important contribution of animal models is the discovery of genes that may predispose to OM. Genetic work has identified the key role of innate immunity in the inflammatory response of the ME. It is well recognized that, in addition to humoral immune defects, subtle defects in mucosal immunity such as mannose binding ligand defects render children more susceptible to OM. Using murine models, a crucial role for proteins in the Toll receptor pathways was identified.[60–62] MyD-88 signaling may also be crucial for defense against bacterial pathogens in AOM.[54,60] Indeed, defects in chemokines such as IL-8, MCP-1 and CCL3, which play integral roles in promoting early neutrophilic inflammation,[63–65] can predispose animals to AOM.[66] In contrast, deleting CCR5 can ameliorate the severity of bacterial OM.[57]

The role of mast cells and innate immune responses in AOM has been the subject of multiple studies. Mast cells, as primarily mucosal leukocytes, are the most common hematopoietic cells found in the normal ME, including the lining of the ME, ET and the TM. This has led to a focus on allergy in the pathogenesis of otitis. However, it is unlikely that the primary role of the mast cell in OM is via its ability to bind IgE on FcεR1, but rather its role in binding IgG via Fc gamma receptors. In *cKit* knockout mice, which are unable to produce mast cells, infection induced into the ME did not cause inflammation, mucosal changes or remodeling found in mast cell sufficient mice or *cKit* knockout mice that had received infusions of normal mast cells.[67] ME fluid harbors mast cell mediators in both acute and chronic models of OM, underlining the role of mast cells in the normal host response against bacteria.[68]

Another major advantage of the expanding role of murine models is the ability to detect new genes that may predispose to OM. Defects that affect the development of ET and ME include mutations in the transcription factor EVI1 and the eyes absent homolog *Eya1*.[69–71] A mouse model of deafness known to develop chronic suppurative OM, Jeff, carries a mutation in an F-box gene, *Fbxo11*, predisposing to development of cleft palate.[72–74] Even well-known genetic syndromes such as DiGeorge/velocardiofacial syndrome have been advanced in the study of OM pathogenesis by murine models.[75] This is complemented by genome wide association studies in several cohorts of human subjects that identified predisposing single nucleotide polymorphisms in innate immune pathways such as IL-1β and CXC3R1.[76,77]

Etiology

ACUTE OTITIS MEDIA AND OTITIS MEDIA WITH EFFUSION

Bacteria are found in approximately 60% to 70% of children with AOM who undergo tympanocentesis.[78] Historically, *Streptococcus pneumoniae*, *Moraxella catarrhalis* and nontypable *H. influenzae* were the predominant causative bacteria in AOM. Group A β-hemolytic *Streptococcus, Staphylococcus aureus* and, more rarely, anaerobes, account for a minority of cases. Viruses alone are recovered from ME fluid in about 15% of cases.[79,80] Since the routine institution of the heptavalent pneumococcal conjugate vaccine (PCV7), the microbiology of AOM has changed (Table 25-1). About 50% of children requiring myringotomy for AOM refractory to second-line antimicrobial treatment had positive cultures, most growing organisms such as *S. pneumoniae*, *Staph. aureus* and coagulase negative

https://CafePezeshki.IR

TABLE 25-1 Bacteria Cultured from Middle Ear Effusion Tympanocentesis of Acute Otitis Media

Bacteria	Percentage
Haemophilus influenzae	51
Streptococcus pneumoniae	38
Moraxella catarrhalis	12
Staphylococcus aureus	5
Two pathogens	12
No growth	30

Staphylococcus.[81] Finnish and US trials have demonstrated that PCV7 has resulted in a 6% overall reduction in the clinical incidence of AOM[82] which may diminish ROM and the need for tympanostomy tube placement.[83,84] The majority of the effect is in younger children, while children who were vaccinated later in life had less effect from PC7.[17] Studies with more extensive vaccine coverage will be highly instructive in determining if there is a broader effect; in terms of healthcare dollars, 5% to 6% difference has significant impact.[17]

Penicillin-resistant *S. pneumoniae* is a significant clinical problem and is found in up to two thirds of pneumococcal isolates.[85] Approximately 50% of *H. influenzae* and 90% of *M. catarrhalis* strains produce β-lactamase, making them resistant to amoxicillin. Additionally, while antibiotic prescriptions for AOM have decreased somewhat, there is an increase in treatment of OM with broad-spectrum antibiotics including single-dose third-generation cephalosporins. This may well impact antibiotic resistance patterns.[86]

Previously it had been assumed, incorrectly, that chronic middle ear fluid (MEF) effusions were sterile. In several studies, about 50% of the chronic, persistent ME effusions had positive cultures for bacteria whose microbiology was similar to that found in acute otitis.

Mediators of Allergy and Otitis Media with Effusion

Studies have focussed on analysis of the inflammatory infiltrate found in MEEs from OME. There is no uniform infiltrate; both Th1 and Th2 inflammation have been found in analyses of ME fluid.[87] MEEs with infiltrates characteristic of allergic inflammation have been studied in detail. Eosinophilia and proteins derived from eosinophil degranulation are unique features of ME disease in allergic patients.[88] Statistically significant differences in major basic protein and IL-5 mRNA were found in ME biopsy specimens, suggesting both eosinophil recruitment and degranulation in the ME. Elevated levels of IL-4, mast cell-derived tryptase, eosinophilic cationic protein and RANTES (regulated upon activation normal T cell-expressed and secreted) were all found in higher concentration in children with atopic backgrounds compared with nonatopic children.[89]

Using a cohort of 75 children skin tested prior to surgery for OME, Sobol and colleagues[90] and Nguyen and colleagues[91,92] studied cellular components and cytokine expression in MEEs of patients undergoing tympanostomy tube insertion. The incidence of atopy (positive skin tests to at least one of 12 common allergens) in these three studies was 24% to 30%. Atopic children had significantly higher levels of eosinophils, T lymphocytes, and IL-4$^+$ and IL-5$^+$ cells on immunohistochemistry compared with the nonatopic group, and a trend toward higher mast cells and basophils. Nonatopics had higher IFN-γ^+ cells.[90] Th2 cells and cytokines were found in ME fluid in atopic children and in biopsy specimens from adenoid tissue and the torus tubarius, demonstrating a strong correlation between allergic inflammation in MEE and the upper airway.[91,92] A UK study with an incidence of atopy of 7% defined four groups of children with OME based on their MEE infiltrate and cytokine profiles.[87,93] Two groups were predominantly Th1 (subacute and chronic), one had Th1-Th2 overlap, and one was strongly Th2. A strong correlation between mucin production and the Th2 cytokines IL-4 and IL-13 was observed.

Diagnosis of Otitis Media

ACUTE OTITIS MEDIA

The American Academy of Pediatrics (AAP) and American Academy of Family Physicians released clinical practice guidelines in 2013 outlining the diagnosis of AOM.[7] The guidelines stipulate three criteria that must be fulfilled. There must be acute, abrupt onset of signs and symptoms of AOM such as otalgia, otorrhea, irritability and fever. There also must be a documented MEE. One can document this on examination of the ME by noting one of the following: a bulging TM, an air-fluid level behind the TM, otorrhea, or limited TM mobility on tympanometry, pneumatic otoscopy or acoustic reflectometry. The patient must also have signs or symptoms of inflammation in the ME, such as distinct erythema of the TM. However, crying and/or fever can both result in an erythematous TM.[94,95] The diagnosis of AOM is often difficult in infants who are too young to clearly express themselves. They often have co-existing viral URTI, and it is often a challenge to clear the external ear canal of cerumen. The ultimate management of the infant or child will differ depending on the physician's degree of certainty of the diagnosis of AOM. The most recent guidelines also differentiate between children who are under 24 months and older children and classify AOM as mild, moderate or severe, based on visualization of the tympanic membrane and pneumatic otoscopy.[7] These stricter criteria may assist in decreasing unnecessary antibiotic prescriptions.

CHRONIC OTITIS MEDIA WITH EFFUSION

The AAP, American Academy of Family Physicians, and American Academy of Otolaryngology and Head and Neck Surgery developed clinical practice guidelines describing the diagnosis and management of OME in children.[7] According to these evidence-based guidelines, during follow-up of all children with OME, it is important to document the laterality, duration of effusion and presence and severity of any associated symptoms at each clinical assessment. The presence of OME can be confirmed by a combination of visual inspection, tympanometry and pneumatic otoscopy. Children at 'high risk' for development of speech, language or learning problems as a result of MEE causing hearing loss should be promptly evaluated and may need more timely surgical intervention than low-risk children. A low-risk child with OME can be managed with watchful waiting for 3 months from the onset of the effusion (if known), or from the date of diagnosis. All children with OME lasting >3 months should have a hearing test and be reexamined at 3- to

https://CafePezeshki.IR

6-month intervals until the effusion is no longer present, significant hearing loss is identified or structural abnormalities of the eardrum or ME are suspected[9,95] (Figure 25-1).

CHRONIC OTITIS MEDIA AND ALLERGY

Some children presenting with OM have associated rhinitis. If chronic, it is important to determine whether this rhinitis is infectious or allergic. Prolonged, perennial or recurrent seasonal rhinitis with itching and sneezing suggests an allergic basis, as does co-existent allergic conjunctivitis. A family history of allergy and/or a personal history of atopic dermatitis, allergic asthma and food allergies also raise clinical suspicion of allergic rhinitis.

It is advisable that children with persistent OME be screened for allergic rhinitis by taking a clinical history addressing symptoms, signs and timing for allergic rhinitis. If this is suspected, these children should be referred to a specialist in allergy for further evaluation and investigations.[39] Skin prick testing is preferred to serologic anti-IgE antibody tests for the detection of IgE antibodies to specific inhalant allergens because of the increased clinical sensitivity and lower cost. For either test result to be considered clinically relevant there must be a correlation between exposure to a particular allergen and clinical symptoms. Total serum IgE levels are not useful, as they do not define specific allergen sensitivities.

DIAGNOSTIC TECHNIQUES

Physical Findings

Otoscopic inspection requires visualization of the TM. The normal TM is thin, translucent, neutrally positioned and mobile. The bony ossicles, particularly the malleus, are generally visible through the TM. Adequate assessment requires that the physician take note of the TM's thickness, degree of translucency, position and its mobility to applied pressure. A bulging eardrum and air bubbles or air-fluid levels indicate the presence of excessive ME fluid and document effusion. Various degrees of bulging may assist in better classifying the severity of the illness, whereas hyperemia and erythema alone without fluid or indications of pressure changes are much less sensitive indicators.[7] The ear canal may be filled with pus which, when removed, will usually reveal an inflamed TM with perforation (Figure 25-2).

Children with AOM may also have co-existent sinusitis as a complication of a viral URTI. It is also important to be aware

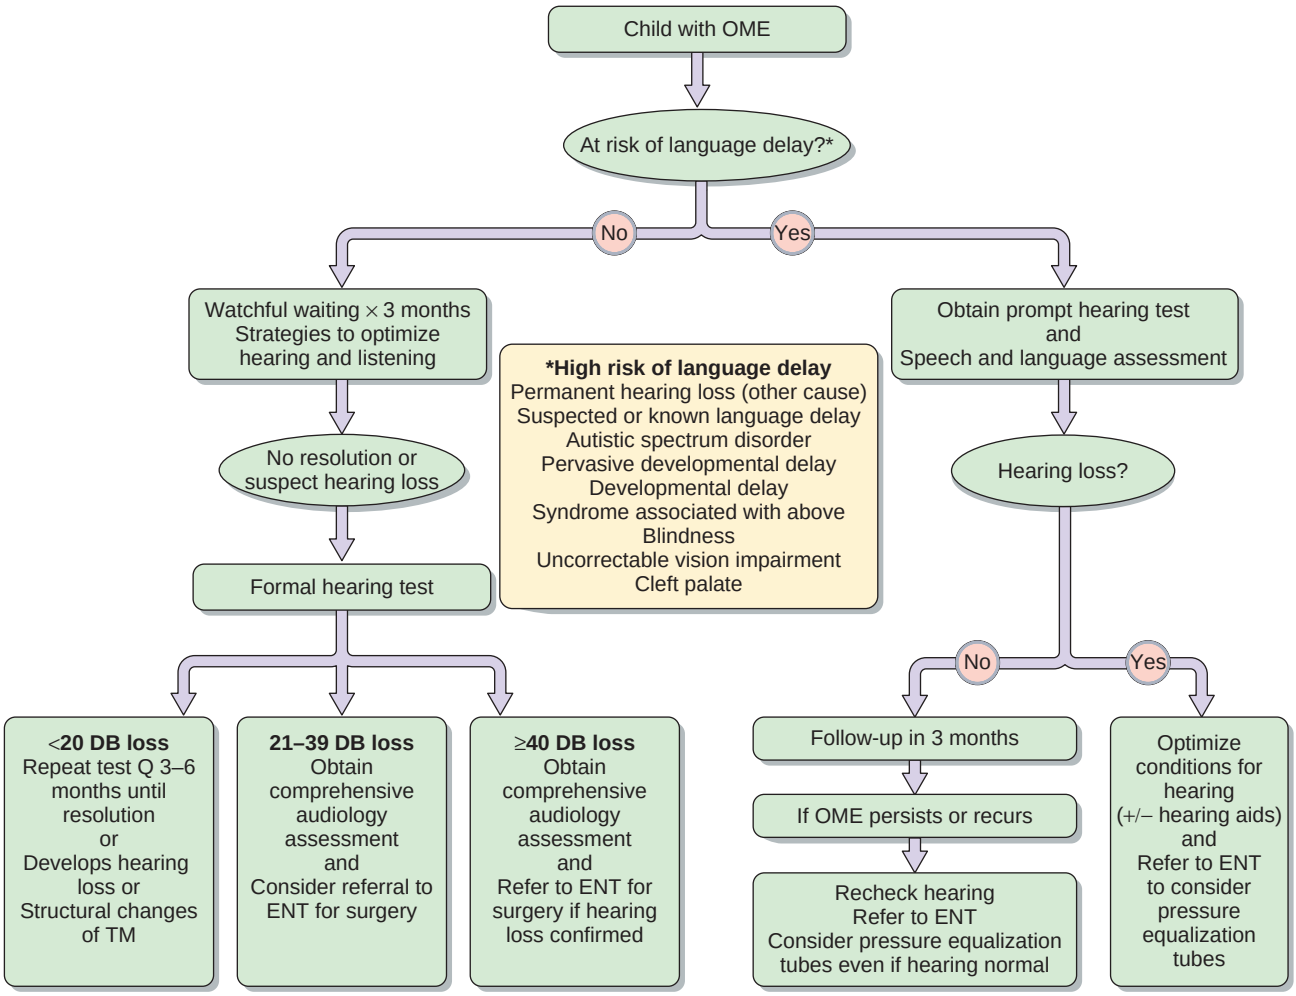

Figure 25-1 Algorithm for management of otitis media with effusion. *(Modified from Mandel EM, Casselbrant ML. Acute otitis media in decision making. In: Alper CM, Myers EN, Eibling DE, editors. Ear, nose, and throat disorders. Philadelphia: WB Saunders; 2001.)*

https://CafePezeshki.IR

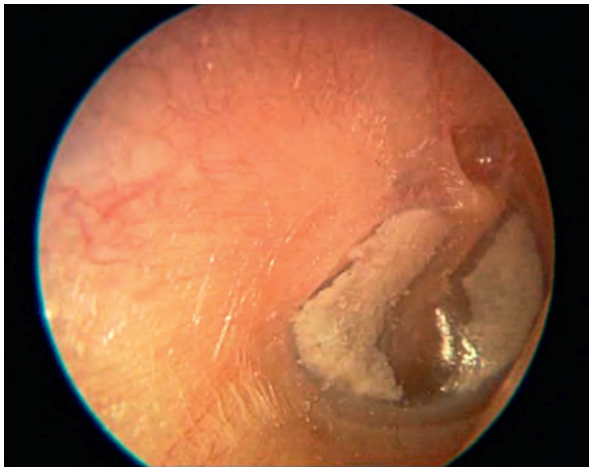

Figure 25-2 Demonstration of acute otitis media with effusion.

of more severe, acute complications of AOM. These include co-existent mastoiditis, meningitis, brain abscess, sepsis and/or bacteremia. These complications are more likely to arise in children with underlying ME malformations, cochlear implants and immunodeficiency. One long-term complication of neglected otitis with recurrent inflammation is the development of a cholesteatoma, a cyst-like mass with a lining of stratified squamous epithelium filled with desquamating debris, which can predispose to infectious complications and hearing loss. Other long-term complications include hearing loss, tympanosclerosis and vestibular problems.[96]

Pneumatic Otoscopy

Clinicians should use pneumatic otoscopy as a diagnostic method for OME.[7,97] A meta-analysis showed that, when done by trained observers, pneumatic otoscopy has a sensitivity of 87% and specificity of 74%.[98] Choosing the correct size of speculum to fit the patient's ear canal and obtaining a good pneumatic seal during an otoscopic examination both help to ascertain the motility of the tympanic membrane. The loss of normal movement of the eardrum during the gentle application of air pressure via a hand-held bulb indicates a loss of compliance of the eardrum. This may be seen with either an ME effusion or increased stiffness from scarring or thickening of an inflamed eardrum.

Tympanometry

When otoscopic findings are unclear or otoscopy is difficult to perform, tympanometry can be useful in evaluating children older than 4 months.[99] This instrument, which measures the compliance of the eardrum as well as ME pressure, is also helpful in clinical practice in confirming the diagnosis of OME. Unlike pneumatic otoscopy, which requires clinicians to be specifically trained in order for it to be an accurate tool, tympanometry is technically straightforward with better diagnostic accuracy.[9]

Audiogram

An audiogram to evaluate for conductive hearing deficit is necessary for the management of recurrent and chronic OME. OME is most often associated with conductive hearing loss of about 25 to 30 dB, directly attributable to the effects of fluid in the ME.[100–102]

DIAGNOSIS OF IMMUNODEFICIENCY SYNDROMES

The possibility of an immunodeficiency syndrome should be considered if a child has an increased susceptibility to infections. One consensus statement suggests that eight or more diagnosed episodes of AOM should raise suspicion for an underlying immunodeficiency. The combination of multiple episodes of AOM, accompanied by recurrent sinusitis, pneumonia or other infections, warrants a formal immunologic assessment (see www.info4pi.org).

The initial laboratory tests performed should include a complete blood count and leukocyte differential to ensure that there is no underlying lymphopenia or neutropenia. Defects of humoral immunity most often present with recurrent oto-sino-pulmonary infections.[103] Thus, the quantification of serum immunoglobulins including IgG, IgA, IgM and IgE is indicated. It is also mandatory to assess the child's response to vaccines (diphtheria, tetanus, *H. influenzae* type B, *Pneumococcus*) to determine the child's capacity to mount an immune response and sustain immunologic memory.[104,105] If the initial work-up is unremarkable, but one still suspects an underlying immunodeficiency, second-line investigations can be considered. Defects in the innate barrier system, such as inner ear malformations, implanted foreign bodies, cystic fibrosis and primary ciliary dyskinesia, can all lead to recurrent AOM. B and T lymphocyte enumeration by flow cytometry or lymphocyte proliferation assay may also be indicated. While recurrent AOM is unlikely to be the only presenting symptom of an early-component complement deficiency, depending on associated clinical features, levels of C3, C4, mannose binding ligand and total hemolytic complement can be measured.[106] Less common conditions that can also predispose to recurrent oto-sino-pulmonary infections include specific polysaccharide antibody deficiency[105] and IRAK-4 deficiency (a defect in signaling through Toll-like receptors).[107,108] A large variety of B cell defects have been recently characterized genetically, and recurrent ear and sinus infections are important components of these humoral immune defects.[109] Defects in cell-mediated immunity, both primary and secondary (such as HIV), can also predispose patients to have recurrent AOM.

Treatment

ACUTE OTITIS MEDIA

The therapy for AOM is outlined in Figure 25-3. If there are no potential or documented complications, the initial management consists of treating associated pain and deciding if antibiotics are indicated. Several meta-analyses have found that OM resolves without antibiotics in 80% of children over 2 years old and in 30% of children younger than 2 years of age.[110,111] In children under the age of 2, two large placebo-controlled trials of amoxicillin-clavulanate or placebo clearly demonstrated more rapid resolution and decrease of symptoms with antibiotics compared to placebo.[112,113] Thus, the decision to institute therapy or continue observation is clearly dependent on age, and these studies and others led to modifications of recent guidelines.

Antibiotics should continue to be provided as first-line therapy for children with clear visual signs of otitis media, moderate or severe otalgia and fever ≥39°C. An AAP

https://CafePezeshki.IR

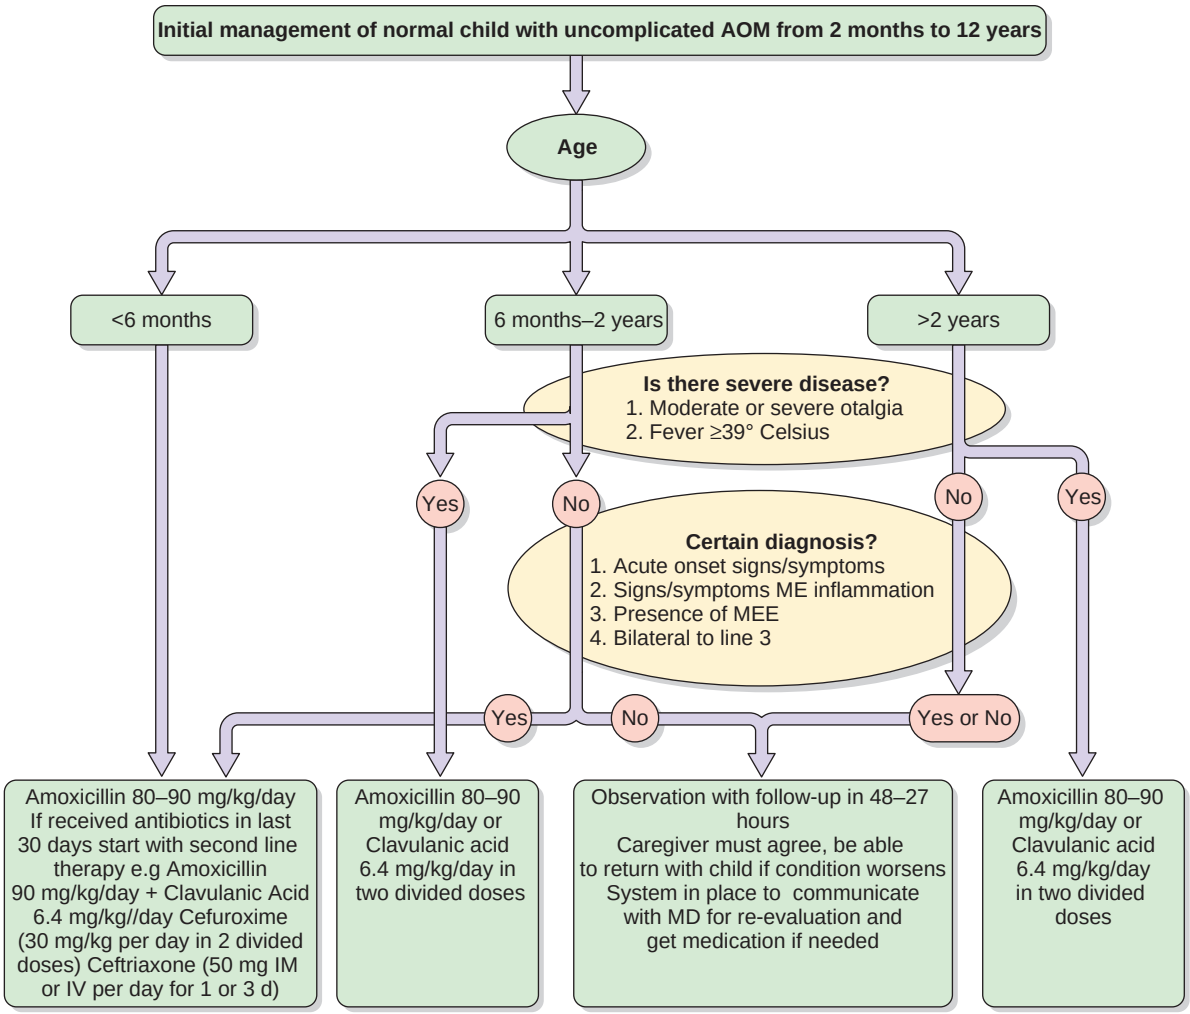

Figure 25-3 Algorithm for management of acute otitis media.

subcommittee review recommended that selected patients can be managed with 'observation only' providing pain control without antibacterial treatment for 48 hours, in consultation with the caregiver, and as long as follow-up is ensured. This is not an option in patients with known or suspected immunodeficiencies, infants under 6 months of age and children presenting with severe disease (moderate-severe otalgia *or* fever >39°C). This option can be considered for children older than 2 years of age without severe disease *or* uncertain diagnosis. For children aged 6 to 24 months with an uncertain diagnosis of AOM *and* non-severe disease, observation can be considered only if good follow-up is ensured, otherwise antibiotic therapy may be preferable.[7] If symptoms worsen on follow-up, the patient should then be treated with antibiotics.

In keeping with the findings of Hoberman and Tahtinen,[112,113] a large meta-analysis found that if a child is younger than 2 years of age with bilateral acute OM, they are more likely to 'fail' the 'observation only' option and eventually require antibiotics. In this trial 55% of children in the 'observation only' group versus 30% of children treated initially with antibiotics still had pain, fever or both on days 3 to 7 after diagnosis[114] There does not appear to be an increase in severe complications such as mastoiditis, bacteremia or meningitis with this approach.

According to treatment guidelines, the majority of children with AOM who require antibiotics should receive amoxicillin 80–90 mg/kg/day + Clavulanic Acid 6.4 mg/kg//day. Amoxicillin is considered first-line therapy because it covers strains of *S. pneumoniae* that are both sensitive and intermediately resistant to penicillin and it has a narrow microbiologic spectrum. High-dose amoxicillin-clavulanate (80–90 mg/kg/day) is preferred for severe illness (moderate to severe otalgia and/or fever >39°C) in order to cover β-lactamase-producing *H. influenzae* and *M. catarrhalis*. In penicillin-allergic patients, azithromycin, clarithromycin or trimethoprim-sulfamethoxazole are potential alternatives. A recent practice parameter from the Joint Council of Allergy, Asthma and Immunology stated that 'cephalosporin treatment of patients with a history of penicillin allergy, selecting out those with severe reaction histories, show a reaction rate of 0.1%'. They recommend a cephalosporin in cases without severe and/or recent penicillin allergy reaction history when skin test is not available.[115]

Antimicrobials should be prescribed for 10 days in children younger than 6 years and for 5 to 7 days in children over 6 years of age.[7]

In the event of no clinical improvement within 48 to 72 hours, the child should be re-evaluated. The physician should

https://CafePezeshki.IR

ensure that the patient does not present signs of complications of AOM and reassess if the patient still meets diagnostic criteria for AOM. If the diagnosis of AOM is maintained, and the patient was initially observed, antibiotics should be prescribed. A patient initially treated with amoxicillin should be switched to amoxicillin-clavulanate. If the patient fails to respond to second-line antibiotics, one to three daily doses of parenteral ceftriaxone may be given. If this too fails, therapeutic and diagnostic tympanocentesis should be done. A culture of the ME fluid can help tailor antimicrobial therapy. In the case of penicillin-allergic patients, clindamycin is the optimal second-line therapy. When a patient has had an episode of AOM in the previous 30 days, a second-line antibiotic should be prescribed initially because the causative organism is more likely to be penicillin resistant. When symptoms of the acute infection improve, the patient should be scheduled for follow-up in 4 to 6 weeks to determine if OME persists. If OME is present at follow-up, the clinician should consider follow-up, audiology testing and, if necessary, tympanostomy on a case-by-case basis (see Figure 25-3).

Antimicrobial prophylaxis for recurrent acute OM, usually with trimethoprim-sulfamethoxazole, has demonstrated efficacy, but because of the problem of increased bacterial resistance, this therapy should be limited to selected cases.[103] Data from a recent Cochrane review do not support the use of decongestant treatment in children with AOM, given the lack of benefit and increased risk of side-effects.[116]

OTITIS MEDIA WITH EFFUSION

OME may be a complication of AOM or it may be detected as an occult condition without previous signs or symptoms of an infection. OME is frequently asymptomatic but may cause a hearing loss or balance disturbance.[117] If the patient is identified as not at 'high risk' of suffering language or developmental delay as a result of hearing loss secondary to OME, the OME has been present for less than 3 months, and the patient is asymptomatic, then the patient should be re-examined at 4 to 6 weeks to determine whether the effusion has resolved. An effusion that persists for longer than 3 months should prompt a hearing evaluation with audiometry. A normal audiogram for at least one ear is reassuring and the patient can then be rechecked periodically. This watchful waiting strategy is employed because up to 90% of OME will resolve spontaneously after 3 months.[94] Children should have scheduled pediatric follow-up every 3 to 6 months, verifying if hearing is normal and the tympanic membrane examination free of pathology such as retraction pockets, atelectasis or cholesteatoma. Children with moderate (>40 dB) hearing loss should be referred for consideration of surgery, whereas low-risk children with mild hearing loss can continue to be observed with close follow-up and strategies to optimize hearing, such as minimizing background noise and standing close to the child when speaking.[102]

In patients with OME in whom persistent nasal obstruction is documented, allergy should be considered. If allergic rhinitis is documented in association with OME, management should include intranasal corticosteroids and avoidance of offending allergens. Antihistamine therapy and decongestants alone have been proven to be ineffective for OME in multiple meta-analyses,[116] as have antibiotics for treatment of asymptomatic OME.[118] Oral steroids are not recommended for the management of chronic OME or recurrent OM, and the risks of systemic steroids largely outweigh any potential short-term benefits.[119]

There are no placebo-controlled trials that document the efficacy of immunotherapy for reducing the frequency or promoting the resolution of OME. Recently, a community-based ENT practice examined the effect of treating patients who warranted pressure equalization (PE) tubes for OME with immunotherapy. Although this study strongly supported the use of immunotherapy in the treatment of subjects with OME, there were methodologic problems with the evaluation and treatment of the subjects.[120] Similar methodologic issues were found in an older pediatric otolaryngologic study.[121]

In some cases of OME, surgical management is indicated. The surgical management of OME includes the insertion of tympanostomy tubes, also known as ventilation tubes or pressure equalization (PE) tubes, to promote drainage of persistent unresolved effusions and improve hearing. According to the AAP guidelines on management of OME, the indications for consultation with an otolaryngologist to consider insertion of tympanostomy tubes include OME lasting 4 months or longer with persistent hearing loss, recurrent or persistent OME in high-risk children regardless of hearing status, and OME associated with structural damage to the TM or ME. The decision of whether or not to proceed to surgery should be individualized. Children with OME of any duration who are at 'high risk' of language delay are candidates for earlier surgery.[8] Other plausible indications for referral include the following: (1) appropriate medical management has not been successful in alleviating the OME; (2) recurrent OME (three or more episodes in the preceding 6 months); (3) OME persisting for more than 6 months; (4) documented persistent conductive hearing loss.[94]

There continues to be a great deal of controversy regarding the indications for PE tube placement in children with OME. One must weigh the benefits of PE tube placement against the risks of surgery, including mortality with anesthesia and TM perforation. While PE tubes decrease by about half the number of days per year that children have OME, hearing improves only minimally (about 10 dB).[100] A third of children have relapse of OME after their PE tubes fall out, and later require repeated PE tube placement. Furthermore, low-risk children with long-standing OME and hearing loss derived no benefit from the insertion of PE tubes, and only one RCT has shown minimal improvement with PE tube placement in children with OME and hearing loss that resulted in disruptions of speech, language, learning or behavior.[100,122]

Conclusions

Otitis media is a multifactorial illness that affects many children. It may be an acute, chronic or recurrent disease. The roles of infection, ET obstruction, allergy and host defense defects have been delineated. Infection and ET obstruction are the principal contributing factors in acute OM. However, in a child who has clinically significant allergic rhinitis, the role of allergy in chronic or recurrent OM cannot be ignored. Clinicians should be diligent about using the available tools and most recent evidence-based techniques when diagnosing AOM and OME, and not hesitate to involve consultants such as allergist-immunologists, otolaryngologist and audiologists when clinically indicated. In treating patients with OM, being mindful of indications for treatment, considering the adverse effects

https://CafePezeshki.IR

of various therapies, treating associated co-morbidities, and identifying children at risk for language delays reduce the healthcare costs as well as increasing the wellbeing of these children (Box 25-4).

ACKNOWLEDGMENTS

I would like to thank Dr Phillip Fireman for allowing me to incorporate portions of his excellent original chapter on otitis media into this work.

I would like to thank Dr Sam Daniel, Otorhinolaryngologist at the McGill University Health Care Center for his expertise and help with this chapter.

BOX 25-4 KEY CONCEPTS

Otitis Media

- Acute otitis media, a frequent multifactorial illness of early childhood, can evolve into a chronic otitis media with effusion associated with obstruction of the Eustachian tube.
- Viral upper respiratory infection often precedes acute otitis media, with bacteria cultured in 70% of patients with acute otitis media and 50% of patients with otitis media with effusion.
- Chronic otitis media with effusion of more than 3 months' duration promotes a conductive hearing deficit with potential resultant speech pathology.
- Increased frequency of bacterial resistance to antibiotics requires judicious selection of antibiotics without excessive use.
- Epidemiologic and experimental studies suggest a role for allergic rhinitis in the patient with chronic otitis media with effusion and nasal obstruction but not in acute otitis media.

26 Sinusitis

KENNY H. CHAN | MARK J. ABZUG | ANDREW H. LIU

KEY POINTS

- Sinusitis is diagnostically challenging because symptoms (i.e. nasal discharge, congestion and cough), signs and radiographic findings are similar to those in common upper respiratory tract infections. Coronal sinus CT scans may be helpful in chronic, recurrent or complicated sinusitis.
- Respiratory infections (viruses, bacteria), bacterial biofilms and microbiome disruption have pathogenic roles. The most common causes of bacterial sinusitis are *Streptococcus pneumoniae* (20–30%), *Haemophilus influenzae* (20–30%) and *Moraxella catarrhalis* (10–20%); 30–35% are sterile.
- Antibiotic resistance is common: *Streptococcus pneumoniae* (15–50% penicillin resistant), *Haemophilus influenzae* (25–80% β-lactamase positive), and *Moraxella catarrhalis* (90–100% β-lactamase positive). Antral irrigation can provide sinus specimens for bacterial culture and targeted antimicrobial therapy in patients with chronic, refractory and complicated disease.
- Children with chronic sinusitis have mucosal pathology and inflammation that typically differs from adults. In adults, chronic sinusitis is characterized by mucosal thickening, goblet cell hyperplasia, subepithelial fibrosis and persistent Th2-type eosinophilic inflammation. In children, pan-immune inflammation ($CD8^+$ T lymphocytes, B lymphocytes, neutrophils) with reduced basement membrane thickness, fewer mucous glands, and less epithelial injury is common.
- Management of uncomplicated, acute sinusitis consists of antimicrobial treatment aiming for symptom relief and prevention of complications and recurrence. Severe intraorbital and intracranial complications are uncommon today.

This chapter on sinusitis in children will provide an overview of the pathogenesis and management of acute and chronic sinus disease. Although acute sinusitis has been substantially investigated, relatively little is known about chronic sinusitis in children.

Sinus Development in Childhood

There are four pairs of paranasal sinuses in humans: maxillary, ethmoid, frontal, and sphenoid. The maxillary and ethmoid sinuses are present at birth and invaginate to become radiographically visible in the first 1 to 2 years of life (Figure 26-1). In comparison, frontal and sphenoid sinuses begin to develop in the first few years of life and gradually become pneumatized and radiographically visible between 7 and 15 years of age. The maxillary, anterior ethmoid and frontal sinus ostia enter the nasal cavity through the middle meatus, under the middle turbinate (i.e. osteomeatal complex; see Figure 26-1). The sphenoid and posterior ethmoid ostia join the nasal cavity through the superior meatus, above the middle turbinate.

Clinical Definitions of Sinusitis

Several descriptive modifiers for sinusitis are commonly used. In terms of sinusitis duration, (1) *acute* sinusitis refers to sinus symptoms of 10 to 30 days, with complete resolution of symptoms,[1] (2) *subacute* sinusitis refers to symptoms that last 30 to 90–120 days, and (3) *chronic* sinusitis is used for symptoms that last more than 90–120 days. *Recurrent* sinusitis occurs in patients who improve with sinus therapy but experience multiple episodes. *Refractory* sinusitis refers to patients who do not respond to conventional therapy for sinusitis.

The uses of the term *sinusitis* and *rhinosinusitis* have been debated; *sinusitis* implies that the disease is the manifestation of an infectious process of the sinuses.[2] In comparison, the term *rhinosinusitis* implies that the nasal and sinus mucosae are involved in similar and concurrent pathogenic (e.g. inflammatory) processes.[1] In this chapter the two terms will be used interchangeably.

Epidemiology

Sinusitis is a common problem in childhood. In a study of 1- to 5-year-old children seen in pediatric practices, 9.3% met the clinical criteria of sinusitis (i.e. ≥10 days of symptoms).[3] In a large birth cohort study primarily intended to study the natural history of childhood asthma (Children's Respiratory Study, Tucson, Arizona), 13% of 8-year-old children reported physician-diagnosed sinusitis within the past year.[4] Of children with sinusitis, 50%, 18% and 11% had sinusitis diagnosed for the first time at ages 6 years, 3 years and 2 years, respectively. The main risk factors for sinusitis were current allergic rhinitis and grass pollen hypersensitivity.

The US National Center for Health Statistics reported that, from 1980 to 1992, sinusitis was the fifth leading diagnosis for which antibiotics was prescribed.[5] The annual outpatient visit rates for sinusitis increased about 3-fold over this period and the use of amoxicillin and cephalosporin antibiotics for sinusitis also increased significantly. Antibiotic resistance of bacterial pathogens from the sinuses of children with acute[6] and chronic sinusitis[7] is common. Severe alterations in quality of life can result from chronic recurrent sinusitis in children. Using a standardized child health questionnaire, children with chronic sinusitis and their parents reported more bodily pain and

https://CafePezeshki.IR

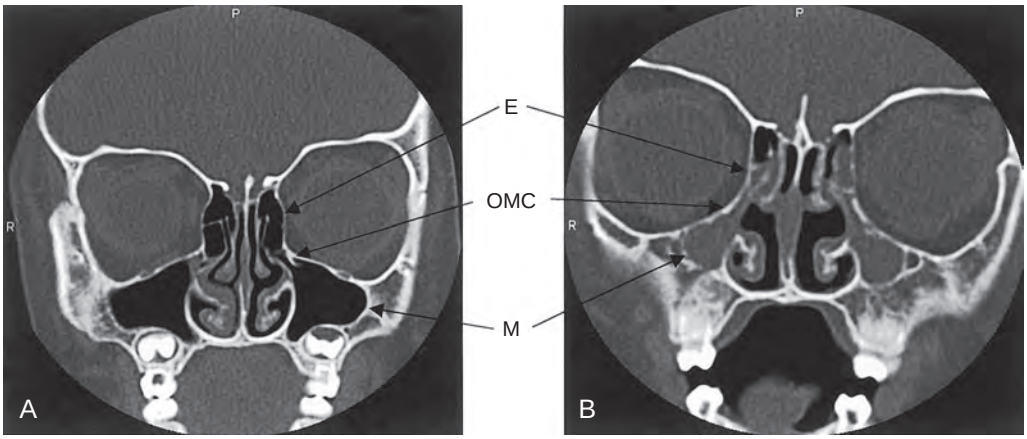

Figure 26-1 Computed tomography scans of the paranasal sinuses. Coronal views of a 4-year-old child with **(A)** normal maxillary and ethmoid sinuses and patent osteomeatal complex and **(B)** opacified maxillary and ethmoid sinuses consistent with sinusitis. *E* – Ethmoid sinus; *M* – Maxillary sinus; *OMC* – Osteomeatal complex.

greater limitation in their physical activity than were typically reported by children with asthma or juvenile rheumatoid arthritis.[8] Complications of sinusitis, such as intracranial or intraorbital extension of bacterial infection from the sinuses, are medical emergencies that are life-threatening.

Etiology

A combination of anatomic, mucosal, microbial and immune pathogenic processes is believed to underlie sinusitis in children. Children with congenital mucosal diseases (e.g. cystic fibrosis, ciliary dyskinesias) and lymphocyte immune deficiencies (congenital and acquired) typically have chronic recurrent sinus disease. Also, allergic airway diseases in children have both epidemiologic and pathogenic links to sinusitis.

ANATOMIC PATHOGENESIS

Anatomic obstructions of the sinus ostia in the nasopharynx have long been suspected causes of sinusitis. The pathophysiology of osteomeatal obstruction leading to sinusitis is believed to be similar to that of otitis media.[9] For the middle ear space, animal model studies reveal that a lack of ventilation (i.e. oxygenation) of the middle ear results in negative pressure in the closed space, leading to mucosal vascular leakage, edema, inflammation and middle ear fluid accumulation.[10,11] Both anatomic obstructive lesions and mucosal disorders such as mucosal injury from viral upper respiratory tract infections (URTIs), inhalant allergies, cystic fibrosis and ciliary dyskinesias may begin this cascade of pathogenic events. Anatomic variations associated with sinusitis in children in uncontrolled studies include concha bullosa (10%), paradoxical turbinates (4–8%), lateralized uncinate process with hypoplastic maxillary sinus (7–17%), Haller cell (5–10%) and septal deviation (10%).[12,13] Recent studies have failed to establish a relationship between anatomic variations and the severity and extent of chronic sinusitis in children.[14,15] Adenoid hypertrophy has also been implicated as a possible predisposing factor to sinusitis in children by serving as a mechanical obstruction to nasal drainage; however, an etiologic role has not been established.[16,17] Therefore, it is not prudent to base surgical intervention on anatomic variations alone.

MICROBIAL PATHOGENESIS

Both viral and bacterial infections have integral roles in the pathogenesis of sinusitis. Viral URTIs commonly cause sinus mucosal injury and swelling, resulting in osteomeatal obstruction, loss of ciliary activity and mucous hypersecretion. Indeed, radiologic sinus imaging studies of adults and children with common colds revealed that sinus mucosal abnormalities are the norm, and even air-fluid levels in the maxillary sinuses and opacification of the maxillary sinuses are common.[18,19] Specifically, coronal sinus computed tomography (CT) scans of adults with URTIs revealed that 87% had abnormalities of one or both maxillary sinuses, 77% had obstruction of the ethmoid infundibulum, 65% had abnormal ethmoid sinuses, 32% had abnormal frontal sinuses and 39% had abnormal sphenoid sinuses.[19]

Sneezing and nose blowing are thought to introduce nasal flora into the sinuses. Chronically infected adenoids, which may be colonized by bacterial biofilms, and intracellular bacteria (in particular, *Staphylococcus aureus*) in the nasopharynx have been proposed as nasopharyngeal reservoirs of pathogens that may be introduced into the sinuses.[17,20] Normal nasopharyngeal flora such as alpha streptococci and anaerobes may elaborate bacteriocins and other inhibitory compounds that interfere with colonization and infection by pathogenic bacteria.[21] Bacterial growth conditions are favorable in obstructed sinuses, reflected by bacterial concentrations of up to 10^7 bacterial colony-forming units (cfu)/mL in sinus aspirates. Additionally, bacterial biofilms have been demonstrated in sinus mucosal specimens obtained from 45% to 80% of children and adults with chronic sinusitis.[22,23] White blood cell counts in excess of 10,000 cells/mL in sinus aspirates are evidence of a robust inflammatory response to infection. The combination of infection, biofilm formation and inflammation can result in intense epithelial damage and transmucosal injury.[24,25]

Microbiology of Acute and Subacute Sinusitis

The gold standard for microbiologic diagnosis of bacterial sinusitis has been the recovery of $\geq 10^4$ cfu/mL of pathogenic bacteria from a sinus aspirate.[1,26] Studies employing sinus aspirates indicate that the pathogens responsible for acute and subacute sinusitis are similar to each other and mirror those responsible for acute otitis media[26–31] (Table 26-1). *Streptococcus*

https://CafePezeshki.IR

TABLE 26-1 Microbiology of Acute, Subacute and Chronic Sinusitis

Microorganism	FREQUENCY		
	Common	Occasional	Uncommon
Streptococcus pneumoniae	A, C		
Haemophilus influenzae, nontypable	A, C		
Moraxella catarrhalis	A, C		
Streptococcus pyogenes		A, C	
Other streptococcal species (including *Streptococcus milleri*)		A, C	
Staphylococcus aureus (including methicillin-resistant *S. aureus*)		C	A
Diphtheroids		C	
Coagulase-negative staphylococci		C	
Other Gram-negatives, *Moraxella*, *Neisseria*		C	A
Anaerobes		C	A
Respiratory viruses		A, C	
Fungi (*Aspergillus*, *Alternaria*, other dematiaceous fungi, zygomycetes)*		C	A
Acanthamoeba†			A

A – Acute and subacute sinusitis; *C* – Chronic sinusitis.
*Primarily in immunocompromised hosts or associated with allergic fungal sinusitis.
†Primarily in immunocompromised hosts.

pneumoniae is recovered in approximately 20% to 30% of cases, nontypable *Haemophilus influenzae* in approximately 20% to 30%, and *Moraxella catarrhalis* in approximately 10% to 20%. Similar to observations for acute otitis media, a modest reduction in the proportion due to *S. pneumoniae* and a corresponding increase in the proportion due to *H. influenzae* is suggested in populations with routine pneumococcal conjugate vaccination of young children.[21] A significant proportion of *S. pneumoniae* isolates have intermediate or high-level resistance to penicillin due to alterations in penicillin-binding proteins (up to 15–50%). *H. influenzae* and *M. catarrhalis* isolates are frequently β-lactamase positive (25–80% and 90–100%, respectively), and a minority of *H. influenzae* are ampicillin resistant due to altered penicillin-binding proteins and/or an efflux pump.[21,32] Actual resistance rates vary with time period, geographic region and the prevalence of risk factors for resistance (e.g. age <2 years, daycare attendance, recent antibiotic exposure). *Streptococcus pyogenes* and other streptococcal species are generally recovered in only a small number of cases, although several series have highlighted a frequent association between recovery of *Streptococcus anginosus* group with acute sinusitis leading to intraorbital and/or intracranial complications in children and adults.[33,34] *Staphylococcus aureus* and anaerobes are uncommon causes of acute and subacute pediatric sinusitis; however, they are more frequently identified in severe, complicated disease, or, in the case of anaerobes, associated with dental disease.[35] Less commonly recovered bacteria include Gram-negative organisms such as *Eikenella corrodens* and other *Moraxella* and *Neisseria* species. Fungi are uncommonly recovered in acute sinusitis except in immunocompromised patients.[27] The protozoan *Acanthamoeba* has also been identified as a rare cause of sinusitis in severely immunosuppressed hosts.[36,37] Sinus aspirates are sterile in approximately 30% to 35% of children with clinically and/or radiographically diagnosed sinusitis.[1,26,30,38] Acute sinusitis in children has been associated with rhinovirus URTIs.[39] Chronic rhinosinusitis (CRS) has also been associated with nasal respiratory viruses. Comparing nasal lavage from CRS participants with non-CRS controls: nasal respiratory virus detection (50% vs 26%), especially rhinovirus (26% vs 10%), parainfluenza virus (23% vs 8%), influenza virus (13% vs 4%), RSV (11% vs 2%), and multiple respiratory viruses (24% vs 4%, respectively).[40] Respiratory viruses have been recovered from ~10% of sinus aspirates, although sinus aspirates and biopsy investigations with more sensitive modern viral detection methods may provide additional insights.[26] Whether or not respiratory viruses have a direct pathogenic role in sinusitis is poorly understood, but it is clear that viral rhinosinusitis and bacterial sinusitis may have overlapping clinical and radiographic features that make clinical diagnosis of the latter entity challenging.[32]

Microbiology of Chronic Sinusitis

Infection is a key component in pediatric chronic sinusitis, although concomitant factors may be an important contributor to the chronic inflammatory process.[41] In numerous studies, 65% to 100% of children with chronic sinusitis have positive cultures of sinus aspirates.[7,42–46] Rates of recovery of specific organisms vary among studies; this variability is likely to be explained by differences in patient populations, sinuses evaluated, specimen collection methods and microbiologic culture techniques. Despite these differences, certain general observations can be made. *S. pneumoniae, H. influenzae* and *M. catarrhalis* are frequently isolated from children with chronic sinusitis, mirroring acute and subacute sinusitis[7,43,47] (see Table 26-1). With increasing chronicity, other organisms may also be recovered, including *S. aureus, S. pyogenes,* alpha streptococci (including *Streptococcus anginosus* group), group D streptococci, diphtheroids, coagulase-negative staphylococci, *Neisseria* species, Gram-negative aerobic rods (including *Pseudomonas aeruginosa*), and anaerobes; infection is frequently polymicrobial.[42,44–46] *S. aureus* and anaerobes tend to be disproportionately associated with protracted, severe or complicated disease.[48–51] In concert with the overall increase in community-acquired methicillin-resistant *S. aureus* (MRSA) infections, an increased frequency of MRSA-associated sinus infections has been observed.[52] Recovery of anaerobes (e.g. *Peptococcus*, *Peptostreptococcus*, *Propionibacterium acnes, Prevotella*, *Veillonella*, *Fusobacterium*, *Bacteroides* and *Actinomyces*) has varied widely from less than 5% to more than 90%, depending on the populations and sinuses evaluated and microbiologic methods employed.[42–46,53,54] Many anaerobic isolates are β-lactamase producing.[35,55]

In a study using modern profiling techniques to determine the sinus microbiome in chronic rhinosinusitis, an abundance of a single fastidious species, *Corynebacterium tuberculostearicum*, and depletion of *Lactobacillus sakei* was identified

https://CafePezeshki.IR

compared with healthy controls.[56] In a mouse model, *C. tuberculostearicum* was demonstrated to be a sinus pathogen following pretreatment with amoxicillin-clavulanic acid, and protection against this organism was conferred by pretreatment with *L. sakei*.

Fungi, including *Aspergillus*, *Alternaria* and other dematiaceous species (e.g. *Bipolaris* and *Curvularia*), and zygomycetes are occasionally isolated, although invasive disease is uncommon except in immunocompromised children.[45] Respiratory viruses are occasionally identified in sinus mucosal or lavage specimens.[57,58] Interestingly, bilateral cultures of the sinuses are often discordant.[7,46]

Antibiotic resistance has emerged as an important factor in the microbiology of chronic sinusitis. For example, in a 4-year retrospective review of maxillary sinus aspirates from children with sinusitis for more than 8 weeks, rates of nonsusceptibility of *S. pneumoniae* (recovered in 19% of cultures) were 64% for penicillin, 40% for cefotaxime and 18% for clindamycin.[7] Of *H. influenzae* isolates (recovered in 24%), 44% were nonsusceptible to ampicillin, and all *M. catarrhalis* isolates (recovered in 17%) were β-lactamase positive.

IMMUNE PATHOGENESIS

There are few studies in the literature on the immunopathology of sinusitis in children. Most of our knowledge is derived from studies conducted on adults with chronic hyperplastic sinusitis and nasal polyposis (CHS/NP). In adults, chronic sinusitis is characterized by mucosal thickening, goblet cell hyperplasia, subepithelial fibrosis and persistent inflammation[59] (Figure 26-2). These fibrotic changes are thought to be driven by activated eosinophils and their products, including the profibrotic transforming growth factor-β,[60] GM-CSF[61,62] and interleukin (IL)-11.[63] Tissue fibroblasts are stimulated to increase the synthesis and deposition of collagen and matrix products, resulting in thickening of the sub-basement membrane layer.

Current views associate sensitivity to aeroallergens as a primary pathologic mechanism in the development of chronic sinusitis in both adults[64,65] and children.[66] Many studies have shown that the composition of the inflammatory substrate in chronic sinusitis is similar to that seen in allergic rhinitis and the late-phase response to antigen challenge.[64,67]

Th2-Mediated Eosinophilic Inflammation

Although many immune cell types are involved in the pathogenesis of chronic sinusitis, a specific subclass of T lymphocytes (i.e. T helper cell type 2 [Th2] lymphocytes) and eosinophils appear to have a central role. The orchestration of cellular recruitment and activation of the inflammatory infiltrate in CHS/NP has been largely attributed to the Th2 cells and their cytokines (i.e. IL-3, IL-4, IL-5, IL-9, IL-13, GM-CSF). Among immune cell types, eosinophils are the most characteristic and are found in 80% to 90% of nasal polyps.[68] A histopathologic study has investigated the inflammatory cells in pediatric chronic sinusitis and reported similar findings: the numbers of eosinophils, and to a much lesser extent mast cells and T

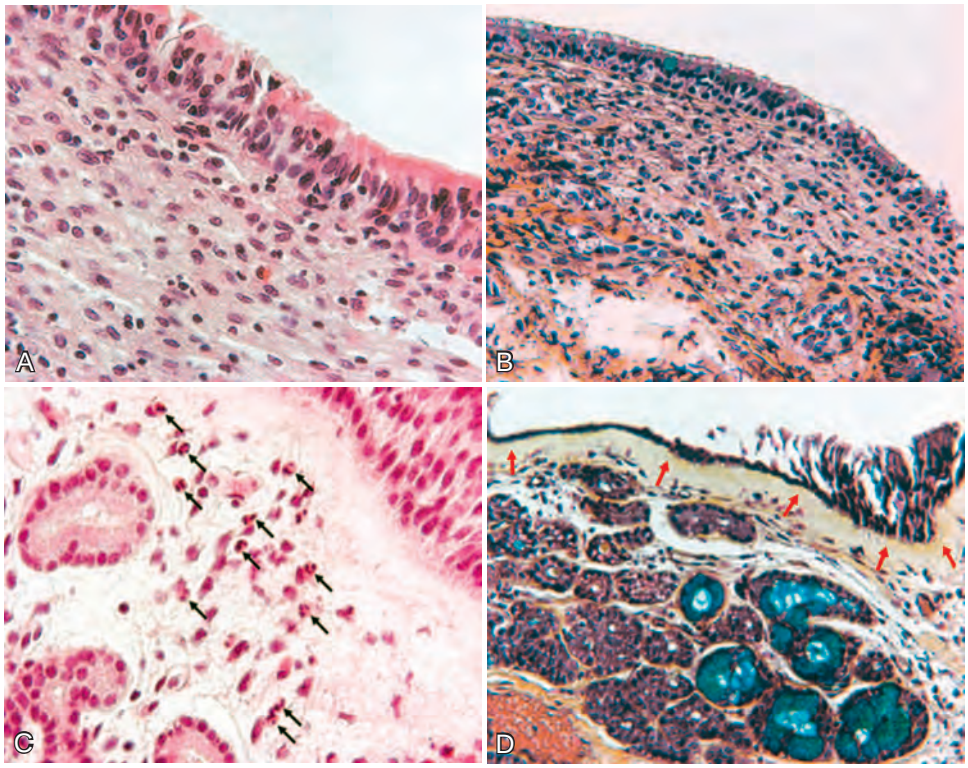

Figure 26-2 Chronic sinusitis: sinus mucosal biopsies from children (A and B) and adults (C and D). **(A)** and **(C)**: Hematoxylin and eosin stained (original magnification ×400). Arrows on the adult photo (C) point to some of the eosinophils in this image. There is a relative abundance of lymphocytes and scarcity of eosinophils in the pediatric specimen (A) compared with adult tissue (C). **(B)** and **(D)**: Pentachrome stained (original magnification ×200). Basement membrane thickening, mucous gland hyperplasia and hypertrophy, and loss of columnar epithelium in the adult sample (D) are not seen in the pediatric sample (B).

https://CafePezeshki.IR

lymphocytes, are significantly increased in children with chronic sinusitis compared to control subjects[69] (see Figure 26-2). The degree of tissue eosinophilia was not affected by the allergic status of patients. This is in agreement with published studies on chronic sinusitis in the adult population where the level of eosinophilic infiltration was found to be similar between allergic and nonallergic patients with either chronic sinusitis without nasal polyps[70,71] or CHS/NP.[72,73] Levels of neutrophils are also increased in the sinus lavage fluid of adults with chronic sinusitis, particularly in nonallergic patients.[74]

Allergic fungal sinusitis (AFS), an uncommon condition due to an intense and chronic allergic reaction to fungi growing in allergic mucin within the sinus cavities, is believed to be pathogenically similar to allergic bronchopulmonary mycoses.[75,76] *Aspergillus* and dematiaceous fungi (e.g. *Alternaria, Curvularia, Bipolaris*) have been cultured from affected sinuses. Nasal polyposis, facial deformity, bony erosion of the sinuses, proptosis and fungal hyphae in allergic mucin filling the sinuses are common in children with AFS.[77–79] Because of its destructive nature, AFS is managed aggressively, with topical and oral corticosteroids after surgical debridement.[75,79] Antifungal therapy (e.g. itraconazole) has been associated with clinical improvement, oral steroid reduction and resolution of disease in some series.[80,81]

Chronic rhinosinusitis in young children differs from the common pathology in older children and adults. Sinus mucosal biopsies from younger children (median age 3.9 years; range 1.4–8.2) with chronic rhinosinusitis (i.e. despite at least two courses of antibiotics, one with a second-line agent), when compared with adult sinusitis controls, had significantly fewer eosinophils, less basement membrane thickness, fewer submucosal mucous glands and less epithelial injury.[82] These young children had more $CD8^+$ (cytotoxic T lymphocytes), $CD20^+$ (B lymphocytes), myeloperoxidase-positive (neutrophils) and $CD68^+$ (monocytes, macrophages) cells in sinus epithelium and/or submucosal tissues.[83] Those whose sinus cultures grew a bacterial pathogen (55%) had significantly more submucosal neutrophils. This pan-immune histopathology might indicate inadequate and/or dysregulated immune responses to bacterial biofilms, pathogenic microbiomes and/or common respiratory viruses.

Asthma and Allergy Risk Factors

Along with histologic evidence that the immune pathologic processes of chronic sinusitis and asthma can be similar, epidemiologic, radiographic and clinical studies also link sinusitis with asthma. In a large European survey study, a strong association of asthma with chronic rhinosinusitis (adjusted odds ratio 3.47) was observed at all ages, and was stronger in those also reporting allergic rhinitis (aOR 11.85).[84] Using plain radiography of the sinuses, the prevalence of radiographic sinus abnormalities was significantly higher in asthmatic children (31%) than nonasthmatic controls (0%).[85] In asthmatic children who were hospitalized for an acute exacerbation, significant radiographic abnormalities of the sinuses were revealed in 87%.[86] A study of patients undergoing surgery for chronic sinusitis found that sinus CT evidence of extensive disease was associated with asthma, allergen sensitization and peripheral blood eosinophilia.[87] Of those with eosinophilia, 87% had extensive sinus disease.

Allergic rhinitis and inhalant allergen sensitization have also been associated with sinusitis in children. In a large birth cohort study, both allergic rhinitis and grass pollen sensitization were significant and independent risk factors for sinusitis in childhood (i.e. age 8 years).[4] Experimentally, in allergic rhinitis subjects, nasal provocation with allergen induced sinus radiographic changes (i.e. mucosal thickening, sinus opacification) and symptoms of headache and pressure in the maxillary sinuses.[88]

GENETIC RISK FACTORS

Association studies between chronic sinusitis and a few candidate gene markers have been reported. Chronic rhinosinusitis, and sometimes nasal polyposis, are hallmark features of cystic fibrosis (CF) and primary ciliary dyskinesia, two autosomal recessive inherited disorders. A small proportion of chronic sinusitis patients without CF are carriers of mutations in the cystic fibrosis transmembrane regulator (*CFTR*) gene, especially in association with the M470V polymorphism;[89,90] however, siblings of CF patients, who are all *CFTR* mutation carriers, do not have an increased prevalence of rhinosinusitis.[91] Modest linkages of single-nucleotide polymorphisms (SNPs) in other CRS candidate genes include TNF-α (CHS/NP),[92] LTC4 synthase,[93] TGF-β1,[94] TNF-β2 (chronic sinusitis),[95] and the major histocompatibility B54 haplotype.[96] A replication study of 53 CRS-associated SNPs replicated significance for SNPs in seven good gene candidates, especially prolyl-tRNA synthetase 2 (odds ratio 0.77), transforming growth factor B1 (OR 0.81) and nitric oxide synthase 1 (OR 0.84).[97]

OTHER RISK FACTORS

Medical conditions that render children susceptible to acute and chronic sinus disease include immune deficiencies (especially patients with T and B lymphocyte defects, AIDS and those receiving immunosuppressive medications) and primary ciliary dyskinesias. The association of gastroesophageal reflux disease (GERD) with chronic sinusitis has also received attention. GERD, diagnosed by pH-monitored nasopharyngeal acid reflux[98] or esophageal biopsy,[99] was associated with rhinosinusitis in children. Phipps and colleagues[100] also reported significantly increased nasopharyngeal reflux in children with chronic sinusitis when compared with a historical control group. Antireflux treatment of their GERD-positive cohort resulted in a 79% improvement in chronic sinusitis symptoms.

Sinusitis Management

OVERVIEW

Medical histories and physical examinations can help to distinguish sinusitis in children from URTIs and other masqueraders and to identify complications from sinusitis and underlying risk factors for chronic recurrent disease. Radiographic imaging studies are particularly helpful in evaluating children with chronic, recurrent or complicated sinusitis. Sinus washings for bacterial culture and targeted antimicrobial therapy, while ideal, are surgical procedures (e.g. antral irrigation) that require general anesthesia in children. Therefore, their use is generally reserved for (1) children with chronic sinusitis that does not adequately improve with multiple courses of antibiotics, (2) children with sinusitis with complications, and (3) sinusitis in immunocompromised hosts. Differential diagnostic considerations are provided in Box 26-1.

https://CafePezeshki.IR

BOX 26-1 DIFFERENTIAL DIAGNOSIS AND RISK FACTORS FOR ACUTE AND CHRONIC SINUSITIS IN CHILDREN

ACUTE SINUSITIS

- Prolonged viral upper respiratory tract infection
- Foreign body in the nose
- Acute exacerbation of inhalant allergies
- Acute adenoiditis or adenotonsillitis

CHRONIC SINUSITIS

- Rhinitis, allergic and nonallergic
- Anatomic causes of nasopharyngeal obstruction
  - Turbinate hypertrophy
  - Adenoid hypertrophy
  - Nasal polyps
  - Severe septal deviation
  - Choanal atresia
  - Asthma
- Neoplasms of the nose and nasopharynx
  - Juvenile angiofibroma
  - Rhabdomyosarcoma
  - Lymphoma
  - Dermoid cyst
- Cystic fibrosis
- Lymphocyte immune deficiencies
  - B lymphocytes – antibody deficiencies
  - T lymphocyte deficiencies – congenital and acquired
- Primary ciliary dyskinesias
- Wegener's granulomatosis
- Churg-Strauss vasculitis
- Dental caries/abscess
- Gastroesophageal reflux disease with nasopharyngeal reflux

Consensus-based guidelines on the management of sinusitis in children have been published, from the American Academy of Pediatrics (AAP),[1] the Infectious Diseases Society of America (IDSA),[101] the American Academy of Allergy, Asthma and Immunology[102] and the American Academy of Otolaryngology–Head and Neck Surgery.[103] These consensus guidelines, along with randomized controlled trials, systematic reviews and meta-analyses of specific management topics, have been considered in the following discussion.

HISTORY AND PHYSICAL EXAMINATION

Acute Sinusitis

Persisting, non-improving symptoms, such as nasal discharge (76%) and cough (80%), lasting longer than 10 to 14 days are the most common presentation of acute sinusitis in children.[1,26,101] Nasal discharge can be of any quality, and cough can be daytime, nighttime or both. Fever may accompany the illness. Less common presentations include severe symptoms such as high fever, purulent nasal discharge or facial pain for 3 to 4 days or longer at the start of illness, or worsening symptoms after 5 to 6 days of a viral URTI that had been improving.[1,101]

Although headaches and sinus tenderness are generally believed to be the hallmarks of sinusitis, a study of 200 sinusitis patients did not find a significant correlation of facial pain or headache with abnormal findings on sinus CT.[104] Additionally, the reported regions of facial pain did not correlate with radiographically identified sinus abnormalities. The nasal cavity is usually filled with discharge and the nasal mucosa and turbinates are generally edematous. Following decongestion of the nasal cavity, purulent drainage coming from the middle meatus can sometimes be observed in older children. Tenderness over the frontal sinus in older children may indicate frontal sinus disease, but tenderness, in general, is uncommon in children with acute disease. Transillumination, considered by some to be a useful tool in adults, is unreliable in children.

Chronic Sinusitis

The most common symptoms associated with chronic sinusitis in children are nasal discharge (59%), facial pain/discomfort (33%), nasal congestion (30%), cough (19%) and wheezing (19%).[103] Nasal discharge can be of any quality, but purulent discharge is the most common. Daytime mouth-breathing and snoring are common complaints. Examination of the nasal cavity may or may not reveal nasal discharge. The nasal turbinates are generally enlarged and can be edematous or erythematous. Although facial pain or discomfort may be a common complaint, tenderness over the sinuses is an uncommon finding in children.

RADIOGRAPHIC IMAGING

A consensus report provided by the American College of Radiology[105] provided appropriateness criteria of different radiographic imaging modalities in assessing pediatric sinus disease. Currently, coronal CT is the recommended examination for imaging persistent or chronic sinusitis in patients of any age. Plain sinus radiographs (Waters and Caldwell projections), although widely available, can both underdiagnose and overdiagnose sinus soft tissue changes. Magnetic resonance imaging provides superior soft tissue delineation; however, it is expensive, has limited availability and does not provide bony details of the osteomeatal complex. Conventional tomography, nuclear medicine studies and ultrasound have significant limitations for imaging the sinuses.

It is tempting to consider sinus mucosal abnormalities and associated anatomic variations seen in imaging studies in symptomatic patients as clear indications for sinusitis therapy (e.g. antimicrobial therapy and sinus surgery). However, the clinical importance of such findings is challenged by studies that have revealed a high prevalence of such soft tissue findings in people without sinusitis symptoms or with URTIs.[18,19] In these studies, URTI symptoms and associated radiographic sinus abnormalities have improved without specific sinusitis therapy (i.e. no antibiotics or surgery for sinusitis).

The American College of Radiology consensus report has the following recommendations: (1) the diagnoses of acute and chronic sinusitis should be made clinically and not on the basis of imaging findings alone; (2) no imaging studies are indicated for acute sinusitis except for cases where complications are suspected or cases that are not responding to therapy; and (3) if imaging information in patients with chronic sinusitis is desired, coronal sinus CT is recommended. The use of plain radiographs of the sinuses (i.e. Waters and Caldwell views) is generally discouraged in this report, except in children younger than 4 years of age. The use of Waters view radiographs in children is supported by a study in which the sensitivity and specificity of a Waters view radiograph to diagnose chronic sinusitis in children were 76% and 81%, respectively.[106] In the same study, limited coronal CT scans were better than sinus x-rays and nearly as good as full sinus CT evaluations.

https://CafePezeshki.IR

SINUSITIS COMPLICATIONS

Complications of sinusitis (Table 26-2) are generally believed to be acute events that result from a combination of outflow obstruction and pathogenic bacteria in the sinuses. Intracranial extension of infection is by direct erosion, thrombophlebitis or extension through preformed pathways (e.g. fracture lines). The incidence of intracranial complications in children hospitalized for sinusitis was 3%.[107]

Orbital complications from sinusitis are primarily the result of acute ethmoid disease but could occasionally be extensions of frontal disease.[108] A classic description of the progression of sinusitis to orbital complications is as follows: inflammatory edema, orbital cellulitis, subperiosteal abscess, orbital abscess and cavernous sinus thrombosis.[109] The most common presentations of orbital complications include eyelid edema, orbital pain, diplopia, proptosis, and chemosis, as well as fever, nasal discharge and headache.[110] In a cohort of hospitalized children with orbital complications from sinusitis, 72% had a history of a URTI and 24% had received oral antibiotic therapy prior to their presentation with orbital complications.[110] It can be difficult to differentiate between preseptal cellulitis and orbital cellulitis on clinical parameters alone (i.e. based on lid edema and pain), without an imaging study. In orbital cellulitis, proptosis progresses and chemosis, ophthalmoplegia and reduced visual acuity may ensue. Orbital abscesses and cavernous sinus thrombosis caused by bacterial sinusitis are uncommon today.

Intracranial complications from sinusitis primarily result from frontal or sphenoid sinus disease.[107] There are many similarities between the pathogenesis of intracranial extension of sinusitis and that of otitis media. Intracranial complications in the preantibiotic era were devastating, with mortality rates of up to 75%. Current mortality rates for these complications are between 10% and 20%. Cavernous sinus thrombosis is a unique intracranial complication of ethmoid and sphenoid sinusitis by direct extension or venous communication. This complication is characterized by a toxic-appearing patient with infectious/inflammatory involvement of cranial nerves III, IV and VI, resulting in ophthalmoplegia. Progressive disease within the cavernous sinus can lead to carotid artery thrombosis and mycotic aneurysm formation, resulting in neurologic sequelae and death.

Complications of maxillary sinusitis are rare. Mucoceles in the maxillary sinus are occasionally encountered in children with cystic fibrosis. Osteomyelitis of the maxillary sinus, more prevalent in the preantibiotic era and in adults with dental disease, is rare today.

TABLE 26-2 Sinusitis Complications (by Sinus Involvement)

Complication	Maxillary Sinus	Ethmoid Sinus	Frontal Sinus	Sphenoid Sinus
Osteomyelitis	+		+ +	
Mucocele	+ +	+ +	+ +	+
Preseptal cellulitis		+ + +		
Orbital cellulitis		+ + +	+	
Subperiosteal abscess		+ + +		
Orbital abscess		+		
Meningitis			+ +	
Epidural abscess			+ +	
Subdural abscess			+	
Brain abscess			+	

+++ – Frequent, ++ – less frequent, + – least frequent.

Sinusitis Treatment

ANTIMICROBIAL THERAPY

Acute and Subacute Sinusitis

The goals of therapy for acute and subacute sinusitis are to hasten clinical improvement, prevent intracranial and orbital complications, and prevent mucosal damage that may predispose to chronic sinus disease[27,28] (Box 26-2). The actual benefit of antibiotics in achieving these goals has not been conclusively proven. A pivotal randomized trial showed that antibiotic therapy (amoxicillin or amoxicillin-clavulanic acid) for acute sinusitis, defined by clinical and plain radiograph criteria, was associated with symptom resolution in 66% of children at 10 days, significantly greater than the 43% rate of resolution among placebo-treated subjects.[111] Two subsequent randomized trials call into question the benefit of antibiotic treatment. One compared amoxicillin, amoxicillin-clavulanate and placebo in children with clinically diagnosed acute sinusitis and found no differences in symptom improvement at 14 days (79–81%), or relapse or recurrence rates.[112] The other compared cefuroxime and placebo in children with nonimproving respiratory symptoms and abnormal maxillary sinus ultrasonography; no difference in rates of improvement or cure at 14 days (84–91%) was observed.[113] A fourth trial randomized children with acute sinusitis to receive amoxicillin-clavulanate or placebo. Antibiotic treatment was associated with a superior cure rate (50% vs 14%) and less treatment failure (14% vs 68%).[114] In the IDSA guidelines, a meta-analysis of antibiotic randomized, controlled

BOX 26-2 KEY CONCEPTS

USE OF ANTIMICROBIALS IN SINUSITIS

- For acute and subacute sinusitis, target therapy toward the same pathogens responsible for acute otitis media: *Streptococcus pneumoniae, Haemophilus influenzae* and *Moraxella catarrhalis.*
- Broad-spectrum antibiotics targeting β-lactamase-producing organisms and resistant *S. pneumoniae* should be used when there is:
  Poor response to first-line antibiotics
  Moderate-severe, chronic or recurrent disease
  Complicated or potentially complicated disease (including frontal or sphenoidal involvement)
  High risk for first-line antibiotic-resistant organisms: antibiotic therapy within the preceding 30–90 days, daycare attendance, age <2 years, high endemic rates of resistant pathogens
- Treat acute sinusitis for at least 10–14 days and until asymptomatic plus an additional 7 days.
- Consider sinus aspiration for microbiologic identification and targeted antimicrobial therapy if disease is:
  Severe
  Associated with orbital or intracranial complications
  Unresponsive to multiple antibiotic courses
  In immunocompromised patients

https://CafePezeshki.IR

trials of children with acute sinusitis concluded modest benefit, with approximately five children requiring therapy for one additional child with cure or improvement.[101] Meta-analyses of studies in adults with acute sinusitis suggest similar modest benefit of antibiotic therapy, in part because approximately two thirds of adults with acute sinusitis improve without antibiotic treatment.[101,115–119]

Despite lack of definitive proof of efficacy, antibiotic treatment is recommended for most children with acute and subacute sinusitis because bacterial pathogens are recoverable from the majority of affected sinuses,[1,17] antibiotic treatment may be associated with greater rates of clinical improvement, and preventing sinusitis complications is a major concern.[1,101] Several days of watchful waiting for spontaneous clinical improvement prior to initiating antibiotic treatment is an alternative for persistent, non-severe symptoms.[1] There is a paucity of trial data in children to indicate which antibiotics may be superior, although studies performed in adults suggest comparable clinical efficacy of commonly used agents.[21] Antibiotic selection is frequently directed by typical susceptibility profiles of frequently isolated bacteria and pharmacokinetic properties of candidate antibiotics[27,28] (Table 26-3). Because their microbiology is similar, the approach to antibiotic selection for acute and subacute sinusitis is similar. Amoxicillin is commonly recommended for previously untreated, mild and uncomplicated acute sinusitis based on its excellent tolerability, low cost, narrow spectrum and track record for both sinusitis and otitis media; this option is preferred in the AAP guidelines for uncomplicated, mild-moderate disease in children lacking risk factors for antibiotic resistance.[1,120,121] This parallels recommendations for adults, in whom meta-analyses of randomized trials support the efficacy of amoxicillin (and penicillin) for acute sinusitis.[115,122,123] However, a 5% to 20% failure rate can be expected with amoxicillin because of resistant *S. pneumoniae, H. influenzae* and *M. catarrhalis*.[1,31] High-dose amoxicillin (80–90 mg/kg/day) can be used to improve eradication of potentially non-susceptible *S. pneumoniae* in children with risk factors for antibiotic resistance (e.g. antibiotic therapy within the preceding 30 to 90 days, daycare attendance, age <2 years, and/or high local rate of penicillin-nonsusceptible *S. pneumoniae*).[1,27,101] Initial therapy with a broader antibiotic targeting β-lactamase-producing organisms and resistant *S. pneumoniae* should be considered in the following circumstances: a history of poor response to amoxicillin; moderate-severe, complicated or potentially complicated disease (including frontal or sphenoidal involvement); protracted or recurrent disease; and high risk for antibiotic resistance (age <2 years, day care, recent antibiotic use).[1,31,101,121] Amoxicillin-clavulanic acid (80–90 mg/kg/day of amoxicillin component) is generally recommended in these situations and, in the ISDA guidelines, is preferred first-line therapy.[1,101] Alternatives include cephalosporins (e.g. cefuroxime, cefpodoxime, cefprozil, cefdinir, cefixime), combination cephalosporin with clindamycin to provide extended Gram-positive (e.g. *S. pneumoniae*, methicillin-susceptible and methicillin-resistant *S. aureus*) and anaerobic coverage, or the fluoroquinolone levofloxacin.[1,101] Macrolides (e.g. azithromycin) are generally not recommended because of increasing resistance of *S. pneumoniae* and *H. influenzae* unless other options are limited by allergies.[1,27,101,121] The role of trimethoprim-sulfamethoxazole has similarly been reduced by increasing resistance of both *S. pneumoniae* and *H. influenzae;* it remains an option in patients with β-lactam allergy or known infection with methicillin-resistant *Staphylococcus aureus*.[1,27,28,101,121]

TABLE 26-3 Selected Antibiotics for Acute, Subacute and Chronic Sinusitis

Antibiotic	Comments
Penicillins Amoxicillin Amoxicillin-clavulanate	Untreated, mild, uncomplicated disease; high dose targets resistant *Streptococcus pneumoniae* Poor response to amoxicillin; moderate-severe, complicated or protracted disease; or high risk for antibiotic resistance High dose of amoxicillin component targets resistant *S. pneumoniae*
Cephalosporins Cefuroxime Cefpodoxime Cefprozil Cefdinir Cefixime Cefotaxime Ceftriaxone	Poor response to amoxicillin or amoxicillin-clavulanate; moderate-severe, complicated or protracted disease; penicillin allergy; or high risk for antibiotic resistance. May be combined with clindamycin for additional Gram-positive (*S. pneumoniae*, *S. aureus*, streptococci) coverage. Intravenous agents (cefotaxime, ceftriaxone) for severe or complicated disease or disease unresponsive to oral antibiotics
Macrolides Clarithromycin Azithromycin	Recommended only if significant β-lactam allergy limits other options; increasing resistance of *S. pneumoniae* and *Haemophilus influenzae*
Trimethoprim-sulfamethoxazole	Recommended only if significant β-lactam allergy limits other options or if known methicillin-resistant *Staphylococcus aureus*; increasing resistance of *S. pneumoniae* and *H. influenzae*
Clindamycin	Activity against Gram-positive aerobes (including many *S. pneumoniae*, many methicillin-susceptible and methicillin-resistant *S. aureus*, and streptococci) and anaerobes; can be combined with cephalosporin to provide broad coverage; option if significant β-lactam allergy or poor response to β-lactam antibiotics
Levofloxacin	Fluoroquinolone antibiotic; option if severe penicillin allergy or poor response to β-lactam antibiotics
Vancomycin	Intravenous; severe or complicated disease or disease unresponsive to oral antibiotics

If amoxicillin is chosen for initial therapy, lack of clinical response within 48 to 72 hours should prompt a change to a broader agent (e.g. amoxicillin-clavulanate).[1,28,31] If amoxicillin-clavulanate is used initially without clinical response, include either a combination of cephalosporin with clindamycin, or levofloxacin.[1,101] If the disease becomes severe, protracted, associated with orbital or intracranial complications, or unresponsive to multiple antibiotic trials, sinus lavage for microbiologic diagnosis and/or intravenous antibiotics (e.g. cefotaxime, ceftriaxone, vancomycin, clindamycin) can be considered.[1,19,121] In immunocompromised hosts, sinus lavage should be considered earlier because of their increased risk for atypical and resistant organisms and their impaired immune response to them.[31,121]

There has been no systematic evaluation of the optimal duration of antibiotic therapy for acute sinusitis in children. Data obtained in adults suggest that treatment for 10 days affords microbiologic cure rates in excess of 90%, whereas 7-day

https://CafePezeshki.IR

courses are associated with microbiologic failure in 20%. However, treatment courses as short as 1 to 5 days in children have had encouraging clinical results in a limited number of trials.[124–126] In general, a 10- to 14-day treatment course is recommended for the majority of children, tailored to a patient's response (e.g. treat until asymptomatic plus an additional 7 days).[1,31,101,121,127] Longer courses (e.g. 3 to 4 weeks) should be considered for severe disease or if resolution is unusually slow.[27,32,121,127]

Chronic Sinusitis

Few studies of the efficacy of antibiotics in hastening clinical improvement from and preventing complications of chronic sinusitis have been reported; furthermore, their findings are inconsistent. In atopic children with chronic sinusitis, amoxicillin and trimethoprim-sulfamethoxazole were associated with higher response rates than either erythromycin or an oral antihistamine/decongestant without antibiotic.[128] However, in other studies of subacute or chronic sinusitis, response rates with antibiotic therapy plus decongestant were not greater than those with decongestant plus nasal saline[129] or with placebo or drainage procedures.[47]

Despite lack of firm evidence of efficacy, antibiotics are generally prescribed for chronic sinusitis because pathogenic bacteria in the sinuses have been well documented. Broad-spectrum antibiotics are chosen for empirical therapy, with the choice dependent on previous treatments and anticipated resistance patterns of pathogens such as *S. pneumoniae, H. influenzae, M. catarrhalis and S. aureus* (see Table 26-3). Favorable options include amoxicillin-clavulanic acid, cefuroxime and third-generation cephalosporins such as cefpodoxime and cefdinir. If these agents are unsuccessful, a trial of clindamycin to target β-lactam-resistant *S. pneumoniae,* methicillin-susceptible and methicillin-resistant *S. aureus,* and anaerobes is reasonable.[27,130,131] Trimethoprim-sulfamethoxazole may be helpful for a patient with known infection with methicillin-resistant *S. aureus* resistant to clindamycin. The roles of oxazolidinones (e.g. linezolid) and newer fluoroquinolones such as levofloxacin for pediatric chronic sinusitis are yet to be determined. After multiple failed antibiotic courses, concern for resistant organisms increases, and sinus lavage for culture and susceptibilities should be considered to facilitate targeted antibiotic treatment.[7,31,43,121,132] Nasal swabs have insufficient positive predictive value to accurately guide antibiotic therapy.[1,38,46,57,101,133] Middle meatus swabs may have better, although still imperfect, correlation with sinus cultures.[1,46,57,101,134] Patients with very resistant isolates and/or extremely refractory disease may benefit from intravenous therapy with agents such as cefotaxime, ceftriaxone, cefuroxime, ampicillin-sulbactam, ticarcillin-clavulanate, piperacillin-tazobactam, vancomycin or clindamycin.[43,121,132,135] For invasive fungal sinusitis, surgical debridement and systemic antifungal therapy are indicated.[136]

The optimal duration of therapy is unknown. A minimum of 14 days is generally recommended if there is a prompt response. Longer courses (e.g. 3–6 weeks) can be considered for slower responses, and treatment for 7 days beyond the patient becoming symptom-free has been suggested.[32,121,127] It has been suggested that prolonged courses of intravenous antibiotics may be effective for treating bacteria in sinus-containing biofilms; however, this concept remains to be proven.[17]

Antibiotic prophylaxis with agents such as amoxicillin or sulfonamides was previously used for children with recurrent sinusitis by analogy with recurrent otitis media.[31,103] An alternative approach was short-term, preemptive prophylaxis with the onset of URTIs in children who have frequently recurrent sinusitis triggered by URTIs, a strategy that was beneficial for recurrent otitis media.[137] However, increasing rates of antibiotic resistance and the resulting impetus to reduce antibiotic exposure have restricted prophylactic antibiotic strategies in recent years.[32,138]

SINUS SURGERY

Acute Sinusitis

The indications to perform sinus surgery on a child with acute and uncomplicated sinusitis are limited. Acute sinusitis symptoms are generally relieved by medical therapy consisting of antibiotics and adjunctive medical therapy. However, acute frontal or sphenoidal sinusitis in an adolescent may benefit from emergent surgical drainage for pain relief. In immunocompromised hosts, sinus irrigations to obtain specimens for microbial staining and culturing may be needed to identify potentially unusual, opportunistic pathogens.

Chronic Sinusitis

Endoscopic sinus surgery (ESS) was popularized after sinus surgery using endoscopes was imported from Europe by American surgeons in the 1980s. The safety and efficacy of this procedure in pediatric sinusitis cases have been reported, based primarily on satisfaction questionnaires.[139–141] A meta-analysis using data from 13 studies on the outcomes of pediatric ESS concluded that ESS is a safe and effective treatment of chronic sinusitis in children.[142] However, it is important to note that the studies included in this analysis lack an untreated control group, and most of the data sources were retrospective chart reviews.

Others have reported symptomatic and clinical improvements following ESS in special populations such as children and adults with asthma[143,144] and cystic fibrosis,[145] although polyp recurrence in cystic fibrosis exceeds 50%.[142] Opposing this trend have been sporadic commentaries challenging the impression that pediatric sinusitis is a surgical disease.[138,146] Indeed, in a cohort of children who underwent ESS at an early age, a markedly higher rate of revision surgeries (50%) was required (e.g. for postsurgical osteomeatal scarring), in comparison with a control group of young, chronic sinusitis patients who had not had prior sinus surgery (9%).[147]

Despite its unproven clinical efficacy and uncertain indications, ESS has safety attributes that surpass those of its predecessors. ESS with pediatric instrumentation can provide sinus drainage and sinus ablation. Specifically, the ostium of the maxillary sinuses can be widened by endoscopic antrostomy. By performing endoscopic ethmoidectomy, the ethmoid cells and polypoid tissue can be removed, frontal duct drainage can be enhanced and the sphenoid sinus can be entered and drained. A technologic advance in ESS, balloon sinuplasty, uses angioplasty balloon technology to expand the sinus ostium to increase sinus aeration and/or establish drainage. The therapeutic benefit of balloon sinuplasty has not yet been determined.[148] However, the light angioplasty guide wire can be used to enter the frontal sinus for bacteriologic sampling and irrigation.

Surgery for Sinusitis Complications

The type of sinusitis complication dictates whether an otolaryngologist will need the additional expertise of an

https://CafePezeshki.IR

ophthalmologist or a neurosurgeon. Generally, the participation of a pediatrician or an infectious disease consultant in the care of a child with sinusitis complications is beneficial.

Subperiosteal and orbital abscesses can be drained through either an external or endoscopic approach. Small epidural abscesses may be treated medically. Other intracranial abscesses are usually drained by a neurosurgeon. Complicated frontal sinusitis (e.g. mucocele, osteomyelitis of the frontal bone) is treated through an external approach, with the intent to achieve drainage and debridement. Severe cases in which long-term antimicrobial therapy has failed may need sinus obliteration, cranialization and/or other reconstructive procedures. Mucoceles of the ethmoid and sphenoid sinuses can be drained endoscopically. Children with toxic shock syndrome from sinusitis should undergo sinus irrigation for culture and drainage. Neurosurgical drainage is sometimes indicated.

Adjunctive Surgical Procedures

Adenoid hypertrophy is a cause of chronic sinusitis and the benefits of adenoidectomy for chronic sinusitis have been suggested by earlier uncontrolled studies.[149,150] A meta-analysis of 10 trials (six cohort and four case series) showed significant reduction of postoperative sinusitis symptoms.[151] The basis for improvement by adenoidectomy is unknown. No correlation between maxillary sinus and adenoid cultures in patients with chronic rhinosinusitis was found.[16] An abundance of bacterial biofilm coating the surface of adenoid surgical specimens in patients with chronic rhinosinusitis vs obstructive sleep apnea was observed.[152] Chronic sinusitis patients with nasal obstruction from adenoid hypertrophy are likely to have some symptomatic benefit from an adenoidectomy regardless of effects on the sinuses.

Some children with chronic sinusitis have inferior turbinate hypertrophy causing nasal obstruction. There are no published reports on the efficacy of inferior turbinate cauterization or reduction in the treatment of chronic sinusitis. In subjects in whom intranasal corticosteroid therapy for nasal obstructive symptoms associated with inferior turbinate hypertrophy has failed, a turbinate reduction procedure for symptomatic relief may be considered.

ADJUNCTIVE MEDICAL THERAPY

Clinicians have used an assortment of agents in conjunction with oral antibiotics for the treatment of both acute and chronic sinusitis in children, including nasal saline washes (isotonic and hypertonic), topical and oral decongestants and antihistamines, topical anticholinergics, leukotriene receptor antagonists, topical anti-infectives and corticosteroids (intranasal and oral). The use of these agents is largely based on their theoretical benefits of improving associated rhinitis and rhinorrhea by decreasing mucosal inflammation, edema and mucous production, and increasing mucociliary transport, thereby improving nasal patency and presumably ostial drainage. They are generally discouraged in treating acute sinusitis in children.[1,101] Cochrane reviews addressing the efficacy of intranasal saline washes[153] and intranasal corticosteroids[154] for rhinosinusitis in adults concluded significant improvement by saline washes as monotherapy and in combination with intranasal corticosteroids for chronic sinusitis symptoms. For acute sinusitis, there was limited support for intranasal corticosteroids as monotherapy or in combination with oral antibiotics.[154,155] In adults with chronic rhinosinusitis with nasal polyposis, intranasal corticosteroids improved polyp scores and patients' symptoms, and reduced postoperative polyp recurrence.[156] Topical and systemic antifungal therapies have been purported to benefit patients with chronic rhinosinusitis. A recent systematic review with meta-analyses found no significant benefit and higher adverse event reporting in the antifungal-treated groups.[157]

Conclusions

Sinusitis in children is a common problem. Diagnosis is challenging due to the overlap of symptoms, physical findings and radiographic findings with those of common URTIs. Sinusitis rarely leads to severe, life-threatening complications as a result of direct extension of bacterial infection from the sinuses. Management of uncomplicated, acute sinusitis consists of antimicrobial treatment aiming for symptom relief and prevention of complications and recurrence. Radiographic imaging studies (e.g. coronal sinus CT scans) may be helpful in chronic, recurrent or complicated sinusitis. Antral irrigation can provide sinus specimens for bacterial culture and targeted antimicrobial therapy in patients with chronic, refractory and complicated disease. Sinus surgery in uncomplicated sinusitis, especially in young children, should generally be avoided. Great reductions in mortality caused by sinusitis complications coincide with advances in antimicrobial and surgical therapies.

27 Chronic Cough

HENRY MILGROM

KEY POINTS

- Cough is an important defense mechanism.
- Cough is a common manifestation of disease in childhood.
- Cough may be classified as acute (lasting <3 weeks), subacute (lasting 3 to 8 weeks), or chronic (lasting >8 weeks).
- The cause of chronic cough can be determined in most patients; specific therapy based on a systematic evaluation is usually successful.
- Congenital anomalies and aspiration are relatively uncommon causes of chronic cough in children.

Introduction

Cough is a widespread sign and symptom of diseases ranging from uncomplicated respiratory tract infections to serious illnesses affecting several organ systems. It is a source of discomfort for the young patient and anxiety for the parents.[1,2] In the years 1995–1996, 24 million annual physician visits for cough took place in the USA, the largest number documented for a single symptom.[3] Nearly half the patients were younger than 15 years old. In this young cohort, cough accounted for 8.5% of all medical appointments.[3] Pediatric texts generally describe chronic cough as a condition that persists for more than 3 weeks. This observation suggests that chronic cough is likely to improve in time without treatment.[4] A better informed classification by Irwin and colleagues divides cough into three categories: acute, lasting less than 3 weeks; subacute, lasting 3 to 8 weeks; and chronic, lasting more than 8 weeks.[5] Irwin's definition of chronic cough excludes most self-limiting cases. A chronic cough by these criteria often lasts much longer than 8 weeks and requires medical attention.

Viral infections of the upper respiratory tract are the most common causes of acute cough. Typically, the symptoms resolve within 10 to 14 days.[6] Patients with subacute cough most often have a history of recent upper respiratory tract infection or seasonal allergic rhinitis (e.g. postinfectious cough, bacterial sinusitis and asthma). Children with chronic or recurrent episodes of dry, nonproductive cough over several months, require careful and systematic evaluation for the presence of specific diagnostic indicators.[7] They pose a perplexing problem in pediatric practice and call for a careful evaluation. Cough may be a manifestation of an underlying disorder that must be identified and treated. Many children with chronic cough have experienced repeated treatment failures, and the families have come to regard the condition as permanent and untreatable. Fortunately, in most cases, this presupposition is inaccurate, but a systematic approach to the diagnosis is necessary, and therapy, to be effective, may have to be directed simultaneously at more than one involved cough mechanism. Evidence-based algorithms to manage the chronic cough of children based on validated outcome measures and a priori definitions to designate resolution should be put to use.[8,9] Child-specific cough management protocols are advocated in Australia, the USA and the UK.[6]

Differential Diagnosis
(Figure 27-1, Box 27-1)

The differential diagnosis of cough in childhood varies with the age of the patient, the duration, character and time of occurrence of the cough, associated signs and symptoms, and the patient's exposure history. In the neonatal period, congenital abnormalities, especially pulmonary or cardiac, must be considered. Prematurity, especially in a patient who had required mechanical ventilation, may lead to bronchopulmonary dysplasia or the development of tracheal or bronchial stenosis. Vomiting and regurgitation may be the presenting signs and symptoms of gastroesophageal reflux (GER) or a tracheoesophageal fistula. Recurrent choking or cough associated with difficulty in sucking or swallowing suggests aspiration. Cough may occur in the course or following resolution of a respiratory infection. Attendance in daycare increases the risk of upper respiratory symptoms and infections in young children. In the toddler, foreign body aspiration and cystic fibrosis are added to the list of causes. A history of fever and/or presentation in winter suggests a viral etiology; seasonal occurrence suggests asthma or seasonal allergic rhinitis; year-round symptoms suggest perennial allergic rhinitis. Maternal smoking, in particular, appears to influence the development of respiratory symptoms in young children.[10] In the older child, immune deficiency, tuberculosis and psychogenic cough enter into the differential diagnosis. Sinusitis, postnasal drip and GER may contribute to cough at any age. Cigarette smoking and psychogenic causes also require consideration among adolescents.[11] A recent study showed that in otherwise healthy children with unexplained chronic cough, a significant proportion of the coughs was preceded by episodes of reflux. Most of these episodes were acidic in older children but not in infants[12](Figure 27-3). Early evaluation and treatment of children with recurrent cough, sinusitis, foreign-body aspiration or GER are important to prevent bronchiectasis.[13]

How often do normal children cough? Accurate answers come from studies that used cough recorders. Cough frequency over 24 hours was 11.3, with a range of one to 34 in 41 children free from respiratory infection for at least 1 month. Only two children coughed at night.[14] In children with chronic cough, the frequency was 65/day and in normal controls 10/day.[15]

BOX 27-1 DIFFERENTIAL DIAGNOSIS OF CHRONIC COUGH

- Congenital anomalies
  - Connection of the airway to the esophagus
    - Laryngeal cleft
    - Tracheoesophageal fistula
  - Laryngotracheomalacia
    - Primary laryngotracheomalacia
    - Laryngotracheomalacia secondary to vascular or other compression
  - Bronchopulmonary foregut malformation
  - Congenital mediastinal tumors
  - Congenital heart disease with pulmonary congestion
  - Chiari type I malformation
- Infectious or postinfectious cough
  - Recurrent viral infection (infants and toddlers)
  - Chlamydial infection (infants)
  - Whooping cough-like syndrome
    - *Bordetella pertussis* infection
    - *Chlamydia* infection
    - *Mycoplasma* infection
    - Cystic fibrosis (infants and toddlers)
  - Granulomatous infection
    - Mycobacterial infection
    - Fungal infection
  - Suppurative lung disease (bronchiectasis and lung abscess)
    - Cystic fibrosis
    - Foreign body aspiration with secondary suppuration
    - Ciliary dysfunction
    - Immunodeficiency
      - Primary immunodeficiency
      - Secondary immunodeficiency (acquired immune deficiency syndrome)
    - Paranasal sinus infection
    - Cough-variant asthma
- Rhinitis related
  - Allergic rhinitis
  - Rhinosinusitis
  - Vasomotor rhinitis
  - Postnasal drip
- Gastroesophageal reflux without aspiration
- Vocal cord dysfunction
- Aspiration (fluid material)
  - Dyskinetic swallowing with aspiration
    - General neurodevelopmental problems
    - Möbius' syndrome
    - Chiari malformations
  - Bottle-propping and bottle in bed (infant and toddlers)
  - Gastroesophageal reflux
- Foreign body aspiration (solid material)
  - Upper airway aspiration (tonsillar, pharyngeal, laryngeal)
  - Tracheobronchial aspiration
    - Esophageal foreign body with an obstruction or aspiration resulting from dysphagia
- Physical and chemical irritation
  - Smoke from tobacco products (active and passive)
  - Wood smoke from stoves and fireplaces
  - Dry, dusty environment (hobbies and employment)
  - Volatile chemicals (hobbies and employment)
  - Dampness
  - Mold
- Psychogenic cough
- Habit cough

Modified from Brown MA, Morgan WJ. Clinical assessment and diagnostic approach to common problems. In: Taussig LM, Landau LI, editors. Pediatric respiratory medicine. St Louis: Mosby; 1999.

Unfortunately, most studies rely on parents to give an account of their child's cough, a method that has been shown to provide inaccurate information.[16,17] When questionnaires administered to parents about their child's coughing were compared to overnight recordings performed in 145 homes, the agreement was low.[18]

Pathophysiology
(Figures 27-2 and 27-3)

Cough serves as a protective mechanism to clear the respiratory tract and to defend it against the aspiration of noxious materials. While mechanical barriers limit the exposure of the respiratory tract to inhaled pathogens, the mucociliary apparatus and cough act to expel any organisms that may have bypassed the primary defenses. Two associated processes, bronchoconstriction and mucus secretion, add to its effectiveness. Recurrent partial collapse or incomplete inflation of the lungs and pneumonia associated with ineffective cough attest to its importance.[19]

Cough is executed as a complex reflex, an automatic or involuntary response to a stimulus, completed by the afferent and efferent pathways and a putative cough center in the brain, but also, at least in part, intensified or restrained under voluntary control. The main afferent pathways of cough originate in nerve receptors immediately beneath the respiratory epithelium in the larynx and the tracheobronchial tree, and in extrapulmonary

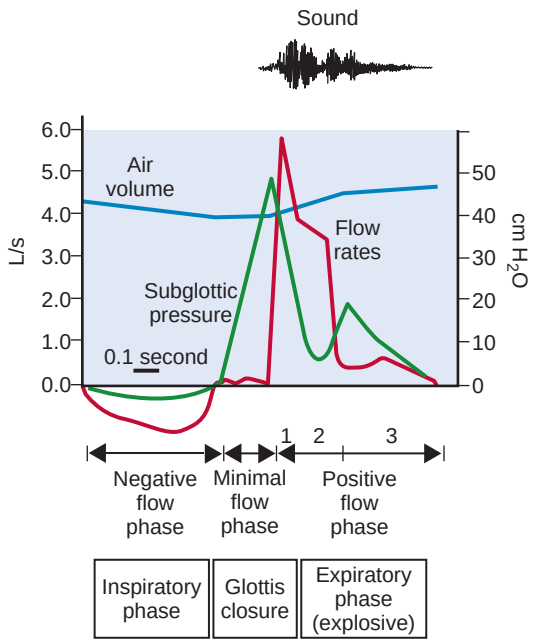

Figure 27-2 Changes in flow rate, air volume, subglottic pressure and sound level generated during the act of coughing. *(From Bianco S, Robuschi M. Mechanics of cough. In: Braga PC, Allegra L, editors. Cough. New York: Raven; 1989.)*

https://CafePezeshki.IR

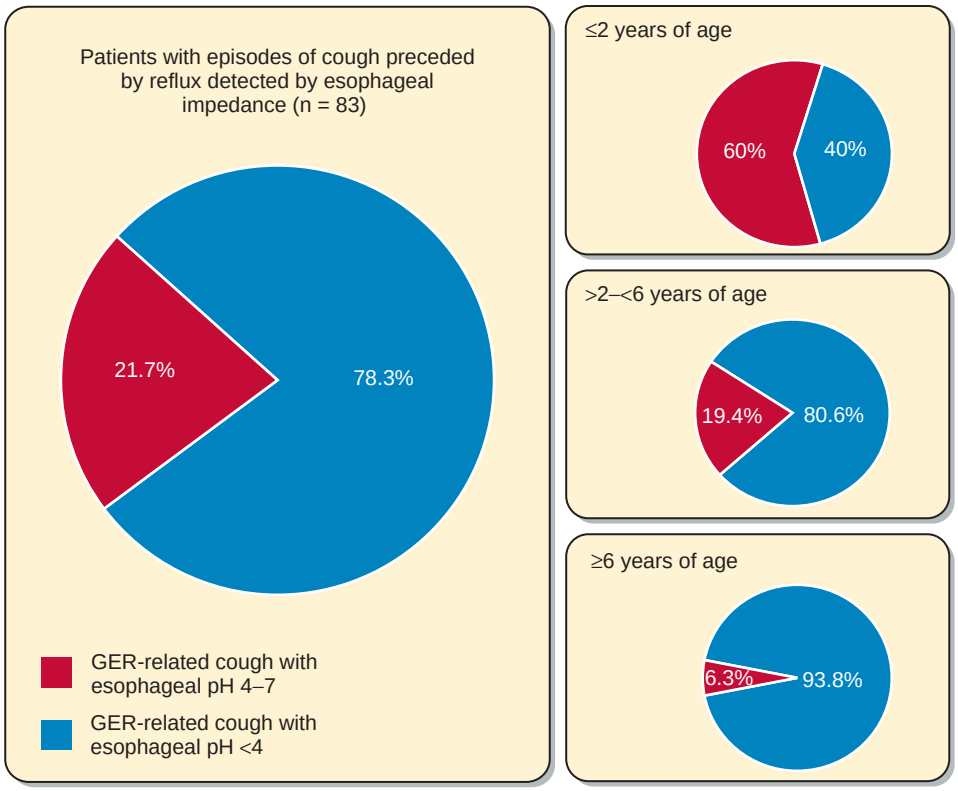

Figure 27-3 Proportion of children with cough preceded by reflux with pH 4–7 or <4, n = 8. The three small panels on the right present the data by age: <2 years (n = 15), >2–<6 years (n = 36), ≥6 years (n = 32). *(From: Ghezzi M, Guida E, Ullmann N, Sacco O, Mattioli G, Jasonni V, Rossi GA, Silvestri M. Weakly acidic gastroesophageal refluxes are frequently triggers in young children with chronic cough. Pediatr Pulmonol 2013;48:295–302).*

sites: the nose, the paranasal sinuses, the pharynx, ear canals and ear drums, the pleura, the stomach, the pericardium and the diaphragm. Nerve impulses from the tracheobronchial tree pass through the vagus, the principal afferent pathway. Cough may result from direct stimulation of this nerve.[20] The trigeminal, glossopharyngeal and phrenic nerves conduct impulses from extrapulmonary sites.[21] Axon reflexes traveling through branches of sensory end-organs may cause the release of neuropeptides and subsequent smooth muscle contraction, mucus secretion and epithelial injury. Thus, sensory signals taking part in cough may trigger or enhance bronchospasm. Reflexes regulate the parasympathetic nervous system, and chronic cough lowers the threshold for sensory signals. Efferent impulses of the cough reflex are transmitted to the respiratory musculature through the phrenic and other spinal motor nerves, and to the larynx through the recurrent laryngeal branches of the vagus. The vagus also provides efferent innervation to the tracheobronchial tree where its branches mediate bronchoconstriction.

Cough and Bronchospasm

Cough and bronchospasm are two closely related reflexes that enhance one another, but neither depends on the other for its action.[22] Cough clears the airways effectively only at high lung volumes; sufficient air velocity to shear mucus from bronchial walls can be achieved only down to the sixth or seventh generation of airway branching.[23] Co-existing bronchoconstriction adds to the effectiveness of cough by extending peripherally the region of rapid and turbulent airflow. Challenge with either methacholine or histamine provokes both cough and bronchoconstriction.[24] However, the receptors for both reflexes are functionally distinct, and either response can arise independently. Challenge with hyperosmolar solutions causes both cough and bronchoconstriction, but hypo-osmolar solutions tend to bring about cough alone.[25] Pretreatment divides induced cough from bronchoconstriction.[26] When aerosolized water serves as the provoking agent, inhaled lidocaine blocks cough but not bronchoconstriction. When inhaled capsaicin is used to provoke cough, opiates administered systemically suppress cough whereas those administered by inhalation suppress bronchoconstriction.[26] Bronchoconstriction, but not the urge to cough, can be blocked by pretreatment with intravenous atropine, consistent with the role of cholinergic pathways in the efferent limb of reflex bronchoconstriction. The mechanisms that trigger cough and bronchospasm following exercise or exposure to cold air appear to be different. Cough results mainly from excessive water loss, while bronchoconstriction follows airway rewarming.[27] Cold, air-induced bronchoconstriction can be blocked by β-adrenergic agents, but cough cannot. Cough most often results from excitation of receptors concentrated in the larynx and proximal airways, while bronchoconstriction can be triggered from the lower airways as well. Finally, inflammatory changes in the airways may result in cough without simultaneously giving rise to bronchospasm.[28]

Cough-Variant Asthma

Childhood asthma is a syndrome of inflammation in medium and small airways that gives rise to hyperresponsiveness and

https://CafePezeshki.IR

constriction of the bronchial smooth muscle, edema and disruption of the mucosa, and obstruction of the airway lumen.[29] Inflammation may lead to airway remodeling with proliferation of smooth muscle and deposition of matrix proteins. Cough-variant asthma is associated with the same disordered physiological processes and presenting signs, but overt wheezing is absent, and cough is the most discernible clinical sign. However, substantial evidence shows that awareness of symptoms by children with asthma is poor,[30] and both children and their parents may be more aware of cough than of other symptoms that may be present as well.

The diagnosis of asthma on the basis of cough alone accounts for the profusion of cases of cough-variant asthma that are open to doubt.[31] In 1991, 10% of children with cough as the only symptom were diagnosed as having asthma; 2 years later, the figure had increased to 22.6%. Whereas in the past, cough may have been underrecognized as a sign of asthma, at present the opposite appears to be true.[32,33] This is borne out by reports in which children with persistent nocturnal cough improved after 2 weeks of placebo therapy and received only modest additional benefit from a course of high-dose inhaled corticosteroids.[34] Inhaled albuterol and beclomethasone in children with cough, but without wheezing, were no more effective than placebo in reducing cough frequency.[35] Surprisingly, even the documentation of airway hyperreactivity did not predict a child's response to these asthma medications. A study of nocturnal cough showed that in the absence of wheeze, shortness of breath or tightness of the chest, cough did not indicate hidden or atypical asthma in most children.[36] Children under 4 years of age with frequent recurrent wheeze and a stringent index for the prediction of asthma at school age showed significantly higher median fractional exhaled nitric oxide (NO) levels (11.7 [11.85]) (median [interquartile range]) than children with recurrent cough but no history of wheeze (6.5 [5.5]; P < .001) and those with early recurrent wheeze and a loose index for the prediction of asthma at school age (6.4 [6.5]; $P < .001$). No difference in FeNO levels was found between children in the latter two groups ($P = .91$).[37] A prospective study of infants followed up to age 11 years, showed that recurrent cough present early in life resolved in the majority of children. Children with recurrent cough but without wheeze did not have airway hyperresponsiveness or atopy, and significantly differed from those with classical asthma, with or without cough.[38] Brooke and colleagues reassessed, during the early school years, a cohort of children identified as having recurrent cough in the preschool period. Seventy of 125 (56.0%; 95% CI 47.3–64.5%) were symptom-free at follow-up, 46 (36.8%; 95% CI 28.7–45.5%) continued to have recurrent cough in the absence of colds, and only nine (7.2%; 95% CI 3.6–12.8%) reported recent wheezing. The authors concluded that long-term recurrent cough in some children is consistent with the diagnosis of cough-variant asthma, but that few progress to develop asthma characterized by wheeze.[39]

Isolated cough is rarely due to asthma and often fails to respond to asthma medications.[40] On the other hand, patients with a prolonged history of cough who respond to treatment with asthma medications or show evidence of bronchospasm or hyperresponsiveness without concurrent wheezing may be considered to have cough-variant asthma. Patients may be free of bronchoconstriction at the time of their evaluation. Their history of respiratory disease may be difficult to assess, while physical findings and routine pulmonary function tests may disclose no evidence of airway obstruction. In such cases, evaluation of airway function by bronchial provocation with methacholine, histamine or exercise is recommended. In children too young to perform pulmonary function testing, the diagnosis of cough-variant asthma may be confirmed by the patient developing unequivocal evidence of reversible airways obstruction later in the clinical course and by the patient's response to asthma therapy.

Cough During and After Respiratory Infection

Children have an average of six to eight respiratory infections per year, a number that may be higher in those with siblings or in daycare. Repeated infections common in winter months may result in a chronic cough. Acute bronchitis usually follows the symptoms of upper respiratory illness. Cough associated with infection with respiratory syncytial virus (RSV), other respiratory viruses and cytomegalovirus, *Mycoplasma pneumoniae, Chlamydia trachomatis, Ureoplasma urealyticum, Pneumocystis jiroveci* (formerly *carinii*), *Corynebacterium diphtheriae* and *Bordetella pertussis* often lasts beyond the acute stage. Measles causes a cough with coryza, conjunctivitis and fever. In the immunized patient, atypical measles is more likely to cause cough or pneumonia than the characteristic rash.

Persistent bacterial bronchitis (PBB) is an increasingly diagnosed form of chronic wet cough that occurs in children with a history of mild asthma or possibly misdiagnosed asthma.[41] Some of the children have a history of invasive medical therapy (prolonged ventilation, cardiac surgery) and many have an underprivileged background. These children have a chronic wet productive cough with bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis* persisting in the airways, and an associated neutrophilia. Spirometry and chest x-rays are typically normal. The cough responds to a course of antibiotic (e.g. amoxicillin-clavulanate for 2–4 weeks).[42] Prolonged duration of cough and increased neutrophil counts are related to worse high-resolution computed tomography scan scores. A recent retrospective study identified a cohort of children with protracted bacterial bronchitis that for the most part had started in infancy.[43] Almost three quarters of the children had an associated airway malacia. These children responded well to antibiotics, although a significant number relapsed and needed additional courses of treatment.[43] A favorable response to a course of antibiotics confirms the diagnosis of PBB and further investigations may be unnecessary. Children who do not respond to treatment require investigation for specific causes of suppurative lung disease. This includes a sweat test and genotyping for cystic fibrosis, exhaled NO, evaluation of ciliary ultrastructure and beat frequency, white cell count, immunoglobulin levels and functional antibody studies, barium swallow, swallowing videofluorscopy and esophageal reflux studies.[41]

The pathogenesis of postinfectious cough is not known. Children with persistent postinfectious cough do not have airway eosinophilia typical of untreated asthma, but some manifest increased reactivity of the airways. These observations suggest that postinfectious cough has different pathophysiological features from asthma.[44] The infection causing the cough, in most cases, remains unidentified. The diagnosis is clinical and one of exclusion. It should be considered in patients with normal chest x-rays and pulmonary function tests who cough only after respiratory tract infections. Postinfectious cough generally regresses over time, but it often recurs. Its resolution may

https://CafePezeshki.IR

be accelerated by the administration of inhaled corticosteroids or ipratropium bromide.[45]

ACUTE VIRAL BRONCHIOLITIS

Bronchiolitis occurs in epidemics during the winter months in temperate regions, and during the hottest months and the rainy season in tropical climates. Cough set off by microorganisms contributes to their spread and survival. RSV is the leading cause of epidemic bronchiolitis, accounting for over 40% of cases. Influenza, parainfluenza type 3 and adenovirus are responsible for many of the remaining cases. The human metapneumovirus and bocavirus also play a significant role.[46] The risk of RSV illness in the first year of life is over 60%, and it will have infected nearly all children by the age of 2 years.[47] RSV lower respiratory tract infections lead to 125,000 hospital admissions per year in the USA. Eighty percent occur in infants with a peak incidence at 2 to 8 months.[48] RSV accounts for 25% of all acute hospitalizations in children younger than 5 years with chronic lung disease. Between 0.5% and 3.2% of children with RSV infection require hospitalization, and there are approximately 4500 deaths per year. Environmental risk factors for severe RSV infection include poverty, crowding, exposure to tobacco smoke and malnutrition. Older children and adults develop antibodies to RSV, but the immunity is incomplete, and re-infection may occur at any age. In these older patients, infection with RSV usually takes the form of an upper respiratory illness, often with bronchitis.

There is a general consensus that following even mild RSV bronchiolitis, children are at increased risk for repeated bouts of respiratory symptoms during the first 3 years of life.[49] Stein and colleagues reported a relationship between RSV infection and recurrent respiratory symptoms up to 6 years of age, but not to asthma after the of age 13 years.[50] However, more recent evidence points to an association between severe RSV infection early in life and increased incidence of asthma and eczema later.[51] Further, hospitalization for bronchiolitis in infancy is associated with an increased risk of asthma, and an increased use of asthma medication at 28 to 31 years of age.[52]

MYCOPLASMA PNEUMONIAE

Most *Mycoplasma pneumoniae* infections in infants and young children are asymptomatic or are associated with upper respiratory symptoms only.[53] However, it is the most frequent cause of pneumonia in children between 5 and 15 years of age,[54] and a cause of bronchiolitis in all age groups. *Mycoplasma pneumoniae* pneumonia presents with a gradual onset of malaise, fever and headache. Cough begins several days after the onset of the illness and often persists for weeks. It may be productive of white or blood-tinged sputum. Physical findings include crackles, rhonchi and bronchial breath sounds. The incidence of wheezing with the acute infection has been reported to be 40%. X-ray findings, though not diagnostic, frequently show unilateral lower lobe involvement. The pattern is initially reticular and interstitial. Later, patchy segmental consolidation is seen. Hilar adenopathy and pleural effusions may be present. Ten percent of the children develop an exanthem and 36% have elevated hepatic transaminases. The diagnosis can be made by measuring specific IgM antibody. A rise in IgG antibody takes between 1 and 2 weeks post infection. Cold agglutinins are positive in about 40% to 60% of patients; however, the results are not specific. There is little evidence that treatment with antibiotics is helpful during the acute illness; however, macrolide antibiotics may shorten the duration of fever and respiratory symptoms.

Infection with mycoplasma may produce a long-term impairment in lung function even in asymptomatic children. Clinical reports, throat culture and serological studies, and animal models suggest a role for mycoplasma in airway hyperresponsiveness. In nonasthmatic subjects, significant response to bronchodilators has been noted 1 month after infection. More significantly, abnormal forced expiratory volume in 1 second (FEV_1) and forced expiratory flow after 50% of the expired vital capacity have been noted up to as long as 3 years after initial infection.[55]

BORDETELLA PERTUSSIS (see Box 27-2)

Before widespread vaccine coverage started in the late 1940s, there were as many as 270,000 cases of pertussis diagnosed in the USA per year, with as many as 10,000 deaths, predominantly among infants. Pertussis reached epidemic proportions every 2 to 5 years. Immunization with diphtheria–tetanus–pertussis (DTP) using whole *Bordetella pertussis* reduced the average incidence of pertussis in the USA from 157 per 100,000 population in the early 1940s to fewer than one in 1973. However, the cycles of outbreaks continued because neither infection nor immunization produces lifelong immunity to pertussis.[56]

Because of concerns over the safety of the DPT vaccine, beginning in the early 1990s, the USA started the transition from DPT to diphtheria–tetanus–acellular pertussis (DTaP) for the immunization of children.

Pertussis is now resurgent, and many cases are occurring in vaccinated children and adolescents. In countries using acellular vaccines, waning immunity is at least part of the problem.[57] It appears that vaccination rates in the young population are satisfactory, but the same is not true for older individuals, including health workers.[58–60] In the years 2005–2010, the incidence of pertussis rose to between four and nine per 100,000.[56] A study was conducted from 2006 to 2011 to assess the risk of pertussis in children relative to the time elapsed after the fifth dose of DTaP. This period included a large outbreak in 2010. DTaP was being used for all five recommended doses. Year on year after the fifth dose of DTaP there was a 42% increase in odds of acquiring pertussis.[61]

As many as 90% of nonimmune household contacts acquire the disease. Infection in immunized children and older persons is often mild. The burden of disease assessed by rates of complications and death remains greatest in the youngest patients, but there has been a recent resurgence of less severe pertussis

BOX 27-2 RISK FROM DISEASE VS RISK FROM DTaP

PERTUSSIS

Pneumonia: 1 in 8
Encephalitis: 1 in 20
Death: 1 in 1500

DTaP

Continuous crying, then full recovery: 1 in 1000
Convulsions or shock, then full recovery: 1 in 14,000
Acute encephalopathy: 0–10.5 in 1,000,000
Death: None proven

https://CafePezeshki.IR

in adolescents and adults. These groups constitute a major source of disease transmission to younger children. Increased exposure to pertussis in the community, delay in identification and treatment, and high contact rates among children attending school or daycare contribute to the spread of the disease. It is important to note that pediatric healthcare workers are at particular risk for pertussis exposure, infection and subsequent disease transmission to susceptible patients.[62] In 2011, Tdap vaccination coverage among health workers was only 26.9%.[58]

The widespread use of whole-cell pertussis vaccine in combination with diphtheria and tetanus toxoids (DTP), starting in the USA in the late 1940s, led to a historic low point of 1010 cases of pertussis in 1976. However, since the early 1980s, cases of pertussis have increased with cyclical peaks every 3 to 4 years. In 1996, the US Centers for Disease Control and Prevention reported 7796 cases of pertussis, almost half of whom were aged 10 years or older. In the same year, acellular pertussis vaccines were licensed and recommended for routine immunization of infants.[3] The effectiveness of the complete vaccination series is 80% (95% CI 66–88%). Receiving fewer than three doses constitutes a significant risk factor (relative risk 5.1; 95% CI 3–8.6%).[63]

In the unvaccinated child, infection with *Bordetella pertussis* leads to a catarrhal phase lasting 1 to 2 weeks with rhinitis, conjunctivitis, low-grade fever and cough. *B. pertussis* infection causes infiltration of airway mucosa by lymphocytes and polymorphonuclear leukocytes, necrosis of the midzonal layers of the mucosa and injury to the ciliated epithelium of the respiratory tract. A stage of tracheobronchitis, lasting 1 to 6 weeks, ensues with episodes of paroxysmal cough that increase in number and severity. Repetitive forceful coughs during a single expiration are followed by an abrupt inspiration that produces the characteristic whoop. Many children experience post-tussive emesis. Fever is absent or minimal. Convalescence takes weeks to months. Pertussis is more severe in the first year of life. A clinical case is defined as an acute cough illness lasting a minimum of 14 days in a person with at least one pertussis-associated symptom (i.e. paroxysmal cough, post-tussive vomiting or inspiratory whoop) or 14 days of cough during an established outbreak. A confirmed case is a cough illness of any duration in a person from whom *B. pertussis* has been isolated, or that meets the clinical definition and is confirmed by polymerase chain reaction or an epidemiological connection to a laboratory-confirmed case.[3] Although *B. pertussis* infection should be suspected in children with paroxysmal cough, other organisms, most notably adenovirus, parainfluenza viruses, RSV and mycoplasma, have been implicated.[40]

There is growing evidence that *B. pertussis* is an important cause of persistent cough in adolescents and adults. Pertussis has been implicated in 16% of cases of chronic cough of adults in Denmark. Susceptibility to infection with *B. pertussis* recurs several years after vaccination. Moreover, cases of laboratory proven reinfection have been reported.[64] *B. pertussis* should be considered in patients with symptoms of typical or atypical whooping cough, irrespective of their vaccination status or past history of the disease.[64] By demonstrating *B. pertussis* in an adult, one can reassure him/her that the symptoms will subside without the need for extensive evaluation and treatment, and recommend measures to protect others, especially unvaccinated infants.[65] Droplet precautions are recommended for 5 days after initiation of effective therapy or until 3 weeks after the onset of paroxysms if appropriate antimicrobial therapy has not been given. Erythromycin or clarithromycin eliminates pertussis from the nasopharynx in 3 to 4 days, decreasing the spread of the disease.[66] Given within 14 days of onset, these antibiotics may abort pertussis. Once paroxysms of cough develop, antibiotics have little effect on the course of illness. An association between erythromycin and idiopathic hypertrophic pyloric stenosis has been reported in infants.[67] There are no such reports for clarithromycin.[68]

In addition to maintaining high vaccination rates among preschool children, effort must be directed at the identification and treatment of pertussis cases to prevent further spread of the disease. Erythromycin (40–50 mg/kg per day orally in four divided doses, maximum 2 g/day) for 14 days is recommended for all close contacts irrespective of age or immunization status. Exposure of infants to children and adults with cough illnesses should be minimized.

A major public health challenge at present is to address the illness in adolescents and adults. A rational strategy might be a universal booster vaccination for adolescents and a program targeted at those adults most likely to have contact with infants.

CHLAMYDIA TRACHOMATIS

Infants with *C. trachomatis* infection present with a high-pitched, staccato, nonproductive cough and tachypnea without fever that begins around 4 weeks of age and lasts for several weeks, even after therapy with erythromycin.[69] Concomitant conjunctivitis is a frequent finding.

MYCOBACTERIUM TUBERCULOSIS

Pediatric pulmonary tuberculosis remains a major cause of morbidity and mortality worldwide.[70] From 1985 to 1992, the number of cases of childhood tuberculosis (TB) increased; however, between 1992 and 1998, the numbers declined substantially in all age groups. The incidence of TB among children is lower than among adults, and most of the pediatric morbidity and mortality occur in children younger than 5 years of age. In the USA, the groups with the highest rates include immigrants from Asia, Africa and Latin America, the homeless and residents of correctional facilities.[71]

Children contract TB from adults and adolescents; disease transmission among youngsters is most uncommon. When the tuberculin skin test converts to positive, most *M. tuberculosis* infections in children are asymptomatic. The radiographs at that time are usually negative, and the primary infection progresses slowly. Infection with *M. tuberculosis* that becomes symptomatic usually involves the hilar and mediastinal lymph nodes as well as lung parenchyma. Early manifestations become evident 1 to 6 months after initial infection. They include fever, weight loss, cough, night sweats and chills. Chest x-rays may show lymphadenopathy of the hilar and mediastinal nodes, involvement of a lung segment or lobe with atelectasis or infiltrate, cavitary lesions and miliary disease. Tuberculous meningitis may be an early finding. Later extrapulmonary manifestations may involve the middle ear, mastoid, bones, joints, skin, and kidneys.[71]

The recommended treatment regimen for TB disease consists of an initial 2-month phase of four drugs: isoniazid, rifampin, pyrazinamide and ethambutol, followed by a 4-month continuation phase of isoniazid and rifampin. Ethambutol is generally not used for young children whose visual acuity

https://CafePezeshki.IR

cannot be monitored. Streptomycin may be substituted for ethambutol, but must be given by injection. Ethambutol (or streptomycin) can be discontinued when drug susceptibility results show the infecting organism to be fully drug-susceptible.[71]

Children from Asia or Africa where tuberculosis is endemic may have cough, often with hemoptysis, and without fever, as a result of an infestation with a fluke of the genus *Paragonimus* acquired by eating undercooked freshwater crab or crawfish.

Cough Associated with Allergic Rhinitis, Rhinosinusitis and/or Postnasal Drip

Allergic rhinitis and rhinosinusitis (both described elsewhere in this text) are associated with cough that results from postnasal drip and irritation of the larynx. Chronic sinusitis may be an early manifestation of immunodeficiency or ciliary dysfunction. Irwin and colleagues identified postnasal drip as the most common cause of chronic cough among their patients.[5] The diagnosis can be established by history. Mucoperiosteal changes on x-ray or sinus computed tomography (CT) of an atopic child in the absence of opacification or air-fluid levels and acute symptoms do not constitute an indication for treatment with antibiotics or sinus surgery. A most effective treatment is once or twice daily nasal irrigation with normal saline buffered by bicarbonate, followed by the instillation of a nasal corticosteroid spray.

Cough Associated with Compression Syndromes

TRACHEOBRONCHOMALACIA

Tracheo- or broncho-malacia is characterized by flaccidity or congenital absence of the cartilaginous rings supporting the trachea and/or the bronchi. Although most infants are asymptomatic, some present with cough, often described as brassy, paroxysmal dyspnea, wheezing and stridor.[40] Chest x-rays frequently show recurrent 'pneumonia' that results from the collapse of segments of the airway during expiration. Increased secretions associated with respiratory infections precipitate symptoms. The caliber of the airways on chest x-ray varies from normal to markedly reduced depending on the phase of respiration. The appearance of pneumonia is most often caused by atelectasis, but secondary infection of the collapsed lung may occur. Prolongation of the expiratory phase and suprasternal and intercostal retractions are common. The diagnosis is established by observation of the collapse of tracheal or bronchial walls on fluoroscopy or bronchoscopy. Intrinsic airway stenosis or extrinsic compression exaggerates the manifestation of tracheomalacia. These complications must be considered during endoscopy. If associated bronchospasm is present, it must be treated aggressively. Although the symptoms usually subside by 12 to 18 months of age, some infants may require a trial of continuous positive airway pressure or mechanical ventilation.

VASCULAR RINGS

The trachea can become partially obstructed by a vascular abnormality involving a right aortic arch with left ligamentum arteriosum or persistent ductus arteriosus, double aortic arch, anomalous innominate or left carotid artery. These abnormalities are generally referred to as vascular rings. Typical symptoms include inspiratory stridor, expiratory wheezing and a barking cough. Respiratory distress may be present, especially during feeding or when infection intervenes. Feeding difficulties may be present in the first few weeks of life. There may be recurrent pneumonia and atelectasis.

The presence of vascular rings must be considered in any infant with stridor. The chest x-ray may show a right or an indeterminate aortic arch. Tracheal compression by an anomalous innominate artery causes a curvilinear indentation of the anterior trachea. While barium esophagrams may show characteristic indentations from various anomalies of the aortic arch, magnetic resonance imaging (MRI) with its multiplanar images has become the imaging procedure of choice at many institutions. Laryngotracheobronchoscopy is useful in excluding upper airway obstruction. Tracheal compression viewed endoscopically may be recognizable as a pulsatile, extrinsic mass. Vascular rings may be life-threatening, but with prompt recognition and surgical treatment, they are usually completely correctable.[11,72]

MEDIASTINAL MASSES

Mediastinal masses may be present at birth. Children under 2 years are likely to present with respiratory symptoms including dyspnea, cough, stridor and chest pain. Additional signs and symptoms may include cyanosis, atelectasis, superior vena cava syndrome, Horner's syndrome, dysphagia, spinal cord compression, intercostal nerve neuralgia, and cervical lymphadenopathy. These masses may be categorized as congenital or neoplastic. Most neoplastic tumors are malignant, and prompt diagnosis and treatment are required. In a large number of older children, the masses are asymptomatic and are recognized co-incidentally on chest x-rays. The asymptomatic masses are often benign. Chest x-rays provide information about location, size and presence or absence of calcifications. The barium swallow may be helpful in defining the anatomy. CT and MRI provide the most useful information for further diagnosis and treatment. Other helpful tests include percutaneous biopsy, bone marrow aspiration, urinary catecholamines and skeletal survey. Monoclonal antibodies have been used for diagnosis, assessment of response to therapy and monitoring for relapse.[72]

BRONCHIAL STENOSIS

Bronchial stenosis is a fixed narrowing of the bronchus, usually not associated with other congenital malformations, although co-existing segmental bronchomalacia, most commonly of the left main bronchus, has been reported. In the past, tuberculosis was a common cause of bronchial stenosis. It can occur at any level along the bronchial tree, although it most commonly involves a main bronchus, just distal to the carina. The degree of stenosis is variable. Wheezing, both inspiratory and expiratory, is a typical presenting symptom. It may be associated with cough, dyspnea and stridor. Chest x-rays reveal recurrent atelectasis that may become secondarily infected. Hyperinflation is usually noted on the x-rays of patients with stenosis of the main bronchus. In patients with segmental bronchomalacia, the involved lung is usually hyperlucent. If the orifices of the upper lobes or right middle lobe are involved, there may be

https://CafePezeshki.IR

an associated collapse. Recurrent consolidation or persistent collapse is a common radiological finding of stenosis of a lobar bronchus. Diagnosis is accomplished by endoscopy. Treatment varies with the severity of obstruction. In some cases, the administration of bronchodilators and chest physical therapy is sufficient; more severe cases may require positive pressure ventilation or surgery to remove the stenotic segment. Lobar resection may be necessary to control persistent infection.[73]

TRACHEAL STENOSIS

Signs and symptoms of congenital tracheal stenosis include persistent cough and respiratory distress in the newborn period. Patients may have expiratory stridor and wheezing. History of feeding difficulties is common. Chest x-rays and fluoroscopy may reveal a missing segment of the trachea. Radiographs of the neck that are highly penetrated may show tracheal narrowing. In congenital tracheal stenosis there is intrinsic narrowing of the tracheal lumen caused by complete cartilaginous rings. The size of the lumen can be assessed by CT or MRI. The definitive diagnosis is made by endoscopy. The differential diagnosis includes extrinsic compression of the trachea by vascular rings or mediastinal masses. Tracheotomy may be necessary to maintain a patent airway. Endoscopic procedures can be used to treat thin tracheal webs and unilateral lesions. Conservative management of patients with mild symptoms should be attempted. Dilation of tracheal stenosis may provide a temporary solution until definitive surgical repair can be accomplished. Surgical treatment is associated with significant morbidity and mortality.[73]

Cough Associated with Aspiration Syndromes

Aspiration pneumonia is a common disorder frequently mistaken for nonspecific respiratory infection, while aspiration bronchitis is often mistaken for asthma. In infants, these conditions are most commonly associated with the inhalation of milk as a result of one of three disorders: impairment of sucking or swallowing likely to be neurogenic in origin, GER or tracheoesophageal fistula. These are conditions that must not be overlooked.

The initial step in diagnosis is to observe the child, while nursing, for difficulty with sucking or swallowing or for associated cough or choking. Gross structural abnormalities of the mouth, jaw or palate can be noted. Placing a finger in the baby's mouth can assess the act of sucking. X-rays of children with aspiration bronchitis typically show perihilar thickening and increased bronchovascular markings, while those of children with aspiration pneumonia show patchy areas of uniform opacity that may have a segmental or lobar distribution. In infants, the posterior parts of the upper and lower lobes are most commonly involved, with the right side predominating. Fluoroscopy is used to evaluate the anatomy of the upper airway and esophagus and the swallowing function. Esophageal pH probe or impedance probe monitoring establishes the presence of reflux.[74] Bronchoscopy and microscopic examination for lipid-laden macrophages substantiate the diagnosis of aspiration.

Tracheoesophageal fistulas require prompt surgical repair. The management of a child with a swallowing disorder requires the assistance of a clinic that specializes in this problem.

Gastroesophageal Reflux
(see Figure 27-3)

GER is a common cause of chronic cough in individuals of all ages and of apnea in infants, even without co-existing aspiration. Its most likely mode of action is through vagal stimulation, although aspiration must be considered. GER has been documented in about half of adults with chronic cough, and it commonly occurs in children.[75] The respiratory manifestations of GER – cough, wheezing, sore throat, hoarseness, throat clearing, choking and throat irritation – often persist in the absence of more familiar symptoms such as heartburn and regurgitation.[76] Proton pump inhibitors or H_2 blockers effectively reduce the respiratory complications of GER. However, higher than standard doses may be necessary and therapy may need to be continued for several months before a therapeutic effect is achieved. Laparoscopic fundoplication has been performed safely, even in high-risk children.[77]

Foreign Body

A foreign body may lodge in the hypopharynx, larynx, trachea, bronchus or esophagus. Aspiration of a foreign body into the airway typically causes stridor. It is a pediatric emergency requiring immediate management by a specialist, even though unsuspected bronchial foreign bodies may be present for a long time and lead to chronic bronchitis and bronchiectasis. Unrecognized esophageal foreign bodies resulting in tracheal compression have caused recurrent wheezing or cough without dysphagia for as long as a year. Cough, wheezing or dyspnea may date from the time of aspiration or may begin later, after edema and inflammation have set in and reflex bronchospasm has resulted. The majority of aspirated foreign bodies are foods such as peanuts or sunflower seeds, but a remarkable variety of objects has been removed at bronchoscopy. It is of note that peanuts release oils that irritate the bronchial mucosa, causing inflammation and edema. Other organic solids, such as beans, peas, corn or seeds, can absorb water and increase considerably in size.

In one third of patients with foreign body aspiration, the actual event goes unobserved by caregivers.[78] The diagnosis may be suspected on the basis of history and physical findings. Classical signs are wheezing, cough and decreased breath sounds. Use of a differential stethoscope may be helpful in detecting localized airway obstruction. The diagnosis is established by radiographic findings and ultimately by bronchoscopy. Chest x-rays show atelectasis in cases of complete obstruction of a bronchus. In cases of partial obstruction, the foreign body may act as a valve that allows air entry but impedes exhalation from a portion of a lung. Comparison of inspiratory and expiratory radiographs shows a hyperinflated obstructed portion in comparison to the unaffected lung following expiration. On decubitus radiographs and fluoroscopy, the dependent lung should show less inflation unless obstructive hyperinflation from the valve-like mechanism is present. Bronchoscopy provides decisive evidence for diagnosis and treatment. Rigid bronchoscopy is preferred because it allows for the removal of the foreign body at the time of diagnosis. Treatment with bronchodilators, postural drainage and chest physical therapy as an alternative to bronchoscopic removal of the foreign body is no longer recommended.

https://CafePezeshki.IR

Cystic Fibrosis

Cystic fibrosis is diagnosed with increasing frequency during neonatal screening. The presenting symptoms of this disease are cough, poor weight gain and abnormal stools. The earliest symptom is usually a loose cough. Most patients experience recurrent lower respiratory infection before 12 months of age, but the age of onset is variable. Purulent bronchitis may be associated with wheezing and cough, and the diagnosis of asthma is often made in error. Purulent chronic cough in children must always be regarded as a pathological finding.[40]

Allergic Bronchopulmonary Aspergillosis

Timely diagnosis of allergic bronchopulmonary aspergillosis (ABPA) is important because untreated ABPA results in progressive, irreversible lung damage. ABPA is a disease differentiated by recurrent infiltrates on chest x-ray, markedly elevated serum immunoglobulin E (IgE), eosinophilia and underlying asthma. Clinically it is characterized by afebrile episodes of cough, sputum production, dyspnea and wheezing.

Hypersensitivity Lung Disease

Hypersensitivity pneumonitis or extrinsic allergic alveolitis is a syndrome that results from sensitization to inhaled organic dusts, which in children are most often avian antigens. Bird fancier's disease has been reported to occur in families. During acute attacks, patients suffer from both respiratory and systemic symptoms, including cough, dyspnea, temperature as high as 40°C, chills and myalgia.

Vocal Cord Dysfunction

Vocal cord dysfunction (VCD) is a condition characterized by a paradoxical adduction of the vocal cords on inspiration that causes shortness of breath, cough and stridor.[79] VCD in children commonly occurs during exertion and must be differentiated from exercise-induced bronchospasm (EIB). VCD has been documented in adolescents, usually female athletes.[80] Among these patients, perfectionism, depression and anxiety are common.

The chest x-rays in uncomplicated VCD are normal. Spirometry shows blunting or truncation of the inspiratory portion of the flow-volume curve. Because of the episodic nature of VCD, the flow rate patterns may vary, and during asymptomatic periods, normal flow-volume curves are likely to be found. It is possible to replicate symptoms and spirometric findings of VCD by exercise or inhalation challenge, but negative results do not rule out the diagnosis. Observation of the vocal cords of a patient experiencing either spontaneous or induced symptoms by flexible fiberoptic rhinolaryngoscopy documents the presence of VCD.[79] The examination can be videotaped or photographed for the medical records. Complications are rare and discomfort is minimal. In VCD, the vocal cords adduct anteriorly from the vocal process, and the posterior glottic chink remains open. The adduction occurs during inspiration or in both the inspiratory and expiratory phases. The adduction of vocal cords with an open glottic chink in a symptomatic patient unequivocally establishes the diagnosis of VCD.

In the author's experience, the most successful treatment of VCD is that derived from breathing exercises used for hyperfunctional voice disorders to decrease the laryngeal muscle tone. These techniques are likely to desensitize the cough pathways.[79,81] In some extreme cases, hypnosis, biofeedback and psychotherapy have been used successfully. An approach reserved for acute attacks is the administration of a mixture of helium and oxygen. More aggressive therapies under study for patients with intractable, recurrent symptoms include injection of botulinum toxin directly into one vocal cord or sectioning of the laryngeal nerve.[79,81]

Psychogenic Cough

Although it has been suggested that psychogenic cough typically ceases at night and has a barking or honking character, in actual fact, there are no distinguishing clinical features, and the diagnosis should be considered only after other possibilities have been excluded.[45] In some cases, a complete evaluation may require an assessment of the psychosocial factors that influence the origin, progression, persistence and/or exacerbation of chronic cough. Some children derive secondary gain in the form of greater attention or emotional support from their parents. In others, trauma such as physical abuse or school phobia may cause a conversion syndrome. A psychological evaluation may be necessary to focus on specific detrimental effects of the cough, a disruptive process that may affect negatively a broad spectrum of social and interpersonal experiences. This may range from distress at school to exclusion from play, social functions or participation in sports. As in other chronic medical conditions, emotional responses to the symptom may need to be addressed. Depression and frustration are the most common adjustment reactions, but negative responses may range over the entire affective spectrum.

Patients with psychogenic cough often believe that they have a serious chest problem. The diagnosis has been made in 3% to 10% of children with cough of unknown etiology that persists for more than 1 month. In 17 published reports, 149 of 153 patients were under 18 years of age. While wholly psychogenic cough is rare, children and/or parents may exaggerate some or all aspects of the cough. Occasionally it is difficult to reconcile the parents' or child's accounts with clinical findings. The parents may demand inappropriate treatment and may instill in the child the belief that he/she is physically disabled. When clinical findings differ from the history, confirmation of the cough by the use of a recording device and/or admission to the hospital for observation may be invaluable. The circumstances call for sympathy and understanding, and the doctor's responsibility to the child must take precedence over the doctor-parent relationship.

Habit cough, a diagnosis of exclusion, results from the lowering of the threshold for sensory signals in chronic nonproductive cough that may become self-perpetuating and persist even after the initial inciting reason is no longer present.

Evaluation

Information about the history of onset, character of the cough (harsh, dry, productive, paroxysmal), triggers, time of occurrence and accompanying symptoms or sensations may offer clues about its etiology. A detailed health history must be obtained with attention to the neonatal period; feeding

https://CafePezeshki.IR

problems; congenital malformations affecting the heart, great vessels, nasopharynx and upper respiratory tract, and gastrointestinal tract; respiratory infections; signs and symptoms of chronic illness; respiratory symptoms including those relating to the upper airway, such as postnasal drip or irritation, and lower respiratory tract, such as wheezing, dyspnea and exercise tolerance; heartburn; nocturnal symptoms; and environmental exposures, including cigarette smoke, at home, at school, at daycare, and at the homes of close playmates. The social history provides information about family or school problems that may contribute to psychogenic cough.

The physical examination focuses on the head and neck and the respiratory and cardiovascular systems. Signs of allergic rhinitis, stridor, tachypnea, hyperinflation, wheezes, crackles, rhonchi (with special attention paid to unilateral or asymmetric findings), heart murmurs, gallops and congestive heart failure are sought.

Eosinophils on the nasal smear suggest allergic rhinitis and neutrophils infectious sinusitis. Eosinophils in the sputum suggest asthma. Pulmonary function testing should be undertaken in any child capable of performing the necessary maneuvers. Generally, useful data include a complete blood count with differential, serum IgE, allergy skin tests, an examination of the vocal cords, chest and sinus x-rays and/or CT, bronchial challenge, and esophageal pH or impedance monitoring.[82] Exhaled NO may help to identify toddlers with recurrent cough who will go on to develop asthma. Other laboratory tests based on clinical findings comprise specific studies recommended for the conditions discussed above. They include sputum culture, immunoglobulins, purified protein derivative (PPD), sweat test and ciliary biopsy. Bronchoscopy is rarely indicated. For dynamic evaluation of compression syndromes, flexible bronchoscopy provides the best detail, but if a foreign body aspiration is likely, rigid bronchoscopy should be used. Cough with hemoptysis is an indication for a chest x-ray, chest CT and bronchoscopy.

Environment

It is important to obtain an environmental history of children with chronic cough because it may be possible to improve their surroundings. Environmental history for chronic cough should include exposure to cigarette smoke in all children, to aeroallergens, especially indoors, in older children, and dietary history in infants and toddlers. In utero exposure to mainstream smoke from the mother and even to environmental tobacco smoke changes fetal lung development and causes airflow obstruction and airway hyperresponsiveness. Children exposed to environmental tobacco smoke postnatally have more symptoms of cough, wheeze, respiratory illnesses, decreases in lung function and increases in airway responsiveness.[83] A survey of respiratory symptoms in children aged 12 to 14 years was conducted throughout Great Britain as part of the International Study of Asthma and Allergies in Childhood (ISAAC). The response rate was 79.3%, and 25,393 children in 93 schools participated.[84] Cough and phlegm were associated with active and passive smoking. Gas cooking was significantly associated with dry night cough. The prevalence of cough and phlegm tended to be higher in metropolitan areas; the opposite applied to asthma. Exposure to any passive smoking raised the odds ratio (OR) for night cough (OR = 1.8), snoring (OR = 1.4) and respiratory infections during the first 2 years of life (OR = 1.3). Respiratory problems were more prevalent in homes with reported molds or dampness with adjusted OR ranging from 1.32 (95% CI 1.06–1.39) for bronchitis to 1.89 (95% CI 1.58–2.26) for cough.[85] There is an association between coal fires and nocturnal cough.[86]

Treatment

The goal of clinical evaluation of chronic cough is to identify its causes and to prescribe specific remedies such as modification of the child's environment and treatment of postnasal drip or GER. Antiasthma drugs are not reliably effective in patients with chronic dry cough, nevertheless a 2- to 4-week course of a potent inhaled corticosteroid should be administered to children with prolonged cough without wheeze who have not already received such therapy, especially if they have obstructive pulmonary function tests or positive bronchial challenge results. Inhaled corticosteroids should be discontinued in children who have received an adequate trial and are continuing to cough, and whose pulmonary function tests are normal. Failure to improve after 4 weeks of inhaled corticosteroids and/or normal pulmonary function tests calls for consideration of alternative diagnoses and for proceeding with the clinical evaluation described above. New treatment should be directed at all conditions identified as potentially responsible for the patient's cough and should include breathing exercises.[79]

Health information available on the Internet relating to treatment of cough is generally unreliable. A review of websites identified more incorrect than correct information, and only one of 19 received a high score.[87] Parents may hold unrealistic expectations and may demand needless medications. In such cases, it is best to acknowledge the child's discomfort, to give a realistic time course for resolution of symptoms and to promote active management with non-pharmacological treatments. Patient education fulfills an important role in the management of chronic cough. The patient and family who understand how individual mechanisms contribute to the cough and where each type of treatment fits, carry out their regimen with greater adherence and reduced anxiety. They cope more effectively with the symptoms, especially during periods of exacerbation. On rare occasions, it may be necessary to enlist the help of a psychotherapist to help the family accept the diagnosis and to adhere to therapy.

Over-the-counter pediatric cough and cold medications are widely marketed and used despite lack of evidence of efficacy and numerous recent reports challenging their safety. Serious adverse effects have been associated with accidental overdose, inadvertent misuse and drug-drug or drug-host interactions in children given standard doses.[88] An estimated 7091 children under 12 years are treated annually in the USA in emergency departments for adverse drug events attributable to cough and cold medications. Most visits (64%) are for children aged 2 to 5 years. Unsupervised ingestions account for 66% of estimated emergency department visits.[89] Data obtained from 4267 children enrolled from 1999 to 2006 in the Slone Survey, a random digit-dial telephone survey of medication use by the US population, disclosed that in a given week, 10.1% of US children use a cough and cold medication. Exposure is highest to decongestants (6.3%; mostly pseudoephedrine) and first-generation antihistamines (6.3%; the most common were chlorpheniramine, diphenhydramine and brompheniramine), followed by antitussives (4.1%; mostly dextromethorphan) and expectorants (1.5%; almost exclusively guaifenesin). Multiple-ingredient

BOX 27-3 KEY FEATURES

EVALUATION OF CHRONIC COUGH

- Cough is a common manifestation of disease in childhood.
- Cough is an important defense mechanism.
- Cough functions as a complex neurological reflex.
- Cough may be classified as acute (lasting <3 weeks), subacute (lasting 3–8 weeks) or chronic (lasting >8 weeks).
- Persistent bacterial bronchitis (PBB) is characterized by a chronic wet productive cough, with bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis* persisting in the airways and an associated neutrophilia. Spirometry and chest x-rays are typically normal. The cough typically responds to a course of antibiotics (e.g. amoxicillin-clavulanate for 2–4 weeks).[42]
- The cause of chronic cough can be determined in most patients; specific therapy based on a systematic evaluation is usually successful.
- A chest radiograph should be obtained in children with chronic cough to rule out lower respiratory tract and cardiac pathology.
- Postnasal drip, acting alone or with other conditions, is the most common cause of chronic cough.
- Asthma is very often associated with chronic cough, but few children with chronic cough develop asthma.
- Cough-variant asthma is suggested by (1) airway obstruction and reversibility, (2) airway hyperresponsiveness and/or (3) clinical improvement after treatment with asthma medications.
- Gastroesophageal reflux may cause or intensify chronic cough through a vagal reflex or as a result of aspiration of stomach contents.
- Postinfectious cough resolves over time; the use of oral or inhaled corticosteroids or ipratropium bromide may shorten its duration.
- Congenital anomalies and aspiration are relatively uncommon causes of chronic cough in children.
- Bronchiectasis is a rare cause of chronic cough in children.
- Psychogenic cough and habit cough are diagnoses of exclusion.

products accounted for 64.2% of all cough and cold medications used. Exposure to antitussives, decongestants and first-generation antihistamines was highest among 2- to 5-year olds (7.0%, 9.9% and 10.1%, respectively) followed by children younger than 2 years (5.9%, 9.4% and 7.6%, respectively).[90] During 2004 to 2005, an estimated 1519 children under 2 years of age were treated in US emergency departments for adverse events associated with cough and cold medications. A review by the Food and Drug Administration (FDA) covering several decades identified 123 deaths related to the use of such products in children under 6 years of age.[88,91] The infants ranged in age from 17 days to 10 months. Postmortem testing showed evidence of recent administration of pseudoephedrine, antihistamine, dextromethorphan and/or other cold-medication ingredients.[92] On a positive note, pseudoephedrine use by children appears to be declining since the institution of the 2005 Combat Methamphetamine Epidemic Act.[90] In the Slone survey conducted from 1999 to 2006, use in 2006 (2.9%) was significantly lower than in 1999–2005 (5.2%).

Conclusions

Our goals are not merely to find effective therapies for chronic cough, but also to identify and eliminate factors that predispose children to this aggravating problem. In the meantime we must strive to limit harm, such as children's exposure to tobacco smoke and families' reliance on over-the-counter medications. In addition to pertussis, outbreaks of *H. influenzae*, mumps and measles have been linked in the USA to vaccine avoidance. We should continue to reassure parents and to encourage them to vaccinate not only their children but also themselves. Every healthcare visit should be viewed as an opportunity to review the patient's immunization history and to ensure that everyone is fully vaccinated.

The key features of chronic cough are summarized in Box 27-3.
