28 Immunology of the Asthmatic Response

OSCAR PALOMARES | CEZMI A. AKDIS

KEY POINTS

- Asthma is a complex syndrome that includes many disease phenotypes and endotypes.
- Allergic asthma and Type 2 asthma represent the most common phenotype with lung eosinophilia. Both ILC2 and Th2 cells, as well as type 2 cytokine-producing natural killer (NK) T cells, may contribute to this form.
- In addition to Th1 and Th2 cells, other T cell subsets contribute to the development of allergic asthma at different stages including Th1, Th17, Th9, Th22 and different populations of T_{REG} cells.
- The innate immune system participates in the initiation and maintenance of both allergic and nonallergic asthma. Activated NKT cells in the lung produce proinflammatory cytokines contributing to bronchial hyperreactivity.
- Epithelial cell activation essentially contributes to the inflammatory burden.
- Remodeling in asthma includes basement membrane thickening, myofibroblast differentiation, smooth muscle hyperplasia, epithelial activation and angiogenesis, and is controlled by the immune system.
- Immune tolerance with the induction of T and B regulatory cells is effective in treatment and prevention in mouse models and represents the major mechanism of action of allergen-specific immunotherapy (AIT) for the treatment of allergic rhinitis and asthma in humans.

Asthma is a very common chronic disorder of the airways characterized by variable and recurring symptoms, airflow obstruction, bronchial hyperresponsiveness (BHR) and underlying inflammation.[1–3] It is a complex syndrome that develops after environmental exposures such as innocuous allergens, infectious agents and air pollutants in genetically susceptible individuals with differences in severity, co-morbidities, natural history and treatment response.[4] The asthma syndrome encompasses several disease subtypes defined by distinct pathophysiologic mechanisms, called endotypes.[3] Some examples of these asthma endotypes include aspirin-sensitive asthma (ASA), allergic bronchopulmonary mycosis (ABPM), allergic asthma, asthma predictive indices (API), late-onset asthma in adulthood and cross-country skier's asthma. Among them, allergic asthma is one of the best characterized. Recent advances have significantly contributed to our knowledge of the mechanisms underlying this endotype. It is characterized by an inflammatory immune response with high levels of T helper cell type 2 (Th2) lymphocytes, type 2 innate lymphoid cells, eosinophils and basophils together with activation of the tissue cells, particularly epithelium and smooth muscle cells, that leads to mucus production, mucosal edema, reversible airway obstruction, BHR and airway remodeling. Allergic asthma is associated with specific IgE sensitization to indoor and outdoor allergens,[5,6] and sometimes with elevated total serum IgE levels,[7] which represent major risk factors for the development of asthma and persistent wheezing in children.[8]

Mechanisms of the Allergic Inflammatory Response

The immune response in allergic asthma consists of two main phases: (1) sensitization and memory and (2) the effector phase, which can be further subdivided into the immediate-phase response (IPR) and the late-phase response (LPR).[9] During the sensitization phase of asthma the differentiation and clonal expansion of allergen-specific $CD4^+$ Th2 cells producing IL-4 and IL-13 are essential to induce class switch to the ε immunoglobulin heavy chain in B cells and the production of allergen-specific IgE antibodies (Abs). Allergen-specific IgE binds to the high-affinity FcεRI on the surface of mast cells and basophils, thus leading to the patient's sensitization (Figure 28-1). A memory pool of allergen-specific T and B cells is also generated. The IPR, which is also called the type I hypersensitivity response, occurs after new encounters with the causative allergen, which induces cross-linking of the IgE-FcεRI complexes on sensitized effector cells, leading to the release of anaphylactogenic mediators responsible for the classical symptoms of IPR, which induce increased vascular permeability, extravasation of fluid into the tissues and smooth muscle contraction (Figure 28-2). If contact with the allergen persists, the LPR occurs 6 to 12 hours later. Activated allergen-specific Th2 cells produce IL-4, IL-5, IL-9 and IL-13, which play a key role in the maintenance of allergen-specific IgE levels, eosinophilia, recruitment of inflammatory cells to inflamed tissues, production of mucus and decreased threshold of contraction of smooth muscles, leading to increased inflammation associated with BHR, a cardinal feature of asthma (Figure 28-2).[10,11] Recently, other cytokines including thymic stromal lymphopoietin (TSLP), IL-25, IL-31 and IL-33 produced in epithelial cells have been shown to participate in the Th2 response and inflammation.[12–14]

Th2 CELLS AND Th2 CYTOKINES

$CD4^+$ Th2 cells are present in lung biopsy specimens and bronchoalveolar lavage (BAL) fluid from patients with allergic asthma and play a prominent role in the initiation and

https://CafePezeshki.IR

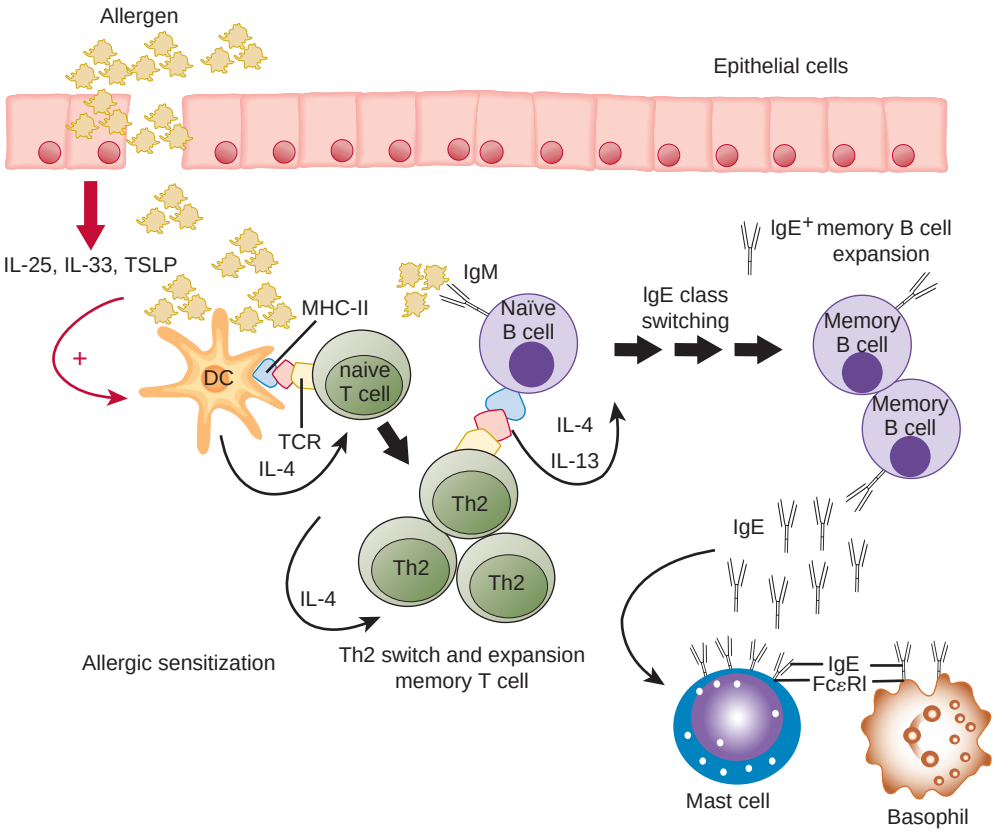

Figure 28-1 Schematic representation of the sensitization phase in asthma. Allergen-specific $CD4^+$ Th2 cells producing IL-4 and IL-13 are generated in a process depending on dendritic cells (DCs). Epithelial cell-derived thymic stromal lymphopoietin (TSLP), IL-25 and IL-33 may play a role in this Th2 response. Th2 cells contribute to the IgE class switching on B cells. IgE binds to FcεRI on mast cells and basophils, the effector cells, thus leading to the allergic sensitization of patients.

development of the disease. Although several cell types produce Th2 cytokines, including mast cells, basophils, natural killer T (NKT) cells and the recently identified type 2 innate lymphoid cells (ILC2), Th2 lymphocytes are still considered fundamental in allergic asthma. Initially, mouse models demonstrated that depletion of $CD4^+$ T cells prevents the development of asthma.

IL-4 plays a major role in the development of protective immune responses to helminths and other extracellular parasites,[15] but it also has a central role in the regulation of allergic asthma, being the major stimulus for the differentiation of antigen-stimulated naïve T cells into Th2 cells.[16–18] IL-4 is also essential for human and mouse B cell switch to IgE and IgG4 or IgG1, respectively, and increases the expression of class II MHC molecules, CD23 and IL-4R in B cells. IL-4 increases the production of cysteinyl leukotrienes from IgE-primed mast cells,[19] and together with TNF-α the expression of vascular cell adhesion molecule-1 (VCAM-1) on vascular endothelial cells. IL-4- and IL-4Rα-deficient mice have severely compromised Th2 differentiation and their serum levels of IgG1 and IgE are strongly reduced.[20]

IL-5 is another central Th2 cytokine, which is simultaneously produced with IL-4 under the control of the transcription factor GATA-3 with a central role in allergic asthma.[21] IL-5, together with IL-3 and granulocyte-macrophage colony-stimulating factor (GM-CSF), leads to growth, activation, differentiation, survival and mobilization of eosinophils to the lungs as a key feature of asthma.[22–25] Eotaxin-2, an eosinophil chemokine, seems to be crucial for IL-5-induced IL-13 production and BHR and has a role in remodeling.[26,27] IL-5 levels and eosinophils are increased in BAL and in biopsies of asthmatics and they correlate with severity of the disease.[28] Eosinophils produce cysteinyl leukotrienes and may enhance the production of IL-13,[29] which can directly induce BHR. IL-5-deficient mice are resistant to induction of experimental asthma.[30] The treatment of asthma with anti-IL-5 antibodies (mepolizumab, reslizumab) reduced blood eosinophilia and sputum eosinophils, but few or no effects on asthma symptoms were observed in the initial clinical trials.[31–33] Recent studies reported significant reductions in exacerbation rates in refractory eosinophilic asthma[34] and steroid-dependent asthma with sputum eosinophilia.[35]

IL-13 is another Th2 cytokine that has been shown to play a critical role in asthma.[16] IL-13 shares with IL-4 one receptor chain, IL-4Rα. IL-13 does not promote Th2 differentiation, because T cells do not express the IL-13 receptor. IL-13 is also able to activate eosinophils and mast cells, recruits eosinophils and prolongs their survival.[36] It up-regulates the levels of CD23 and MHC II on B-cells and induces the expression of different adhesion molecules on monocytes. IL-13 also plays an important role in tissue remodeling and fibrosis, and TGF-β has been linked to these effects.[37,38] The role of IL-13 in asthma is supported by epidemiologic data showing that IL-13 polymorphisms lead to a higher frequency of asthma exacerbations in childhood and elevated total IgE and blood eosinophilia.[39] IL-13 knockout mice fail to mount a profound goblet cell hyperplasia without affecting IL-4- and IL-5-producing cells,

https://CafePezeshki.IR

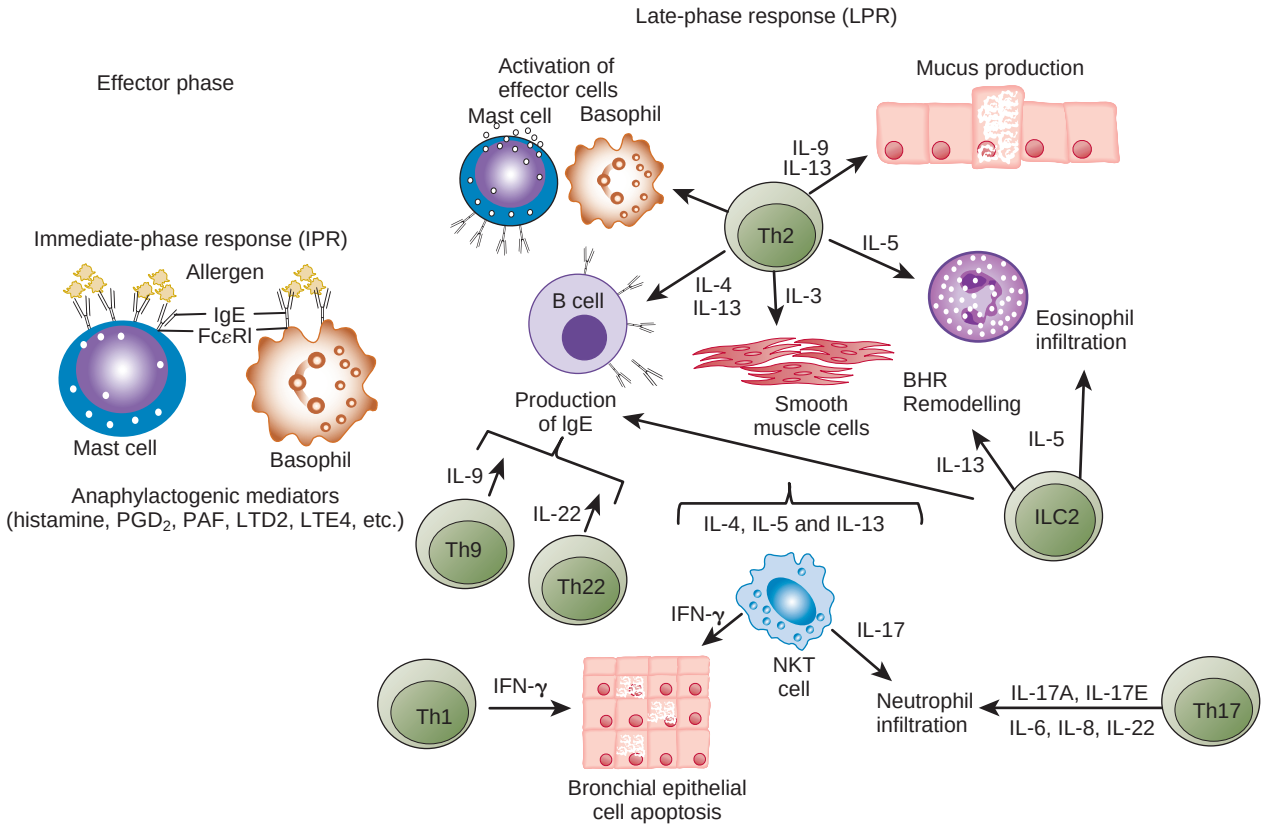

Figure 28-2 Schematic representation of the effector phases, the immediate-phase response (IPR) and the late-phase response (LPR), in asthma. In the LPR, the contribution of Th2 cells and other cell subsets including Th1, Th17, Th9, Th22, NKT cells and ILC2 is shown. Type 2 immunity of Th2 cells and ILC2 play a major role by producing the Th2 type effector cytokines such as IL-4, IL-5, IL-9 and IL-13. IL-4 and IL-13 are important in IgE production, whereas IL-5 has effects on eosinophil survival, Th1 cells and IFN-γ affect epithelial apoptosis and shedding, Th17 cells impact on neutrophilic inflammation, and IL-9 on mucus production.

mast cell cytokine production and IgE levels.[40,41] Specific overexpression of IL-13 in the lung leads to typical features of asthma.[42] Although all these findings indicate that IL-13 is a critical cytokine required for the development of asthma, an IL-4 mutant protein blocking the binding of both IL-4 and IL-13 to IL-4Rα was able to reduce the severity of the LPR, but not BHR in clinical trials.[43] This suggests that other factors, in addition to IL-13/IL-4, function to induce BHR in patients with asthma.

THE DEVELOPMENT OF THE Th2 RESPONSE

There are two types of IL-4 binding receptors: the type I and type II IL-4R.[44] Both types have the IL-4Rα chain in common. Type I IL-4R binds IL-4 exclusively and consists of IL-4Rα (CD124) and the common gamma chain γc (CD132), which is also a receptor for IL-2, IL-7, IL-9, IL-15 and IL-21. Type II IL-4R binds IL-4 and also IL-13 and consists of the IL-4Rα chain and the IL-13Rα1 chain.[45] Whereas the signals of the type II IL-4R are mediated by signal transduction and activator of transcription (STAT3), the signals of the type I IL-4R are transduced by STAT6. Binding of IL-4 to the IL-4 receptor complex promotes intracellular signaling cascades involving several Jaks members that culminate with the phosphorylation and activation of STAT6 that enhance Th2 cell differentiation. The binding of IL-13 to its receptors, which consist of IL-13Rαl and IL-13Rα2 and the IL-4Rα chain, also results in phosphorylation of STAT-6. STAT-6 then translocates to the nucleus and binds to STAT-6 transcriptional elements or interacts with additional Th2-associated transcription factors such as GATA-3, which is selectively expressed in Th2 cells and is critical for Th2 cytokine expression.[46] Increased expression of both STAT-6 and GATA-3 has been observed in bronchial mucosa of asthmatic patients.[47,48]

THE Th1/Th2 PARADIGM

After the discovery of Th1 and Th2 cells in 1986,[49] it was suggested that a Th2 response underlies the development of allergic diseases, and that Th1 responses are predominant in infections and autoimmunity (Figure 28-3). Following these initial findings, the general dogma was that a switch toward a Th1 response would be required for successful treatment of allergies by AIT and a switch toward a Th2 response would be beneficial for treatment of autoimmunity. Th1 cells secrete IFN-γ, particularly induced by IL-12, which is secreted from dendritic cells (DCs). Th2 cells secrete IL-4, IL-5 and IL-13 induced by IL-4. Th1 cells were thought to balance Th2 responses and protect against allergic diseases, as has been shown in models of infection with intracellular bacteria. In humans, infants with higher levels of IFN-γ in their cord blood were demonstrated to be less likely to develop atopy.[50] Furthermore, expression of T-bet, the master switch transcription factor for Th1 development and IFN-γ production, is decreased in the airways of patients with asthma.[51] Moreover, patients with allergic asthma display low

Figure 28-3 Th1, Th2 and T_{REG} cells. After the discovery of Th1 and Th2 cell subsets in 1986, it was thought that Th1 cells play a role in infections and autoimmunity and Th2 cells in allergic disease. Both subsets were thought to have reciprocal roles in counter-regulating the other. Although there is reciprocal regulation between individual Th cell subsets, T_{REG} cells play a major role in immune tolerance in allergy, autoimmunity, organ transplantation, cancer, pregnancy and chronic infections.

levels of the Th1-driven cytokine IL-12,[52] as well as lower expression of IL-12R.[53]

Beyond the Th2 Paradigm in Allergies and Asthma

The Th2 paradigm of asthma explains many features of asthma, but there are many other observations that cannot be explained exclusively by this paradigm. For example, non-Th2 factors such as IFN-γ, neutrophils and IL-17 are present in the airways of many patients with asthma, particularly patients with severe asthma and corticosteroid-resistant asthma, suggesting that IFN-γ and IL-17 are proinflammatory cytokines. Depending on the stage of inflammation they contribute to ongoing allergic asthma and Th1 and Th17 are not necessarily polarized as cells that oppose Th2 cells (Figure 28-2). It was demonstrated that Th1 cells contribute to exacerbation of the LPR by inducing apoptosis of the airway epithelium in atopic patients,[54,55] and that neutralization of IL-17 and Th17-related functions in an experimental asthma model reduces neutrophilia, while increasing eosinophil infiltration in the lung.[56] In addition, two novel Th cell subsets have been identified according to their cytokine signature, Th9 and Th22 cells (Figure 28-2). However, their exact contribution to the initiation and continuation of allergic asthma needs to be further explored.[57–59] The prevalence of Th1- and Th17-mediated autoimmune diseases such as type 1 diabetes, inflammatory bowel disease and multiple sclerosis has significantly increased, as has that of atopic diseases, in westernized cultures over the past decades. This might be partially explained by environmental changes that have occurred in westernized cultures that could have altered the function of a specific T cell population with suppressive capacity – regulatory T cells (T_{REG}; see below) – thus enhancing the development of not only Th2- but also Th1- and Th17-mediated diseases.

Other observations that cannot be explained by the Th2 paradigm of asthma are: (1) low levels of Th2 cells in the airways of patients with severe asthma and with steroid-resistant asthma; (2) that viral infection, exercise and air pollution are common nonallergic factors that normally induce symptoms of asthma; (3) that only around 30% to 40% of patients with allergic rhinitis develop asthma; (4) therapies targeting Th2 factors in clinical trials have not always been as effective as predicted.[5,60] Therefore, other innate and adaptive inflammatory pathways must be considered beyond the Th1/Th2 paradigm to explain the development of asthma.

NEW T CELL SUBSETS

Regulatory T Cells and Immune Tolerance

T_{REG} cells comprise a group of different T cell subsets with suppressive capacity that are essential for the induction of immune

https://CafePezeshki.IR

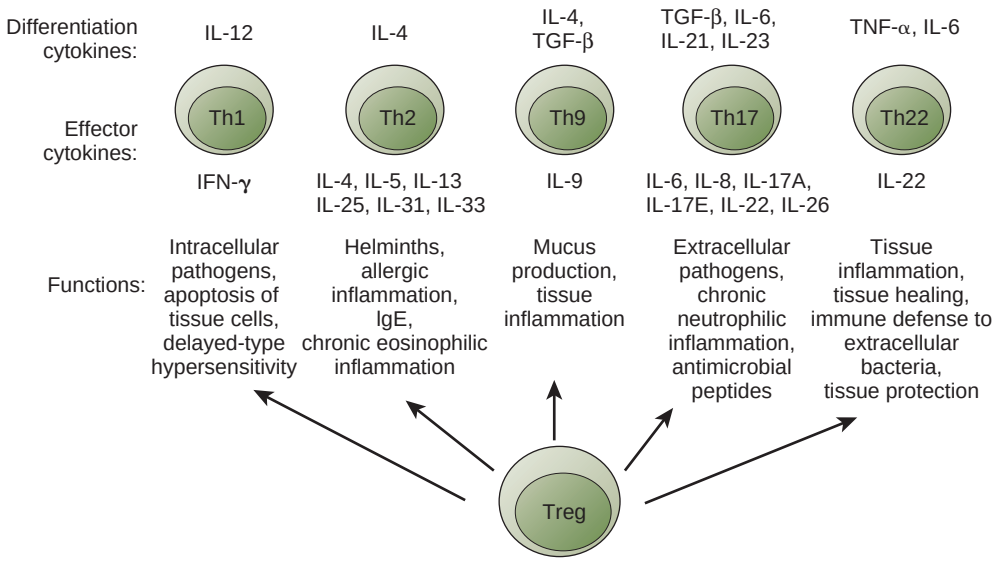

Figure 28-4 Antigen presentation by dendritic cells to naïve T cells and other factors (innate immune response substances, vitamins, cytokines in the environment) induce the T cells to produce interleukins and differentiate into Th1, Th2, Th9, Th17 or Th22 cells. These T cell subsets can promote different types of inflammatory responses based on their respective cytokine profiles, responses to chemokines and interactions with other cells. T_{REG} cells directly or indirectly suppress all other effector T cell subsets.

tolerance (Figure 28-4).[61] T_{REG} cells can be broadly divided into two main groups: (1) the thymus-derived naturally occurring $CD4^+CD25^+$ forkhead box protein 3 $(FOXP3)^+$ T_{REG} cells, also called natural T_{REG} (nT_{REG}) cells, and (2) the inducible T_{REG} (iT_{REG}) cells. nT_{REG} cells constitutively express high levels of the alpha chain of the IL-2 receptor (CD25) and the suppressor costimulatory molecules CTLA4 and PD1.[62,63] The expression levels of GITR, CD103 and CD122 on nT_{REG} cells correlate with their suppressive activity.[64] In mice, FOXP3, the master transcription factor for T_{REG} cell generation, is specifically expressed by nT_{REG} cells,[65,66] but in humans it might be also expressed in activated T cells.[67] Mutations in *FOXP3* lead to the immune dysregulation polyendocrinopathy enteropathy X-linked syndrome (IPEX) or the X-linked autoimmune and allergic dysregulation syndrome (XLAAD), diseases characterized by severe autoimmune and allergic phenotypes.[68,69] Similar phenotypes are reported for scurfy mice due to *FOXP3* mutations and impaired capacity to generate functional T_{REG} cells.[70] iT_{REG} cells generated in the periphery after antigenic stimulation are characterized by high levels of IL-10 production and play a key role in the maintenance of healthy immune response to allergens.[71,72] iT_{REG} cells suppress effector T cell responses by mechanisms that depend on IL-10 and also TGF-β, and produce perforin and granzymes to kill antigen-presenting cells.[72] In humans, Type 1 iT_{REG} (Tr1) cells inhibited the proliferation and cytokine responses of naïve as well as established Th1 and Th2 cells, including allergen-specific Th2 cell lines.[73] Healthy and allergic individuals display three different allergen-specific T cell subtypes as Th1, Th2 and Tr1 in different ratios.[74,75] The imbalance between Th2 and Tr1 cells, depending on the dominant subset, may induce allergy development or recovery. Immune tolerance to venom allergens is an appropriate model for high-dose tolerance to allergens in humans. During the exposure to venom allergen, venom-specific IL-10-secreting Tr1 cells are clonally differentiated from allergen-specific Th1 and Th2 cells.[71] Interestingly, histamine receptor 2, which is also up-regulated on specific Th2 cells, suppresses allergen-stimulated T cells and enhances IL-10 production related to the tolerance mechanism. Nonallergic beekeepers have an approximately 1,000 times higher allergen-specific IgG4 versus allergen-specific IgE ratio compared to bee venom allergic individuals.[76] Another tolerance model with cat allergen also showed elevated levels of allergen-specific IgG4 levels after exposure to high-dose cat allergen.[77] This also represents immune tolerance to the Th2 type immune response to specific allergen. Together these outcomes may infer that pets in the house may induce tolerance and decrease the risk of asthma.

Interestingly, it has recently been shown that functional allergen-specific T_{REG} cells are generated in human tonsils by mechanisms partially depending on plasmacytoid dendritic cells (pDCs) and that triggering of TLR4 or TLR8 and proinflammatory cytokines, such as IL-1β and IL-6, breaks allergen-specific T cell tolerance in human tonsils and peripheral blood.[78,79] Considering that the relatively large lingual tonsil is not removed by tonsillectomy and remains intact for life, these data suggest that the tonsils are the organs where immune tolerance induction during successful sublingual immunotherapy (SLIT) may take place, thus representing a potential novel target for future therapeutic interventions.

Th17 Cells

A new T cell lineage secreting large quantities of IL-17A, also known as IL-17, was identified and called Th17 cells.[32,33] Th17 cells are essential for the elimination of extracellular pathogens[80,81] and they might also play a role in the development of psoriasis, Crohn's disease and rheumatoid arthritis.[82] They produce proinflammatory cytokines such as IL-17A, IL-17F, IL-22 or IL-26 after activation.[83–85] The main cytokines involved in Th17 development and expansion include TGF-β, IL-6, IL-1β, IL-21 and IL-23.[84,86] The retinoic acid receptor-related orphan receptor γt/C2 (RORγt/RORC2), in mice and humans respectively, is the master transcription factor involved in Th17 cell development.[87] Several studies in mouse models and human data suggest that Th17 cells play a pathogenic role in the

https://CafePezeshki.IR

development of allergic diseases.[64,88] Th17 cells contribute to neutrophilic inflammation in acute airway inflammation models.[56,89] IL-17 is demonstrated to be the main cytokine driving the granulocyte influx observed in the lungs of allergic asthma models.[90,91] In humans, it was shown that Th17 cells contribute to allergic airway disease by inducing airway smooth muscle cell migration.[92] Genetic polymorphism studies demonstrated an association of IL-17 and asthma.[93]

Th9 and Th22 Cells

Recent findings showed that TGF-β alone converts Th2 cells into selective producers of IL-9 (Th9), and that in combination with IL-4 it is able to promote the generation of Th9 cells.[47,48] IL-9 significantly contributes to the development of allergic asthma by directly acting on T cells, B cells, mast cells, eosinophils, neutrophils and epithelial cells and promoting eosinophilic inflammation, BHR, elevated IgE levels and increased mucus secretion (Figure 28-2).[94–98] The expression of IL-9 and IL-9 receptor is increased in bronchial tissue of atopic asthmatic subjects.[99] Supporting this role, mice selectively overexpressing IL-9 in the lung developed many features that resembled human asthma.[94,95]

Th22 cells represent a novel Th cell subset characterized by particularly high production of IL-22, which might be also produced by other T cells such as Th0 and Th17 cells.[85,100–102] The exact role of IL-22 in asthma is not fully understood yet and further research is required. It was reported that Th22 cells together with Th17 cells contribute to enhance migration of airway smooth muscle cells, thus increasing the accumulation of such cells in asthma (Figure 28-2).[82,92] As previously discussed, Th17 cells induce BHR in steroid-resistant asthma, but whether this effect might also be partially due to IL-22 remains elusive.[16,103] IL-22 could also inhibit allergic airway inflammation in the effector phase by altering the function of DCs and inhibiting IL-25 production from lung epithelial cells.[104]

B Regulatory Cells and Allergen Tolerance

Very recent findings demonstrated that IL-10-secreting B regulatory (Br1) cells might also play an essential role in the generation of a healthy immune response to allergens.[105] Human IL-10-secreting Br1 cells are able to suppress antigen-specific $CD4^+$ T cell proliferation. In addition, the major bee venom allergen phospholipase A (PLA)-specific B cells from nonallergic beekeepers showed increased expression of IL-10 and IgG4 and the frequency of IL-10-secreting PLA-specific B cells increased in allergic patients receiving allergen-specific immunotherapy. These data provide novel information on IL-10-secreting Br1 cells in allergic inflammation in humans.

In a recent study analyzing the role of IL-10 in particular, solely IL-10-overexpressing human B cells acquired a prominent immunoregulatory profile comprising up-regulation of suppressor cytokine signaling-3 (SOCS3), glycoprotein A repetitions predominant (GARP), CD25 and PD-L1.[106] Concurrently, their secretion profile was characterized by a significant reduction in proinflammatory cytokines (TNF-α, IL-8 and MIP-1α) and augmented production of antiinflammatory IL-1RA and vascular endothelial growth factor (VEGF). IL-10-overexpressing B cells secreted less IgE, and potently suppressed proinflammatory cytokines in peripheral blood mononuclear cells, maturation of monocyte-derived dendritic cells (promoting a tolerogenic phenotype) and antigen-specific proliferation in vitro.

Innate Inflammatory Mechanisms in Asthma

Compelling experimental evidence has demonstrated that asthma does not exclusively depend on Th2 adaptive immune responses, and it is increasingly seen as a disease that has a strong innate immune component. Today, it is accepted that the classical Th2 cytokine signature of allergic asthma might not simply reflect an adaptive Th2 cellular response.[5] Different innate immune system cells in the lung such as epithelial cells, DCs, other airway cells, neutrophils, eosinophils, NK cells and NKT cells as well as ILC2 also significantly contribute to the initiation and maintenance of allergic asthma.[60] In contrast to the adaptive immune system, the response mounted by the innate inflammatory system does not involve memory and is less sensitive to corticosteroids,[107] which could explain the apparent resistance to steroid treatments in many forms of asthma and severe asthma. The innate immune system cells express a wide range of pattern recognition receptors (PRRs) that allow them to recognize molecular patterns released from pathogens (pathogen-associated molecular patterns, PAMPs) or from damaged tissues (damage-associated molecular patterns, DAMPs).[108,109] Innate immune system cells respond to environmental insults such as cigarette smoke that may directly damage respiratory tissues, activating damage PRRs, or to respiratory viruses activating Toll-like receptor (TLR)3, TLR7 or TLR8, which leads to inflammation, and synergize to significantly exacerbate lung inflammation.[109,110] In the same way, other PRRs including C-type lectin receptors, scavenger receptors or nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) could also contribute to enhance inflammation after exposure to protease-containing allergens, pathogens or pollution.[64] Lung epithelial cells do not only represent a structural barrier, they also contribute to mount proper immune responses by secreting different types of mediators such as chemokines (RANTES/CCL5, eotaxin/CCL11 and MCP-1/CCL2), growth factors (platelet-derived growth factor, fibroblast growth factor and endothelins), nitric oxide that increases airway inflammation,[111] as well as cytokines such as IL-25, IL-33 and TSLP (see below) that may activate innate cells, including mast cells, basophils and NKT cells or ILC2.[5]

IL-25, also known as IL-17E, is a member of the IL-17 cytokine family produced by Th2 polarized T cells[112] and in vitro cultured mast cells[113] and epithelial cells.[114,115] Recent data suggest a crucial role for IL-25 in asthma by favoring the production of Th2 cytokines, enhancing IgE synthesis, inducing mucus production and epithelial hypertrophy or augmenting the numbers of eosinophils in blood.[116] IL-25 mediates its effects through the induction of Th2 cytokine production (IL-4, IL-5 and IL-13) in non-B/non-T (NBNT) $c\text{-}kit^+Fc\varepsilon RI^-$ cells in mesenteric lymph nodes, in a subset of natural killer T (NKT) cells[117] and in ILC2.[118] Eosinophils and basophils from atopic individuals have also been described as sources of IL-25. The latter may maintain reactivity of Th2 central memory cells that express the IL-25R upon stimulation by the innate immune system.[14] In mouse models, IL-25 expressed in the lungs of sensitized mice upon antigen inhalation is sufficient to induce allergic diseases of the airways and administration of anti-IL-25 monoclonal antibodies (mAbs) reduced IL-5 and IL-13 production, eosinophilic infiltration, goblet hyperplasia and BHR.[119]

https://CafePezeshki.IR

This indicates that IL-25 is a potent inducer of Th2 type immunity in the lung by its effects on several different cell types.

IL-33 is a cytokine that plays a significant role in the regulation of mucosal immune responses of the airways.[120] It is mainly produced by bronchial epithelial cells, but also by fibroblasts and smooth muscle cells. The receptor for IL-33 is ST2, which is mainly expressed on Th2 cells, mast cells, some NKT cells and mucosal ILC2.[118,121] IL-33 levels are increased in the serum of allergic patients suffering from anaphylaxis and different studies demonstrated that IL-33 potently activates human eosinophils and mediates direct degranulation of mast cells in the absence of allergen.[122,123] In mice, IL-33 is able to generate airway inflammation through a process depending on IL-5-producing T cells but not IL-4.[124] Administration of neutralizing antibodies or transfer of soluble ST2 impairs Th2 type inflammation in asthma in mice.[125,126] Administration of exogenous IL-33 leads to lymphocyte-independent airway hyperreactivity and goblet cell hyperplasia in mice.[120]

Thymic stromal lymphopoietin (*TSLP*) is another cytokine mainly produced by human lung and skin epithelial cells that acts on DCs, increasing the expression of different costimulatory molecules, including OX40-L, which in turn promotes the generation of IL-4-, IL-5- and IL-13-producing T cells and inhibiting IL-10 and IFN-γ.[127] In addition, TSLP-activated DCs induce the production of Th2-attracting chemokines and activation-regulated chemokine (TARC) and monocyte-derived chemokine (MDC). The expression of TSLP is significantly increased in the asthmatic airways and in the skin of atopic dermatitis patients, respectively, and correlates with disease severity.[128,129] These data demonstrate that TSLP is also a Th2-promoting cytokine that significantly contributes to the pathogenesis of human asthma.

ANTIGEN-PRESENTING CELLS

Antigen-presenting cells (APCs) are able to capture environmental allergens in the airways, skin or mucosa, migrate to the nearest lymph nodes and present the processed antigenic peptides to T cells. The most potent stimulators of naïve T cells are DCs lining the mucous membranes of the airways.[71] In contrast, alveolar macrophages, which are abundant in the lung, phagocytize antigens, but they are not able to up-regulate the expression of CD80 or CD86 costimulatory molecules and actively tolerize $CD4^+$ T cells. In humans, circulating DCs can be broadly divided into two groups: (1) myeloid dendritic cells (mDCs), and (2) plasmacytoid dendritic cells (pDCs).[130] mDCs can be further divided into type 1 mDCs expressing BDCA1 and type 2 mDCs expressing BDCA3.[131] Both mDCs and pDCs express a different repertoire of TLRs and display a diverse cytokine signature after microbial stimulation.[132] mDCs induce naïve $CD4^+$ T cells to produce large quantities of IFN-γ but few Th2 cytokines, whereas pDCs were initially described as inducer $CD4^+$ T cells to produce Th2 cytokines but not IFN-γ. For a long time, it was believed that only immature or partially mature DCs generate functional T_{REG} cells[133] and that mature DCs induce specific effector Th cells after encountering different stimuli in specific environments.[134,135] Recent findings indicate that fully mature pDCs are also able to induce functional T_{REG} cells[64,136] in humans, thus indicating that pDCs constitute a unique DC subset exhibiting intrinsic tolerogenic capacity.[78,137,138] In mice, depletion and adoptive transfer of pulmonary pDCs in experiments demonstrated this DC subset to be essential for the prevention of allergic sensitization and asthma development.[139]

MAST CELLS AND NEUTROPHILS

Mast cells play a key role in both the IPR and LPR effector phases of allergic asthma.[140] Sensitized mast cells are activated in an IgE-dependent manner after new encounters with the offending allergens contributing to the IPR. Mast cells contribute to the development of BHR in asthmatic individuals, who show significantly higher numbers of activated mast cells compared to healthy individuals.[141] During the LPR, eosinophils, basophils, neutrophils and activated T cells massively infiltrate the exposed areas and trigger potent inflammatory responses which, depending also on the IPR, contribute to the generation of BHR and the chronic symptoms of asthma. IL-17-mediated neutrophil infiltration is a very important feature of severe asthma that has been correlated with disease severity.[142]

BASOPHILS

In addition to the classical role of basophils during the IPR, several studies have demonstrated that they also express class II MHC molecules and are able to prime naïve $CD4^+$ T cells into Th2 cells.[143,144] They produce large quantities of IL-4, IL-13 and TSLP[145] and it was shown that they could also play a role in the sensitization phase of allergic asthma by enhancing adaptive immunity and Th2 responses.[143,144] A recent study demonstrated that inflammatory DCs were necessary and sufficient for induction of Th2 immunity and features of asthma, whereas basophils were not required, thus suggesting a model whereby DCs initiate and basophils amplify Th2 immunity to house dust mite allergen.[146]

NATURAL KILLER T CELLS

Due to their unique expression of the invariant T cell receptor (TCR) and their capacity to rapidly produce cytokines after activation, the natural killer T (NKT) cells are considered as a cell subset belonging to the innate immune system with the capacity to amplify adaptive immune responses. NKT cells might be involved in the development of BHR, and different subsets of NKT cells were described in different models of asthma. For the development of BHR in a model of allergic asthma, NKT cells producing IL-4 and IL-13 were required (Figure 28-2).[147] In an asthma model induced with ozone to mimic air pollution, NKT cells producing IL-17 were required to induce neutrophil infiltration in the airways,[148] however, in a model of virus-induced BHR, $CD4^-$ NKT cells were required.[149] In both cases, Th2 cells and adaptive immunity were necessary for NKT cells to promote BHR, which might help to explain some forms of nonallergic asthma. The frequency of NKT cells in the lungs of asthma patients appears to be highly variable and related to asthma severity and symptom control.[150]

NATURAL KILLER CELLS

NK cells encompass different subsets of lymphocytes that do not express CD3, CD4 or CD8. They are essential for killing tumor and virus-infected cells as well as in controlling certain microbial infections. Subsets of NK cells ($CD56^{bright}$ $CD16^{dull}$) are able to produce high levels of cytokines including IFN-γ, tumor necrosis factor (TNF)-α, TGF-β, IL-5, IL-10 and IL-22

https://CafePezeshki.IR

after stimulation. NK cells contribute to exacerbate airway inflammation and increase Th2 cytokines and eosinophilia as demonstrated after depletion experiments in a mouse model.[151] In contrast, TLR9-L-activated NK cells produced high levels of IFN-γ, suggesting a protective role in the development of asthma.[152] Activated NK cells also produced IL-22, which in turn favored the production of antimicrobial peptides and enhanced epithelial cell integrity.[82] In addition, a tiny NK cell subset that secretes mainly Th2 cytokines but not IFN-γ has been shown to contribute to IgE production in humans.[153]

γδ CELLS

T cells expressing γδ T cell receptors (γδ T cells) are normally found in high numbers in mucosal tissues, where the contact with allergenic proteins occurs. Although their main function seems to be associated with the generation of immune responses against bacterial antigens, they were also shown to play an important role in allergic sensitization.[154] After allergen challenge, a population of γδ T cells producing Th2-type cytokines was described.[155] In humans, the role of γδ T cells in asthma is controversial; some studies report increased γδ T cell numbers in BAL fluid from patients with asthma,[156] whereas others show decreased numbers of peripheral blood γδ cells.[157]

$CD8^+$ T CELLS

$CD8^+$ T cells can be classified as type 1 (producing IFN-γ) or type 2 (producing IL-4 and IL-5). Exogenous allergens are cross-presented to allergen-specific $CD8^+$ cells through class I pathways, but the precise role of $CD8^+$ cells in asthma is not clear and may depend on the relative numbers of both types in the lungs and blood of asthmatic individuals. It was initially suggested that type 2 $CD8^+$ cells may contribute to asthma pathogenesis.[158] Type 1 $CD8^+$ cells were shown also to enhance asthma symptoms,[159] but they could also display a protective role by eliminating allergen-specific Th2 cells.

TYPE 2 INNATE LYMPHOID CELLS (ILC2)

Type 2 innate lymphoid cells (ILC2) were initially described in the gut but they are also abundant in lungs and mucosa. They have been shown to produce large quantities of Th2 cytokines after activation with IL-25 and IL-33, playing an important role in virus-induced BHR and allergic asthma.[5,118] ILC2s require the transcription factors RORα and GATA3 for their development and mainly produce IL-5, IL-9 and IL-13 after activation. Different studies demonstrated that ILC2s play an important role in BHR induction after influenza virus infection through a process depending on IL-33 produced by activated alveolar macrophages.[118,160] In addition, other studies have demonstrated in mice a role for ILC2 in the pathophysiology of asthma and allergic inflammation.[118,161] These data could help to explain virus-induced and allergen-induced BHR and asthma through a common pathway to generate Th2 responses.

Airway Remodeling in Asthma

Asthmatic airways are characterized by structural airway changes known as airway remodeling, including smooth muscle hypertrophy, goblet cell hyperplasia, subepithelial fibrosis and angiogenesis. Epithelial and mesenchymal cells are in close contact, forming a truly epithelial-mesenchymal unit that coordinates the initiation of proper responses to injury in the lung. This unit coordinates growth and the response to damage after injury from the environment, potential alterations of which are related to the development of asthma.[162] For this important role, they use cytokines and growth factors such as TGF-β, epithelial growth factor (EGF) and VEGF. One of the main features associated with persistent asthma is structural remodeling due to the conversion of mesenchymal cells into myofibroblasts, producing large amounts of interstitial collagens and leading to fibrosis and thickening of the subepithelial basement membrane (lamina reticularis).[163] TGF-β produced by resident tissue induces the synthesis of collagen I and inhibits collagenase production in an autocrine manner, thus contributing particularly to airway remodeling and fibrosis in the pathogenesis of asthma.[164,165] TGF-β also plays an important role in the control of airway inflammation and restoration of healthy immune responses to allergens.[164] Other alterations observed in the airway include thickening of the bronchial wall, mucus hypersecretion, hyperplasia and hypertrophy of the smooth muscle layer, and neovascularization.[5] Genetic polymorphisms in asthma susceptibility have been described for several genes including *ADAM33* and filaggrin (*FLG*) genes.[163,166]

The Role of Cell Trafficking and Migration in Pulmonary Inflammation

The homing of the inflammatory cells to the lung is a key aspect in the development of asthma and lung inflammation. Cell trafficking to the lung in asthma is a very complex and redundant process that involves different cytokines, chemokines, adhesion molecules and matrix metalloproteinases (MMPs).

During allergic inflammation, several cells in the lung rapidly produce the chemokines MCP-1/CCL2, MCP-2/CCL8 and eotaxin/CCL11, and basophils expressing the chemokine receptors CCR2, 3 and 4 are the first cells to be recruited. Patients with allergic asthma have significantly higher expression levels of CCR3 and eotaxin/CCL11.[167] The chemokines MCP-3/CCL7, MCP-4/CCL13 and VCAM-1 and MadCAM-1 also direct the recruitment of eosinophils expressing CCR3, CXCR4 and α4β1/VLA-4 and α4β7/LPAM-1 integrins into the lung.[168] Once inflammatory cells are recruited to the lung, migration into the tissues requires firm adhesion. Extravasation/diapedesis is a complex process that is also regulated by different integrins, chemokines and cytokines through the regulation of the expression of proteinases such as MMPs and matrix-degrading enzymes that allow the leukocytes to penetrate through the basement membrane and into the tissue stroma. In a mouse model of asthma, the expression of MMP2 and MMP9 is significantly increased in BAL fluid after allergen challenge.[169] Supporting these data, inhibition of MMP2 with TIMP-2 impaired the egression of eosinophils from the lungs into the airway lumen and the MMP2-deficient mouse model died of asphyxia after allergen challenge due to severe airway inflammation.[170]

Epithelial Cell Activation and Barrier Function in Asthma

The epithelial barrier function of bronchial epithelial cells in the asthmatic lung, sinus epithelial cells in the sinus tissue of

https://CafePezeshki.IR

chronic rhinosinusitis patients as well as keratinocytes in the skin of atopic dermatitis patients have been demonstrated to be defective.[171–174] These recent studies suggest that tissue integrity is disturbed in patients so that allergens, bacterial toxins and other particles are able to penetrate the epidermis and the lung epithelium, where they may activate the immune system and lead to severe chronic inflammation in both diseases. Epithelial tight junctions (TJs) are responsible for the regulation of paracellular flux and epithelial impermeability. TJs consist of different transmembrane and scaffold adapter proteins and form the most apical intercellular junction essential for barrier function between epithelial cells.[175] In addition, they prevent foreign particles, such as allergens, from entering into the subepithelial layers. In contrast, opening of TJs can lead to drainage of inflammatory cells toward the lumen, supporting the resolution of pathologic processes. Consequently, they can be considered as gatekeepers that could contribute both to aggravation of inflammation-related tissue damage or resolution of inflammation via drainage. It has been shown that TJs are disrupted in airways of patients with asthma as assessed by biopsies, as well as in air-liquid interface epithelial cell cultures from the asthmatic bronchi.[172]

THE ROLE OF RESPIRATORY VIRUSES IN ASTHMA DEVELOPMENT AND EXACERBATIONS

A large number of epidemiologic studies have shown that asthma exacerbations with acute airway obstruction and wheezing are associated with infections triggered by specific respiratory viruses such as rhinoviruses and, to a lesser extent, respiratory syncytial virus.[1,176] The persistence of respiratory viruses, virus load and virus co-infections have been related to more severe respiratory illnesses. In addition, high rates of respiratory bacterial infections have been associated with asthma exacerbations, indicating that in general respiratory infections may exacerbate rather than prevent the development of asthma. Other studies reported the opposite effect, suggesting that infections might contribute, with different mechanisms during sensitization and effector phases preventing the development of asthma or enhancing symptoms of already existing asthma.

Rhinovirus

Rhinovirus, the common cold virus, is the most frequent type of viral infection associated with asthma exacerbations. The detailed underlying immunologic mechanisms are not completely known, but infection of epithelial and bronchial endothelial cells with rhinovirus generates a plethora of proinflammatory mediators that contribute to the worsening of asthma episodes.[1,2] At the T cell level, human rhinovirus infections might contribute to the generation of Th2 cells and inhibit Th1 or IL-10-producing T_{REG} cells.[177] Additionally, virus-specific $CD8^+$ cells producing type 2 cytokines may develop during viral infections.[178] Rhinovirus infections in atopic asthmatic patients lead to more severe and prolonged lower respiratory tract symptoms compared to nonatopic subjects. Clinical trials showed that this might be due to impaired innate and adaptive immune responses in the airways of asthmatic patients.

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is the most common viral infection during the first 3 years of life, leading to acute viral bronchiolitis associated with the subsequent development of recurrent wheezing.[179] In addition, allergic asthma increases the risk of RSV infection of the lower respiratory tract and hospitalization, and early wheezing is also a strong risk factor for subsequent RSV hospitalization.[180] RSV infection impairs the capacity of epithelial cells to induce T_{REG} cells that are able to suppress undesired adaptive immune responses in the respiratory mucosa, and consequently effector T cells are activated leading to airway inflammation.[181] RSV is also able to promote airway remodeling, which in turn increases the susceptibility of the lung epithelium to initiate allergic responses to inhaled allergens.[182] Treatment of children hospitalized with RSV bronchiolitis with the antiviral ribavirin decreased the risk of subsequent allergic sensitization and development of asthma.[183] In the same way, treatment with palivizumab, a monoclonal antibody preventing RSV infection, of premature infants also reduced subsequent recurrent wheezing.[184]

The Hygiene Hypothesis

As a consequence of excessive hygiene, the production of IL-10 and TGF-β by epithelial cells, DCs and B cells in the mucosa is impaired, inhibiting T_{REG} cell activity and increasing Th1 and Th2 cell responses, which accounts for the observed increase in prevalence not only of Th2-mediated allergic diseases but also of Th1-mediated autoimmune disorders.[185,186] Different microorganisms may promote tolerogenic local environments at the mucosal surfaces, diminishing inflammation. A dearth of such specific microorganisms due to the lifestyle of westernized societies might contribute to altered homeostasis and lead to inflammation of the mucosal surfaces. These changes impair the functional features of antigen-specific T_{REG} cells to suppress effector T cell response against normally innocuous antigens, thus enhancing Th2 and Th1 pathologic immune responses and leading to allergic and autoimmune diseases.[64]

ROLE OF BACTERIAL ENDOTOXINS

In contrast to respiratory viral infection, recent studies indicate that early gastrointestinal exposure to Gram-positive commensal bacteria, *Bifidobacterium* and *Lactobacillus* strains, and their derived products, promotes the maturation of the immune system and may protect against the development of asthma.[64,187,188] The exact mechanisms involved in such effects are starting to be deciphered in detail and the activation of TLRs on innate immune system cells such as DCs seems to be of great importance. Different epidemiologic studies on farm environments showed that bacterial lipopolysaccharide exposure and subsequent activation of TLR4-signaling constitute a key mechanism to inhibit the development of Th2-biased immune responses, explaining the observed protective effects against asthma development in such situations.[189] The contribution of other TLRs and PRRs to such effects is an exciting area of research that needs to be further explored.[164,190]

Asthma Treatment and Induction of Immune Tolerance for Protective Immunity?

Most available treatments for asthma are effective at controlling symptoms; only conventional immunotherapy attempts to

https://CafePezeshki.IR

modify the course of the disease. Inhaled corticosteroids are still the mainstay for the treatment of asthma, but limited adherence is a major drawback to the success of such therapy. Allergen-specific immunotherapy (AIT) consists of the administration of increasing doses of the causative allergen to induce a state of immune tolerance.[191] Conventional subcutaneous immunotherapy (SCIT) has been shown to be efficient in controlling established disease. However it carries the problems of severe side-effects and long duration, leading to low patient adherence.[192] Numerous studies in the last two decades have provided a plausible explanation for multiple mechanisms of AIT inducing both rapid desensitization and long-term allergen-specific immune tolerance, and suppression of allergic inflammation in the affected tissues. During AIT, peripheral tolerance is induced by the generation of allergen-specific regulatory T cells, which suppress proliferative and cytokine responses against the allergen of interest. T regulatory cells directly or indirectly suppress effector cells of allergic inflammation, such as mast cells, basophils and eosinophils. T_{REG} cells and particularly IL-10 also have an influence on B cells, inhibiting IgE production and inducing the production of blocking type IgG4 antibodies against venom allergens. They also inhibit infiltration of inflammatory cells into tissues, control tissue remodeling and promote tolerogenic DCs (Figure 28-5). These findings together with the new biotechnological approaches create a platform for the development of advanced vaccines. Moreover, reliable biomarkers could be selected and validated with the intention of selecting the patients who will benefit most from this immune-modifying treatment. Thus, AIT could provide a complete cure for a larger number of allergic patients and novel preventive approaches need to be developed.

Different strategies have been employed to improve the efficacy and safety and reduce treatment time of AIT. For example, coupling of allergens with CpG oligonucleotide motifs (TLR-9 ligand) was shown to inhibit BHR and eosinophil infiltration in a model of asthma and to reduce symptoms in patients with allergic rhinitis.[193] Different therapeutic strategies have been tested or are currently under development including alternative routes of administration such as sublingual (SLIT) or oral (OIT) routes.[191] Novel approaches attempt to generate functional allergen-specific T_{REG} cells by manipulating DC function through the administration of different agents, using allergen peptides or by the administration of probiotics such as *Lactobacillus* or *Bifidobacterium*.[108,191] Novel findings demonstrated that the use of biologic agents might also represent an alternative strategy for the treatment of asthma. For example, omalizumab (human anti-IgE mAb) was shown to be effective in the treatment of moderate-to-severe asthma.[194] Other mAbs blocking the function of key Th2 cytokines such as dupilumab (targeting the α subunit of the IL-4-receptor), lebrikizumab (targeting IL-13) or benralizumab (targeting IL-5 receptor α) have been also tested with promising results.[108]

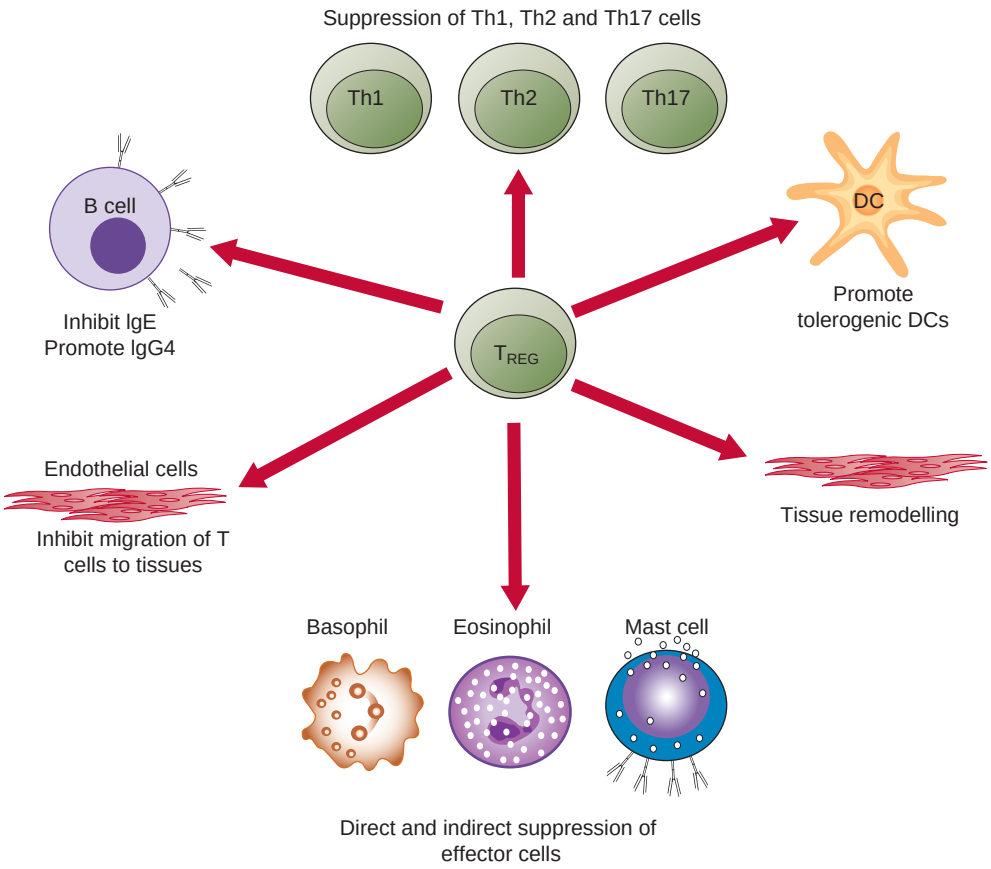

Figure 28-5 Different mechanisms employed by T_{REG} cells to suppress allergic reactions. T_{REG} cells directly inhibit Th1, Th2 and Th17 cells and effector cells. They also promote tolerogenic DCs, the induction of IgG4 and inhibition of IgE, inhibition of T cell migration to tissues and tissue remodeling.

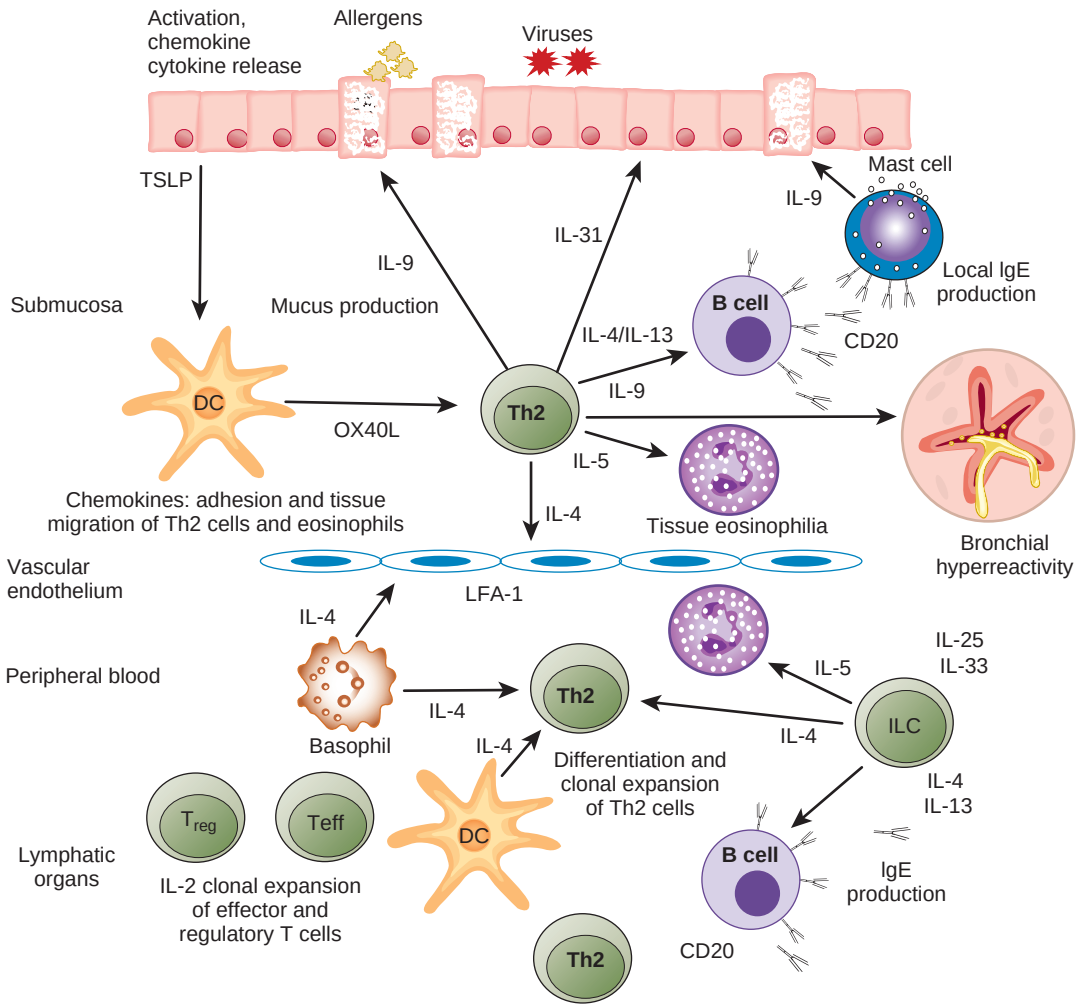

Figure 28-6 Asthmatic inflammation (effector phase). Epithelial cell activation with production of proinflammatory cytokines and chemokines induces inflammation and contributes to a Th2 response with TNF-α, IL-13, TSLP, IL-25, IL-31 and IL-33. Migration of inflammatory cells to asthmatic tissues is regulated by chemokines. Th2 and eosinophil migration are induced by eotaxin, monocyte-derived chemokine (MDC) and activation-regulated chemokine (TARC). Epithelial apoptosis and shedding is observed, mainly mediated by IFN-γ and TNF-α. The adaptive Th2 response includes the production of IL-4, IL-5, IL-9 and IL-13. Innate lymphoid cells, particularly ILC2, also secrete IL-5 and IL-13. Tissue eosinophilia is regulated by IL-5, IL-25 and IL-33. Local and systemic IgE production is observed in bronchial mucosa. Cross-linking of IgE receptor FcεRI on the surface of mast cells and basophils and their degranulation take place upon allergen challenge.

Conclusions

Our knowledge of the mechanisms operating in allergic asthma has increased markedly over the past years, which has significantly contributed to improvements in the diagnosis, management and treatment of the disease (Figure 28-6). Critical mediators involved in the Th2-biased asthmatic immune response and airway remodeling have been identified. Better understanding of the contribution of the innate immune system to the development of asthma, including the recently discovered ILC2, demonstrated that the Th2 cytokine signature might not simply reflect an adaptive Th2 cellular response but the integration of a much more complex network of cells and molecules. Rhinovirus and RSV infections have been associated with asthma exacerbations and, in the same way, asthma has frequently been related to increased susceptibility to infection with rhinoviruses and RSV as well as with changes in the microbiota not only in the airways but also in the intestinal tract. The hygiene hypothesis postulated that lack of microbial exposure and loss of commensal bacteria could explain the increased prevalence of Th2-biased allergic asthma. The generation of functional allergen-specific T_{REG} cells is a key event in the generation of healthy immune responses to allergens. Compelling experimental evidence demonstrated that T_{REG} cells in cooperation with other cell types such as B_{REG} cells or DCs producing high levels of IL-10 and/or TGF-β play an essential role in the initiation and maintenance of immune tolerance to allergens. Although initial therapies were based on relieving airway obstruction in asthma, current therapy focuses on reducing airway inflammation and neutralizing the effects of mast cell mediators. Better understanding of the molecular and cellular events implicated in the pathogenesis of the allergic diseases will contribute significantly to the development of better prevention strategies and alternative therapeutic options, including the use of immunotherapy combined with biologics.

Guidelines for Treatment of Asthma: A Global Concern

ALLAN BECKER

KEY POINTS

- Guideline development is increasingly driven by published data (i.e. evidence based).
- Guidelines increasingly focus on asthma control rather than severity.
- Asthma control defines current 'impairment' and provides an indication of 'future risk' for an exacerbation.
- For the young child with asthma there are limited published data to help direct recommendations for assessment and management strategies.
- Implementation of guidelines is a major challenge which national or global guideline strategies and local champions can help to direct.

Guideline Development

By the late 1980s, it was apparent that an epidemic of asthma had begun, particularly among children.[1] This was emphasized by the dramatically increased mortality rates for asthma in New Zealand,[2] which became the impetus for Australia and New Zealand to establish the first guidelines for the management of asthma in 1989.[3] Shortly thereafter, consensus reports by expert panels on asthma assessment and management from Canada[4] and from Britain[5] were published as guidelines. This was followed shortly by the National Asthma Education and Prevention Program (NAEPP) Expert Panel Report from the USA in 1991.[6] These early guidelines were based on expert opinion and provided consensus approaches to the diagnosis and management of asthma.

The first international consensus report was coordinated by the National Heart Lung and Blood Institute (NHLBI) and published by the National Institutes of Health (NIH) in 1992.[7] Subsequently, the NHLBI, in cooperation with the World Health Organization, launched the Global Initiative for Asthma (GINA) in 1993. The first GINA report was published by the NIH in 1995 as a 'Global Strategy for Asthma Management and Prevention.'[8] This was the first publication that aimed to provide a global approach to asthma and especially focussed on developing countries. As with previous guidelines, this was representative of expert opinion and consensus among those experts as to the best approach to asthma management.

Each of the initial guidelines primarily focussed on asthma in adults. Exemplary of the problems with developing a consensus around asthma in childhood was the situation at the initial Canadian Consensus Conference in 1989. At that workshop, pediatricians met as a separate subgroup to discuss the recommendations which were evolving within the expert group as a whole. Given the relative lack of research in children with asthma and a wide range of expert opinion on optimal approaches to treatment, the pediatricians were unable to develop any consensus focusing on the management of asthma in the pediatric population. However, over the next few years, pediatric-focussed guidelines began to emerge from national guideline committees with one of the earliest being from the British Thoracic Society[9] in the mid-1990s. From that document, it became clear that separate categories and approaches to the diagnosis and management of asthma would be essential for school-aged children and for preschool children if the very best recommendations were to be developed. This was one of the first guidelines to bring focus to the issue of pediatric asthma, especially to recognition of the fact that there were few data upon which to build any recommended interventions for management of asthma in the young child.

Evidence-Based Medicine

The development of the initial asthma guidelines was driven by expert opinion and these were consensus based. However, by the early 1990s it was recognized that it would be important to define the quality of data and to begin to focus on evidence-based recommendations. Unfortunately, as evidenced by the very carefully structured British Thoracic Society guidelines, when an attempt was undertaken to rigorously define the quality of evidence for management of asthma in children, the best available evidence for pediatric asthma remained at the lowest level of quality (i.e. expert opinion generating a consensus).[9] The levels of evidence used in a number of guidelines, including the GINA strategy and the NAEPP guidelines, are shown in Table 29-1. This approach still underpins current GINA and NAEPP recommendations, including those recommendations for children.

Although the initial pediatric guideline recommendations reflected expert opinion, an important outcome was the recognition that there was a substantial lack of data to help guide recommendations for the management of children with asthma. As a result, a key component of the first Canadian Pediatric Asthma Guidelines[10] published in 2005 was a section entitled 'Implications for Research.' This important component of a number of national guidelines was a stimulus toward promoting research in children and recognizes in particular that the development of the majority of cases of asthma begins in the preschool years[11] (Figure 29-1).

Increasing research in childhood asthma was important in facilitating development of the National Heart Lung and Blood Institute National Education Prevention Program Expert Panel Report 3: Guidelines for the diagnosis and management of

https://CafePezeshki.IR

TABLE 29-1

Evidence Level	Sources of Evidence	Definition
A	Randomized controlled trials (RCTs) and meta-analyses Rich body of data	Evidence is from end-points of well-designed RCTs or meta-analyses that provide a consistent pattern of findings in the population for which the recommendation is made Category A requires substantial numbers of studies involving substantial numbers of participants
B	RCTs and meta-analyses Limited body of data	Evidence is from end-points of intervention studies that include only a limited number of patients, post hoc or subgroup analysis of RCTs or meta-analysis of such RCTs In general, Category B pertains when few randomized trials exist, they are small in size, they were undertaken in a population that differs from the target population of the recommendation, or the results are somewhat inconsistent
C	Non-randomized trials Observational studies	Evidence is from outcomes of uncontrolled or non-randomized trials or from observational studies
D	Panel consensus judgment	This category is used only in cases where the provision of some guidance was deemed valuable, but the clinical literature addressing the subject was insufficient to justify placement in one of the other categories The Panel Consensus is based on clinical experience or knowledge that does not meet the criteria listed above

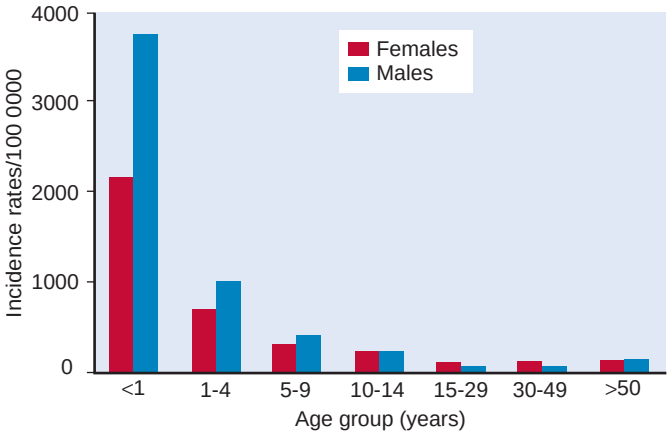

Figure 29-1 Annual incident rates per 100,000 person-years by sex and range for definite + probable asthma cases among Rochester residents 1964–1983. *(Data from Yunginger JW, Reed CE, O'Connell EJ, Melton LJ 3rd, O'Fallon WM, Silverstein MD. A community-based study of the epidemiology of asthma. Incidence rates, 1964–1983. Am Rev Respir Dis 1992;146(4):888–94.)*

asthma published in 2007.[12] In that report, there was a strong focus on asthma in the preschool years (children 0–4 years of age) and in school-age children (5–11 years of age). Although there has been more research relating to asthma and the young child over the past decade, data to substantially update guidelines for children with asthma during the preschool years remain limited. In 2008, GINA approached the issue of asthma in the young child and established a panel of pediatric asthma experts to focus on the issues of concern in these young, preschool children. In 2009, GINA published the 'Global Strategy for Asthma Management and Prevention in Children 5 Years and Younger' with an emphasis on challenges in the diagnosis and management of asthma in these preschool children.[13] Recommendations in the report were based on the best evidence available. However, because of the relative paucity of randomized or even observational clinical trials in this population, many recommendations remained at level D, i.e. panel consensus judgment. The expert opinion approach based on available data and consensus opinion published by GINA provides a strategy for the development of guidelines by local and national organizations which are pertinent to their specific population characteristics, available healthcare resources and local or national environments.

Guidelines are commonly developed by a panel of experts where the intent is to produce recommendations based on the best evidence available. Increasingly, there are pressures to produce recommendations based on the quality of a body of evidence assessed independently by a multidisciplinary team. Increasing adherence and focus to better define the quality of evidence remains a problem where there is a lack of substantive data. This is most apparent in the assessment and management of asthma in children during the preschool years. We require substantially more research in this area, both more structured randomized controlled trials and improved observational studies. Until such data are more abundant, guideline recommendations for the young child will continue to rest on expert panels with the appropriate clinical experience to provide the best possible recommendations for consideration in the development of local and national guidelines.

Asthma Severity and Control

Initially, most asthma guidelines focussed on defining levels of asthma severity. However, conceptually to guidelines developers, and of particular importance to patients with asthma and their families, asthma control is a far more important focus. As the focus in guideline development shifted to assessment of asthma control, it became increasingly apparent that asthma control should be considered within two distinct domains: symptom control, which can be considered to represent the current level of 'impairment', and 'future risk' for asthma worsening or exacerbation. These domains are now well recognized and are regularly an important component of guidelines. As noted in the previous edition of this textbook, 'Impairment is the assessment of the frequency and intensity of symptoms as well as the functional limitations that the patient is experiencing now or in the past because of his or her asthma. Risk is the estimate of the likelihood of an asthma exacerbation, progressive loss of pulmonary function over time caused by asthma, or an adverse event from medication or even death. The assessment of severity and control provide guidance on the direction taken, stepping up or stepping down medications.'[14]

https://CafePezeshki.IR

TABLE 29-2 GINA Assessment of Asthma Control in Children 5 Years and Younger

A. SYMPTOM CONTROL		LEVEL OF ASTHMA SYMPTOM CONTROL		
In The Past 4 Weeks, Has the Child Had:		**Well Controlled**	**Partly Controlled**	**Uncontrolled**
• Daytime asthma symptoms for more than a few minutes, more than once a week?	Yes☐ No☐	None of these	1–2 of these	3–4 of these
• Any activity limitation due to asthma? (Runs/plays less than other children, tires easily during walks/playing?)	Yes☐ No☐			
• Reliever medication needed* more than once a week?	Yes☐ No☐			
• Any night waking or night coughing due to asthma?	Yes☐ No☐			

B. FUTURE RISK FOR POOR ASTHMA OUTCOMES

Risk Factors for Asthma Exacerbations within the Next Few Months

- Uncontrolled asthma symptoms
- One or more severe exacerbation in previous year
- The start of the child's usual 'flare-up' season (especially if fall/autumn)
- Exposures: tobacco smoke; indoor or outdoor air pollution; indoor allergens (e.g. house dust mite, cockroach, pets, mold), especially in combination with viral infection
- Major psychological or socioeconomic problems for child or family
- Poor adherence with controller medication, or incorrect inhaler technique

Risk Factors for Fixed Airflow Limitation

- Severe asthma with several hospitalizations
- History of bronchiolitis

Risk Factors for Medication Side-Effects

- Systemic: Frequent courses of OCS; high-dose and/or potent ICS
- Local: moderate/high-dose or potent ICS; incorrect inhaler technique; failure to protect skin or eyes when using ICS by nebulizer or spacer with face mask

ICS – inhaled corticosteroids, OCS – oral corticosteroids.
*Excludes reliever taken before exercise
This GINA asthma symptom control classification corresponds to 'current control' in GINA pediatric report 2009. Before stepping up treatment, ensure that the child's symptoms are due to asthma, and that the child has good inhaler technique and good adherence to existing treatment.

One example of asthma control parameters is the GINA 2014 assessment of asthma control for children 5 years and younger (Table 29-2).[15] For older children, the additional measurement of forced expiratory volume in 1 second (FEV_1) contributes to a better understanding of the risk factors for future asthma control. Whenever possible, pulmonary function should be a routine component of asthma assessments.

Management of Asthma for Children

Asthma therapy must take into consideration the level of asthma symptom control (i.e. impairment) and future risk. In school-age children, this tends to be rather more straightforward than in the preschool child with recurrent wheezing episodes and a less certain asthma diagnosis. Although 'not all that wheezes is asthma', much of what wheezes or has severe, paroxysmal cough is treated as asthma. While there is increasing recognition of the heterogeneity of asthma phenotypes at all ages, management of wheezing syndromes in early life is a particular problem. Many children with asthma during the preschool years have only infrequent episodes of viral-induced wheezing and few, if any, interval symptoms. However, even if infrequent, these wheezing episodes can be quite severe. Thus, symptom frequency and severity are not equally matched. The optimal management of these children remains a concern to many healthcare professionals. In addition, in many countries, there are limited 'approved' medications for use in this population. This is a problem in a population most in need of research but difficult to study in large part because of the lack of objective outcome parameters. As a result, 'expert opinion' and general consensus remain the core of most recommendations. Further, this is a population in which long-term adverse effects of most interventions remain poorly studied.

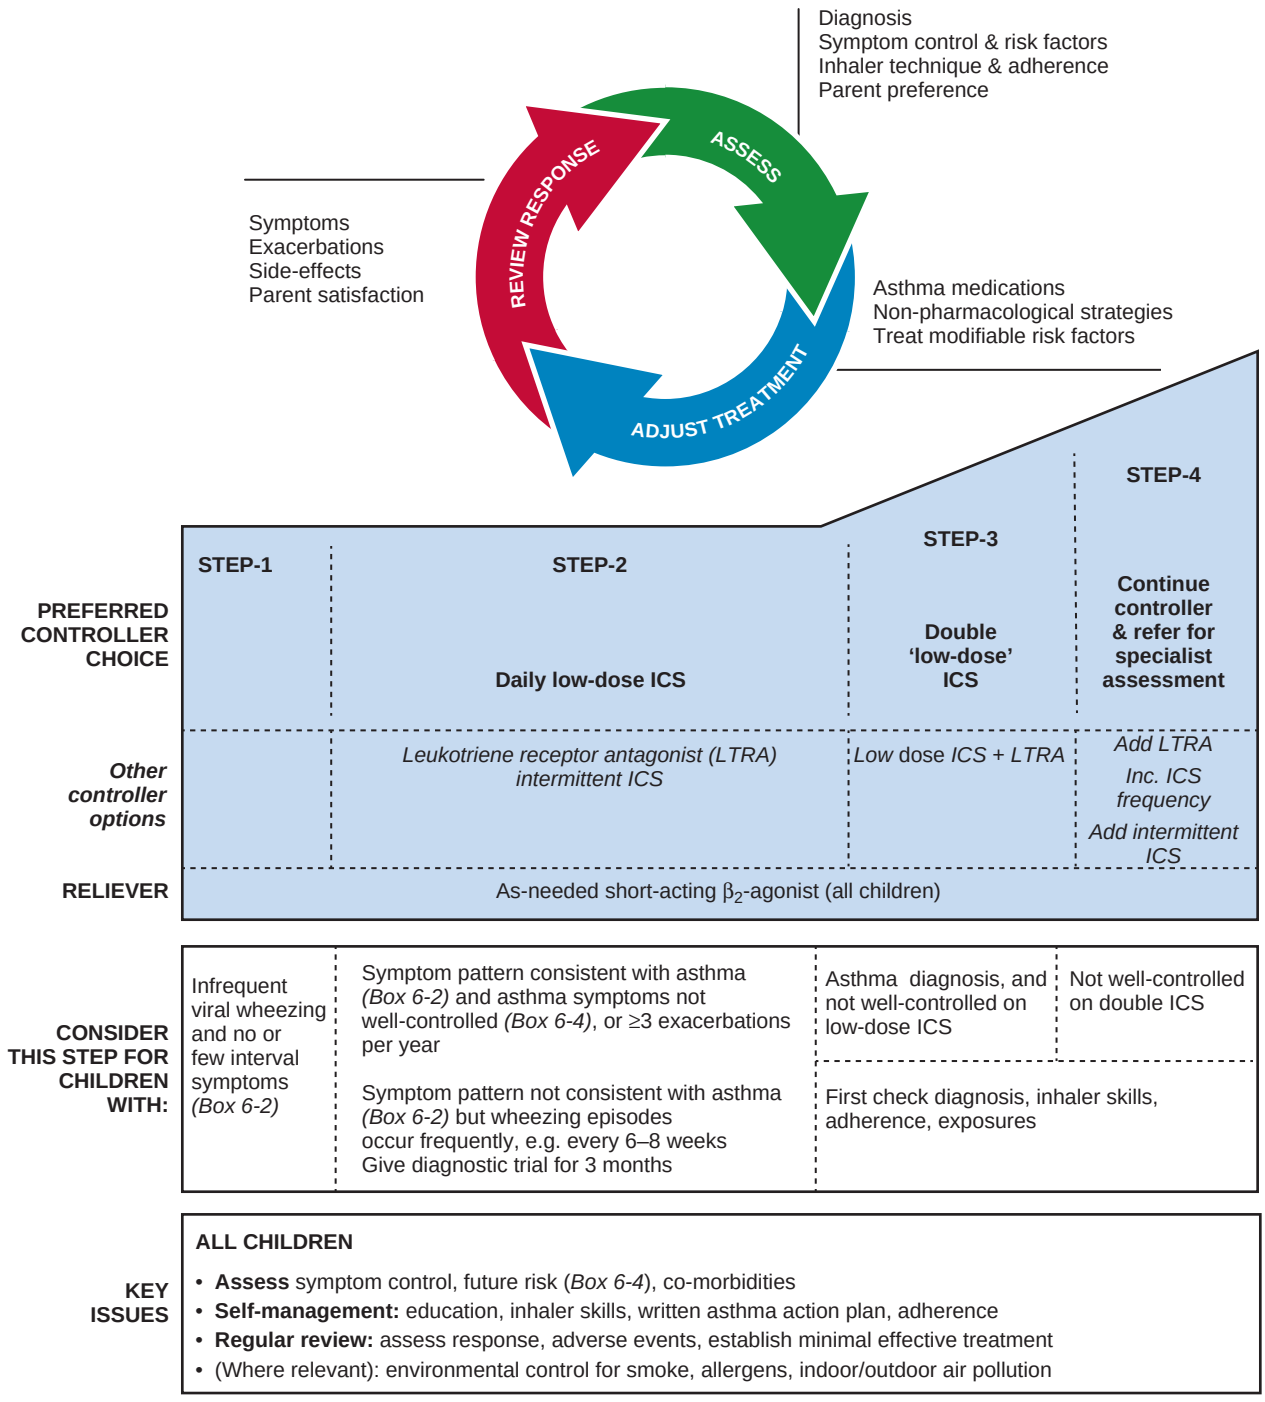
For school-age children, the approach to management remains similar to that for the adolescent and adult populations. Figure 29-2 from the most recent GINA Global Strategy for Asthma Management and Prevention, revised 2014, provides treatment recommendations for the preschool child with asthma.[15] It is representative of a 'typical' approach to management of asthma in the young child based on the available data (often extrapolated from studies in older children) as interpreted by 'asthma experts'.

Regardless of the pharmacological approach to the management of asthma, all guidelines continue to support the importance of education for children and their families.

Have Guidelines Benefitted Children and Their Families?

Although the appraisal of guidelines, research and evaluation (AGREE) process defines the quality of asthma guidelines to be 'low', asthma guidelines do continue to improve.[16] A recent editorial questioned whether practice guidelines are of any benefit to patients.[17] After all, benefits to children and their families should be the primary objective for framing pediatric guideline development. The author of that editorial suggested that 'Published guidelines are therefore not an adequate

https://CafePezeshki.IR



ICS: inhaled corticosteroid; intermitt: intermittent. See Box 6-6 for definition of 'low-dose' ICS in children 5 years and younger.

Figure 29-2 Stepwise approach to long-term management of asthma in children aged 5 years and younger.

substitute for actual successful clinical experience by specialists during residency.[17] Although this is not a simple issue, it may be particularly important for young children, and the concerns raised in that editorial must be addressed. Development of guidelines is typically followed by widespread dissemination of a document, usually with substantial documentation as to the quality of recommendations. As previously noted, 'Of necessity to establish the quality, or weight, of the recommendations, the documents must present data and… the quality and depth of material also supports the likelihood of publication to enable these primary dissemination approaches.'[18] These 'weighty' documents are frequently translated into shortened summary publications and often one- or two-page pocket guides are developed which can be particularly helpful to trainees and primary care physicians.

While dissemination is generally considered to be straightforward, implementation of guidelines has been a major concern, particularly at the local level. There have been a

https://CafePezeshki.IR

number of studies aimed at improving adherence to asthma guidelines. A recent systematic review demonstrated that use of decision support tools with feedback on audit and support from a clinical pharmacy were the most likely approaches to improve provider adherence to asthma guidelines.[19] However, even with complicated and expensive interventions, only a limited number of studies have been associated with an improvement in healthcare status.[19] A recent review asked 'Have expert guidelines made a difference in asthma outcomes?'[20] That review, which considered both controlled and observational trials, was unable to demonstrate substantive impact on health outcomes and noted that we need to 'better understand the gaps between guidelines recommendations and translation to clinical practice… to improve asthma outcomes.'[20] Nevertheless, there are studies, such as one from Costa Rica, that demonstrate substantive impact with decreasing trends in hospitalization and mortality from asthma after institution of a national asthma program.[21]

The quality of asthma guidelines has improved over time.[16] It is increasingly clear that guidelines are important in order to provide the best available data combined with advice based on expert opinion. However, to be of benefit to patients and their families, adaptation and implementation of guidelines must be undertaken at national and, possibly even better, at local levels, and supported by local champions with appropriate stakeholder involvement.[22]

30 Functional Assessment of Asthma

DAVID P. NICHOLS

KEY POINTS

- Asthma pathology has defining physiologic correlates, including airflow limitation, heightened airway responsiveness to stimuli and improved airflow in response to bronchodilators.
- Spirometry is the most common quantitative test used to measure airflow obstruction.
- Serial tests of lung function are valuable in following the course of asthma.
- Decreases in airflow plus hyperinflation (i.e. air trapping) are seen in acute asthma.
- During exacerbations, signs and symptoms of asthma often resolve before lung function returns to normal.
- Hypoxemia is common in asthma exacerbations while hypercapnia is a sign of more severe airflow limitation.

Asthma is characterized by intermittent airway obstruction, which commonly manifests as shortness of breath, cough, wheezing and chest tightness. However, even moderate degrees of airflow obstruction may not be symptomatic or clinically apparent. When present, the degree of airflow limitation varies greatly, from mild and self-limited to life-threatening. Between these extremes are gradations of obstruction that can be quantified. Testing airflow, along with the change in response to therapies or challenges (e.g. exercise, mannitol, methacholine), is useful when assessing and managing patients with asthma. This chapter deals with functional assessments of asthma in the pediatric patient, emphasizing tests that reflect airway and lung function. The primary focus is on studies that can be easily performed in an office or clinic setting, but tests that require more sophisticated equipment usually unavailable in these locations are also noted. Furthermore, because asthma often first presents in preschool children, tests of lung function that may be performed in the youngest patients are mentioned. Equipment necessary to measure pulmonary function in these young children typically exists only in centers with expertise in pediatric pulmonary medicine. However, knowledge of airway function close to the onset of disease is an important subject of ongoing investigations into the pathogenesis of the disorder, and newer techniques may be more amenable to widespread use in outpatient clinics.

A decline in airway function as measured by pulmonary function tests often reflects a change in airway structure; therefore, this chapter begins with an overview of the pathology of asthma. Greater detail on this subject can be found in other chapters. Appreciating the correlation between airway structure and function is important to clinical management. For example, understanding the pathologic findings in severe asthma helps one to recognize components contributing to obstruction that are poorly responsive to acute treatment and take time to resolve. This will be reflected in tests of airway function soon after a patient is ill. Similarly, tests that define airway responsiveness may also correlate with lung pathology in subjects in whom the disease is clinically quiescent.

This chapter will also review how tests of lung function can help identify diseases that may mimic asthma and will consider the ways in which pulmonary function tests may help guide therapy in both acute and chronic conditions. Studies involving infants, children and adolescents are cited whenever possible. Investigations into structural and functional assessments of the disease in adults are cited when they provide additional insight into the process.

The Pathology of Asthma

Fatal asthma is typified by marked airway inflammation with mucus and cellular debris, epithelial desquamation, subepithelial collagen deposition and airway wall thickening resulting in luminal obstruction.[1–3] Several factors contribute to airway wall thickening, including smooth muscle hypertrophy, edema, goblet cell hyperplasia and tissue infiltration by inflammatory cells. These features have been noted at autopsy, not only in adults but also in pediatric patients of varying ages.[4] Similar pathologic findings can be seen in biopsies from severe but nonfatal asthma.[5]

With the more recent use of bronchoalveolar lavage (BAL) and endobronchial biopsies to address asthma pathogenesis, it is apparent that airway inflammation is a hallmark of even clinically mild asthma.[6,7] Common features include infiltration of airways by eosinophils, activation of T cells within airways, increase in mast cell numbers and desquamation of airway epithelium.[8] These studies have been performed primarily in adults, with a loose correlation found between indices of inflammation and the level of airway responsiveness to provocative agents such as histamine and methacholine. Less information is available from pediatric patients, but work using BAL in older children and adolescents suggests that pathologic findings are similar to the abnormalities described in adults.[9,10] For example, Ferguson and colleagues[10] reported an association between the level of airway responsiveness to histamine and both eosinophil numbers and mast cell tryptase within BAL fluid of 6- to 16-year-old children. A more recent study found that, among preschool children with wheezing, increased airway smooth muscle present in endobronchial biopsy was associated with having asthma at school age.[11]

The Physiology of Asthma

Asthma is defined by physiologic abnormalities. As noted earlier, these abnormalities include variable airflow limitation,

https://CafePezeshki.IR

increased responsiveness of airways to provocation (i.e. bronchoconstriction) and improved airflow in response to bronchodilators (reversibility). Given these features and the common discrepancy between lung function and patient symptoms, asthma is a disease that is best quantified by objective testing. Several measures of lung mechanics have been used to describe asthma during both symptomatic and asymptomatic phases of the disease.[12] These measures include lung volumes, the pressure-volume characteristics of the lung, resistance to airflow and flow rates. A discussion of each of these measures in childhood asthma is presented, emphasizing flow rates and lung volumes as these are most commonly used by practicing physicians treating children.[13] Airway hyperresponsiveness, a fundamental feature of this disease, is also discussed.[14,15]

SPIROMETRY

Spirometry is the most common technique used to assess pulmonary function. It is helpful to understand several key elements of spirometric assessment before discussing the role of this test in patient care. First, values obtained by spirometry are reported as absolute volume and, more importantly, in reference to that predicted for normal lung function based on the age, sex, height and race or ethnicity of the patient. Therefore, it is critical that these demographic factors are correctly noted and used. If spirometry test results are unexpectedly higher or lower than suggested by the history and examination, one is wise to double-check the accuracy of these demographic data. Second, the quality of both patient technique and effort will greatly affect spirometry data. Studies suggest that many tests performed in routine outpatient clinics are of suboptimal quality but that limited staff training can significantly improve this.[16,17] Most children can learn to perform spirometry tests with reasonable quality by the age of 5 to 7 years. Third, those interpreting spirometry tests should be properly trained. Physicians should be familiar with useful quality criteria that have been published by the American Thoracic Society/European Respiratory Society (ATS/ERS),[18] including forced expiratory time, repeatability and back extrapolated volume. However, data suggest that the clinical utility of spirometry data in children may depend more on the experience of the interpreter than on rigid numerical test parameters.[19] In other words, pediatric spirometry test results that do not meet published numerical quality standards are often still useful – especially when considered in the context of an individual patient.

Providers should also be aware of important efforts to improve spirometry interpretation. A notable international collaboration has recently produced the largest reference data set for spirometry to date. The Global Lung Function Initiative (GLI) reference equations include over 74,000 spirometric measurements from healthy, nonsmoking males and females aged 3 to 95 years, provided by over 70 organizations worldwide.[20] This includes spirometric indices from five ethnic groups and over 30,000 healthy young people between 2.5 and 18 years old. Using modern statistical techniques, these data have been used to generate the Quanjer GLI-2012 prediction equations, endorsed by all major respiratory societies and incorporated by manufacturers into many lung function devices. Ongoing efforts will contribute even greater representation of ethnic backgrounds into this reference data set, providing more reliable normal values across age and demographic characteristics. Also, many providers have moved to reporting data as Z-scores rather than percent predicted of normal. A Z-score of −1.64 represents the 5th percentile and has been proposed as a lower limit of normal for spirometry. Ninety-five percent of healthy subjects will fall within ± 2 Z-scores. Interpretation by lower limit of normal using Z-score is independent of age, height, sex and ethnic group, and may more clearly show how abnormal (i.e. far from the median) an individual's lung function is at the time of testing. Similar prevalence rates for impaired FEV_1/FVC ratio and FEV_1 have been reported when transitioning from the familiar Hankinson and Wang equations to the GLI-2012.[21–23]

Definitive Characteristics of Asthma

A. AIRFLOW LIMITATION

The usual method of measuring the degree of airflow limitation is to assess lung function during a maximal forced exhalation.[24] The subject exhales forcibly from total lung capacity (TLC) to residual volume (RV) into either a spirometer or through a flow meter by which flow is integrated to give volume. The results are usually expressed as either a time-based recording of expired volume (spirogram) or a plot of instantaneous airflow against lung volume (maximal expiratory flow-volume [MEFV] curve). The tests of lung function derived from a spirogram are the forced vital capacity (FVC; TLC minus RV), the forced expiratory volume during the first second of exhalation (FEV_1), and the forced expiratory flow from 25% to 75% of the FVC ($FEF_{25–75}$). From the flow-volume curve, the maximal expiratory flow rate (MEFR) achieved approximates the peak expiratory flow rate (PEFR) obtained from a flow meter. Flow rates at and below 50% of the vital capacity (VC) are also obtained as part of this maneuver. Because airflow is related to lung volume, plethysmography combined with the MEFV maneuver plotted as a flow-volume curve or loop allows assessment of the relationship between airflow and absolute lung volumes (Figure 30-1). Measurement of flow rates in this manner may be informative when an isovolumetric shift occurs (discussed later). The effect of lung volume on airflow also highlights the importance of subject effort and technique.

In subjects with airflow obstruction due to asthma, the expected pattern of altered flow rates during an exacerbation can be predicted based on airway pathology and obstructive physiology. On spirometry, both the FEV_1 and $FEF_{25–75}$ are diminished, although the former is more preserved as a percent of predicted than the latter. Since the FVC is usually relatively preserved, the FEV_1/FVC ratio is reduced. On the MEFV curve, the expiratory portion of the loop typically becomes concave, or 'scooped out' (see Figure 30-1) due to a greater impairment in flows at low lung volumes. These flows are the first to decrease and the last to return to normal. The MEFR, like its counterpart, the FEV_1, is more preserved during acute attacks and is quicker to normalize.

In a minority of cases, the spirogram or MEFV curve alone will not reflect significant airway obstruction. However, if subjects are studied with both an MEFV maneuver and plethysmography to assess lung volumes, they will have a displacement of the flow-volume curve to a higher lung volume without a change in the configuration of the curve itself. Thus, if flow is measured as a percent of the VC, no change in flow is appreciated. However, when the same curve is plotted as a function of the absolute lung volumes present before and after onset of symptoms, substantial changes in flow become apparent at the

https://CafePezeshki.IR

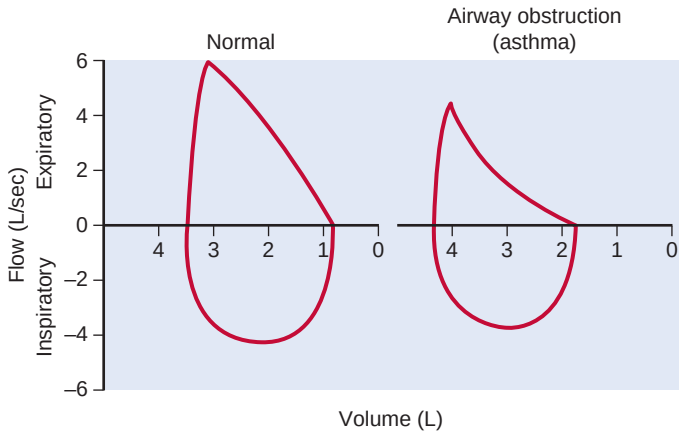

Figure 30-1 Maximal inspiratory and expiratory curves that together constitute a flow-volume loop are shown in a patient with asthma when the disease is under control *(left loop)* and when control is lost *(right loop)*. Flow is shown on the y-axis, whereas absolute lung volume is displayed on the x-axis. The point of maximal inspiration (TLC) is the point of zero flow on the left side of the loops while the point of maximal expiration (RV) is the point of zero flow at the right side of the loops. When asthma control is lost, hyperinflation is noted, with an increase in RV. In addition, expiratory flow rates decrease, as demonstrated in the maximal expiratory portion of the curve, which becomes concave. With milder instability, as shown in this example, the inspiratory portion of the loop is fairly well preserved. With more severe obstruction, inspiratory flows will be more compromised. *(From Wenzel SE, Larsen GL. Assessment of lung function: pulmonary function testing. In: Bierman CW, Pearlman DS, Shapiro GS, Busse WW, editors. Allergy, asthma, and immunology from infancy to adulthood. 3rd ed. Philadelphia: WB Saunders; 1996.)*

same lung volume, that is, at an isovolume. This represents an isovolumetric shift to a higher lung volume. The factors responsible for isovolumetric shifts are poorly defined but may include closure of some airways with loss of the contribution of these more obstructed units to the flow-volume pattern.

In acute asthma, loss of symptoms and signs of asthma does not mean that lung function has returned to normal. Classic studies by McFadden and colleagues[25] demonstrated that when patients with severe, acute asthma became asymptomatic, the overall mechanical function of their lungs in terms of the FEV_1 was still only 40% to 50% of predicted normal values. Thus loss of clinical signs of airway obstruction does not necessarily mean there has been physiologic recovery. This highlights the important role of measuring lung function when managing patients with asthma, especially those prone to severe airflow obstruction or those who have difficulty appreciating decline in lung function.

The use of peak flow meters within the home is an inexpensive method of monitoring a flow rate to assess asthma stability.[26] Although there are limitations, in that the PEFR may be normal while other spirometric indices are abnormal,[27] home monitoring of lung function can contribute to the care of selected patients. In this respect, significant changes in PEFR may be manifest before symptoms are evident, particularly in patients with limited recognition of early disease exacerbation. These devices may also be especially helpful in defining the presence and severity of nocturnal asthma.[28] The diurnal variation of PEFR (i.e. the difference between morning and evening measurements) is normally less than 10%. A PEFR variability of greater than 15% to 20% has been used as one defining feature of nocturnal asthma. Patients with such variability should be regarded as having more severe asthma and inadequate disease control. Additionally, given that excessive diurnal variations in lung function during recovery from status asthmaticus have been associated with an increased risk of sudden death,[29] this vulnerable period of time may warrant close monitoring both in the hospital and home environment. Therefore, in more severe patients or those with limited recognition of signs and symptoms of exacerbation, monitoring the PEFR as part of their daily routine may allow for earlier recognition of loss of control with more timely intervention. Finally, it should be noted that the PEFR maneuver is technique- and effort-dependent with most home meters. This should be considered in younger patients and those who may have secondary gain with asthma-related illness.

B. HEIGHTENED AIRWAY RESPONSIVENESS

Airway responsiveness is commonly defined as the ease with which airways narrow in response to various nonallergic and nonsensitizing stimuli, including inhaled pharmacologic agents (e.g. histamine, methacholine, mannitol) as well as natural physical stimuli (e.g. exercise, exposure to cold air). Heightened airway responsiveness to several stimuli causing bronchoconstriction and reduced airflow is a hallmark of asthma.[14,15] Even when conventional assessments of lung function are normal in children with chronic stable asthma, the airways often exhibit this heightened responsiveness. The most common method of quantifying airway responsiveness is to assess lung function (usually FEV_1) before and after inhaling increasing concentrations of methacholine. The test is concluded when a defined decrease in lung function has been achieved; for the FEV_1, this is usually a 20% decrease from baseline values. The more responsive the airways, the less methacholine is needed to decrease lung function. Exercise often increases FEV_1 in healthy patients, therefore a decrease of as little as 10% from baseline may reflect exercise-induced bronchoconstriction.

The level of airway responsiveness to pharmacologic agents has been noted to correlate roughly with the severity of disease in both adults and children.[14,30,31] Thus asthmatic subjects who are the most responsive are generally the most symptomatic (wheeze, cough, chest tightness) and require more medications to control their disease. Although there can be great variability in responsiveness within groups of patients classified by disease severity,[32] the concept that the level of responsiveness correlates with disease severity is important when considering factors that lead to loss of asthma control. In this respect, the level of airway responsiveness is not static in either normal individuals or asthmatic subjects but may increase or decrease in response to various stimuli. When responsiveness increases, control of the disease is often lost in that this is when asthmatic subjects develop signs and symptoms of their disease. In general, stimuli that increase responsiveness are found in our environment and induce or exacerbate airway inflammation. For children, these stimuli commonly include various viral respiratory infections, air pollutants (including cigarette smoke) and allergens.[33]

A viral respiratory infection is a common antecedent to acute episodes of asthma in children.[34] This has been documented for several respiratory viruses, including respiratory syncytial virus[35] and rhinovirus.[36] In terms of air pollutants, both nitrogen dioxide[37] and ozone[38] have been shown to enhance airway responsiveness. Cigarette smoke is arguably the most

https://CafePezeshki.IR

serious environmental air pollutant in terms of the respiratory health of children and has been implicated in the onset as well as the perpetuation of the disease.[39–41] In addition, exposure of atopic individuals to relevant allergens can lead to significant increases in airway responsiveness that persist for days to months.[42,43] These classes of disease precipitants are often considered separately, but they assuredly have combined effects in an asthmatic subject's airways which contribute to disease instability.[36]

Just as airway responsiveness will increase in response to certain stimuli that lead to airway inflammation, the level of responsiveness will also decrease if measures are taken to decrease inflammation within airways.[33] These measures include use of medications with anti-inflammatory properties (e.g. inhaled corticosteroids), long-acting bronchodilators and the avoidance of relevant allergens (atopic asthmatic subjects) and cigarette smoke.[15]

C. IMPROVED AIRFLOW IN RESPONSE TO BRONCHODILATORS

Increased pulmonary function, often measured by FEV_1 or $FEV_{25–75}$ and in response to short-acting bronchodilators such as inhaled β-agonists, is another defining feature of asthma. An increase in FEV_1 by 12% predicted or more is often used to define a significant response to bronchodilator medication. Greater improvement in $FEF_{25–75}$ is typically required (e.g. 25% predicted) and this more variable parameter is not used by all centers to determine response to bronchodilators. When testing response to other forms of inhaled bronchodilators it is important to understand the pharmacokinetics and predicted time needed for a medication to take effect.

LUNG VOLUMES

During an exacerbation of asthma, all of the various capacities and volumes of gas contained in the lung may be altered to some extent. The RV, functional residual capacity (FRC) and TLC are usually increased (RV > FRC > TLC), whereas the VC and its subdivisions are decreased (see Figure 30-1). These alterations have been described during natural exacerbation of asthma in adults[44] and children.[45] Although laboratory induced changes in lung volumes (exercise, histamine challenge) may be immediately normalized with inhalation of a bronchodilator, it may take weeks after an episode of severe, acute asthma for the RV to return to a normal range.[12] The mechanisms responsible for the increases in RV, FRC (hyperinflation) and TLC (overdistension) are not completely understood. However, several factors have been identified that may contribute, including a generalized decrease in the elastic properties of the lung, a ball-valve phenomenon caused by swollen and mucus-plugged airways, and tonic activity in the intercostal muscles and diaphragm during episodes of obstruction.[12]

ARTERIAL BLOOD GASES

The primary function of the lung is to provide for gas exchange such that oxygen is taken up and delivered to the body while carbon dioxide is eliminated. This function may be altered when control of asthma is lost. Several studies of acute asthma have correlated arterial blood gases with the level of airway obstruction. One of the classic descriptions is the work of McFadden and Lyons.[46] These authors studied a large population (101 subjects) who, because of age (14 to 45 years) and medical history, were unlikely to have their asthma complicated by bronchitis and emphysema. This study and others (cited later) provide an important description of the expected abnormalities in gas exchange as a function of the degree of airway obstruction.

Oxygen Tension

McFadden and Lyons[46] found that the characteristic blood gas pattern in patients who were experiencing acute asthma was hypoxemia associated with respiratory alkalosis. The hypoxemia was the most consistent abnormality found in their study. A near linear correlation was found between values of FEV_1 and arterial oxygen tension (Figure 30-2, *top*). Patients with an FEV_1 of 50% to 85% of their predicted normal values were arbitrarily classified as having mild airway obstruction; those with values of 26% to 50%, moderate obstruction; and those with values of less than 25%, severe obstruction. The mean values of arterial oxygen tension (in mm Hg as measured at sea level) ranked by disease severity were 82.8, 71.3 and 63.1, respectively. Thus there was almost a 20-mm Hg difference in arterial oxygen tensions between the mild and severe groups. Just as important, it was also noted that some degree of hypoxemia was encountered at all levels of airway obstruction. In terms of studies in children, Weng and colleagues[47] noted similar findings in asthmatic subjects who were 14 months to 14 years old. The study found that all symptomatic asthma patients were hypoxemic,

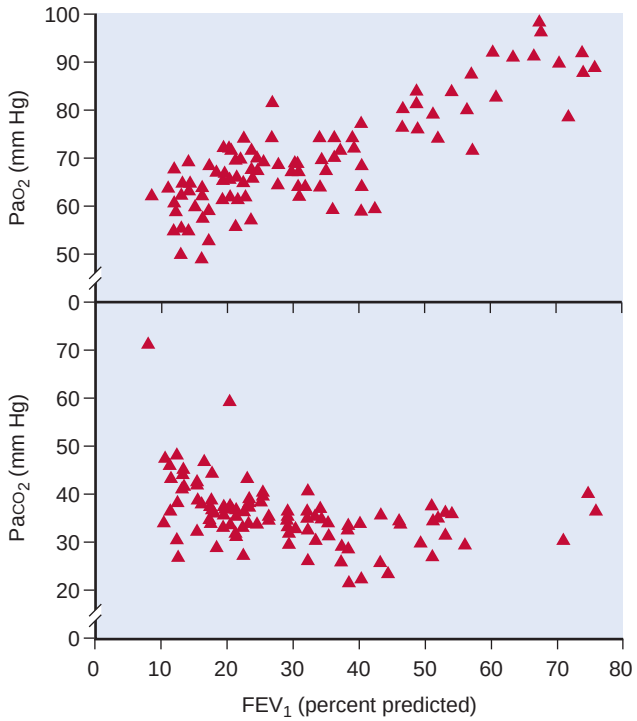

Figure 30-2 The relationship between arterial oxygen (mm Hg) and degree of airway obstruction (FEV_1 as a percent of predicted) **(top)** and the relationship between arterial carbon dioxide (mm Hg) and FEV_1 **(bottom)**. Although the level of hypoxemia correlates with the level of airway obstruction, an elevation in carbon dioxide levels is seen only when the FEV_1 is markedly compromised. *(Data from McFadden ER Jr, Lyons HA. N Engl J Med 1968;278:1027–32.)*

https://CafePezeshki.IR

with the level of hypoxemia correlating with the degree of airflow obstruction.

Several mechanisms are likely to contribute to the hypoxemia just described. The primary mechanism is thought to be an alteration in ventilation-perfusion ratios.[46,47] For severely obstructed subjects, in whom atelectatic alveoli are still being perfused, transitory anatomic shunts may also contribute to the hypoxemia. In the most severely obstructed subjects, alveolar hypoventilation is also likely to be important.

The normal response of the body to a decrease in arterial oxygen is to increase ventilation. A reduced chemosensitivity to hypoxia coupled with a blunted perception of dyspnea may predispose patients to fatal asthma attacks. Kikuchi and colleagues[48] found that adult patients with a history of near-fatal asthma had respiratory responses to hypoxia that were significantly lower than responses in normal subjects and in asthmatic subjects without near-fatal attacks. The lower hypoxic response was seen in conjunction with a blunted perception of dyspnea. These abnormalities could occur because of preexisting genetic factors as well as adaptation of the body to recurrent hypoxia. The relative importance of these and other factors is unknown. Children with poor perception of airway obstruction may be at risk for fatal or near-fatal asthma.[49]

Carbon Dioxide Tension

McFadden and Lyons[46] demonstrated that respiratory alkalosis often accompanies hypoxemia in asthmatic subjects experiencing exacerbations. In terms of carbon dioxide tensions, their study suggested that most attacks were associated with alveolar hyperventilation and that hypercapnia was not likely to occur until extreme degrees of obstruction were reached. Plotting airway obstruction (percent predicted FEV_1) against the carbon dioxide tension indicated that hypercapnia was not seen until the FEV_1 fell to less than 20% of its predicted value (see Figure 30-2, *bottom).* Thus a 'normal' or elevated $PaCO_2$ in a patient with acute asthma is cause for concern.

Arterial Values of pH

Arterial pH values in acute asthma typically reflect this respiratory alkalosis. In the study of McFadden and Lyons,[46] 73 of the 101 subjects had a respiratory alkalosis (mean pH 7.46); 21, normal pH; and 7, respiratory acidosis (mean pH 7.32). Weng and colleagues[47] reported similar results in children. A metabolic acidosis may also be seen in acute asthma. Although this is not commonly seen in adults, it has been noted in combination with a respiratory acidosis in children with severe asthma.[47,50] This acid-base imbalance is usually associated with very severe airway obstruction.[51] Although the mechanisms responsible for the metabolic acidosis remain to be clarified, we know that these subjects are in imminent danger of respiratory failure.[47]

Functional Assessments of Asthma in Infants and Small Children

Assessment of lung function in a quantitative manner in infants and small children is very challenging. Noninvasive assessment of arterial oxygenation and gas exchange may be relatively straightforward, but measuring pulmonary mechanics, including airflow and lung volumes, is more problematic. Foremost among the problems encountered in working with young subjects is that many are unable to cooperate in the performance of conventional respiratory maneuvers. There has been progress in addressing spirometric lung function in healthy preschool children,[52] but limits remain related to the age and developmental level of the child. Thus assessments in the youngest subjects must be done while they are sedated and asleep. In this respect, methods exist for assessing lung function in infants using spirometric techniques in which the patient is passive and forced exhaled flows are generated from near TLC to RV through rapid compression of the chest.[53] When this is accomplished, functional measures may be obtained that are similar to those in older children and adults. Although it is beyond the scope of this chapter to discuss in detail the methods that are used for these studies, it is important to point out that insight into normal maturation of airway function has been gained by this and similar approaches. For example, the highest flow rates corrected for lung size are found in newborns and healthy premature infants, with size-corrected flows decreasing to values found in older children and adults by the end of the first year of life.[54] In addition, normal infants bronchoconstrict when exposed to low concentrations of bronchoreactive agents such as methacholine[55] and histamine[56] as well as to the physical stimulus of cold, dry air.[57] Goldstein and colleagues[58] also found that the response in infants to the inhaled bronchodilator albuterol as assessed by forced expiratory flows was greatest in the youngest subjects. Montgomery and Tepper[59] demonstrated that normal infants and young children have a decrease in airway responsiveness to methacholine as they become older. Taken together, these studies suggest that an insult to an airway at a young age may interfere with this normal age-related decrease in responsiveness.

The onset of asthma is commonly during the early years of life. This has been noted in several studies, including work from Europe[60] as well as the USA.[61,62] Investigations of asthma often try to focus on disease pathogenesis closer to the time of onset. One practical consequence of this is that younger subjects must be assessed, given that the onset of disease is often in preschool children. In terms of quantitative assessments that help categorize disease severity as well as the effects of any intervention, measurements of lung function become essential. Groups have conducted longitudinal studies beginning in infancy and followed into childhood to phenotype young children based on the onset and persistence of wheeze, and atopy.[63,64] These and other similar studies help improve our understanding of asthma development but current prediction algorithms to identify asthma in individual school age children have modest diagnostic value.[65] Conventional methods to assess lung function in infants and preschool children are technically and logistically challenging when considering multicenter studies involving large numbers of subjects.[66] These measures are similarly impractical in the day-to-day care of young asthmatic subjects within many clinical settings. However, newer techniques offer promise when the assessment must be done in a time-effective manner in subjects with limited developmental ability to cooperate and concentrate on a particular task.

Forced oscillation is one of several more recent techniques that have been used to obtain lung function measures in young subjects.[54,67,68] This method involves the application of sine waves to the airway opening via a mouthpiece while the child breathes normally (tidal breathing). Several variables can be assessed, including resistance, reactance and resonant frequency of the respiratory system. Although use of this technique has

https://CafePezeshki.IR

not been applied to large populations of children, published results demonstrate a reasonable agreement with more traditional measures of lung function.[69] This technique has been successfully used in young children with acute asthma[70] and has also been used to quantify the response to bronchoconstrictor and bronchodilator agents[69,70] in clinically stable asthmatic children.[71,72] Use of this approach is also feasible when assessing lung function responses to chronic therapy in very young[73] as well as older children with asthma.[74,75] Therefore, forced oscillation may prove useful in following the course of the disease.

Another more recent form of lung function assessment that can be used in awake preschool children is the lung clearance index (LCI). This is a measure of inhomogeneity in ventilation obtained by using the multiple-breath inert gas washout technique. LCI measurements are obtained during tidal breathing and have been used to detect airway disease in infants and children with cystic fibrosis.[76,77] How this technique may be useful in asthma management is yet to be established.

Uses of Assessments of Lung Function

The preceding paragraphs have provided an overview of the tests of lung function that are commonly used to provide a functional assessment of asthma. Reference has been made to pathologic and physiologic correlates in the disease. This section is provided to address practical ways in which these functional assessments are commonly used. In this respect, we concentrate on lung function in diseases that may masquerade as asthma and therefore must be considered in the differential diagnosis of children with wheezing and other nonspecific pulmonary symptoms. We also address how these tests may be used to assess and follow asthma once that diagnosis has been established. In terms of the latter, the value of functional assessments during both acute and chronic phases of the disease is considered.

FUNCTIONAL ASSESSMENTS OF DISEASES THAT MASQUERADE AS ASTHMA

Shortness of breath, cough, wheezing and chest tightness are not specific for asthma. Thus children who present in this manner may have other medical conditions. The differential diagnosis of wheezing and dyspnea in pediatric subjects is influenced by the age of the patient. The younger the child, the more one has to consider congenital problems involving the airways or cardiopulmonary system. This is especially true for infants and toddlers. In terms of older children and adolescents, the confounding conditions will be more analogous to the problems seen in adults. When considering the possible causes, an assessment of lung function will often help arrive at the correct diagnosis.

Children with bronchiolitis obliterans have experienced insults to their lungs (e.g. adenovirus infection, Stevens-Johnson syndrome with pulmonary involvement) that have led to scarring within small airways and severe airway obstruction.[78] They may present with dyspnea and/or wheezing, leading to the impression that they have asthma. On assessment of lung function, they demonstrate an obstructive pattern with evidence of hyperinflation and decreased expiratory flow rates. The same pattern is seen in other obstructive processes, including asthma and cystic fibrosis. In bronchiolitis obliterans the correct diagnosis may be suggested by the lack of significant reversal of the airway obstruction with therapy that includes bronchodilators and/or corticosteroids, combined with other results such as lung imaging.

Pediatric patients with interstitial lung disease (ILD) may also present with a history of dyspnea and poor air exchange on physical examination.[79,80] These patients classically have an FEV_1 that is diminished, but the FVC is also reduced, and therefore the FEV_1/FVC ratio is normal even before a bronchodilator is given. In addition, lung volumes are often decreased in ILD. This pattern is restrictive in nature compared with the obstructive pattern seen in asthma where total lung volume is normal or may be increased. The disease processes that lead to ILD are diverse. Because the causes and treatments, as well as the prognosis, are very different to those of asthma, it is critical to be able to recognize this pattern on assessment of lung function and to address the potential causes that lead to interstitial disease. A reduced FVC on spirometry suggests that total lung capacity may be decreased and should prompt consideration of lung volume testing (plethysmography). In children with asthma, it is also prudent to consider if poor technique or air trapping may be present and contributing to a low FVC.

Vocal cord dysfunction (VCD), a functional disorder of vocal cords that mimics attacks of asthma and/or upper airway obstruction, has received widespread attention.[81,82] Paroxysms of wheezing and dyspnea seen with VCD are refractory to standard therapy for asthma. During symptomatic episodes, the maximal expiratory and inspiratory flow-volume loop may resemble a variable extrathoracic obstruction (Figure 30-3). The diagnosis can be confirmed in a symptomatic subject by laryngoscopic examination, which demonstrates that the wheezing and/or stridor is associated with paradoxical adduction of the vocal cords during inspiration and sometimes during the entire respiratory cycle. Both the flow-volume loops and the laryngoscopic findings are completely normal when the subjects are asymptomatic. In the vast majority of patients VCD is subconscious and may be associated with stress. In pediatric patients as young as 4 years, underlying factors such as stress related to athletic or academic performance may be found.[83–85] It must be noted that VCD and asthma frequently co-exist in children.[84] Truncation of the inspiratory portion of the flow-volume loop together with a concave shape of the expiratory curve may then be found. Treatment of VCD is primarily accomplished through speech therapy together with psychotherapy in selected patients.[82] Conditions such as chronic postnasal drip and gastroesophageal reflux may irritate the larynx and are also believed to contribute to VCD.[86] Although rarely needed, breathing a mixture of 70% helium/30% oxygen can relieve dyspnea and abort acute attacks.

Just as flow-volume loops may be helpful in making a diagnosis of VCD, they can also aid in the diagnosis of other types of obstructive lesions in the proximal airways (larynx and trachea) that may present with wheezing. For example, with a lesion that is circumferential, preventing either compression or dilation of the airway with respiratory efforts, a 'fixed' pattern is seen (see Figure 30-3) with truncation of both the inspiratory and expiratory curves. Subglottic stenosis and vascular rings that surround an airway might present with such a pattern. If a lesion permits compression or dilation with respiration, the pattern will depend on the location of the lesion (intrathoracic or extrathoracic). With an extrathoracic problem, a picture like

https://CafePezeshki.IR

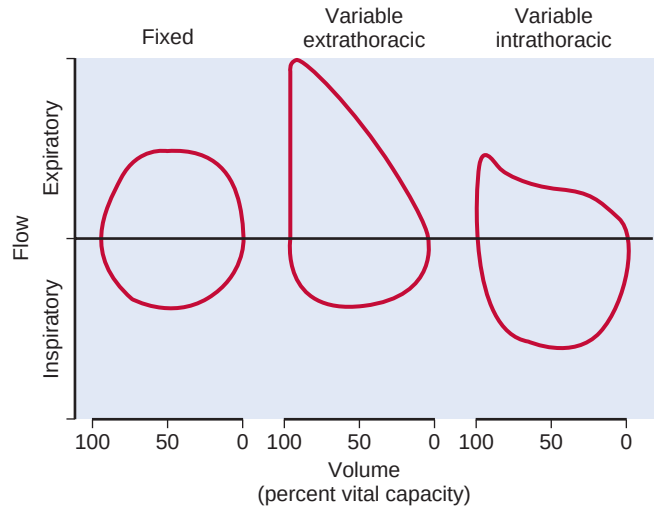

Figure 30-3 Flow-volume loops are displayed for various types of obstructive lesions in the proximal airways (larynx and trachea) that may present with wheezing. For comparison, the normal contour of a flow-volume loop is shown (see left side of Figure 30-1). With a lesion that is circumferential, preventing either compression or dilation of the airway with respiratory efforts, a 'fixed' pattern is seen with truncation of both the inspiratory and expiratory curves. Subglottic stenosis and vascular rings that surround an airway might present with such a pattern. If a lesion permits compression or dilation with respiration, the pattern will depend on whether the lesion is intrathoracic or extrathoracic. With extrathoracic lesions (vocal cord dysfunction) *(middle),* the inspiratory curve is more affected. An intrathoracic lesion (mass that compresses only part of the airway, tracheomalacia) *(right)* will have more of an effect on expiratory flow rates. *(From Wenzel SE, Larsen GL. Assessment of lung function: pulmonary function testing. In: Bierman CW, Pearlman DS, Shapiro GS, Busse WW, editors. Allergy, asthma, and immunology from infancy to adulthood. 3rd ed. Philadelphia: WB Saunders; 1996.)*

that noted previously regarding VCD is seen. With an intrathoracic lesion, greater impairment of expiratory flow rates will be found.[24] One example of such an intrathoracic lesion is tracheomalacia.

FUNCTIONAL ASSESSMENT OF ACUTE ASTHMA

The severity of acute asthma may be gauged by findings on physical examination, tests of lung function, and the adequacy of oxygenation and ventilation (oximetry, arterial blood gases). Pertinent findings on physical examination include use of the accessory muscles of respiration, particularly the sternocleidomastoid muscle, which is an indication of significant airflow obstruction.[87] The presence of a pulsus paradoxus of greater than 20 mm Hg is also a useful indicator of severe airflow limitation in children with acute asthma.[88,89] The finding of a 'quiet chest' in an anxious patient struggling to breathe is an ominous finding.

Although it is critical to recognize and appreciate the importance of these physical findings, quantitative assessments are also of great value in the patient with acute asthma. In asthmatic subjects who are extremely breathless, tests of lung mechanics, although highly desirable, may be difficult or impossible to obtain. Repeated spirometry alone may lead to greater airway obstruction in some children with moderate to severe acute asthma, precluding this manner of assessing the subject. When tests can be performed, assessments commonly include PEFR and FEV_1. Flow rates on presentation are important, but a lack of improvement in lung function after initial treatment may be a better predictor of the need for hospitalization than the pretreatment value.[90]

Oximetry has become the most widely applied and clinically useful tool for assessing oxygenation in emergent situations. Oximeters offer a rapid and reliable noninvasive method of assessing the most vital physiologic consequence of obstructed breathing. Physical signs of hypoxemia, such as irritability, pallor and cyanosis, are variable and may not be present at mild to moderate levels of oxygen desaturation. In children, oximetry provides a gauge of the acuity of their asthma and may be helpful in decision making regarding the need for hospitalization. In a study from Australia, Geelhoed and colleagues[91] found that the initial arterial oxygen saturation was highly predictive of outcome in pediatric asthma patients in an emergency department. A saturation of 91% was found to discriminate between favorable and unfavorable outcomes as defined in part by the need for subsequent care after the initial visit. In addition, continuous measurements of oxygen saturation during therapy allow care providers to quickly address fluctuations in oxygenation that may be the consequence of both the disease and the therapy provided to the patient. In terms of the latter, lung mechanics may improve after inhalation of a bronchodilator while oxygenation deteriorates.[92] This phenomenon is transient and has been attributed in part to the vasodilatory effect of the drugs on the pulmonary vessels, counteracting local vasoconstrictive factors in the lung and promoting 'mismatch' in lung ventilation and perfusion. Providers may be tempted to withhold additional bronchodilators when this occurs; however, these medications are necessary to expedite recovery and supplemental oxygen can be used as necessary to minimize hypoxemia while continuing acute treatment for asthma.

In instances when the episode is mild and the therapy is initiated early within the home environment, administration of bronchodilator treatment via metered dose inhaler or by nebulization may lead to substantial and prolonged bronchodilation. A good response is commonly defined as a return of the PEFR to greater than 80% of that predicted or personal best, with the response sustained for 4 hours.[26] Children who improve with home bronchodilator therapy may then safely repeat this treatment as frequently as every 4 hours. Serial measurements of peak flow before and after therapy are useful not only to assess the severity of acute asthma but also to monitor the response to treatment. A lack of response or an incomplete response to inhalation of a β_2-adrenergic agonist in a patient with asthma should always be a concern and is reason for evaluation and treatment by a physician.

FUNCTIONAL ASSESSMENT OF CHRONIC ASTHMA

As noted earlier, airway obstruction may be present in children with asthma who are asymptomatic. In a subset of subjects who underappreciate or deny symptoms, the degree of obstruction can be quite remarkable. When this is encountered on a child's initial evaluation, the significance of the findings is difficult to assess. Therefore serial tests of lung function in subjects with chronic asthma will be helpful in several respects. First, when several determinations are made over time, the child's personal best lung functions are defined and serve as a point of reference for that child. Second, serial tests of lung function will help support the diagnosis of asthma if fluctuations in PEFR or FEV_1 are noted spontaneously or as a result of therapy. When little or

https://CafePezeshki.IR

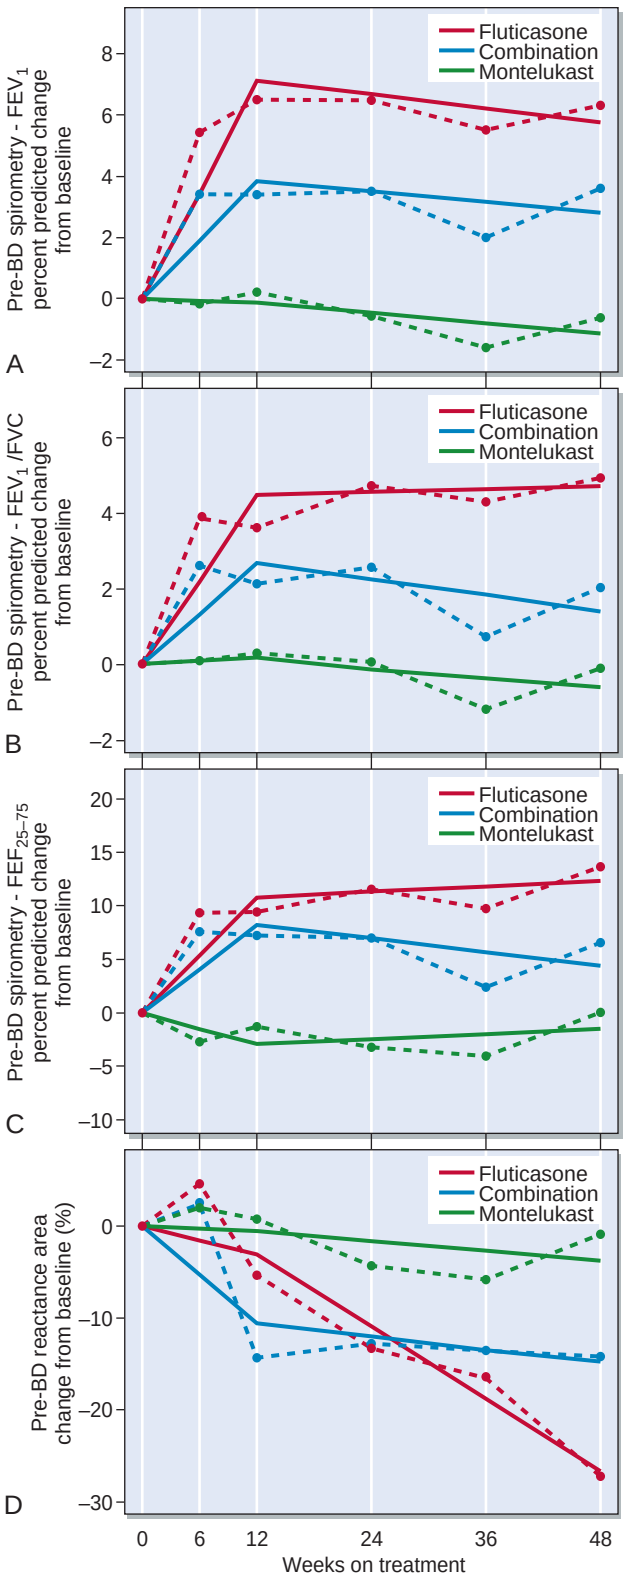

Figure 30-4 Changes in FEV_1 (A), FEV_1/FVC (B), $FEF_{25–75}$ (C) and XA (D) over time are shown for three treatment groups as both mean data at each measurement point (dashed lines) and as a regression model with a change point at 12 weeks of therapy (solid lines). During the first 12 weeks of therapy, the slopes of FEV_1, FEV_1/FVC and $FEF_{25–75}$ were significant in a positive direction for combination and fluticasone therapy. However, for these spirometric parameters, the pattern over the last period of therapy (12–48 weeks) was different, with all slopes close to zero (non-significant). Conversely, XA significantly improved in the fluticasone treatment group during the latter period, as reflected by the negative slope for change in XA. Pre-BD signifies measures were all performed before bronchodilator. *(From Larsen GL, Morgan W, Heldt GP, Mauger DT, Boehmer SJ, Chinchilli VM, et al. J Allergy Clin Immunol 2009;123:860–7.)*

no reversibility of lung function is found in the face of significant obstruction, other diseases such as bronchiolitis obliterans should be considered. Fourth, simple tests of lung function may help identify subjects with increased risk of future asthma attacks or those at greater risk for the persistence of respiratory symptoms.[93,94]

Serial tests of lung function also help define the effects of various approaches to therapy. This was demonstrated in a long-term study that compared three controller regimens.[95] Children aged 6 to 14 years with mild to moderate persistent asthma were characterized with both impulse oscillometry and spirometry before entry into a clinical trial and then serially during 48 weeks of therapy with either an inhaled corticosteroid, a combination inhaled corticosteroid with a long-acting β-agonist, or a leukotriene receptor antagonist. The spirometric parameters FEV_1, FEV_1/FVC and $FEF_{25–75}$ all demonstrated significant improvement during the first 12 weeks of therapy in the groups receiving corticosteroid and combination therapy. However, improvement appeared to plateau at that time with improvement maintained but not increasing during the latter part of therapy (12 to 48 weeks). Conversely, reactance area (XA), a measurement obtained with oscillometry that reflects both reactance and resonant frequency, demonstrated improvement during the latter part of the study in the corticosteroid treatment arm of the trial. These changes with treatment over time are shown in Figure 30-4. Studies such as this demonstrate not only the time course and magnitude of effects that may be expected with different approaches to therapy, but also suggest that information from oscillometry and spirometry may differ and be complementary.

Conclusions

Asthma is characterized by increased responsiveness of airways to various stimuli, variable airflow limitation and reversible airway obstruction (see Key Points). Given these features, quantitative tests of lung function are useful tools in both diagnosis and management. During acute episodes of asthma, marked decreases in flow rates together with hyperinflation of the lungs are seen in tests of lung mechanics. In addition, hypoxemia is a common finding in subjects with wheezing, whereas hypercapnia develops as a late consequence of severe airflow obstruction. In many patients, clinical signs and symptoms of obstruction resolve long before tests of lung function normalize. In a subgroup of asthmatic patients, lung function will never completely normalize. Serial tests of lung function help define a child's

https://CafePezeshki.IR

personal best lung function values, help support the diagnosis of asthma, give clues to alternate diagnoses and complicating problems, and help identify subjects with increased risk of future asthma instability. Serial tests of lung function also help define the effects of various approaches to therapy. A fundamental knowledge of the pathophysiology of acute and chronic asthma is necessary to fully interpret functional studies and to provide effective treatment for patients with this common yet potentially life-threatening condition.

Infections and Asthma: Impact on the Natural History of Asthma

DANIEL J. JACKSON | ROBERT F. LEMANSKE, JR. | JAMES E. GERN

KEY POINTS

- Wheezing viral respiratory illnesses are the most common initial presentation of childhood asthma.
- Once asthma is established, viral infections, most notably rhinovirus (RV), are the most frequent trigger of severe asthma exacerbations. RV-C appears to be a particularly pathogenic virus in children with asthma.
- Evidence has recently emerged to suggest that bacterial pathogens in the lower airway may contribute to the expression of asthma. Ongoing studies are critical to our understanding of the role of the airway microbiome in asthma inception and exacerbation.
- Synergistic interactions between underlying allergy and virus infections play an important mechanistic role in asthma inception and exacerbation, and are an important therapeutic target.
- Novel therapies are needed to prevent and treat virus-induced wheezing and asthma exacerbations.

Introduction

Respiratory infections can cause wheezing illnesses in children of all ages and also influence the development and severity of asthma in several ways. First, viral wheezing episodes during infancy are a critical risk factor for asthma inception. Once asthma is established, viral upper respiratory tract infections (URTIs) are the most common trigger for acute exacerbations. Furthermore, a potential role for particular bacterial pathogens in the development of wheezing and asthma exacerbations has been identified. This chapter will review the relationships between infections and asthma inception and exacerbation. Additionally, we discuss mechanisms by which infections lead to lower respiratory inflammation and airway dysfunction. Finally, we discuss treatment strategies for virus-induced wheezing and exacerbations of asthma.

Relationships Between Early Life Infections and Childhood Asthma

VIRUSES

Viral respiratory illnesses leading to wheezing are one of the most common causes of hospitalization during infancy. Using multiple virus detection methods, including polymerase chain reaction (PCR), Jartti and colleagues[1] investigated the etiology of wheezing illness in 293 hospitalized children. Of the 76 infants with virus detected, 54% had respiratory syncytial virus (RSV), 42% had picornaviruses (human rhinovirus [RV] and enterovirus) and 1% had human metapneumovirus (hMPV). In older children, respiratory picornaviruses, most commonly RV, dominated (65% of children aged 1 to 2 years and 82% of children aged ≥3 years). Outpatient wheezing illnesses are also extremely common in young children, and viruses have been implicated in 67% to 90% of these episodes in different populations.[2,3]

Wheezing with viruses during infancy is often an early manifestation of asthma. Several large, long-term prospective studies of children have demonstrated that RSV bronchiolitis is a significant independent risk factor for recurrent wheezing and asthma, at least within the first decade of life.[4,5] A recent clinical trial comparing palivizumab (anti-RSV monoclonal antibody) to placebo in near preterm infants demonstrated reductions in recurrent wheezing during the first year of life in the children treated with palivizumab.[6] This is the strongest level of evidence to date in support of a causal role for RSV in recurrent wheezing. However, a longitudinal, population-based cohort study has demonstrated that the association between RSV lower respiratory infections during early life and both frequent (more than three episodes) and infrequent wheezing (less than three episodes) decreases with age and becomes nonsignificant by the age of 13 years.[4] These data suggest that although RSV infections contribute substantially to the risk of recurrent wheezing and asthma in early childhood, other co-factors (e.g. genetic, environmental, developmental) also contribute to the expression of asthma or modification of phenotypes over time. Interestingly, a 2013 study identified unique immune response profiles during and after RSV bronchiolitis in comparison with bronchiolitis caused by other viruses.[7]

With the development of molecular diagnostics, significant evidence has emerged to suggest that wheezing illnesses caused by RV identify children at highest risk for childhood asthma.[2,8] The Childhood Origins of ASThma (COAST) birth cohort study confirmed prior associations between RSV wheezing in the first 3 years of life and childhood asthma, but demonstrated that RV wheezing during this time is associated with a greater, 10-fold increased risk of childhood asthma.[2] Mechanisms by which recurrent RV infections may lead to wheezing and airway remodeling, particularly in susceptible hosts, have been described.[9] A new species of RV, RV-C, was recently discovered,[10,11] and has been shown to be an important cause of lower respiratory illnesses and wheezing in children.[12–14] A longitudinal analysis within the COAST study demonstrated that both RV-A and RV-C were more likely than RV-B to cause moderate-to-severe respiratory illnesses in infants.[15] Whether RV-C wheezing illnesses confer a greater risk of childhood asthma development is currently unknown.

Molecular diagnostics are not universally available to clinicians, so the question of whether season of wheezing is helpful

https://CafePezeshki.IR

in delineating risk is an important one. Bronchiolitis during infancy is associated with an approximately 2-fold increased risk of early childhood asthma; however, this risk differs by season of bronchiolitis. Bronchiolitis occurring during RV-predominant months (spring and fall) was associated with an estimated 25% increased risk of early childhood asthma compared with RSV-predominant (winter) months. However, the proportion of associated asthma after winter season bronchiolitis is greater than RV-predominant months because of higher rates of bronchiolitis during the RSV season.[16] Season of birth also appears relevant: children born close to the onset of the winter virus season are most prone to the development of lower respiratory tract symptoms, and this is likely due to a developmental component in relationship to the timing of the winter virus peak.[17,18]

BACTERIA

It has been proposed that chronic bacterial infections or colonization with pathogenic bacteria could initiate chronic lower airway inflammation, impaired mucociliary clearance, increased mucus production and ultimately asthma.[19,20] Organisms primarily implicated in this process include *Chlamydophila pneumoniae*,[21–23] *Mycoplasma pneumoniae*,[24,25] *Streptococcus pneumoniae, Haemophilus influenzae* and *Moraxella catarrhalis*.[20] Studies of chronic mycobacterial or *Chlamydophila* infection and asthma in children have yielded conflicting results, potentially in part due to the limitations of current diagnostics. Findings of diagnostic tests in the upper and lower airways are not always concurrent, and diagnosis of infection by serology leads to inaccuracies. The role of these bacteria in acute wheezing in young children is also unclear.

Recent publications have suggested that pathogenic bacteria may play a role in both acute wheezing episodes and asthma inception in preschool children. First, Bisgaard and colleagues found that neonates with *S. pneumoniae, H. influenzae* or *M. catarrhalis*, or with a combination of these organisms, in their hypopharynx are at increased risk for recurrent wheeze early in life and the diagnosis of asthma at the age of 5 years.[20] This original observation was made in infants of mothers with asthma, but the researchers were able to replicate some of these findings in an unselected cohort.[26] Further, these pathogens have been detected at higher rates in preschool children during acute wheezing episodes.[27] Interestingly, a similar predominance of Proteobacteria has been identified in the airways of older children and adults with established asthma.[28,29] Furthermore, in both human and animal studies, environmental exposure to 'protective' bacteria appears to have the capacity to prevent the development of wheezing and/or asthma in young children.[30–33] These studies of the role of microbial exposures and the microbiome in asthma inception are intriguing, and additional studies are a high priority to establish causality/protection and the specificity of these observations to asthma pathogenesis, and to define immunoinflammatory mechanisms contributing to these associations in both pediatric and adult patients.

Infections and Acute Exacerbations of Asthma

The relationship between viral infections and exacerbations of asthma has been clarified by the development of molecular diagnostic tests for viruses that are difficult to culture: RV, hMPV and bocaviruses. With the advent of these more sensitive diagnostic tools, information linking common cold infections with exacerbations of asthma has come from a number of sources. Prospective studies of children with asthma have demonstrated that up to 85% of exacerbations of wheezing or asthma in children are associated with viral infections.[34] Although many respiratory viruses can provoke acute asthma symptoms, RVs are most often detected, especially during the spring and fall RV seasons. In fact, the spring and fall peaks in hospitalizations because of asthma closely coincide with patterns of RV isolation within the community.[35] RV infections, most commonly RV-C, are frequently detected in children who present to emergency departments with acute wheezing and in children hospitalized for acute asthma.[12,14,36] Influenza and RSV are somewhat more likely to trigger acute asthma symptoms in the winter but appear to account for a smaller fraction of total asthma flares. Other viruses that are less frequently associated with wheezing and exacerbations of asthma include bocavirus,[37] metapneumovirus[38] and coronaviruses.[39] Together, these studies provide evidence of a strong relationship between viral infections, particularly those associated with RV, and acute exacerbations of asthma.

It is interesting that individuals with asthma do not necessarily have more colds, but have greater lower respiratory tract symptoms associated with colds. A prospective study of colds in couples consisting of one asthmatic and one healthy individual demonstrated that colds cause greater duration and severity of *lower* respiratory symptoms in patients with asthma.[40] These findings suggest that asthma is associated with fundamental differences in the lower airway manifestations of respiratory viral infections. In addition to provoking asthma, RV infections can increase lower airway obstruction in individuals with other chronic airway diseases such as chronic obstructive pulmonary disease[41] and cystic fibrosis.[42] Thus, common cold viruses that produce relatively mild illnesses in most people can cause severe pulmonary problems in susceptible individuals.

The role of respiratory viruses in exacerbations is particularly important in light of recent observations that severe asthma exacerbations may lead to progressive loss of lung function over time.[43,44] As seen in other chronic lung diseases, a paradigm by which recurrent severe exacerbations lead to progressive loss of lung function and enhanced disease severity over time appears to be emerging in asthma.

Sinus Infections and Asthma

The nature of the association between asthma and sinusitis in children (and adults) has been the subject of debate for many years. Much of the difficulty in defining this relationship results from the uncertainties in making the clinical diagnosis of sinusitis, because the signs and symptoms of sinusitis in children overlap with many common childhood respiratory disorders, including the common cold, allergic rhinitis and asthma. As reviewed in Chapter 26, untreated sinus disease may contribute to unstable asthma control in some patients. Because bacterial infections are clearly involved in acute and chronic sinus disease, the mechanisms by which these microbes may promote hyperreactivity in the lower airway have been of great interest. These relationships are covered in depth elsewhere in this text and therefore are not further reviewed in this chapter.

Mechanisms of Infection-Induced Wheezing Illnesses

Clinical studies and in vitro studies have provided a number of insights into the pathogenesis of virus-induced wheezing illnesses and exacerbations of asthma (Box 31-1).

SPREAD OF INFECTION FROM THE UPPER TO THE LOWER AIRWAYS

Respiratory viruses such as RSV and influenza are well known to infect the lower airway, and both can cause bronchitis, bronchiolitis and pneumonia. RV has traditionally been considered to be an upper airway pathogen because of its association with common cold symptoms and the observation that it replicates best at 33–35°C, which approximates to temperatures in the upper airway. In fact, lower airway temperatures are conducive to RV replication down to fourth-generation bronchi and exceed 35°C only in the periphery of the lung.[45] Moreover, some RV types, including RV-C isolates, replicate equally well at 33 and 37°C.[46,47] RV appears to replicate equally well in cultured epithelial cells derived from either upper or lower airway epithelium.[48] Finally, RV has been detected in lower airway cells and secretions by several techniques after experimental inoculation.[49–51] Titers of infectious virus in lower sputum reach or exceed those found in nasal secretions in some individuals.[50] In addition to evidence from experimental infection models, RV is frequently detected in infants and children with lower respiratory signs and symptoms, including children hospitalized for pneumonia.[52,53] Collectively, these findings suggest that respiratory viruses, including RV, can cause wheezing illnesses and exacerbations of asthma mainly by infecting lower airways and causing or amplifying lower airway inflammation.

VIRUS-INDUCED CYTOPATHIC EFFECTS

First, viral infections damage airway epithelial cells and can cause airway edema and leakage of serum proteins into the airway. These effects, together with shedding of infected cells into the airway, can lead to obstruction and wheezing. In addition, viral infections stimulate mucus secretion and can also promote the formation of additional goblet cells (mucoid metaplasia) that can enhance mucus secretion that can persist even after the acute infection has resolved. Virus-induced injury to the epithelium can disrupt airway physiology through a number of different pathways (Box 31-2). For example, viral infections can increase the permeability of the epithelium,[54] which may facilitate contact of irritants and allergens with immune cells, leave neural elements exposed and promote secondary infection with bacterial pathogens. In addition, the combination of epithelial edema and sloughing together with mucus production can lead to airway obstruction and wheezing.

As reviewed under 'Viruses', there is clinical evidence that the RV-B species may be less virulent than other RVs. Moreover, there is corresponding evidence from in vitro studies that RV-B viruses replicate more slowly, produce less cytopathic effect and induce lower interferon and inflammatory responses compared to other RVs.[55] Overall, these viruses appear to be attenuated.

ROLE OF ANTIVIRAL IMMUNE RESPONSES

Virus-induced immune responses are necessary to clear the viral infection but they can also contribute to airway dysfunction and symptoms by causing an influx of inflammatory cells that adversely affect lower airway physiology. Antiviral immune responses are initiated within the epithelial cell and amplified by resident and recruited leukocytes in the airway. For viruses such as RV that infect relatively few cells in the airway, virus-induced inflammation may be the primary mechanism for the pathogenesis of respiratory symptoms and lower airway dysfunction.[56] Viral respiratory infections can also induce the synthesis of many of the factors that regulate airway and alveolar development and remodeling, including vascular endothelial growth factor (VEGF), nitric oxide (NO), metalloproteinases and fibroblast growth factor (FGF).[57–60] How single or repeated bouts of virus-induced overexpression of these regulators of lung development and remodeling affect the ultimate lung structure and function is not known, but they could exert long-term effects on lung function and asthma following viral infection in infancy.

Epithelial Cells

The processes associated with viral replication trigger innate immune responses within the epithelial cell. Virus attachment to cell surface receptors can initiate some immune responses. For example, RSV infection activates signaling pathways in airway epithelial cells through the innate immune system through Toll-like receptor (TLR)-4.[61] Furthermore, the development of oxidative stress during viral infections can activate epithelial cell responses. Inside the cell, viral RNA is detected by innate immune sensors on endosomal surfaces (TLR-3, TLR-7, TLR-8) and intracellular proteins, such as the dsRNA-dependent

BOX 31-1 KEY CONCEPTS

Proposed Mechanisms of Virus-Induced Wheezing

- Viral infection spreads from the upper to the lower airway
- Virus-induced damage to airway epithelium
- Airway edema and transudation of serum proteins
- Mucus hypersecretion
- Cellular inflammation: mononuclear cells and neutrophils
- Neuroinflammation
- Enhanced airway responsiveness
- Interactions between respiratory viral infections and preexisting airway inflammation
- Secondary bacterial infection

BOX 31-2 KEY CONCEPTS

Role of the Epithelium in Virus-Related Inflammation and Injury Pathogenesis

- Airway epithelial cells serve as hosts for viral replication
- Viral replication initiates the immune response to virus
- Interferon secretion to inhibit inflammation and injury of neighboring cells
- Chemokine secretion to recruit leukocytes into the airway
- Virus-induced epithelial cell damage can disrupt barrier function
- Viral infection induces mucus secretion and mucous metaplasia

https://CafePezeshki.IR

protein kinase (PKR) and retinoic acid-inducible gene I (RIG-I), to activate the innate antiviral immune response.[62] Through these pathways, viral replication stimulates antiviral effector molecules such as RNase L, and inhibition of protein synthesis within infected cells. In addition, innate antiviral responses induce chemokines (e.g. CXCL10) that recruit inflammatory cells into the airway and type I (IFN-α and IFN-β) and type III (IFN-λ1 and IFN-λ2) interferons that have autocrine and paracrine antiviral effects.

Leukocytes

Respiratory viruses activate monocytes, macrophages and dendritic cells to secrete an array of proinflammatory cytokines such as IL-1, IL-8, IL-10, tumor necrosis factor (TNF)-α and IFN-γ. In animal models, respiratory viral infections lead to a prominent expansion of mature dendritic cells in the lung.[63] Significantly, pulmonary dendritic cells express high levels of Toll-like receptors, and secrete large amounts of interferons in response to viral infection. Dendritic cell interferon responses are impaired in early life, which likely contributes to increased susceptibility to viral infections in infancy.[64]

Acute respiratory viral infections are often accompanied by pronounced neutrophilia of upper and lower respiratory secretions, and products of neutrophil activation contribute to airway obstruction and lower airway symptoms. For example, neutrophil elastase can up-regulate goblet cell secretion of mucus.[65] P2X7 is a cation channel expressed by leukocytes and airway epithelial cells that is important to pathogen control and neutrophilic inflammation. Attenuated P2X7 function, which is common in mild to moderate asthma, is associated with reduced recruitment of neutrophils to the airway during RV colds, and an increased risk of acute asthma symptoms.[66]

Lymphocytes are recruited into the upper and lower airways during the early stages of a viral respiratory infection, and it is presumed that these cells help to limit the extent of infection and to clear virus-infected epithelial cells. This is consistent with reports of severe viral lower respiratory infections in immunocompromised patients.[67] B cell responses to respiratory viruses also serve to limit duration and severity of illness, as indicated by the finding of frequent and prolonged viral illnesses in patients with X-linked agammaglobulinemia.[68]

Neuroinflammatory Mechanisms

Viral respiratory infections can induce inflammation through mechanisms involving neural mechanisms. These responses are difficult to study in humans, but studies in animal models have provided insights. For example, RSV infection in rodents leads to overproduction of nerve growth factor,[69] which promotes airway inflammation. This observation has also been confirmed in studies of babies with RSV bronchiolitis.[70] In a guinea pig model, virus infection causes dysfunction of M2 muscarinic receptors on parasympathetic nerves, leading to overproduction of acetylcholine and airway hyperresponsiveness. These responses appear to be driven by virus-induced acute phase cytokines such as IL-1β and TNF-α.[71]

Mediators

Mediators that are produced in excess during respiratory illnesses include NO, leukotrienes, prostaglandins, kinins and oxidative metabolites,[72–74] and inhibition of specific mediators can ameliorate some cold symptoms.[75] Histamine does not appear to play a role in common cold pathogenesis.[76]

RELATIONSHIP OF CELLULAR ANTIVIRAL RESPONSES TO OUTCOME OF VIRAL INFECTIONS

Several studies have tested the hypothesis that individual variations in cellular immune responses and patterns of cytokine production are related to the outcome of respiratory infections. In clinical studies, reduced IFN-γ responses of blood mononuclear cells ex vivo are associated with a significant increase in viral respiratory illnesses during infancy.[77–79] In addition, several studies have found that asthma is associated with impaired virus-induced secretion of interferons by airway and peripheral blood cells.[80–83] Together, these experimental findings suggest that individual variability in the cellular immune response to respiratory viruses, and interferon responses in particular, can influence the clinical and virologic outcomes of infection.

INTERACTIONS WITH BACTERIA

It is well established that viral illnesses of the middle ear, sinuses and lungs can promote secondary infections with bacterial pathogens such as *S. pneumoniae*, *M. catarrhalis*, and *H. influenzae*. As reviewed under 'Bacteria', colonization with these bacteria in early childhood is also a risk factor for acute wheezing episodes and asthma.[20] In school-aged children, these pathogens are more likely to be detected in association with a viral infection or just after a viral infection.[84] Furthermore, the risk of illness vs asymptomatic infection was greater in children who had both viruses and bacteria detected. Similarly, for children with asthma, moderate exacerbations were most likely to occur in viral infections in which *S. pneumoniae* or *M. catarrhalis* were also detected.[84] These findings suggest that viruses and bacteria may work together to promote airway pathology and respiratory symptoms.

ENVIRONMENTAL FACTORS AND VIRAL ILLNESSES

Environmental factors strongly influence the probability of exacerbations and appear to act together with viral infections in an additive fashion. As discussed in the next section, allergy is a strong risk factor for the development of asthma after virus-induced wheezing episodes in infancy and is also closely associated with virus-induced exacerbations of asthma in older children and adults with asthma. Accordingly, the combination of allergy and exposure to a relevant allergen contributes to virus-induced exacerbations of asthma.[85] Similarly, exposure to greater levels of air pollutants such as NO_2 and SO_2 also enhances the risk of virus-induced exacerbation.[86,87]

Interactions Between Allergy and Infections

Allergic sensitization has been defined as a clear risk factor for the development of asthma.[88] Children with 'multiple early sensitization' to aeroallergens have been identified as a phenotype at particularly high risk for asthma inception and severe exacerbations leading to hospitalization.[89] A sequential relationship whereby allergic sensitization precedes viral wheezing, most notably with RV, has been described.[90] Furthermore, children

https://CafePezeshki.IR

who develop both risk factors in early life are at highest risk for subsequent asthma.[2,91]

There is convincing evidence to implicate respiratory allergy as a risk factor for wheezing with common cold infections later on in childhood. In studies conducted in an emergency department, risk factors for developing acute wheezing episodes were determined.[85,92,93] Individual risk factors for developing wheezing included detection of a respiratory virus, most commonly RV, positive allergen-specific IgE and presence of eosinophilic inflammation. Notably, viral infections and allergic inflammation synergistically enhanced the risk of wheezing, and higher levels of allergen-specific IgE conferred the greatest risk. This synergism may be particularly notable for RV-C.[14]

There are multiple mechanisms by which viral infections are thought to interact with allergic inflammation in order to lead to airway dysfunction, wheezing and asthma exacerbations.[94] First, viral infections can damage the barrier function of the airway epithelium, leading to enhanced absorption of aeroallergens across the airway wall and enhanced inflammation, while allergic inflammation may also lead to enhanced viral replication.[95,96] Next, allergic inflammation enhances airway responsiveness to RV.[97] There is also significant evidence that allergic asthmatic individuals have impaired antiviral responses as noted above. Furthermore, allergen exposure and high-affinity IgE receptor cross-linking has been shown to impair virus-induced type I and III interferon production in peripheral blood cells.[98,99] This may lead to both enhanced viral replication and also type 2 inflammation.[100,101]

Treatment of Infection-Induced Wheezing and Asthma

VIRUS-INDUCED WHEEZING IN INFANCY

Acute lower respiratory tract illnesses during the first one to two years of life are usually termed 'bronchiolitis' and are most likely due to infection with viral respiratory pathogens. The efficacy of various interventions for the treatment of the acute lower airway symptoms of wheezing, tachypnea, retractions and hypoxemia that occur as a result of these infections has been controversial due to variations in study design, the inability to rapidly and conveniently measure pulmonary physiologic variables, the confounding of results by the inclusion of children with a history of multiple wheezing episodes (i.e. asthmatic phenotypes) and the choice of outcome measures that have been evaluated.[102] In a recent series of meta-analyses evaluating various therapies, the routine use of bronchodilators,[103] steam or nebulized normal saline,[104,105] anticholinergics[106] and steroids[107] has not been shown to be of consistent benefit.

A more recent study suggests that the timing of the administration of epinephrine may influence the observed benefit. In an eight-center randomized, double-blind trial with a two-by-two factorial design, investigators compared inhaled racemic epinephrine with inhaled saline and on-demand inhalation with fixed-schedule inhalation (up to every 2 hours) in infants (>12 months of age) with moderate-to-severe acute bronchiolitis.[108] Length of stay, use of oxygen supplementation, nasogastric tube feeding, ventilatory support and relative improvement in the clinical score from baseline (preinhalation) were similar in the infants treated with inhaled racemic epinephrine and those treated with inhaled saline. However, the strategy of inhalation on demand was superior to that of inhalation on a fixed schedule for many of the outcome measures evaluated.

The atopic background of the patient (eczema or asthma in a first-degree relative) may influence the response to oral corticosteroid administration. Infants aged ≤18 months presenting to a care facility for treatment of moderate-to-severe bronchiolitis and who had a positive history of eczema or were known to have a parent or a full sibling with a prior physician diagnosis of asthma were treated with oral dexamethasone, 1 mg/kg, then 0.6 mg/kg for 4 more days, or matching placebo. All patients received albuterol nebulization delivered through a tight-fitting face mask with pressurized oxygen. Dexamethasone plus albuterol treatment shortened time to readiness for discharge from the unit. However, there was no difference between the treatment groups in terms of infirmary and clinic visits during the week following discharge.[109]

VIRUS-INDUCED WHEEZING IN PRESCHOOL CHILDREN

Therapeutic approaches for virus-induced wheezing in preschool children (ages 2–5 years) are challenging due to the fact that many children only wheeze with the 'common cold' and are totally asymptomatic in between these episodes, while others may have symptoms more or less on a daily basis as well. In addition, these episodes may range in severity from mild wheezing and coughing to severe respiratory distress that requires prompt medical intervention. Standard therapy for virus-induced wheezing in young children generally includes a stepwise addition of medications, typically commencing with a bronchodilator. If lower respiratory tract symptoms become increasingly severe or respiratory distress develops, oral corticosteroids are often added. Recent clinical trials in the management of these wheezing episodes also have included the use of high-dose inhaled corticosteroids (both prophylactically and/or as an acute intervention) and leukotriene receptor antagonists.

THE ROLE OF ORAL CORTICOSTEROIDS IN ACUTE EXACERBATIONS OF ASTHMA IN YOUNG CHILDREN

Numerous studies have been undertaken to assess the role of corticosteroid therapy in acute episodes of asthma in children and adults.[110] Meta-analyses of these studies support the early use of systemic corticosteroids in acute exacerbations based upon a reduction in the admission rate for asthma and prevention of relapse in the outpatient treatment of exacerbations.[111,112] As a reflection of such information, the most recent National Heart, Lung, and Blood Institute (NHLBI) Guidelines for the Diagnosis and Management of Asthma recommend the addition of corticosteroids for asthma exacerbations unresponsive to bronchodilators; in contrast to previous versions of these guidelines, doubling the dose of inhaled corticosteroids to prevent further progression of the airway obstruction is not recommended.[113]

Unfortunately, the applicability of these recommendations to young children and infants whose acute wheezing episode is primarily related to viral respiratory tract infections has not been as thoroughly examined. Moreover, in studies that have been conducted in this age group, the results are conflicting.[114–118] Limitations of these studies include inclusion of multiple

https://CafePezeshki.IR

wheezing phenotypes,[116,118] relatively small sample sizes, poor adherence to study medication and protocol in the outpatient studies,[115,118] and episodes of relatively mild severity in both outpatient and inpatient studies.[115,118] A recent randomized, double-blind, placebo-controlled trial compared a 5-day course of oral prednisolone (10 mg once a day for children 10–24 months of age and 20 mg once a day for older children for a total of 5 days) with placebo in over 650 children between the ages of 10 months and 60 months. The primary outcome, the duration of hospitalization, was no different between the treatment groups.[116] An accompanying editorial for this published study challenged the clinical research community to conduct additional prospective trials to clearly establish the efficacy of oral corticosteroid treatment of these 'asthma-like' episodes in preschool children.[119]

To address these concerns further, the Childhood Asthma Research and Education (CARE) network investigated whether oral corticosteroids reduced symptom scores during acute lower respiratory tract illnesses (LRTIs) in preschool children with recurrent wheeze. The investigators performed post hoc and replication analyses in two outpatient cohorts of children[120,121] aged 1 to 5 years with episodic wheezing that had participated in previous CARE-conducted studies.[122] Comparisons were made of symptom scores during LRTIs that were or were not treated with oral corticosteroids, adjusting for differences in disease and episode severity. The primary outcome was the area under the curve of total symptom scores among the more severe episodes. In both of the two cohorts studied independently, oral corticosteroid treatment did not reduce symptom severity during acute LRTIs. Moreover, subgroups of children who might have been more likely to experience benefit, such as those with asthma risk factors (positive modified asthma predictive index,[123] personal eczema and/or family history of asthma), did not appear to have a greater benefit than those without such characteristics. The investigators emphasized, however, that these results were hypothesis generating and needed to be confirmed in randomized prospective studies.[124] Taken together, however, these studies indicate that acute asthma-like episodes of airway obstruction in preschool children appear to respond less well to oral corticosteroid administration than do similar episodes in older children and adults.

THE ROLE OF INHALED CORTICOSTEROIDS IN THE PREVENTION AND TREATMENT OF ACUTE WHEEZING EXACERBATIONS

The CARE network conducted a 3-year prospective trial in preschool children, all of whom had a modified positive asthma predictive index.[125] The overall goal of the study was to determine if early recognition and treatment of children who were at increased risk of developing childhood asthma could prevent the disease process from expressing itself and, further, if it could reduce losses of lung function that have been described during the first six years of life in children who develop persistent wheezing by age 3 years.[126] Children, 2 to 4 years of age, were randomized to receive either fluticasone propionate 88 μg twice daily or matching placebo using a valved spacer with mask. Treatment was for 2 years followed by a 1-year observation period off all study medication. The primary outcome measure was episode-free days. During the active treatment phase, children receiving inhaled corticosteroid (ICS) had a significantly increased number of episode-free days. In addition, they had significant reductions in oral corticosteroid-requiring exacerbations (37% reduction) and less use of a prespecified step-up plan. Pulmonary function was also significantly better at the end of the treatment period in those children who had received ICS for the previous two years. Unfortunately, about three months into the observation period, there was no longer any significant difference in any of these outcome measures and at the end of the observation period (1 year later), pulmonary function was also no different between the two groups.[127] These data indicate that continuous therapy with ICS in preschool children at high risk of developing asthma reduces lower respiratory tract exacerbations that are most frequently caused by respiratory pathogens in this age group.

Many preschool children wheeze only with respiratory tract pathogens and are asymptomatic between these episodes. Therefore, a 1-year randomized, double-blind comparison among intermittent treatment with high-dose ICS, a leukotriene receptor antagonist (montelukast) and scheduled albuterol (so-called 'standard of care') was conducted in preschool children with histories consistent with this type of respiratory pattern.[120] Therapy was initiated by the family, based on the participant achieving a symptom profile threshold that the child had exhibited in the past that would usually foreshadow the development of more significant lower airway involvement. After 1 year of treatment, the three groups did not differ in proportions of episode-free days (primary outcome), oral corticosteroid use, healthcare utilization, quality of life or linear growth. However, during respiratory tract illnesses, both ICS and montelukast therapy led to modest reductions in trouble breathing and interference with activity scores compared to those children only treated with albuterol. These differences were significant only in those children with a positive asthma predictive index prior to enrollment. In a post hoc analysis, similar findings were obtained when the cohort was stratified by oral corticosteroid use (0 vs ≥1 course) during the year preceding participation in the trial.

The observations that both the continuous[127] and intermittent[120] use of ICS had an effect on both the frequency and severity of exacerbations that were most likely related to a concomitant viral or bacterial respiratory tract illness provided the impetus for a third CARE network-initiated trial.[121] This trial studied 278 children between the ages of 12 and 53 months who all had positive modified asthma predictive indices, recurrent wheezing episodes with a low grade of interval impairment, and at least one exacerbation in the previous year. Children were randomly assigned to receive nebulized budesonide suspensions for 1 year as either an intermittent high-dose regimen (1.0 mg twice daily for 7 days starting at the onset of predefined respiratory tract illness symptoms) or a daily low-dose regimen (0.5 mg nightly) with corresponding placebos in both treatment arms. The two regimens were similar with respect to exacerbation frequency (primary outcome) and other measures of asthma severity including the time to first exacerbation. The mean exposure to budesonide was 104 mg less with the intermittent regimen.

Although the results of this trial indicate that, in preschool children with this type of pre-asthma phenotype, intermittent therapy versus continuous therapy would be a therapeutic consideration, the lack of a placebo group in this study does not permit more exact interpretations of these findings. Inclusion of a placebo group was not permitted by the various human subjects committees of the clinical centers participating in this

https://CafePezeshki.IR

trial. This was due to the intensity of the symptom severity pattern present in the children prior to enrollment in the trial.

ROLE OF LEUKOTRIENES MODIFIERS IN VIRAL-INDUCED WHEEZING

The cysteinyl leukotrienes have been identified as important mediators in the complex pathophysiology of asthma.[128] Leukotrienes are detectable in the blood, urine, nasal secretions, sputum and bronchoalveolar lavage fluid of patients with chronic asthma. In addition, leukotrienes are released during acute asthma episodes. As a result of the potential for these mediators to influence airway tone, inflammatory cascades and mucus secretion, antagonists for their receptors have been developed and extensively studied. The cysteinyl leukotriene receptor antagonist, montelukast, has been the most frequently studied in both preschool and school-aged children.[120,129–136]

In one of the initial clinical trials designed to primarily evaluate safety, patients aged 2 to 5 years were treated for over 12 weeks with montelukast administered as a 4-mg chewable tablet.[129] Efficacy outcomes were also evaluated secondarily. Compared with placebo, montelukast produced significant improvements in multiple parameters of asthma control including: daytime asthma symptoms (cough, wheeze, trouble breathing and activity limitation); overnight asthma symptoms (cough); the percentage of days with asthma symptoms; the percentage of days without asthma; the need for beta-agonist or oral corticosteroids; physician global evaluations; and peripheral blood eosinophils. The clinical benefit of montelukast was evident within 1 day of starting therapy. Improvements in asthma control were consistent across age, sex, race and study center, and whether or not patients had a positive in vitro allergen-specific IgE test.

Robertson et al evaluated the intermittent use of montelukast in 2- to 14-year-old children with histories of intermittent asthma.[136] The family was instructed to begin a 7-day treatment with montelukast (age-appropriate dose) at the onset of asthma symptoms or the first sign of an upper respiratory tract illness that had previously been associated with the subsequent development of lower airway asthma symptoms. Compared to placebo, montelukast treatment resulted in a modest reduction in acute healthcare resource utilization, symptoms, time off from school and parental time off work in children with intermittent asthma.

Bisgaard et al evaluated the efficacy of 1-year daily treatment with montelukast in children with intermittent asthma in reducing exacerbations.[134] The primary efficacy endpoint was the number of asthma exacerbation episodes defined as any three consecutive days with daytime symptoms (average score of four daily daytime symptom questions of at least 1.0 on each day) and at least two treatments of beta-agonist per day, or rescue use of oral/inhaled corticosteroids during 1 or more days, or a hospitalization because of asthma. Over 12 months of therapy, montelukast significantly reduced the rate of asthma exacerbations by 31.9% compared with placebo. The average rate of exacerbation episodes per patient was 1.60 episodes per year on montelukast compared with 2.34 episodes on placebo. Montelukast also delayed the median time to first exacerbation by approximately 2 months and the rate of inhaled corticosteroid courses compared with placebo. Unfortunately, treatment did not reduce the necessity for oral corticosteroid administration. One of the remarkable aspects of this trial was the marked seasonal variation in exacerbation rates, with the summer months having less frequent exacerbations and no observed treatment effects. These data are an excellent documentation of the 'honeymoon' period from asthma symptoms that many clinicians observe in their patients during the summer months, most likely related to reduced numbers of respiratory tract illnesses.

Because infections with RSV in early life have been associated with an increased risk of developing recurrent wheezing and later asthma, two studies have evaluated the effects of montelukast treatment on the development of subsequent reactive airway disease symptoms. In the first 'pilot study',[133] children without a diagnosis of asthma (3–36 months old), hospitalized with acute RSV bronchiolitis, were randomized into a double-blind, parallel comparison of 5 mg montelukast or placebo given for 28 days starting within 7 days of the onset of symptoms. Infants on montelukast were free of any symptoms on 22% of the days and nights compared with 4% of the days and nights in infants on placebo. Daytime cough was significantly reduced, as were exacerbations in those children on active treatment. In contrast, in a follow-up study in children 3 to 24 months of age conducted over a period of 24 weeks, montelukast treatment did not alleviate post RSV-induced respiratory tract symptoms.[135]

In school-aged children, montelukast has been shown to be less effective compared to inhaled corticosteroid treatment in reducing the need for oral corticosteroid use and time to treatment failure over a 1-year time period.[131] Both of these outcomes could be considered surrogates for respiratory pathogen-induced asthma exacerbations or worsening of overall asthma control.

ANTI-INFECTION THERAPY

Therapy for infection-induced asthma could potentially include one or more of the following approaches: avoidance, non-medicinal interventions, vaccination, antimicrobial drug therapy and/or immunotherapy (monoclonal antibodies directed against the relevant pathogens). The ubiquitous nature of respiratory pathogens in the environment and the social nature of interactions in childhood (daycare, school, older siblings, etc.) make avoidance strategies unfeasible. Indeed, on average, children experience 2 to 8 or more 'colds' per year during their preschool years.

The cure for the common cold remains elusive; as such, a number of non-medicinal interventions have been tried. Vitamin C has long been touted for common cold treatment; however, a meta-analysis of common cold treatment studies found no significant effects on either prevention or treatment.[137] A Cochrane review of clinical studies found evidence that zinc lozenges reduce common cold duration but have significant side-effects including bad taste and nausea.[138] Large-scale trials of Echinacea have provided no evidence of efficacy.[139,140] There is evidence that warm drinks, as recommended for generations, can provide symptomatic relief from malaise and nasal symptoms without troublesome side-effects.[141] These approaches obviously are aimed at symptom reduction of the common cold but their effects on asthma control or exacerbations have not been directly evaluated.

Given the close relationship between viral infections and wheezing illnesses in children, it would be attractive to apply antiviral strategies to the prevention and treatment of asthma,

https://CafePezeshki.IR

and both RV and RSV are obvious targets. Attempts at developing an RSV vaccine have so far been unsuccessful; however, recent data have provided renewed encouragement.[142,143] Unfortunately, vaccination to prevent RV infection is even more challenging due to the large number of serotypes. As an alternative, several types of antiviral agents are in development, and several compounds with activity against RV have been tested in clinical trials.

Improved knowledge of RV molecular virology has led to several attempts to develop antiviral agents. Interferon-α has antiviral effects in vitro and shortens the duration and severity of colds, but topical application led to nasal irritation and bleeding.[144–146] Anti-ICAM-1 and soluble ICAM-1 were developed to prevent binding of major group viruses to their receptor.[147–149] Capsid binding agents that bind to the VP1 pocket and inhibit viral binding and/or uncoating[150–152] have shown modest antiviral effects and efficacy in clinical trials.[153,154] An inhibitor to the 3C protease (rupintrivir) also showed broad anti-HRV activity in vitro and efficacy in clinical trials.[155] Unfortunately, these antiviral approaches have not so far led to development of a clinically useful medication. The molecules tested to date have been limited by combinations of modest efficacy, side-effects and/or drug interactions.[156]

Another new approach has been to boost antiviral defenses in the lung with inhaled IFN-β. In a randomized study, subjects with persistent asthma and a history of exacerbations with colds were treated with either nebulized IFN-β or placebo within 24 hours of the onset of cold symptoms.[157] In the intent-to-treat population, there were no significant effects on the asthma symptoms scores (which was the primary outcome) but IFN-β treatment improved recovery of peak expiratory flow. Notably, IFN-β was well tolerated and also induced expression of innate antiviral effectors in the blood and sputum. In a subgroup analysis of study subjects with more severe asthma (British Thoracic Society Step 4 and 5), colds were associated with increased symptoms in the placebo group but not in IFN-β-treated subjects. These exciting new findings, if confirmed, suggest that inhaled IFN-β used at the first sign of a cold could be a useful adjunct to standard therapy in patients with more severe asthma.

Two recent trials evaluating the efficacy of monoclonal antibody therapy directed specifically against RSV and the allergic antibody, IgE, have yielded interesting results. The first trial studied the anti-RSV monoclonal antibody, palivizumab, in a double-blind, placebo-controlled trial: 429 otherwise healthy preterm (33–35 weeks' gestational age) infants were randomly assigned to receive either monthly palivizumab injections or placebo during the RSV season. The prespecified primary outcome was the total number of parent-reported wheezing days in the first year of life. Nasopharyngeal swabs were taken during respiratory episodes for viral analysis. Palivizumab treatment resulted in a relative reduction of 61% in the total number of wheezing days during the first year of life (1.8% vs 4.5% in the placebo group). During this time, the proportion of infants with recurrent wheeze was 10 percentage points lower in patients treated with palivizumab (11% vs 21%). As discussed above, the data generated thus far cannot ascertain what effect such treatment may have on the subsequent development of asthma in later childhood.

The second trial evaluated the anti-IgE monoclonal antibody, omalizumab, which specifically targets the Fc portion of IgE to prevent binding to the surface of cells and is therefore a narrowly focussed intervention for type I hypersensitivity. In a placebo-controlled trial of guidelines-based asthma treatment compared to omalizumab added to standard therapy, omalizumab prevented the seasonal increases in exacerbations during the fall and spring, which are peak times for viral exacerbations (Figure 31-1).[158] Analysis of viruses in nasal secretions during a subset of exacerbations confirmed that the treatment group had fewer viral and nonviral exacerbations. This study provides direct evidence that IgE-mediated inflammation contributes to the risk of virus-induced exacerbations of asthma. These observations indicate that interactions between allergic sensitization (antigen-specific IgE antibody formation) and viral respiratory illnesses play an important role in asthma control. Finally, it will be of interest to determine whether other drugs targeting specific type-2 cytokines (e.g. mepolizumab and IL-5)[159] can also reduce the risk of virus-induced exacerbations.

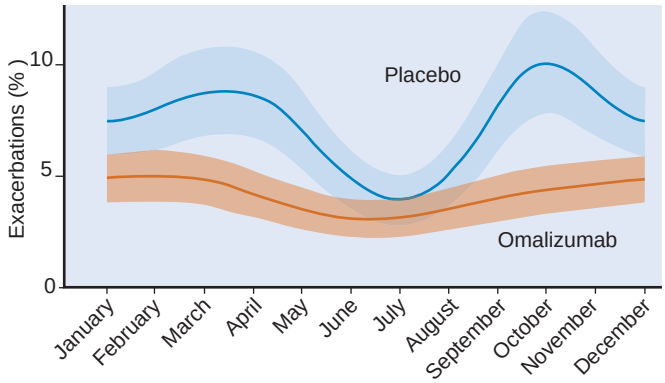

Figure 31-1 The figure shows the seasonality of asthma exacerbations in children and demonstrates that blocking IgE responses with omalizumab blunts the seasonal rise in virus-induced exacerbations. *(With permission from Busse WW, Morgan WJ, Gergen PJ, Mitchell HE, Gern JE, Liu AH, et al. Randomized trial of omalizumab (anti-IgE) for asthma in inner-city children. N Engl J Med 2011;364(11):1005–15.)*

Use of Antibiotics in Asthma

Asthma guidelines both in the USA (http://www.nhlbi.nih.gov/health-pro/guidelines/current/asthma-guidelines/full-report.htm) and internationally (http://www.ginasthma.org) have not recommended the use of antibiotics to treat asthma exacerbations because the majority of the exacerbations have been considered to be triggered by viral respiratory tract infections. Nonetheless, oral antibiotics are frequently prescribed for wheezing illnesses in preschool children (650 antibiotic prescriptions/1,000 wheezing children).[160] Furthermore, recent data indicate that 28% of preschool children who make a physician visit for wheezing receive a prescription for an antibiotic within 2 days of the visit, and 77% receive a prescription for an antibiotic within 7 days. These prescriptions are dominated by azithromycin, the use of which increased 15-fold between 1995 and 2001.[160]

As noted previously, bacteria (either alone or in combination with viral pathogens) have now been demonstrated to potentially play a role in acute wheezing episodes and increases in asthma symptoms in children.[27,84] These observations might be an explanation as to why antibiotic administration has been observed to provide some clinical benefit by practitioners. Recent findings indicate that certain antimicrobials may have

https://CafePezeshki.IR

not only antibacterial properties but antiviral and/or antiinflammatory properties as well.

As a class, macrolides have been demonstrated to provide clinical benefit in airway diseases such as cystic fibrosis[161] and diffuse panbronchiolitis,[162] possibly through mechanisms unrelated to antimicrobial activity. Viral infections, particularly those caused by RV, are associated with neutrophilic inflammation and increased IL-8 expression.[163] Neutrophils are the predominant inflammatory cell at the onset of most infections,[164] including those with RV,[163,165] and although many chemoattractants participate in summoning neutrophils to the site of infection, IL-8 seems to play a central role.[166] Neutrophils are relatively insensitive to the therapeutic effects of corticosteroids[167] but, interestingly, azithromycin has been demonstrated to attenuate immunoinflammatory responses and may reduce the ensuing destructive neutrophilic inflammation. In addition, recent data demonstrated that azithromycin reduces RV replication and increases interferon gene expression in human bronchial epithelial cells.[168] These effects may have substantial clinical relevance, as recent studies have demonstrated that primary bronchial epithelial cells from asthmatics have deficient ex vivo induction of IFN-β and IFN-λ after infection with RV,[81] and the levels of IFN-λ were inversely related to severity of RV-induced asthma exacerbations in terms of decline in FEV_1 and viral load. These findings are especially important because, in children, viral infections have been shown by many investigators to be a major etiologic agent in episodes of clinically significant lower respiratory tract symptoms.[3,92,169]

In contrast to in vitro observations indicating a potential useful role of these agents in treating infection-induced loss of asthma control or exacerbations, their efficacy in humans has not been consistently shown. Black et al were one of the first groups to demonstrate a potential beneficial effect. They studied the effect of roxithromycin in subjects with asthma and immunoglobulin G (IgG) or IgA antibodies to *Chlamydophila pneumoniae*. Subjects were randomized to 6 weeks of treatment with roxithromycin or placebo. This intervention led to improvements in asthma control but the benefit was not sustained.[170] Kraft and colleagues performed an additional study using a different antimicrobial. They found that treatment with clarithromycin for 8 weeks was beneficial in improving lung function, but only in those patients with positive PCR findings for *Mycoplasma pneumoniae* or *C. pneumoniae*.[171] These initial intriguing results were later expanded upon by the Asthma Clinical Research Network who treated asthma patients that were not adequately controlled on inhaled corticosteroid monotherapy with clarithromycin or placebo for 16 weeks. They found that this treatment intervention did not further improve asthma control. Although there was an improvement in airway hyperresponsiveness with clarithromycin, this benefit was not accompanied by improvements in other secondary outcomes.[172] One additional study suggested that some benefit might be possible following intervention with this antimicrobial class. Johnston et al administered the ketolide telithromycin (a semisynthetic derivative of erythromycin) for 10 days to adults with asthma seen within the first 24 hours of acute asthma episodes. This intervention resulted in significant improvements in symptom scores and lung function over the next 7 days relative to placebo.[173] However, there was no relationship between bacteriologic status and the response to telithromycin treatment, suggesting a mechanism of action unrelated to the antimicrobial properties of telithromycin.

Conclusions

Infections play a critical role in the inception and exacerbation of asthma. Viral infections are the most common cause of wheezing in infants and children. Interactions between underlying allergy and virus infections lead to the greatest risk of asthma inception and exacerbation. New data indicate that the airway microbiome may play a critical role in modulating the response to respiratory viral infections, and virus-induced alterations in airway microbial populations likely also contribute to illness severity. Treatment of virus-induced wheezing and asthma exacerbations remains challenging and novel therapies and approaches to the prevention of asthma and asthma exacerbations are needed.

Special Considerations for Infants and Young Children

RONINA A. COVAR | JOSEPH D. SPAHN

KEY POINTS

- The care of infants and small children with suspected asthma deserves special consideration because of the potential to modulate the disease process early on and alleviate the increased morbidity associated with uncontrolled asthma in this age group.
- After confounders and masqueraders of asthma have been excluded in the evaluation of children with suspected asthma, recurrent wheezing in infants and young children still comprises a heterogeneous group of conditions with different risk factors and prognoses.
- The diagnosis of asthma in infants and small children is often based on clinical grounds and complicated by the lack of clinically available tools that meet the criteria for the definition of asthma used in older children and adults such as airway inflammation, bronchial hyperresponsiveness and airflow limitation.
- Difficulties in the management of asthma include limited effective and convenient delivery devices, complete dependence on the caregivers to carry out the treatment regimen, and an inadequate selection of medications completely devoid of adverse effects.
- A partnership approach with emphasis on education, monitoring and training is key in the effective management of chronic cough or recurrent wheezing illnesses in very young children.
- Clinical trials using as needed treatment interventions have shown favorable efficacy outcomes, aimed at preventing severe exacerbations in young children with recurrent wheezing; however, trials aimed at primary prevention are still lacking.

The prevalence of asthma has increased even in the last decade but a better understanding of the mechanisms of asthma and the availability of more effective treatment may be responsible for the stabilization of the steady increase in asthma morbidity and mortality noted since the 1980s.[1] From data in the recent National Surveillance of Asthma,[2] current asthma was reported in 6% of children between 0 and 4 years old, with at least two thirds having at least one asthma attack in the previous year. The most important reason why asthma in infants and younger children deserves special consideration is the fact that healthcare utilization (ambulatory, emergency department visits and inpatient hospital admissions) for children under the age of 4 years is greater than those of other age groups.[2] In addition, younger children with asthma are also more likely to be readmitted to the hospital for acute exacerbations.[3] In a retrospective analysis of 49 asthmatic children whose mean age was 5.2 years (range 2 months to 16 years) admitted to a community-based pediatric intensive care unit over a 10-year period, as many as 75% were 6 years or younger.[4] The public health consequences of dealing with asthma in children include the number of missed work days parents/guardians incur in order to care for an acutely ill child. Some studies have hinted that pulmonary development in infancy can be adversely affected by asthma, resulting in a decrease in lung function of approximately 20% by adulthood.[5]

Relevant clinical practice guidelines developed in recent years have addressed special challenges in the management of asthma in this age group.[6,7] Many issues are unique to this age group: identifying very young children with recurrent episodes of cough and wheeze associated with viral illnesses who will develop persistent asthma later in life, presence of confounding factors or disease masqueraders, who needs controller therapy and when to start treatment, what medications to use, how best to deliver the medications and how to monitor the response to treatment.

Predicting Who is Likely to Develop Persistent Asthma

Recurrent wheezing in infants and young children comprises a heterogeneous group of conditions with different risk factors and prognoses. Viral infections (respiratory syncytial virus, rhinovirus, coronavirus, human metapneumovirus, adenovirus, parainfluenza and adenovirus) are common triggers of wheezing in preschool age children, even in those who will not develop persistent asthma later on. Factors or exposures early in life such as prematurity, fetal nutrition, duration of pregnancy, viral lower respiratory tract infections in the first years of life, cigarette smoke exposure, air pollution, postnatal nutrition, breastfeeding, family size, maternal age, socioeconomic status and allergen exposure have been implicated to varying degrees. Observational studies have also demonstrated an increased risk of asthma attributed to acetaminophen exposure during prenatal periods, infancy, childhood and even adulthood.[8–11] Genetics, atopy and prematurity appear to be the most important host risk factors in the development of asthma.

Several types of 'wheezers' in the young age group based on time of onset and outcome (transient or intermittent vs persistent) have been identified from longitudinal studies.[12,13] The investigators from the Tucson Children's Respiratory Group

https://CafePezeshki.IR

enrolled over 1,000 newborns served by a large health maintenance organization to evaluate factors involved in early-onset wheezing in relationship to persistent wheezing at 6 years of life.[13] About half of the children had at least one episode of wheezing by 6 years of age. Nearly one third of the cohort had at least one episode of wheezing by 3 years of age. Only 40% of children who wheezed early had persistent wheezing at age 6 years. Of the total group, 20% had at least one episode of wheezing associated with a respiratory tract infection during the first 3 years of life but had no wheezing at 6 years ('transient wheezers'), 14% did not wheeze during the first 3 years of life but had wheezing at 6 years ('late-onset wheezers'), and 15% had wheezing at age 3 and 6 years ('persistent wheezers'). The 'transient wheezers' were more likely to have diminished airway function and a history of maternal smoking and were less likely to be atopic. The 'late-onset wheezers' had a similar percentage of atopic children to 'persistent wheezers' and were likely to have mothers with asthma. Hence, there seems to be a similar genetic predisposition for the asthma phenotype characterizing both 'persistent' and 'late-onset wheezers'. Essentially all of the current natural history studies have found that allergic disease and evidence of pro-allergic immune development are significant risk factors for persistent asthma.

An asthma predictive index (API) using a combination of clinical and easily obtainable laboratory data to help identify children age ≤3 years with a history of wheezing at risk of developing persistent asthma was developed from the Tucson cohort.[14] Information on parental asthma diagnosis and prenatal maternal smoking status was obtained at enrollment, while the child's history of asthma and wheezing and physician-diagnosed allergic rhinitis or eczema, along with measurements of blood eosinophil count, were obtained at the follow-up visits. Two indices were used to classify the children. The stringent index required recurrent wheezing in the first 3 years plus one major (parental history of asthma or physician-diagnosed eczema) or two of three minor (eosinophilia, wheezing without colds, allergic rhinitis) risk factors, whereas the loose index required any episode of wheezing in the first 3 years plus one major or two of three minor risk factors. Children with a positive loose index were 2.6 to 5.5 times more likely to have active asthma sometime during the school years. In contrast, risk of asthma increased to 4.3 to 9.8 times when the stringent criteria were used. In addition, at least 90% of young children with a negative 'loose' or 'stringent' index will not develop 'active asthma' in the school age years.

A modified version of the API (mAPI) incorporates inhalant allergen sensitization as an additional major risk factor and food allergen sensitization as an additional minor risk factor to take into account important findings from other longitudinal natural history asthma studies.[15] In the Berlin Multicentre Allergy Study, additional risk factors for asthma and bronchial hyperreactivity at age 7 years included persistent sensitization to foods (i.e. hen's egg, cow's milk, wheat and/or soy) and perennial inhalant allergens (i.e. dust mite, cat), especially in early life.[16,17] In a prospective, randomized, controlled study of food allergen avoidance in infancy evaluating the development of atopy at age 7 years in a high-risk cohort, egg, milk and peanut allergen sensitization were risk factors for asthma.[18] With these additional considerations, an mAPI has been used in an early intervention study for young children with recurrent wheezing.[19] Henceforth, it has been adapted by the NAEPP EPR3 asthma guidelines as a requirement along with a history of four wheezing episodes per year lasting more than 24 hours upon which initiation of controller therapy should be considered.[6]

These wheezing phenotypes derived from epidemiologic and longitudinal data are more helpful for prognostication and usually have limited clinical utility when a medical provider is faced with a child with recurrent wheezing or chronic cough. Hence, other phenotypes may have greater relevance when management decisions have to be made or clinical trials are undertaken. For example, a symptom-based classification, i.e. episodic (wheeze only in discrete time periods, mostly associated with upper respiratory infection) vs multi-trigger (symptom also occurs with activity, laughing, crying or even at night outside of an acute illness), was proposed by the European Task Force in 2008.[20] However its clinical applicability is limited as children can switch between the two categories at different times, and this classification does not consider the frequency, seasonality and severity of the episodes.[21] A preschool child may have exercise-induced wheeze only when he/she is also having an acute episode or shortly after. During the late fall, winter and early spring in most areas in the northern hemisphere, preschool children who are in regular contact with other children can develop back to back viral respiratory illnesses that can each last up to 2 weeks or even longer. A child with a viral illness requiring a hospital admission is in the same classification as a child whose viral-induced wheezing illness is treated with a bronchodilator alone. Lastly, it is not known if there is a unique immunopathologic difference that can affect treatment between the two phenotypes. Therefore, clinical guidelines suggest starting treatment based on frequency of symptoms, severity of episodes and presence of risk factors.

Confounding Factors

The first practical consideration in approaching the wheezing child is to ensure that an alternative diagnosis is not present. In addition, infants and small children have a greater degree of bronchial hyperresponsiveness (BHR), which may predispose them to wheeze.[22]

The differential diagnosis of wheezing in infants and young children includes conditions such as foreign body aspiration, structural airway anomalies, congenital lobar emphysema, abnormalities of the great vessels (e.g. vascular rings), congenital heart disease, cystic fibrosis, recurrent aspiration, immunodeficiency, infections, ciliary dyskinesia and mediastinal masses. Other clinical features, such as neonatal onset of symptoms, associated failure to thrive, diarrhea or vomiting, focal lung or cardiovascular findings, clubbing, constant wheezing, and hypoxemia outside of an acute illness, suggest an alternative diagnosis and require special investigations. Additional factors in addition to age at onset of symptoms that should be taken into consideration include triggers for the respiratory symptoms and aggravating conditions such as nighttime occurrences, environmental exposure, physical exertion, feeding, positioning and infections. Clearly, making the correct diagnosis is essential because the treatment for these conditions can vary substantially. For example, in children with significant gastroesophageal reflux, improvement in asthma symptoms with concomitant reduction in asthma medication use occurred after a prokinetic agent was instituted.[23] A practical approach that can be considered for a young child in whom asthma is strongly suspected is an empiric trial of asthma controller therapy while other evaluations are still being pursued (Figure 32-1).

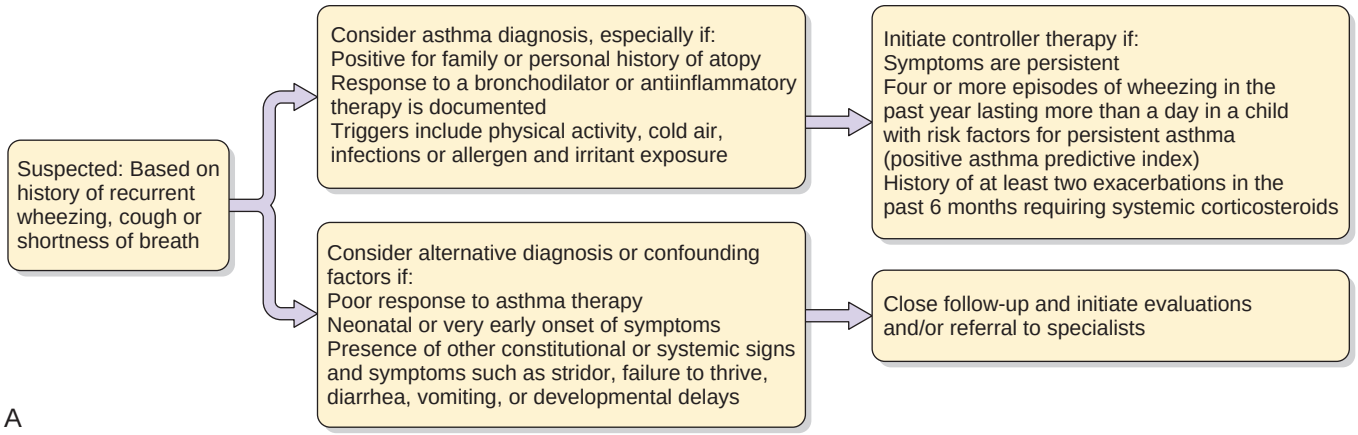

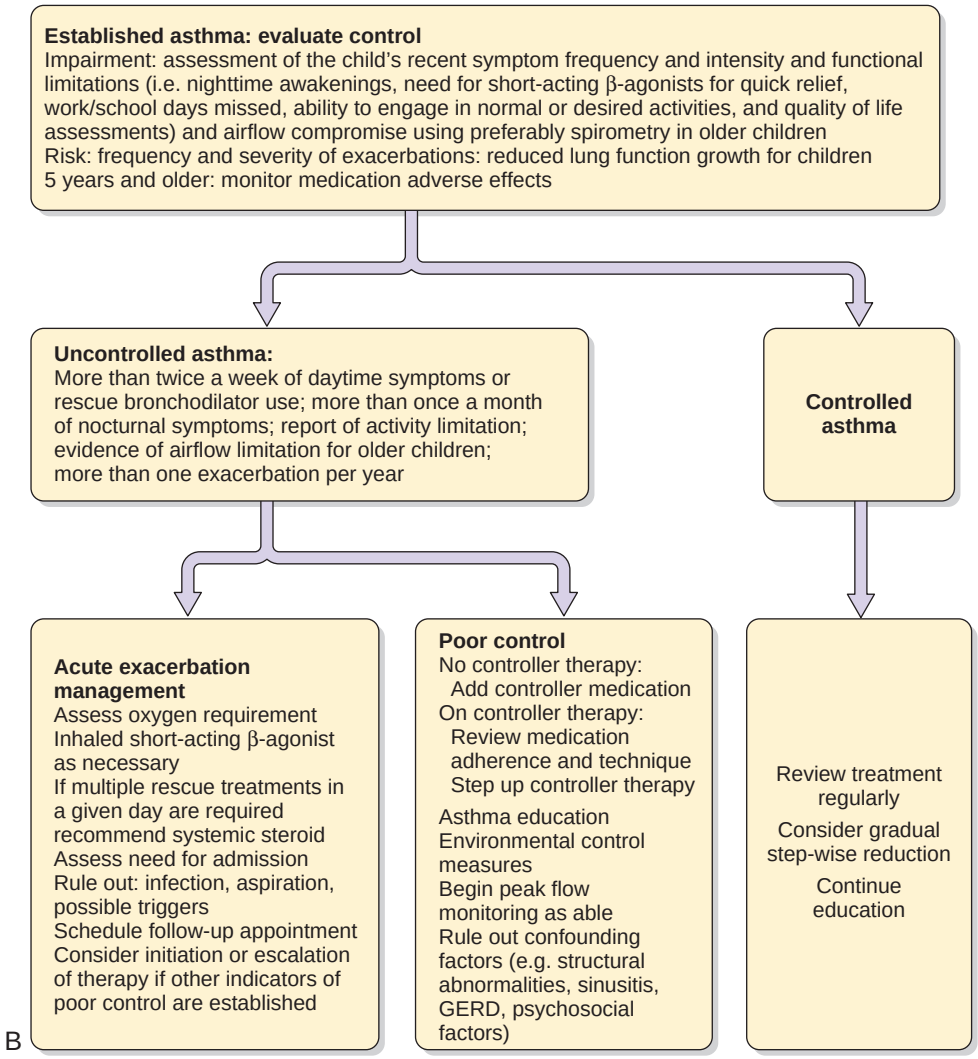

Figure 32-1 Algorithm for suggested management of infants and young children with suspected or established asthma. *GERD* – gastroesophageal reflux disease.

Diagnostic Tools to Evaluate Asthma in Young Children

Preschool children present some diagnostic challenges inherent to their young age such that a confirmation of a diagnosis can be difficult to make. Infants and young children are too young to reliably perform objective measures of disease activity. Furthermore, they are unable to provide their own history so clinicians must depend on the parents'/caregivers' report. Werk et al sought to determine the factors primary care pediatricians believe are important in establishing an initial diagnosis of asthma.[24] Questionnaires on asthma diagnosis consisting of 20

https://CafePezeshki.IR

factors obtained from the National Heart, Lung, and Blood Institute (NHLBI) National Asthma Education Prevention Program (NAEPP) Expert Panel Report 2 (EPR2) guidelines[25] and an expert local panel of subspecialists were sent to 862 active members of the Massachusetts American Academy of Pediatrics. Over 80% of the respondents rated five factors as necessary or important in establishing the diagnosis of asthma: recurrent wheezing, symptomatic improvement following bronchodilator use, presence of recurrent cough, exclusion of other diagnoses, and suggestive peak expiratory flow rate findings. Of note, 27% of the respondents indicated that a child had to be older than 2 years; 18% indicated that fever must be absent during an exacerbation.

The diagnosis of asthma in young children is based largely on clinical judgment and an assessment of symptoms and physical findings. The following characteristics are suggestive of asthma: wheezing or recurrent or persistent nonproductive cough or difficult breathing that may be worse at night or occurring with exercise, laughing, crying or exposure to tobacco smoke in the absence of a respiratory infection; reduced activity or interest in running or playing compared to other children with easy fatigability during walks; presence of other personal allergic diseases (atopic dermatitis or allergic rhinitis) or family history of asthma in first degree relatives; and response to either therapeutic trial of a corticosteroid or a short-acting bronchodilator as needed.[7] Because lung function measurements in infants and small children are difficult to obtain, a trial of treatment is often a practical way to make a diagnosis of asthma in young children.

At present, for adults and older children, easily performed lung function measures and noninvasive markers of airway inflammation can be used to make the diagnosis of asthma, monitor asthma control or guide therapeutic decisions. The following section will highlight available procedures and techniques with the potential to measure lung function and airway inflammation in the young child.

FORCED OSCILLOMETRY

Forced oscillometry is a pulmonary function technique that measures respiratory system resistance (Rrs) and reactance (Xrs) at several frequencies. It involves the application of sine waves through a loudspeaker to the airway opening via a mouthpiece, through which the subject breathes normally for short periods of time. Measurements are carried out during tidal breathing over a 30-second interval with at least three efforts recorded. Given its relative ease of use, it is a reproducible and suitable measure of lung function in younger children.[26] Marotta et al performed pre- and post-bronchodilator spirometry and forced oscillometry in young children at risk for asthma and found no difference in baseline FEV_1 or resistance between children with asthma versus those without; the degree of bronchodilator response differentiated the two groups.[27] Some investigators believe that reactance at low frequencies is a reflection of peripheral airways function.[28]

Using three different lung function measures, Nielsen and Bisgaard evaluated the bronchodilator response of 92 children 2 to 5 years old, 55 of whom had asthma.[29] Children with asthma had diminished lung function compared to nonasthmatic children using any of the following measures: specific airway resistance (sRaw) utilizing whole body plethysmography, or respiratory resistance utilizing either an interrupter technique (Rint) or impulse oscillation technique at 5 Hz (Rrs5). Both asthmatic and nonasthmatic children responded to terbutaline, although children with asthma reversed to a greater extent than the nonasthmatic children. The investigators found that sRaw utilizing body plethysmography best distinguished asthmatics from nonasthmatics based on bronchodilator response. They concluded that assessment of bronchodilator responsiveness using sRaw may help define asthma in young children.

MEASUREMENT OF BRONCHIAL REACTIVITY

As with measurements of airflow limitation, procedures to assess BHR in infants and young children have distinctive challenges. Measurement of BHR using cold air (4 minutes of isocapneic hyperventilation) or dry air (6 minutes of eucapneic hyperventilation) challenge with sRaw as an outcome may be useful, practical alternatives to auscultatory pharmacologic or exercise bronchoprovocation challenges which are more difficult to standardize in young children.[30] Using a dry air challenge, magnitude of response was associated with a wheeze phenotype. Persistent wheezers had a larger increase in sRaw following eucapneic hyperventilation challenge compared with never wheezers, but no significant differences between never wheezers, late-onset or transient wheezers were seen.[31]

MEASURES OF INFLAMMATION

Exhaled nitric oxide (eNO) levels are elevated in patients with asthma[32] and correlate positively with eosinophilic airway inflammation.[33] In addition, they rise during acute exacerbations[34] and fall following oral or inhaled corticosteroid (ICS) therapy.[35,36]

Online[37] and offline[38] eNO measurements can be reliably obtained in very young children. Reference values using an offline tidal breathing method in healthy preschool children have recently been published.[39] Higher mean (±SEM) eNO concentrations (14.1 ± 1.8 ppb) were found in infants and young children (age 7 to 33 months) presenting with an acute wheeze and a history of at least three prior wheezing episodes compared to first-time viral wheezers (age 9 to 14 months) (8.3 ± 1.3 ppb, $P < .05$) and healthy matched controls (5.6 ± 0.5 ppb, $P < .001$). No differences in eNO measurements were seen between the last two groups. In addition, eNO levels were reduced by 52% after steroid therapy to a level comparable to those of the healthy controls and first-time wheezers.[38]

Unlike sophisticated measures of lung function and BHR, eNO can be easily and quickly measured. An elevated eNO in preschool age children has been shown to predict asthma in school age.[40]

In one of the few studies designed specifically to address the role of eosinophil cationic protein (ECP) in young children with recurrent wheezing, Carlsen et al[41] found a strong correlation between serum ECP and response to albuterol/salbutamol using the tidal flow volume loop technique in children 0 to 2 years of age. These investigators suggested that ECP may be measuring airway inflammation and may have some prognostic value in diagnosing asthma in infants and toddlers with recurrent wheezing. The major drawback for ECP is its lack of sensitivity and blood sample collection.

Although direct investigation of the airway using bronchoscopy and biopsy is the gold standard for establishing airway

https://CafePezeshki.IR

inflammation, it has limited clinical applicability, except when other pulmonary abnormalities are being considered. Understanding the underlying pathophysiology of the disease in children is critical in order to identify processes that can be impacted by interventions. Thickening of the bronchial epithelial reticular basement membrane (RBM) and eosinophilic airway inflammation are characteristic pathologic features of asthma found in children as young as 3 years old, but typically occurring between the ages of 6 to 16 years.[42] It is unclear when airway thickening begins since routine biopsy studies are not performed in infants.[43] Studies on bronchoalveolar lavages obtained from wheezing infants and preschool children revealed an overall increase in airway inflammation, though it is rarely eosinophilic. In one study in which bronchial biopsies were performed on symptomatic infants, there was no consistent relationship between RBM thickening and inflammation, clinical symptoms and variable airflow obstruction,[44] similar to findings from biopsy studies in older school aged children with asthma.[45] The use of sensitive, noninvasive physiologic and biologic markers is very limited in the clinical evaluation of young children with asthma and recurrent wheezing.

Management

The goals of asthma management are not different between older children and preschool aged children – to attain good symptom control and allow normal activity levels, reduce exacerbations, optimize lung function and minimize medication side-effects. Available asthma guidelines such as the National Asthma Education Prevention Program Expert Panel Report 3 (NAEPP EPR3)[6] and the Global Initiative for Asthma (GINA) update 2014 report[7] acknowledge the special challenges unique to the management of asthma in preschool children; hence a specific approach and treatment recommendations for preschool children with asthma are presented. Both sets of guidelines emphasize maintenance of asthma control as the goal for asthma management and use of ICS as the preferred therapy for persistent asthma. A comprehensive management is outlined in several components and/or sections and generally includes: establishment of patient/doctor partnership and provision of education to enhance the patient's/family's knowledge and skills for self-management (appropriate use of devices and medications); identification and management of risk and precipitating factors and co-morbid conditions that may worsen asthma; adequate assessment and monitoring of disease activity (including symptom monitoring by parent/caregiver); appropriate selection of medications to address the patient's needs; and management of asthma exacerbations (with provision of a written asthma action plan). The details of each of these elements are discussed in Chapter 29.

Key differences between the two clinical guidelines are apparent. The approach implemented by the NAEPP EPR3 on starting controller therapy is based on the concept of asthma severity, which is the intrinsic intensity of disease and applicable for patients not receiving controller therapy. The guidelines have a separate set of criteria for various age groups and Table 32-1 summarizes the classification of asthma severity for children 0 to 4 years old. The classification of asthma severity is contingent upon the domains of impairment and risk and the level of severity is based on the most severe impairment or risk component. Impairment includes an assessment of the child's recent symptom frequency (daytime and nighttime), need for short-acting β_2-agonists for quick relief, and ability to engage in normal or desired activities. Risk refers to an evaluation of the child's likelihood of developing asthma exacerbations. Of note, in the absence of frequent symptoms, 'persistent' asthma should be considered and therefore long-term controller therapy initiated for infants or children who have risk factors for asthma (i.e. using the mAPI: any of parental history of asthma, physician-diagnosed atopic dermatitis, or sensitization to aeroallergens OR two of the following: wheezing apart from colds, sensitization to foods, or peripheral eosinophilia) *AND* four or more episodes of wheezing over the past year that lasted longer than 1 day and affected sleep OR two or more exacerbations within 6 months requiring systemic corticosteroids.

In the most recent iteration of the GINA global strategy,[7] much emphasis is devoted to a 'shared-care approach' using an effective patient-healthcare provider partnership that has been shown to improve outcomes, and the process of 'assess, adjust treatment, and review response'. Eliciting specific goals of treatment from caregivers and providing education are key elements in this partnership. The process of assessing (diagnosis, symptom control, risk factors, inhaler technique, adherence and parent preference), adjusting treatment (medications, nonpharmacological strategies and treatment of modifiable risk factors), and reviewing response (medication effectiveness and side-effects) is recommended on an ongoing basis.

CONTROLLER THERAPY FOR SMALL CHILDREN WITH PERSISTENT ASTHMA

Based on the NAEPP EPR3 guidelines,[6] upon establishing a diagnosis of asthma in young children, initiation of controller therapy is warranted for persistent asthma. The most important determinant of dosing is the clinician's judgment of the patient's presenting degree of severity. Initiation of long-term controller therapy should also be considered for infants and younger children who have risk factors for asthma (i.e. modified asthma predictive index: parental history of asthma, physician-diagnosed atopic dermatitis or sensitization to aeroallergens or two of the following: wheezing apart from colds, sensitization to foods or peripheral eosinophilia) *and* four or more episodes of wheezing over the past year that lasted longer than 1 day and affected sleep or two or more exacerbations in 6 months requiring systemic corticosteroids.

Medication dose adjustment is appropriate based on levels of asthma control, although dose-response relationships are not well studied. For preschool children already on a controller medication, management is tailored based on the child's level of control. As with the classification of asthma severity, assessment of asthma control is based on both impairment and risk (Table 32-2). The three levels of asthma control are 'well controlled', 'not well controlled' and 'very poorly controlled'. Children whose asthma is not well controlled have daytime symptoms or need for rescue albuterol >2 days/week, nighttime symptoms more than once a month but not more than once a week, 'some limitation' with normal activity, had two to three exacerbations in the past year, and an FEV_1 of 60–80% of predicted (or FEV_1/FVC ratio 75–80%) for children 5 years of age or older. Children with very poorly controlled asthma have symptoms 'throughout the day', nocturnal symptoms more than once weekly, need for rescue albuterol several times per day, 'extreme limitations' with normal activity, had ≥3 exacerbations in the past year, and for children at least aged 5 years, an

https://CafePezeshki.IR

TABLE 32-1 Classifying Asthma Severity and Initiating Treatment in Children Aged 0 to 4 Years: Assessing Severity and Initiating Treatment for Patients Who are not Currently Taking Long-term Control Medications

Components of Severity		CLASSIFICATION OF ASTHMA SEVERITY (0–4 YR)			
			PERSISTENT		
		Intermittent	Mild	Moderate	Severe
Impairment	Daytime symptoms	≤2 d/wk	>2 d/wk but not daily	Daily	Throughout the day
	Nighttime awakenings	0	1–2×/mo	3–4×/mo	>1×/wk
	SABA use for symptoms (not EIB pretreatment	≤2 d/wk	>2 d/wk but not daily and not more than once on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Risk	Exacerbations requiring systemic corticosteroids	0–1/yr	≥2 exacerbations in 6 months requiring systemic corticosteroids, or ≥4 wheezing episodes/1yr lasting >1 day *and* risk factors for persistent asthma		
		Consider severity and interval since last exacerbation Frequency and severity may fluctuate over time Exacerbations of any severity may occur in patients in any severity category			
Recommended step for initiating therapy		Step 1	Step 2	Step 3 and consider short course of oral systemic corticosteroids	
		In 2–6 weeks, depending on severity, evaluate level of asthma control that is achieved. If no clear benefit is observed within 4–6 weeks, consider adjusting therapy or alternative diagnoses			

National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR 3): Guidelines for the Diagnosis and Management of Asthma – Summary Report 2007. J Allergy Clin Immunol 2007;120(Suppl):S94–138. Available at: http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- Level of severity is determined by both impairment and risk. Assess impairment domain by patient's/caregiver's recall of previous 2–4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether a patient's asthma is better or worse since the last visit. Assign severity to the most severe category in which any feature occurs.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma severity. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past 6 months, or ≥4 wheezing episodes in the past year, and who have risk factors for persistent asthma may be considered the same as patients who have persistent asthma, even in the absence of impairment levels consistent with persistent asthma.

EIB – Exercise-induced bronchospasm; *SABA* – short-acting β_2-agonist use.

FEV_1 of <60% of predicted or FEV_1/FVC ratio <75%. Using a validated questionnaire to monitor quality of life for older children is recommended and perhaps the TRACK questionnaire[42] discussed in a subsequent section may now be applied in younger children.

The NAEPP EPR3 provides an expanded stepwise treatment approach (Figure 32-2) even for young children. The choice of initial therapy is based on assessment of asthma severity. For patients who are already on controller therapy, modification of treatment is based on assessment of asthma control and responsiveness to therapy. A major objective of this approach is to identify and treat all 'persistent' and uncontrolled asthma with antiinflammatory controller medication. Management of intermittent asthma is short-acting inhaled β-agonist *as needed* for symptoms and for pre-treatment for those with exercise-induced bronchospasm (Step 1). The type(s) and amount(s) of daily controller medications to be used are determined by the asthma severity and control rating. Even for young children, the preferred treatment for 'persistent asthma' is daily ICS therapy, with or without an additional medication. Alternative medications for Step 2 include a leukotriene receptor antagonist (montelukast) or a nonsteroidal antiinflammatory agent (cromolyn). For young children (≤4 years of age) with moderate and severe persistent asthma, medium-dose ICS monotherapy is recommended and combination therapy of medium-dose ICS plus either a long-acting β-agonist (LABA) or montelukast is to be initiated only as a Step 4 treatment for uncontrolled asthma. Children with severe persistent asthma (Treatment Steps 5 and 6) should receive high-dose ICS, a LABA or montelukast, and an oral corticosteroid, if required. A rescue course of systemic corticosteroids may be necessary at any step.

The 'step-up, step-down' approach initially introduced in the earlier versions of the NAEPP guidelines[21] and slightly modified in the current iteration[6] is discussed in further detail in Chapter 29. The NAEPP guidelines emphasize initiating higher-level controller therapy at the outset to establish prompt control, with measures to 'step down' therapy once good asthma control is achieved. Initially, airflow limitation and the pathology of asthma may limit the delivery and efficacy of ICS such that stepping up to higher doses and/or combination therapy may be needed to gain asthma control. Asthma therapy can be stepped down after good asthma control has been achieved and ICS has had time to achieve optimal efficacy, by determining the least number or dose of daily controller medications that can maintain good control, thereby reducing the potential for medication adverse effects. If step-up therapy is being considered at any point, it is important to check delivery device technique and adherence, implement environmental control measures and identify and treat co-morbid conditions.

The GINA 2014 global strategy also now offers a stepwise approach in the long-term management of asthma in very young children.[7] However, if control is still inadequate despite 3 months of controller therapy, the following should be addressed before any step-up treatment is offered: that any

https://CafePezeshki.IR

TABLE 32-2 Assessing Asthma Control and Adjusting Therapy in Children Aged 0 to 4 Years

Components of Control		CLASSIFICATION OF ASTHMA CONTROL (0–4 YR)		
		Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment	Daytime symptoms	≤2 d/wk but not more than once on each day	>2 d/wk	Throughout the day
	Nighttime awakenings	≤1×/mo	>1×/mo	>1×/wk
	SABA use for symptoms (not EIB pretreatment)	≤2 d/wk	>2 d/wk	Several times per day
	Interference or limitations with normal activity	None	Some limitation	Extremely limited
Risk	Exacerbations requiring oral systemic corticosteroids	0–1/yr	2–3/yr	>3 yr
	Treatment-related adverse effects	Medication side-effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk		
Recommended action for treatment per NAEPP guidelines		Maintain current treatment Regular follow-up every 1–6 months Consider step down if well controlled for at least 3 months	Step up (1 step) and reevaluate in 2–6 weeks If no clear benefit in 4–6 weeks, consider alternative diagnoses or adjusting therapy For side-effects, consider alternative treatment options	Consider short course of oral systemic corticosteroids Step up (1–2 steps), and reevaluate in 2 weeks If no clear benefit in 4–6 weeks, consider alternative diagnoses or adjusting therapy For side-effects, consider alternative treatment options

National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR 3): Guidelines for the Diagnosis and Management of Asthma – Summary Report 2007. Available at: http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- The level of control is based on the most severe impairment or risk category. Assess impairment domain by caregiver's recall of previous 2 to 4 weeks. Symptom assessment for longer periods should reflect a global assessment such as inquiring whether the patient's asthma is better or worse since the last visit.
- At present, there are inadequate data to correspond frequencies of exacerbations with different levels of asthma control. In general, more frequent and intense exacerbations (e.g. requiring urgent, unscheduled care, hospitalization or ICU admission) indicate poorer disease control. For treatment purposes, patients who had ≥2 exacerbations requiring oral systemic corticosteroids in the past year may be considered the same as patients who have not-well-controlled asthma, even in the absence of impairment levels consistent with not-well-controlled asthma.
- Before step-up therapy:
  - Review adherence to medications, inhaler technique and environmental control.
  - If alternative treatment option was used in a step, discontinue it and use preferred treatment for that step.

other possible alternative or confounding condition is entertained; assessment of inhaler technique; adherence is acceptable; and exposure to allergens or tobacco smoke is avoided. The criteria for 'well controlled', 'partly controlled' and 'uncontrolled' asthma according to the GINA global strategy are summarized in Table 32-3, based on a 4-week recall. 'Well-controlled' asthma is characterized by at most daytime symptoms once a week, rescue/reliever treatment less than 2 times a week, absence of any activity limitation due to asthma, and no nocturnal cough or awakenings. 'Partly controlled' asthma has one to two of the following: ≥2 daytime symptoms a week, ≥2 rescue bronchodilator use, any nocturnal cough/awakenings, or limitations of activities. Lastly, 'uncontrolled' asthma is defined as presence of three or all features characteristic of 'partly controlled' asthma present in any week or exacerbation occurring once in any week.

The stepwise approach in the GINA 2014 global strategy has important differences from the NAEPP EPR3[6,7] (Table 32-4). For Step 1 which recommends as needed short-acting β-agonist as the preferred controller choice for children with infrequent viral wheezing, with few or no interval symptoms, intermittent inhaled corticosteroid therapy is an alternative option if short-acting β-agonist treatment is not enough.[46,47] Intermittent high-dose ICS therapy given at the onset of a respiratory illness is further demonstrated to be as beneficial as maintenance therapy with ICS in children with recurrent wheezing and with risk factors for persistent asthma.[48] Because it has the potential to cause side-effects if given quite often during the year at higher doses, this should be considered for families who are able to use this intervention responsibly. Step 2 treatment is recommended for young children with symptom pattern consistent with asthma and not well controlled *or* with 3 or more exacerbations per year *or* with frequent wheezing episodes occurring every 6 to 8 weeks. Similar to the NAEPP EPR3 recommendation are the preferred medication using daily low-dose ICS (for at least 3 months trial) and the alternative option using a leukotriene receptor antagonist, but GINA 2014 global strategy now also includes intermittent ICS for Step 2 as an alternate option. The National Institute of Health sponsored AsthmaNet is currently undertaking a clinical trial comparing these three treatments in young children with persistent asthma. Preferred Step 3 treatment is double 'low-dose' ICS, indicated for children with established asthma not well controlled on low-dose ICS. The alternative option is low-dose ICS with a leukotriene receptor antagonist. The highest step (Step 4) basically proposes a referral to a specialist for expert advice. Additional options

https://CafePezeshki.IR

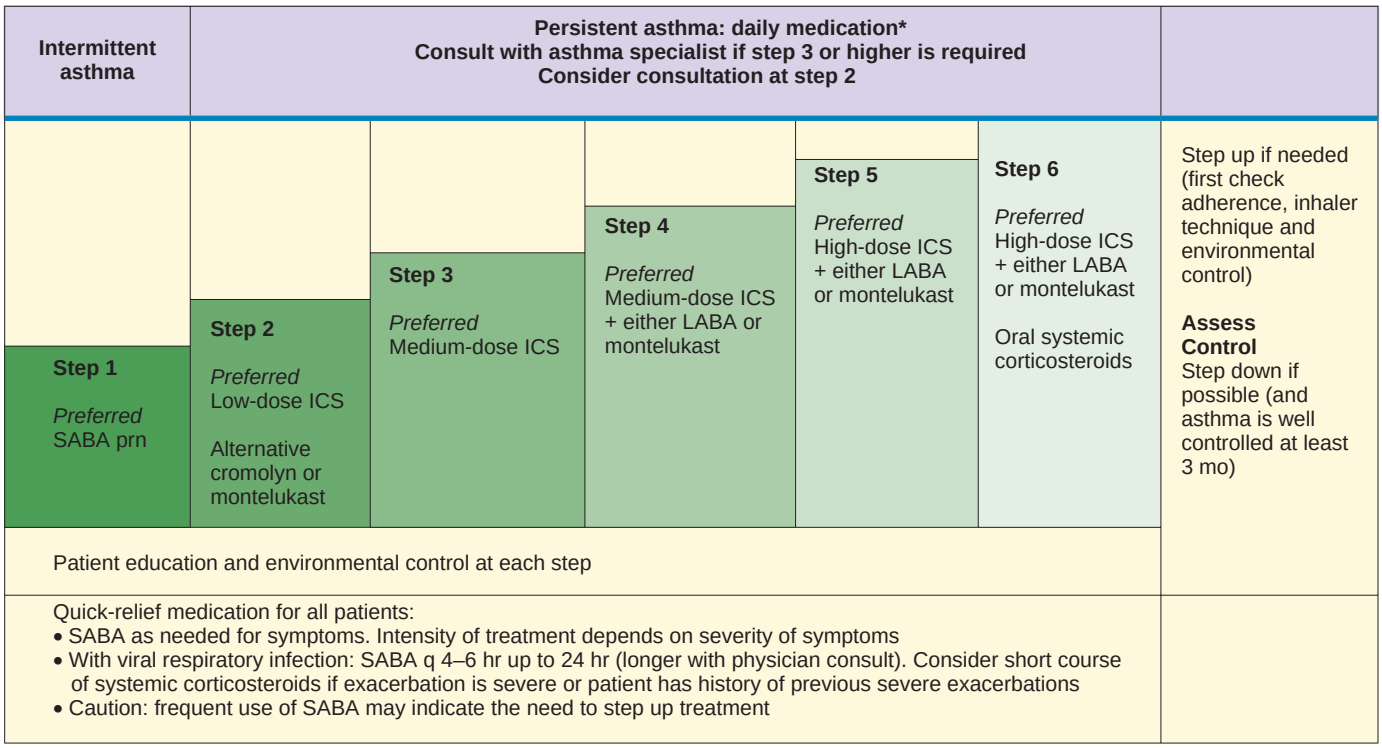

Figure 32-2 Stepwise approach for managing asthma in children aged 0 to 4 years.
*Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.
Notes:
- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- If clear benefit is not observed within 4 to 6 weeks and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children aged 0 to 4 years are limited. Step 2 therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children. The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.

ICS – Inhaled corticosteroid; *LABA* – inhaled long-acting β_2-agonist; *prn* – as needed; *SABA* – inhaled short-acting β_2-agonist. *National Asthma Education and Prevention Program: Expert Panel Report 3 (EPR 3): Guidelines for the Diagnosis and Management of Asthma – Summary Report 2007. J Allergy Clin Immunol 2007;120(Suppl):S94–138. (Available at:* http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm.*)*

include adding a leukotriene receptor antagonist, theophylline or a low-dose oral corticosteroid (for a few weeks only) until control improves, increasing the dose or frequency of ICS delivery or adding intermittent ICS to regular daily ICS, particularly if exacerbations are the main concern. Through all these, the process of assessing, adjusting treatment and reviewing response should be actively enforced. Regular assessment of symptom control and risk of exacerbations, inhaler technique, adherence and parents' understanding and preference should be undertaken. The need for controller therapy should be evaluated and treatment should be adjusted as symptoms in this age group may remit at certain times of the year or even over time. Once therapy is discontinued, a close follow-up within 3 to 6 weeks is ideal, and caregivers should be provided with a written asthma action plan that incorporates early warning signs of worsening asthma control and what to do or who to contact when the child's condition deteriorates.

MONITORING DISEASE ACTIVITY AND RESPONSE

Monitoring disease activity and response to therapy can be assessed using validated instruments. The Asthma Control Test (ACT) for children 12 years of age and older, and the Childhood ACT (cACT) for children 4 to 11 years of age are examples of self-administered questionnaires that have been developed and validated with the objective of addressing multiple domains of asthma control such as frequency of daytime and nocturnal symptoms, use of reliever medications, functional status, missed school or work and so on.[49,50] Recently, a five-item caregiver-administered instrument, the Test for Respiratory and Asthma Control in Kids (TRACK), is the first of its kind to have been validated as a tool to assess asthma control in young children with recurrent wheezing or respiratory symptoms consistent with asthma.[51] This questionnaire includes an assessment of both impairment and risk reflected in the NAEPP EPR3 asthma management guidelines.[6] The items include four impairment questions (three on symptom burden and activity limitations over a 4-week period and one on rescue medication use over a 3-month period) and one risk question on oral corticosteroid use over a 12-month period. Each item has five descriptive ordinal responses which can be scored over a 5-point scale (0, 5, 10, 15, and 20; total score range 0–100). The screening ability of the entire scale showed areas under the receiver operating characteristic (ROC) curve of 0.88 and 0.82, respectively, in the development and validation samples, with a

https://CafePezeshki.IR

TABLE 32-3 GINA Assessment of Asthma Control in Children 5 Years and Younger

A. Level of Symptom Control

	In the past 4 weeks, has the child had:	Yes	No
	Daytime asthma symptoms for more than a few minutes?		
	Any night waking or coughing due to asthma?		
	Reliever medication needed more than once a week (excludes reliever taken before exercise)?		
	Any activity limitation due to asthma? (Runs/plays less than other children, tires easily during walks/playing?)		
Controlled (none of the above)			
Partly controlled (1–2 of these)			
Uncontrolled (3–4 of these)			

B. Future Risk for Poor Asthma Outcomes

Risk factors for asthma exacerbations
- Uncontrolled asthma symptoms
- One or more severe exacerbations in previous year
- The start of the child's usual 'flare-up' season (especially if autumn or fall)
- Exposures: tobacco smoke; indoor or outdoor air pollution; indoor allergens (e.g. house dust mite, cockroach, pets, mold), especially in combination with viral infection
- Major psychological or socioeconomic problems for child or family
- Poor adherence with controller medication, or incorrect inhaler technique

Risk factors for fixed airflow limitation
- Severe asthma with several hospitalizations
- History of bronchiolitis

Risk factors for medication side-effects
- Systemic: frequent courses of oral corticosteroids; high-dose and/or potent inhaled corticosteroids
- Local: moderate/high-dose or potent inhaled corticosteroids; incorrect inhaler technique; failure to protect skin or eyes when using inhaled corticosteroids by nebulizer or spacer with facemask

Adapted from the Global strategy for asthma management and prevention 2014. Available at: http://www.ginasthma.org.

TABLE 32-4 Stepwise Approach to Long-Term Management of Asthma in Children 5 Years and Younger (Global Initiative for Asthma 2014)

	Step 1	Step 2	Step 3	Step 4
PREFERRED CONTROLLER CHOICE		Daily low-dose ICS	Double 'low-dose' ICS	Continue controller and refer for specialist assessment
Other controller options		LTRA Intermittent ICS	Low-dose ICS + LTRA	Add LTRA Increase ICS frequency Add intermittent ICS
RELIEVER	As needed short-acting β_2-agonist			
CONSIDER THIS STEP FOR CHILDREN WITH	Infrequent viral wheezing and no or few interval symptoms	Symptom pattern consistent with asthma and asthma symptoms not well controlled, or ≥3 exacerbations per year Symptom pattern not consistent with asthma but wheezing episodes occur frequently, e.g. every 6–8 weeks Give diagnostic trial for 3 months	Asthma diagnosis, and not well controlled on low-dose ICS First check diagnosis, inhaler skills, adherence, exposures	Not well controlled on double ICS
KEY ISSUES	ALL CHILDREN • Assess symptom control, future risk, co-morbidities • Self-management: education, inhaler skills, written asthma action plan, adherence • Regular review: assess response, adverse events, establish minimal effective treatment • (Where relevant): environmental control for smoke, allergens, indoor/outdoor air pollution			

Adapted from the Global strategy for asthma management and prevention 2014. Available at: http://www.ginasthma.org.
ICS – Inhaled corticosteroid; *LTRA* – leukotriene receptor antagonist.

https://CafePezeshki.IR

diagnostic accuracy of 81% and 78%, respectively. Based on the highest area under the ROC curve, a score of less than 80 provided the best cut-off between sensitivity and specificity for uncontrolled asthma for this group. The pediatric version of the Asthma Control Test (cACT) has been validated for children as young as 4 years of age.

The GINA 2014 global strategy assessment of asthma control is discussed in an earlier section and summarized in Table 32-3.

Inhaled Corticosteroids

ICS are the preferred controller therapy for persistent asthma or asthma that is not controlled. Although there are six ICS available, nebulized budesonide is the only US Federal Drug Administration (FDA)-approved ICS for children less than 4 years of age. The initial studies with nebulized budesonide in young children with moderate to severe persistent asthma found it to be superior to placebo in improving symptoms, decreasing exacerbations, reducing chronic oral prednisone use or improving overall asthma control.[52,53]

Studies have also evaluated the efficacy and safety of nebulized budesonide in children with mild to moderate persistent asthma.[54–56] The efficacy of nebulized budesonide over placebo was consistently demonstrated with improvement in symptom scores, reduction in rescue medication use and improvement in morning peak expiratory flow rates in patients who could adequately perform the procedure. Improvement in symptom scores occurred as early as 2 weeks after starting budesonide.[56] Twice-daily dosing of 0.5 mg appeared to be somewhat more effective than 1 mg administered once daily. The investigators suggested that a dose of 0.25 mg/day may be sufficient for mild asthma, whereas subjects with moderate asthma should be treated with 0.5 to 1 mg/day and those with severe asthma dependent on oral steroids should be treated with 1–2 mg/day. No significant differences in basal cortisol levels or ACTH-stimulated cortisol levels were found between any of the active treatment groups and placebo.

Pharmacokinetics of Nebulized Budesonide in Small Children. Little is known regarding the amount of drug delivered, by any inhaled device and with any drug, to infants and young children with asthma. ICS have the potential for adverse effects, so it is important to deliver the smallest amount of drug required for response. Agertoft et al evaluated the systemic availability and pharmacokinetics of nebulized budesonide in a group of preschool children (mean age 4.7 years) with chronic asthma.[57] Ten children underwent pharmacokinetic studies of both intravenously administered (125 µg) and inhaled budesonide (1 mg delivered by nebulization). The amount of nebulized budesonide delivered to the patient was calculated by subtracting the amount of drug remaining in the nebulizer, the amount emitted into the ambient air, and the amount found in the mouth after rinsing from the initial amount of budesonide in the nebulizer (the nominal dose). The mean dose to the subject was found to be 23% of the nominal dose (231 µg), while the systemic availability was only 6.1% of the nominal dose, or 61 µg. The clearance of budesonide was calculated to be 0.54 L/min with a $t_{1/2}$ of 2.3 hours, and V_{dss} of 55 L. The systemic availability in these small children was approximately half that seen in adults. In addition, the clearance of budesonide in these children was twice that of adults.

Recommended doses of different ICS formulations for children 5 years and younger according to low, medium and high doses in the NAEPP EPR3 and low-dose formulations in the GINA 2014 global strategy are shown in Table 32-5.[6,7]

What type of patient will respond favorably to ICS in this age group is an important question that has yet to be answered. A study by Roorda et al using data from two large placebo-controlled studies evaluated the clinical features of preschool children likely to respond to fluticasone administered via a

pressurized metered dose inhaler (pMDI) with holding chamber and facemask.[58] The investigators identified two clinical features that predicted a positive response to ICS therapy – frequent symptoms (≥3 days/week) and a family history of asthma. The presence of eczema and the number of previous acute exacerbations were not associated with response to fluticasone. Eczema predisposes a child with recurrent wheezing to subsequent asthma,[14] but it does not appear to predict response to ICS therapy. It should be noted that a lack of response over a short course of treatment (12 weeks) does not necessarily mean that a response would not be seen over a much longer period of time (months to years). An NHLBI-sponsored AsthmaNet clinical trial which will be completed in 2015 is evaluating predictors of response to different interventions, specifically daily vs intermitting ICS therapy vs leukotriene receptor antagonist, in preschool aged children with persistent asthma.[59]

The clinical efficacy and safety of intermittent ICS or systemic corticosteroid for young children with associated upper respiratory infection or viral induced wheeze remain controversial. A 2009 study which evaluated 'as needed' high-dose fluticasone propionate (750 μg twice daily) given at the onset of an upper respiratory tract illness found lower rescue oral corticosteroid use in those on active treatment compared to placebo (8% vs 18%, respectively); however this was accompanied by a statistically significant difference in height and weight gain.[46] In another 2009 study, oral prednisolone was found not to be superior to placebo with respect to duration of hospitalization, clinician and parent symptom severity assessment, and hospital readmission for preschool children presenting to a hospital with viral-induced mild to moderate wheezing.[60] A 2011study which evaluated daily vs intermittent high-dose ICS therapy given at the onset of a respiratory illness in preschool aged children with recurrent wheezing and atopic risk factors found no difference between the two treatments with respect to prevention of severe exacerbations.[48]

ICS and Growth in Small Children. Few published studies have evaluated the effects of ICS on the linear growth of preschool children. Reid et al, in an open-label study, measured linear growth velocity in 40 children (mean age 1.4 years) before and during treatment with nebulized budesonide.[61] All of the children had 'troublesome' asthma despite treatment with an ICS administered with a pMDI with spacer and facemask or nebulized cromolyn before entry into the study. They were then administered 1 to 4 mg/day of nebulized budesonide depending on their level of asthma severity. The median intervals of time for linear growth determinations during the run-in period and nebulized budesonide treatments were 6 months and 1 year, respectively. The height standard deviation scores (SDSs) for the group during the run-in period were −0.21, at baseline −0.46, and after at least 6 months of nebulized budesonide −0.17. Note that an SDS of less than 0 denotes impaired growth velocity. Thus the subjects were growing at less than an impaired rate before nebulized budesonide therapy, and the institution of nebulized budesonide did not result in further growth suppression. In fact, there was a trend toward improved growth velocity while on nebulized budesonide.

Skoner et al[62] evaluated the growth of children enrolled in 52-week open-label extension studies of the three efficacy studies of budesonide.[54–56] The dose of budesonide was either 0.5 mg once or twice daily with a taper to the lowest tolerated dose, and conventional asthma therapy consisted of any available therapy including ICS in two of the studies; in total, 670 children participated. The investigators found a modest impairment in growth in only one of the three extension studies. The extension study where a decline in growth was noted consisted primarily of young children with milder asthma who had not been on ICS before entry into the initial study. In contrast, the two extension studies that did not find growth impairment consisted of children with more severe disease and had allowed for ICS use as part of the conventional asthma therapy algorithm. The Skoner study suggests that modest growth suppression can occur in young children receiving nebulized budesonide who have not required ICS therapy in the past and that children with milder asthma may be at greater risk for growth suppression secondary to increased intrapulmonary deposition. Alternatively, the findings may be attributable to the fact that over twice as many children randomized to the conventional asthma therapy arm withdrew from the study because of poor asthma control.

The PEAK and IFWIN studies which used ICS via MDI with a holding chamber and mask have also provided important findings on the adverse effects of long-term ICS on growth in preschool children at risk for persistent asthma.[19,63,64] It is still uncertain if there is a potential for catch up or if the effects in very young children are cumulative. A follow-up study of PEAK participants 2 years after the clinical trial was completed showed no difference in growth between children who were on active ICS therapy compared to those who were randomized to placebo.[64] However, in a post hoc analysis, lower growth velocity was found among participants who were younger and weighed less, probably due to a relatively greater drug exposure. For young children with poor asthma control, the disease itself can negatively impact growth. The growth of 58 children (mean age 3.5 years for males, 4.4 years for females) with asthma was followed over a 5-year period.[65] Each child's asthma was classified as being in good, moderate or poor control according to asthma symptoms during a 2-year observational period before the institution of ICS therapy. The group as a whole had diminished growth velocity to start the study, with a mean height velocity standard deviation (HVSD) score of −0.51. Children whose asthma was in good control had the least evidence for growth suppression before ICS therapy was instituted and continued to grow at the same rate as when on therapy (HVSD score −0.01 pre- vs −0.07 during treatment). In contrast, the subjects whose asthma was poorly controlled grew poorly before and after institution of ICS therapy (HVSD score −1.50 pre- vs −1.55 during treatment). Of interest, those with moderately controlled asthma demonstrated improved growth velocity while on ICS therapy, with their HVSD score increasing from −0.83 to −0.49. The investigators concluded that poor asthma control adversely impacts linear growth to a greater extent than ICS therapy.

Alternative and/or Adjunct Medications

The NHLBI NAEPP EPR3 guidelines recommend cromolyn or montelukast as alternative therapy for younger children with mild persistent asthma and combination therapy using ICS plus either LABA or montelukast for younger children with moderate to severe persistent asthma (Steps 4 and 5).[6] GINA 2014 global strategy recommends leukotriene receptor antagonist or increased or intermittent ICS therapy as alternative options for Step 2 and add-on options for Steps 3 and 4.[7]

https://CafePezeshki.IR

Cromolyn. Cromolyn (Intal) inhibits mediator release from mast cells. It inhibits both the early- and late-phase pulmonary components of the allergic response following inhalation of an allergen in sensitized subjects. A few studies have shown no added benefit with the use of cromolyn over placebo in young children with more severe disease.[66–69] Several efficacy studies that have found cromolyn to have beneficial effects were short-term trials and employed small numbers.[70,71] A meta-analysis of 22 control studies evaluating cromolyn in childhood asthma found it no better than placebo.[72] A multicenter, randomized, parallel-group, 52-week, open-label study in preschool children found nebulized cromolyn (20 mg four times daily) ($N = 335$) to be inferior to nebulized budesonide suspension (0.5 mg daily) ($N = 168$) using several outcome parameters.[73] Children who received inhaled budesonide suspension had a reduced rate of asthma exacerbations per year, longer time to first asthma exacerbation and first use of additional long-term controller therapy; nearly doubled improvements in nighttime and daytime symptom scores by the second week of treatment; and lower use of rescue medications. Although there were no significant differences in the rates of hospitalization and emergency room visits between the two groups, significantly lower urgent care or unscheduled physician visits and oral corticosteroid use were found in children who received the ICS. However, mean height increases from baseline in children randomized to inhaled budesonide and inhaled cromolyn were 6.69 and 7.55 cm, respectively. This difference of 0.86 cm is similar to the difference in height measurements seen in other studies with ICS therapy after 1 year of treatment in both younger and older children.[19,74,75]

Leukotriene Modifying Agents. Leukotrienes are potent proinflammatory mediators that induce bronchospasm, mucus secretion and airway edema. In addition, they may be involved in eosinophil recruitment into the asthmatic airway.[76] Leukotriene modifiers (synthesis inhibitor or receptor antagonist) have beneficial effects in terms of reducing asthma symptoms and supplemental β-agonist use while improving baseline pulmonary function.[77–79] The leukotriene receptor antagonists (LTRA) prevent the binding of LTD_4 to its receptor. This class has a pediatric indication and includes both montelukast (given once daily; has been approved for treatment of chronic asthma for children age 1 year and older) and zafirlukast (administered twice daily; approved for children 7 years and older).

Safety and efficacy studies with the 4-mg chewable montelukast tablet in children aged 2 to 5 years with asthma have been published.[80–82] Almost 700 children 2 to 5 years of age were enrolled to receive montelukast or placebo for 12 weeks in a double-blind, multicenter, multinational study at 93 centers worldwide.[80] Montelukast was well tolerated and was not associated with any significant adverse effects. Montelukast was superior to placebo in reducing daytime symptoms including improvements in cough, wheeze, difficulty breathing and activity level, and nighttime cough. In addition, montelukast therapy was associated with a reduction in rescue β-agonist use and reduced need for prednisone for acute severe exacerbations.

Studies have been done to evaluate the long-term effects of an LTRA (continuous[81] and intermittent[82]) on the occurrence of exacerbations in young children. In a 12-month, double-blind, parallel study which was designed to investigate the role of montelukast in the prevention of viral induced asthma exacerbations in children aged 2 to 5 years with a history of intermittent asthma symptoms, montelukast significantly reduced the rate of asthma exacerbations by 31.9% compared with placebo. Montelukast delayed the median time to first exacerbation by approximately 2 months and the rate of ICS courses compared to placebo.[81] In another study, 220 children aged 2 to 14 years were randomized to receive either intermittent montelukast or placebo at the onset of asthma or upper respiratory tract infection symptoms for a minimum of seven days.[82] The montelukast group had 163 unscheduled health care resource utilizations for asthma compared with 228 in the placebo group (OR = 0.65, 95% CI 0.47–0.89). There was a nonsignificant reduction in specialist attendances and hospitalizations, duration of episode and β-agonist and prednisolone use. These studies suggest that intermittent or persistent therapy with montelukast for children with intermittent asthma symptoms is effective in reducing risk of exacerbations compared with placebo.

Long-acting Inhaled β-Agonists. LABAs are the alternative add-on therapy for children and adults with moderate and severe persistent asthma. The GINA 2014 global strategy does not include LABAs as controller therapy in any of their stepwise algorithms for very young children.[7] They are not viewed as 'rescue' medications for acute episodes of bronchospasm, nor are they meant to replace inhaled antiinflammatory agents. Salmeterol has a prolonged onset of action with maximal bronchodilation approximately 1 hour following administration; formoterol has an onset of effect within minutes. Both medications have a prolonged duration of action of at least 12 hours. As such, they are especially well suited for patients with nocturnal asthma[83] and for individuals who require frequent use of short-acting β-agonist inhalations during the day to prevent exercise-induced asthma.[84] There is an added advantage to the use of these alternative therapies for preschool children who may deserve an extended bronchodilatory coverage for exercise because they are constantly active. Salmeterol via the Diskus™ device is FDA approved for children as young as 4 years of age (50 μg blister every 12 hours), whereas formoterol delivered via the Aerolizer™ is approved for use in children 6 years of age and older (12 μg capsule every 12 hours). Both LABAs are also available as combination pMDI with an ICS (salmeterol and fluticasone [Advair], budesonide and formoterol [Symbicort], and mometasone and formoterol [Dulera]). Although LABAs combined with ICS are recommended for young children in Steps 4 to 6 of the NAEPP EPR3 guidelines (Figure 32-2), they have limited application.[6] The Diskus™ combination product is FDA approved down to 4 years of age but its use requires adequate inspiratory effort to get an optimal delivery of the dry powder. While the pMDI can be used with a holding chamber, it is not currently approved for children younger than 12 years of age. The efficacy and safety of LABA or combination products in younger children with asthma are still uncertain due to lack of studies.

The FDA has requested the manufacturers of LABAs to update their product information warning sections regarding an increase in severe asthma episodes associated with these agents. This action is in response to data showing an increased number of asthma-related deaths in patients receiving LABA therapy in addition to their usual asthma care as compared with patients not receiving LABAs.

Treatment immediately prior to vigorous activity or exercise is usually effective. The combination of a SABA with either cromolyn or nedocromil is more effective than either drug

https://CafePezeshki.IR

alone. Montelukast may be effective for up to 24 hours. Salmeterol and formoterol may block exercise-induced bronchospasm for up to 12 hours. There is one study that has evaluated single-dose bronchoprotective effects of salmeterol given through a Babyhaler spacer device using a methacholine provocation challenge in infants less than 4 years old with recurrent episodes of wheezing.[85] Originally 42 preschool children (age range 8 to 45 months) received one of the 25-, 50- or 100-μg dose of salmeterol and a placebo dose 2 to 7 days apart in a double-blind, randomized fashion, but only 33 completed the study. The investigators found a dose-dependent bronchoprotective effect of salmeterol measured by treatment/placebo methacholine dose ratios. Significant improvements from placebo were found only for the 50 (2.5 fold) and 100 (fourfold) μg doses.

ISSUES RELATED TO THE DELIVERY OF MEDICATIONS TO INFANTS AND SMALL CHILDREN

There are unique challenges relating to the delivery of medications (both oral and inhaled) to infants and young children with asthma. Obviously, liquid preparations are tolerated by infants but chewable tablets/pills can already be consumed by toddlers. Montelukast is available as oral granules or chewable tablet and prednisone/prednisolone comes in either liquid formulations or orally disintegrating tablet preparations. With regard to inhaled medications, certain anatomic and physiologic characteristics of children younger than 6 years are worth considering. First, because infants display preferential nasal breathing and have small airways, low tidal volume and high respiratory frequency, delivery of the drug to the lower airways is often inadequate.[86] Second, it is difficult if not impossible for young children to perform the maneuvers specified for optimal delivery of aerosol therapy such as slow inhalation through the mouth with a period of breath-holding for pMDIs or rapid and forceful inhalation required in the case of dry-powder inhalers (DPIs). Third, delivery devices appropriate for the young child are limited to those that require minimum cooperation from the child and must allow ease of administration for the caregivers. Although at present there are at least three inhaled aerosol delivery systems available for older children and adults, only two are used in this age group: the nebulizer and the pMDI with spacer/holding chamber and facemask. Because of the reliance on the subject's ability to generate a sufficient inspiratory flow and overcome the resistance required of DPIs, preschool age children are unable to use them.

Within these two general types of delivery systems there are numerous products available that vary widely in performance. The pMDI with spacer or holding chamber is portable and inexpensive, takes less time to administer and is likely to be better tolerated than delivery with a nebulizer. Dolovich et al[87] published a comprehensive systematic review to determine if device selection affects clinical efficacy and safety. Randomized placebo-controlled trials that involved various devices for the delivery of β-agonists, ICS and anticholinergic agents in different clinical settings (emergency department, inpatient, intensive care and outpatient) and patient populations (pediatric and adult asthma, and COPD) were included. Reports in which the same drug was delivered with different devices were analyzed. Their findings indicated that the drugs delivered via different formats are equally effective. Appropriate technique, cooperation and convenience determine which delivery may be best.

Asthma clinical guidelines mention the use of inhaled short-acting β-agonist either by pMDI or nebulizer as an initial asthma exacerbation home intervention.[6,7] The GINA global strategy recommends the use of short-acting inhaled β-agonist by pMDI (ideally with a spacer) for home management of mild, moderate and severe exacerbations. GINA also recommends nebulized treatments for severe exacerbations at home and for hospital-based management of acute asthma.[7]

Data in young children clearly support the use of β-agonists, at higher doses, administered via a pMDI with spacer for acute asthma.[88,89] In a study of 60 children between 1 and 5 years of age hospitalized for an asthma exacerbation, Parkin et al found salbutamol (400 to 600 μg, 4 to 6 puffs, based on weight) and ipratropium bromide (40 μg, 2 puffs), both delivered via pMDI with an Aerochamber and mask, to be as effective as nebulized salbutamol (0.15 mg/kg) and ipratropium bromide (125 μg) administered over 15 minutes by facemask.[88] However, nearly one third of the subjects randomized to MDI eventually required a nebulized β-agonist.

Two studies have evaluated lower respiratory tract deposition of a radiolabeled salbutamol/albuterol mixture administered to young children. Tal et al showed that on average, less than 2% of the nominal dose of the albuterol given by a pMDI with a spacer and mask to children less than 5 years old was deposited in the lower respiratory tract with most of the drug remaining in the spacer.[90] Wildhaber et al compared the lung deposition of radiolabeled salbutamol from a nebulizer and a pMDI and spacer in 17 asthmatic children aged 2 to 9 years.[91] Both devices were delivering roughly 5% of the nominal dose to the lower airways. Because of the larger doses of salbutamol administered via the nebulizer (2,000 μg vs 400 μg) than the pMDI, a larger amount of drug was deposited in the airways using the nebulizer (108 μg vs 22 μg, respectively). In addition, both devices were approximately 50% less efficient in children less than 4 years old than in older children.

In general, β-agonist administration by nebulization is still probably a more practical delivery system for most infants and young children with severe acute asthma because it requires the simple technique of relaxed tidal breathing, particularly if it is difficult to use a tight fitting spacer and mask for a pMDI. In addition, oxygen can be used to power the nebulizer, providing β-agonist and supplemental oxygen simultaneously, and it does offer the capability to administer a controller agent and rescue β-agonist at the same time.

With respect to controller therapy, the only available inhaled drugs that are FDA approved for children under 4 years of age are cromolyn solution and budesonide suspension intended for nebulization. However, a pMDI with a spacer device is certainly more convenient and easier to administer. The GINA global strategy prefers the administration of ICS via a pressurized metered dose inhaler (pMDI) with a spacer and either a facemask (for 0 to 3 years of age) or a mouthpiece (for ≥4 years old) for young children with asthma but the dose delivered is variable between spacers.[7] These guidelines mention the use of nebulizers as an alternative delivery system for children who are unable to use the spacer device effectively. Since young children are only expected to perform tidal breathing, the optimal number of breaths to empty the spacer device varies with the tidal volume, dead space and volume of the device. Important measures to maximize delivery of medication to very young

https://CafePezeshki.IR

children include the following: enforcing a tight fitting mask around the child's mouth and nose, encouraging immediate inhalation after actuation, allowing 5 to 6 breaths per single pMDI actuation, making sure that the spacer valve is moving when the child is breathing through the spacer, shaking the inhaler in between actuations and using a lower volume spacer (<350 mL) in these very young children.

The Montreal Protocol, adopted in 1987, mandated a complete elimination of the chlorofluorocarbon (CFC) propellant due to concerns about its damaging effect on the ozone layer. Since 2008, pMDIs now contain hydrofluoroalkane (HFA). However, the pMDI HFAs (even rescue short-acting β-agonists) are approved for use only in children 4 years of age and older. There is no information available on the relationship between lung deposition from HFA pMDI and clinical efficacy or even long-term safety in small children. In addition, no studies exist comparing inhaled medications administered via nebulizer and HFA pMDI with spacer and mask.

Additional factors that should be considered are the costs to the patient (including use of spacer attachments which are not reimbursable) and the use of multiple delivery devices which requires more time for the clinician staff to educate families on proper techniques. To address both issues, perhaps the same type of device can be used for all inhaled drugs for an individual patient. The decision should also incorporate which device the clinician is capable of teaching properly and what the patient/parent prefers. When a child presents with uncontrolled asthma, the assessment should first focus on technique and adherence.

ADHERENCE

The issue of adherence in infants and small children is complicated because the child is entirely dependent on the caregiver to administer the medication. In an observational study of preschool children, Gibson et al sought to evaluate adherence with inhaled prophylactic medications delivered through a large volume spacer using an electronic timer device. Adherence was only 50% with a range of 0% to 94%.[92] In addition, only 42% of the subjects received the prescribed medication on each study day, and reporting of symptoms in the diary cards did not correlate with good compliance with the prophylactic medication, nor was a correlation found between frequency of administration and adherence. In another study, parental reporting of symptom scores correlated with measured bronchodilator use in only 63% of preschool children.[93]

A few studies have attempted to determine why caregivers are unable to administer medications as prescribed. Lim et al asked parents why they were reluctant to administer prophylactic medications (such as ICS) to their young children with asthma. Reasons cited included hesitancy to use medications for fear of dependence, side-effects and overdosage.[94] Fortunately, patient education programs developed for parents of small children with asthma improve asthma morbidity and self-management outcome.[95,96]

NONPHARMACOLOGIC INTERVENTION

Nonpharmacologic measures may be as important not only for young children with established respiratory symptoms, allergies and passive smoke exposure but also in the primary and secondary prevention of asthma.[97–99] The first and likely the most important step toward controlling asthma in sensitized children is to avoid or reduce the patient's exposure to the offending allergen. The environmental interventions that seem to hold the most promise are those that target reducing exposure to indoor allergens and tobacco smoke. Specific environmental control measures are covered in Chapter 21.

Yearly influenza immunization is also strongly recommended for children 6 months of age and older with chronic pulmonary diseases, including asthma. Kramarz et al evaluated the effectiveness of influenza vaccination in preventing influenza-related asthma exacerbations in children 1 to 6 years of age using a retrospective cohort study with the Vaccine Safety Datalink, which contains data on more than 1 million children enrolled in four large health maintenance organizations.[100] Of note, less than 10% of children with asthma were vaccinated against influenza in any of the years studied. Although the incidence rates of asthma exacerbation in those who were vaccinated were found to be higher in the vaccinated group than in those who were not vaccinated, the difference was thought to be largely confounded by asthma severity in the vaccinated group. Using a 'self-control' analysis to correct for this confounder, the risks of asthma exacerbation during each of the influenza seasons were reduced by 22% to 41% with influenza vaccination.

Management of Asthma Exacerbations in Young Children

Exacerbations, also commonly referred to as episodes or flare-ups, are acute deterioration of asthma control characterized by increased symptom severity, sudden change in child's activity or performance (lethargy or lack of interest or exercise intolerance), poor response to or sudden increased need for rescue medication, and breathing difficulty or respiratory distress at its worst. In this age group, these are often preceded by upper respiratory symptoms or viral syndrome. The most effective approach in managing asthma exacerbations involves early recognition of warning signs and early treatment. An action plan should be provided to the family members or caregivers which includes information about what medications to give, medical provider's contact information and when to seek urgent medical attention (such as signs of acute distress, symptoms unrelieved by bronchodilator, increased need for rescue treatment or repeated use of bronchodilator over several hours).[7] A copy should also be given to daycare providers and school personnel.

HOME MANAGEMENT

Early treatment of asthma exacerbations may prevent a life-threatening event or a hospital admission. Initial treatment should be with a SABA (e.g. albuterol or levalbuterol): 2 puffs from an MDI via a spacer device with or without a facemask, which may be repeated every 20 minutes 2 more times, or a single treatment can be given by nebulizer (0.05 mg/kg [minimum dose, 1.25 mg; maximum, 2.5 mg] of 0.5% solution of albuterol in 2–3 mL saline; or 0.075 mg/kg [minimum dose, 1.25 mg; maximum, 5 mg] of levalbuterol).[6] If the response is good as assessed by sustained symptom relief, the SABA can be continued every 3 to 4 hours for 24 to 48 hours. Patients should

https://CafePezeshki.IR

be advised to seek medical care once excessive doses of bronchodilator therapy are used or for prolonged periods (e.g. >6 puffs of inhaled SABA are used within the first 2 hours, >12 puffs/day for >24 hours, or if the child has not recovered after 24 hours).[6,7]

If the child does not completely improve with the initial therapy, the SABA should be continued and the caregiver should contact the physician urgently. If the child experiences marked distress, the caregiver should give the SABA immediately and bring the patient to the emergency department or call 9-1-1 or another emergency number for assistance. Intensification of acute treatment with an oral corticosteroid initiated by family members can be considered but evidence for its early use is debatable.[101] Doubling the dose of inhaled corticosteroids is not proven sufficient to prevent worsening of exacerbations. However, recent studies in small children not on regular controller therapy have shown benefits from using high-dose ICS at the early onset of a respiratory illness in preventing the need for systemic corticosteroid.[46,48] One study has shown the efficacy of starting a short course of montelukast at the onset of a respiratory tract illness in small children with episodic wheezing with respect to reducing symptom burden, healthcare utilization and time off work,[82] but perhaps this benefit from a short course of leukotriene receptor antagonist at reducing symptom burden may only be expected in young children who have atopic risk factors.[102]

MANAGEMENT IN THE EMERGENCY DEPARTMENT OR HOSPITAL

Clinical assessment is used, and scoring systems (e.g. Preschool Respiratory Assessment Measure [PRAM] and the Pediatric Asthma Severity Score [PASS]) have been developed to assess the severity of asthma exacerbations.[103] Severe exacerbations are characterized by any one of the following: altered mental state (agitated, confused or drowsy), oxygen saturation <92%; tachycardia (>200 beats/minute for 0 to 3 years old; >180 beats/minute for 4 to 5 years old); retractions; cyanosis; and 'silent' chest (wheeze inaudible).[7] Functional assessment of a young child's degree of airflow limitation is impractical but oxygen saturation should be obtained. Chest radiographs are not recommended routinely but should be considered to rule out pneumothorax, pneumomediastinum, pneumonia or atelectasis.

Initial treatment can be with a SABA by inhaler (albuterol, 4–8 puffs) or nebulizer (0.15 mg/kg of albuterol 0.5% solution; minimum dose 2.5 mg), or nebulized high-dose SABA plus ipratropium bromide (0.25–0.5 mg), up to three doses in the first hour. Oxygen should be given to maintain oxygen saturation above 93%.[6,7]

Systemic corticosteroids (oral prednisolone 1–2 mg/kg/day; maximum of 20 mg/day for <2 years of age, 30 mg for children 2 to 5 years of age, and 60 mg/day for older children *or* IV methylprednisolone 1 mg/kg every 6 hours)[7] should be instituted if the child responds poorly to therapy at 1 hour or continues to deteriorate or if symptoms recur within 3 to 4 hours or symptoms persist beyond 1 day or if the child has recently been on oral corticosteroids. Sensitivity to adrenergic drugs may improve after initiation of corticosteroids.

If the child shows slow or poor response, continuous bronchodilator treatment for the first hour (0.5 mg/kg/h) can be administered. For older children and adults with severe exacerbation having no response to initial inhaled therapy, or for those who cannot cooperate with or who resist inhalation therapy, adjunctive therapies include intravenous magnesium sulfate (25–75 mg/kg up to 2 g in children) and heliox driven albuterol nebulization, but their use in younger children is not as established. The use of isotonic magnesium sulfate by nebulization (150 mg, 3 doses in the first hour) as an add-on treatment for children as young as 2 years of age with severe exacerbation was found beneficial for those with more severe presentation in the presence of oxygen saturation <92% and with symptoms lasting less than 6 hours.[104]

For impending or ongoing respiratory arrest, epinephrine 1:1,000 or terbutaline 1 mg/mL (both 0.01 mg/kg up to 0.3–0.5 mg) may be administered subcutaneously every 20 minutes for three doses, although the use of intravenous β_2-agonists is still unproven. Children may need ventilatory support with 100% oxygen, intravenous corticosteroids and admission to an intensive care unit (ICU). Further treatment is based on clinical response and objective laboratory findings.

Hospitalization should be strongly considered for any child with a history of respiratory failure or significant psychosocial impediments to optimal acute asthma care. The decision to hospitalize should also be based on presence of risk factors for mortality from asthma, duration and severity of symptoms, course and severity of previous exacerbations, medication use at the time of the exacerbation, access to medical care, and home and psychosocial conditions. Maintenance fluids and electrolyte requirements (both corticosteroids and β_2-agonists can cause potassium loss) should be provided, especially since these young children are likely to have poor oral intake secondary to respiratory distress or vomiting, but they require intensive monitoring as overhydration may contribute to pulmonary edema associated with high intrapleural pressures generated in severe asthma. Antibiotics may be necessary to treat co-existing bacterial infection.

Criteria for discharging young children home should include a sustained response of at least 1 hour to bronchodilator therapy. The child should also be ambulatory according to age expectation, comfortable, and able to keep food or drink down.[7] Prior to discharge, the caregiver's ability to continue therapy and assess symptoms appropriately needs to be considered since children with a recent exacerbation are at risk of recurrent episodes. The caregiver should be given an action plan for management of recurrent symptoms or exacerbations, identification of triggers and how to avoid them, and instructions about rescue and controller medications and their use. Hospitalized patients should receive more intensive education prior to discharge. This is another opportunity to review inhaler technique. The inhaled SABA and oral corticosteroids should be continued, the latter for 3 to 7 days. Finally, the caregiver should be instructed about the follow-up visit, which typically takes place within 1 week. Referral to an asthma specialist should be considered for all children with severe exacerbations or multiple emergency department visits or hospitalizations.

Prevention of Asthma

Given the burden of asthma and recurrent wheezing illnesses in young children, with their associated morbidity and healthcare utilization due to risk of severe episodes, not to mention the high direct and indirect costs that go with them, preventive measures are indeed warranted. To have any chance for success,

https://CafePezeshki.IR

early intervention will require identifying high-risk infants and establishing effectiveness of the intervention strategy in young children while minimizing the potential for adverse effects. This is discussed in more detail in Chapter 39. Primary prevention is ideal but the right intervention is lacking because of the heterogeneous nature of this condition.

Two studies have evaluated the effects of ketotifen and cetirizine, respectively, in preventing the onset of asthma in genetically prone children.[105,106] In a double-blind, placebo-controlled, parallel study, children up to 2 years of age without a prior history of wheezing but with a family history of asthma or allergic rhinitis and presence of elevated serum IgE were randomized to receive either ketotifen (0.5–1 mg twice daily) (N = 45, mean age 11.5 months) or placebo (N = 40, mean age 10.8 months) for 3 years.[43] Only 9% of children on active treatment compared to 35% of the placebo group developed frequent episodes of wheezing during the study period (P = .003). The other study, called the Early Treatment of the Atopic Child, was a randomized, double-blind, parallel group trial that compared cetirizine (0.25 mg/kg twice daily) and placebo.[106] The medications were administered for 18 months to infants between 1 and 2 years of age with atopic dermatitis and a family history of atopy. The primary outcome, which was the time to onset of asthma in the next 18 months after discontinuation of treatment, was not different between the two groups. Half the children in both cetirizine and placebo groups developed asthma (defined as three episodes of wheezing during the 36 months of follow-up) (P = .7). However, in the cetirizine group, infants with evidence of dust mite or grass pollen sensitivity were less likely to have asthma over the 18 months of treatment with a sustained effect for grass-sensitized infants over the 36 months of follow-up compared with those treated with placebo. Furthermore, in the placebo group there was an increased risk of developing asthma in those with baseline sensitivity to egg, house dust mite, grass pollen or cat allergen. These two studies support the role of easily administered preventive measures in delaying or even preventing the development of asthma in genetically predisposed children.

Various other prevention modalities have shown promising potential to modulate asthma development. Given the relevance of environmental and allergen exposure in airway inflammation characteristic of asthma, interventions that can reduce these exposures (e.g. reducing tobacco smoke, dust mite or pet avoidance, and dietary modifications) have been undertaken, with modest overall results, and applicability may be limited by location and individual exposures.[107–116] In addition, the success of interventions targeting reduction of exposure may be dependent on a multifaceted approach, and not just a single measure alone.[117] Recognizing the role of airway infection (including serious respiratory syncytial virus [RSV] and rhinovirus infections in early life) in the development of recurrent wheezing and asthma susceptibility in childhood, perhaps prophylaxis against them might help reduce asthma development. A lower incidence of recurrent wheezing (and even physician-documented episodes) over a 2-year follow-up period was found among preterm infants without chronic lung disease who had received palivizumab (a humanized monoclonal antibody against the RSV fusion protein) compared with preterm infants who had not received palivizumab, prior to enrollment.[118] There was also a significant difference in outcomes between palivizumab-treated and untreated children who were not hospitalized for RSV, suggesting that the effect of palivizumab was not merely to prevent hospitalization but also to avert a lower respiratory tract illness from RSV. In addition, the protective effect of palivizumab appeared to be found in those children without a family history of asthma or atopy.[119]

A bacterial lysate, OM-85 BV, containing standardized lyophilized fractions per capsule from eight bacteria (*Haemophilus influenzae*, *Streptococcus pneumoniae*, *Klebsiella pneumoniae*, *Klebsiella ozaenae*, *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus viridans* and *Neisseria*) is widely used in Europe to reduce acute respiratory tract infections. In a randomized, double-blind, placebo-controlled, parallel group study it has been found to be effective at reducing acute wheezing illnesses in children with a history of recurrent wheezing by 38% compared with placebo.[120] It remains to be evaluated in larger clinical trials if this can be an effective primary intervention modality that will prevent the development of asthma. Immunomodulators, including this immunostimulant, along with probiotics, prebiotics, anti-IgE and specific immunotherapy, are proposed as potential primary prevention interventions by a National Heart, Lung, and Blood Institute workshop committee.[121]

There has been a recent trend toward intervening early in the course of the disease with the hope of altering the natural history of asthma, and clinical trials of what can be considered secondary prevention measures have provided important observations. There have been studies that sought to determine if treatment with an ICS soon after the onset of early indicators of the disease would modify the course of asthma.[19,47,63,102] The study designs varied with respect to the eligibility criteria, age at entry, frequency of past wheezing episodes and manner and duration of treatment (e.g. maintenance vs intermittent or as needed intervention).

The NHLBI Childhood Asthma Research and Education (CARE) network-sponsored Prevention of Early Asthma in Kids (PEAK) study enrolled approximately 300 2-to 3-year-old children with more than three episodes of wheezing and a positive mAPI to receive either fluticasone propionate 88 μg via pMDI or matching placebo twice daily for 2 years.[19] During the third year observation period of interest, no difference in either the proportion of children with active wheezing or lung function measured using forced oscillometry between the two treatment groups was found. However, during the first two years while on treatment, symptom control was better and asthma exacerbations fewer for the active treatment group compared to placebo. A reduction in growth velocity during the first 8 months (6.6 ± 1.0 vs 7.3 ± 1.0 cm/yr between 1 and 8 months, P = .005) and a smaller mean increase in height between 4 and 12 months (4.5 ± 1.1 vs 4.9 ± 1.1 cm, P = .001) were observed in the ICS group. However, during the second year of treatment, the growth velocity in the ICS group was greater than that in the placebo group (7.0 ± 0.8 vs 6.4 ± 0.9 cm/yr, P = .001). Children in the ICS group had an average height percentile of 51.5 ± 29.2 compared to 56.4 ± 27.3 in the placebo group at the end of treatment (P < .001) and 54.4 ± 27.9 compared to 56.4 ± 26.9 at the end of observation (P = .03).

Another study (IFWIN; Inhaled Fluticasone propionate in Wheezy INfants) evaluated whether ICS therapy for infants with a history of wheezing could prevent active asthma and prevent loss of lung function in later childhood.[63] A total of 200 children (mean age at entry 1.2 years) from a birth study cohort with two documented episodes of wheeze or one prolonged episode, more than 1 month duration, and a parental history of atopy

https://CafePezeshki.IR

were randomized to receive fluticasone propionate 100 μg or matching placebo twice daily. At age 5 years, no difference between the ICS and placebo groups in the proportion of children with current wheeze, physician-diagnosed asthma and use of supplemental open-label ICS (fluticasone 100 μg twice daily) was found. Furthermore, the number of exacerbations, lung function (using sRaw through plethysmography with dynamic lung volumes and expiratory flow) and bronchial hyperreactivity (using eucapnic voluntary hyperventilation) were also not different between the groups. Children who were on ICS, particularly after 6 to 12 months, had transient reduction in growth velocity; and those who received both masked and open-label ICS had a slower rate of growth, compared to either the 'masked treatment only' or 'open-label treatment only' groups.

While these two studies demonstrate that long-term treatment with ICS does not modify the course of asthma, they also raise the potential for systemic effects of this intervention which can limit its use for this purpose. Using ICS only for an acute illness and evaluating its long-term impact is attractive not only because it is less burdensome but also it may decrease the risk of growth retardation.

One study, the Prevention of Asthma in Childhood (PAC), sought to determine whether early intervention using intermittent administration of an ICS, when initiated at the first episode of wheezing and during subsequent episodes, could alter the development of asthma.[47] Of 411 infants born to mothers with asthma enrolled at one month of age, approximately 300 children received at least one 14-day course of budesonide 400 μg/day or matching placebo administered via pMDI and holding chamber (mean age at the first course of study medication was 10.7 months). For every acute illness, children were to start either treatment after 3 days of wheezing. Upon completion of this 3-year study, a similar percentage of symptom-free days between treatment groups (83% vs 82% for the budesonide and placebo groups, respectively) was found. In addition, 24% and 21% of children in the budesonide and placebo groups, respectively, had persistent wheezing. The mean duration of each acute wheezing episode was not reduced by budesonide therapy. Lung function using pre-and post-bronchodilator sRaw at age 3 years was comparable between the two treatment groups. Lastly, there was no difference in height between the groups. Thus, intermittent ICS did not alter the natural history of asthma in infants at risk for asthma nor did it change the duration of the acute wheezing episodes.

The NHLBI CARE Acute Intervention Management Strategies (AIMS) study[102] randomized 238 children aged 12 to 59 months who had at least two episodes of moderate-to-severe wheezing requiring either an urgent care visit and/or systemic steroid course in the context of a respiratory tract illness within the past year. Participants were randomized to receive one of the following for 7 days at the onset of symptoms: budesonide inhalation suspension (1.0 mg twice daily) or montelukast group (4 mg once daily) or conventional rescue bronchodilator therapy. The primary outcome was the proportion of episode-free days (i.e. days free from cough, wheeze, trouble breathing, asthma-associated interference with daily activities or awakening from sleep, healthcare utilization due to wheezing, and use of asthma-related non-study medications) over the entire study period. Compared to conventional rescue bronchodilator therapy, neither budesonide nor montelukast initiated at early signs of illness increased the proportion of episode-free days over a 1-year period. In addition, no differential effect on oral corticosteroid rescue, asthma healthcare utilization or quality of life was found. Nevertheless, both active study treatments demonstrated modest reductions in symptom severity score (such as wheezing, trouble breathing or activity limitation) relative to conventional therapy, particularly among children with positive API or prior oral corticosteroid use.

These studies provide important information regarding ICS therapy in young children with recurrent wheezing episodes although the overall results regarding prevention of progression to persistent asthma are not convincing. ICS can be indicated to improve asthma control but should not be expected to prevent the development of asthma or persistent wheezing, even for high-risk subjects.

Conclusion

Chronic cough and recurrent wheezing, typical manifestations of asthma, are quite common in young children, yet these symptoms render different long-term outcomes and, acutely, varying severity. For those with a more persistent pattern, controller therapy is indicated. A significant subset have a severe, intermittent course, and for these patients daily controller therapy may still be beneficial. However, recent studies have suggested the efficacy of 'as needed' high-dose inhaled corticosteroid started at the onset of a respiratory illness, particularly in very young children who have atopic risk factors. The development of persistent asthma and requirement for long-term controller therapy in a very young child can be predicted to a limited degree. Currently no clinically available objective and reliable measure of lung function, bronchial hyperreactivity or airway inflammation exists that is applicable to this age group, hence monitoring the effects of interventions or treatment on prevention of asthma inception, modulation of underlying inflammation, perhaps airway remodeling, prevention of deterioration in lung function over time and induction of physiologic or immunologic remission is not feasible. The need to evaluate objectively the efficiency and safety of the various delivery devices and HFA formulation available for inhaled therapies to infants and young children remains. Only a few medications have been approved for use in this population, and studies have demonstrated effects on asthma control using short-term parameters. Studies on prevention of asthma development are warranted, especially in those who are deemed susceptible. Yet these are the ultimate goals that may motivate patients and families, if indeed interventions can really alter the development and the natural history of their disease. These studies often require large sample size and monitoring over longer periods of time which require enormous resources and the use of practical, objective measures of disease activity which are still lacking.

Inner City Asthma: Strategies to Reduce Mortality and Morbidity

MEYER KATTAN

KEY POINTS

- Racial and ethnic minorities and children with low socioeconomic status living in urban communities have a disproportionate burden of asthma morbidity, mortality and healthcare use.
- Successful interventions targeting inner city children with asthma must be multifactorial and take into account access to care, social, environmental and behavioral factors.
- Community linkages, epidemiologic evaluation, self-management, decision support and improved patient-provider communication are essential ingredients of asthma management programs.
- It is important to determine individual risks and tailor asthma interventions in the context of the physical and social environments.
- Translation of successful evidence-based interventions into practice presents a challenge that requires evaluation and feedback from those implementing these interventions at the community level.

Wide variations exist in the prevalence of childhood asthma worldwide, ranging from less than 1% to as high as 37%.[1] The National Health Interview Survey in 2012 reported that 9.3% of children under age 18 in the USA have asthma and 14% have been diagnosed with asthma at some time in their lives. Small area analyses have demonstrated asthma period prevalence rate in poor urban communities in the USA to be twice the national prevalence rate.[2] Children in poor families are more likely to have current asthma than children in families that are not poor (13% vs 8%). There is variation in prevalence among ethnic groups. Puerto Rican children living in the Northeast USA reported some of the highest prevalence rates. Disparities in morbidity in addition to prevalence are evident. Hospitalization rates and emergency department (ED) visits are highest in poor urban areas.[3,4] Reviews of asthma disparities find that African American and Hispanic children who live in low socioeconomic urban environments experience higher morbidity and mortality than white children.[5,6] In the UK, blacks and south Asians are at significantly increased risk of admission for asthma.[7]

Racial and ethnic minorities that are socioeconomically disadvantaged and disproportionately affected by asthma live predominantly in densely populated urban areas. These so-called 'inner cities' are not uniform in many of their characteristics. The differences include housing stock, climate, environmental exposures, race and ethnicity. As a result of the documented disparities in asthma morbidity, the inner cities have been the focus of studies to determine the characteristics of these areas that contribute to high prevalence and morbidity and to develop interventions.

The relationship of race/ethnicity, environment and socioeconomic status (SES) to asthma morbidity is complex. The hospital readmission rate for asthma is twice as high in African Americans compared to whites. In an attempt to characterize the racial disparities, one study found that traditional SES measures coupled with financial and social hardship explained 50% of the readmission rate.[8] Behavioral factors and patterns of care also determine asthma outcome. Jones et al demonstrated that minority children with wheeze were nearly twice as likely as white children to have used urgent care for asthma, after controlling for disease severity, access to care and environmental factors.[9] Puerto Rican children had more clinic visits for asthma but spent fewer days in the hospital for asthma than African American children.[10] Health beliefs may differ among various cultures. Ethnic minorities with low incomes might regard asthma as less serious than other pressing problems of life.[11] Low parental expectations and competing family priorities are associated with poor asthma control. In a multivariate analysis that included these factors in the analytic model, the association between race/ethnicity and poor asthma control was not significant.[12] In summary, a variety of interrelated factors contribute to morbidity and multifaceted tailored interventions are more likely to succeed.

Challenges to Asthma Management

Despite the existence of effective disease control strategies and medications, asthma remains a major public health problem. Morbidity, direct and indirect healthcare costs and mortality continue to impose a high burden. Individual asthma care is only one component of effective asthma control. Compared with social, environmental and behavioral factors, medical care has only a relatively small influence on health for populations.[13] The role of these factors was evident in the initial studies of the National Inner City Asthma Study (NCICAS). Poor housing stock, crowded living conditions and poor access to appropriate health care despite the availability of insurance are barriers. Exposure and sensitization to allergens such as cockroach and mouse, as well as exposure to indoor pollutants such as environmental tobacco smoke and nitrogen dioxide are high.[14] It is important to note that these risk factors vary from one child to the next.

Interventions aimed at primary prevention of asthma in inner city children are lacking. Longitudinal birth cohort studies are underway that may drive novel interventions. These studies will increase our understanding of the interaction of prenatal factors, viral infections, environmental tobacco smoke,

https://CafePezeshki.IR

microbiome, epigenetics and stress in the development of asthma. There are no effective public health strategies or treatment regimes that reduce the risk of developing asthma or influence its natural history.

Evidence indicates that establishment of a successful asthma management program entails a logical progression through specific developmental stages, starting with political/stakeholder endorsement and commitment, followed by epidemiologic evaluation, evaluation of disease burden, evaluation of access to care and best therapy, and finally optimization and maintenance therapy for individual patients.[15] Applying a model embodying these concepts in an inner city setting for patients with chronically poorly controlled asthma resulted in sustained improvement in asthma control in adolescent patients. The interventions implemented included delivery system redesign to provide standardized and evidence-based care, productive interactions between informed patients and prepared clinicians, self-management support, community linkages, clinical information systems and decision support.[16]

Factors Contributing to Morbidity in Inner Cities (Table 33-1)

ASTHMA KNOWLEDGE AND PATTERNS OF CARE

Insufficient caregiver and child asthma knowledge contributes to asthma morbidity but inability to apply the knowledge and change behavior also plays a role. The NCICAS found that although caregivers of inner city children had reasonably good asthma knowledge, they had difficulty giving responses that could be helpful in asthma management when they were given hypothetical vignettes.[17] The caregiver's expectations regarding his or her ability to manage the child's asthma are predictive of the child's functional status, suggesting that attitudes play a role in determining the child's asthma outcome.[18] Negative beliefs about medications and low expectations about the benefit of the medications are predisposing factors associated with poor clinical outcome. Low parental involvement and delays in recognizing symptoms and initiating therapy are also associated with poor outcomes. Patients and caregivers tolerate poor symptom control and possess inadequate knowledge of correct drug usage.[19] Language barriers between provider and patient or caregiver contribute to underreporting of symptoms and suboptimal communication.[20] The interactions are complex and interventions must identify breakdowns in the pathways to optimize outcomes (Figure 33-1).

Children with lower SES have fewer doctor visits despite more ED visits and hospitalizations.[3,21] Most children have a usual source of primary care but when symptomatic with asthma have difficulty finding care outside the ED.[14] Use of the ED leads to more fragmented care. Children use reliever medication more frequently than antiinflammatory medications.[22,23] In a managed care setting in a low SES group, African Americans fill fewer prescriptions than Caucasians.

ADHERENCE

Overall estimates for adherence to medications are about 50%[24,25] (Box 33-1). In adolescents, asthma prevention and management behaviors were suboptimal with only 36% of those prescribed medication for persistent asthma reporting taking medications daily.[26] Adherence to an asthma management program involves use of controller medication, appointment keeping and applying an emergency plan of action. Barriers to adherence may exist in any of these areas, leading to ineffective control of asthma.[27] Concern about side-effects and negative caregiver beliefs regarding efficacy of medications are more likely in nonadherent compared to adherent children.[27,28] Studies show that caregivers of children with asthma have cultural beliefs about asthma medications that provide the rationale for limiting or discontinuing the use of medications.[29–31] Even when a controller medication was prescribed by a physician, more than one third of caregivers did not report it, and this discordance was related to caregivers' beliefs about treatment.[32] Smith et al reported that suboptimal asthma control and controller medication underuse were highly associated with potentially modifiable risk factors, especially low parental expectations for functioning and symptom control, discordant estimation of asthma control, lack of routines for administering medication, and concerns about asthma medications.[12] Results

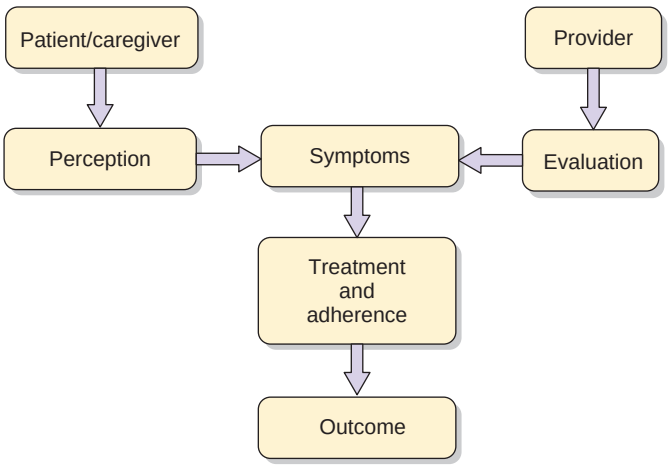

Figure 33-1 Interaction between patient/caregiver and provider. Inaccurate reporting of symptoms or inadequate assessment can lead to suboptimal treatment and poor outcome.

TABLE 33-1 Factors Contributing to Asthma Morbidity in Children of Lower Socioeconomic Status

Access to Care	Environment	Host	Psychosocial	Adherence

BOX 33-1 PREDISPOSING FACTORS FOR POOR ADHERENCE

- Insufficient asthma knowledge
- Inability to translate knowledge into practice
- Negative beliefs about medications
- Cultural beliefs about medications
- Low parental expectations for symptom control
- Competing priorities
- Suboptimal communication between parent and healthcare provider

of a multivariate analysis suggested that low parental expectations and competing priorities mediated the association of race/ethnicity and poor asthma control. Complementary and alternative medicine use in children with asthma is high. Usage is highest in black, poor, lesser educated parents and in children with persistent asthma.[33]

The level of responsibility for asthma management increases with age in inner city children.[17] However, older children may still be ill-equipped to manage the illness independently.[34] A complicating factor is that there is discordance between the caregiver and the child regarding responsibility for the management of the child's asthma.[17]

ACCESS TO CARE

Lack of adequate health insurance is an important barrier to healthcare services for children in the USA. Diagnosis and treatment of asthma are related to healthcare coverage.[35] However, some evidence suggests that asthma-related healthcare differences across groups might exist independently of financial barriers.[11] Despite very high levels of healthcare coverage and access to primary care in an urban population, the overall quality of asthma care and management falls short of that recommended by national guidelines.[36] In the NCICAS, 91% of children had health insurance but only 28% received antiinflammatory medications.[14] This suggests that the delivery or quality of care may contribute to poor outcome. Access to care from asthma specialists is reduced for those who are poor and belong to an ethnic minority. Physicians underprescribe controller medication for inner city children despite guidelines recommending the use of antiinflammatory medications for persistent asthma.[22,23,32] Furhman et al reported that children with asthma hospitalized for an exacerbation had been consistently poorly controlled during the previous year. They were undertreated and insufficiently educated about asthma.[37] However physician adherence to guidelines will not translate into appropriate treatment without attention being paid to caregiver-physician communication.[32]

PSYCHOSOCIAL FACTORS

Behavioral and psychosocial factors can affect asthma morbidity. There are variations in asthma morbidity in neighborhoods with low SES. This indicates that asthma morbidity cannot be explained solely by economic factors and that community factors may be important. Exposure to violence was independently associated with asthma morbidity after simultaneous adjustment for income, employment status, caregiver education, housing problems and other adverse life events, which suggests that exposure to violence is not merely a marker for these other factors. Increased exposure to violence predicts increased symptomatology in a graded fashion.[38] Children spend more time indoors because of fear of violence, which could potentially increase exposure to indoor allergens and irritants.[38] Inner city school children with asthma whose primary caregivers perceived the neighborhood to be unsafe had an increased likelihood of poorly controlled asthma, increased use of rescue medication use and more limitation in activity and nighttime symptoms compared to participants living in safe neighborhoods.[39]

Psychosocial factors, particularly the mental health of children and caregivers, are significant factors in predicting asthma morbidity. In the NCICAS, caregiver mental health as assessed by the Brief Symptom Inventory revealed that children of caregivers who had psychological symptoms were almost twice as likely to be hospitalized for asthma.[40] In adolescents with asthma, number of asthma symptoms, asthma-related school absenteeism, physician visits for asthma and hospitalization for asthma were significantly associated with the number of stressful events, independent of environmental exposures and sociodemographic factors.[41] Interventions that do not address psychosocial issues may have limited impact.

INDOOR ENVIRONMENTAL EXPOSURES

Attention to the indoor environment is of particular importance because children living in urban areas spend approximately 70% of their time indoors, where they are exposed to irritants, allergens and endotoxin.[42] There are many sources of indoor exposure penetrating from outdoor air and generating from indoor sources.

Exposure to environmental tobacco smoke (ETS) in children with asthma living in inner cities is high. Studies in inner cities report that more than half of children with asthma have one or more smokers in the household and over one third of primary caregivers of children with asthma are smokers.[14] Measurement of cotinine levels in children reveal even higher levels of personal exposure ranging from 38% to 69%.[14,43,44] African American children are more likely to be exposed than Latino children.[43,44]

Particulate matter (PM) is a major source of indoor air pollution in inner city homes. Indoor concentrations of PM are related to combustion products as well as to variation in ventilation and air filtration.[45,46] Penetration of particles from outdoor sources contributes about 25% of the indoor concentration. The major indoor source is smoking. In the Inner-City Air Pollution Study (ICAP) the mean indoor value of fine particulate matter ($PM_{2.5}$) in smoking homes was 46.5 $\mu g/m^3$ compared with 17.8 $\mu g/m^3$ in nonsmoking homes. Frying, smoky cooking events, burning incense and cleaning activities such as sweeping are additional sources of PM.[22] Indoor particulate matter has also been shown to be associated with an increase in asthma symptoms and rescue medication use.[47,48]

Nitrogen dioxide is a by-product of combustion sources. Household appliances fueled by gas such as gas stoves or kerosene heaters are the major sources of indoor NO_2.[49] Gas stoves are commonly found in inner city homes. In the seven cities participating in NCICAS, 89% of households had gas stoves.[50] Ventilating with exhaust fans reduces indoor NO_2 levels significantly but the majority of households in NCICAS did not have proper venting. Measurements in inner city households demonstrate high indoor concentrations of NO_2 often

https://CafePezeshki.IR

exceeding the US Environmental Protection Agency outdoor standard (53 ppb).[50,51] Asthmatic children exposed to NO_2 indoors are at risk for increased asthma morbidity.[50–52] NO_2 increases the risk of asthmatic exacerbations following respiratory infections, even at relatively low levels of exposure.[53]

Allergens can be produced from pests (mites, cockroaches, rodents), pets (cats, dogs), plants (pollen) and fungi (mold spores). Cockroach, mice and molds are prevalent in urban areas but there are geographic variations in exposures and sensitization.[54] African American, Mexican American and Puerto Rican children are more likely to be sensitized to cockroach and dust mites.[55,56]

Exposure to indoor allergens among sensitized asthmatic patients is associated with greater asthma severity and increased healthcare utilization. In sensitized children, indoor exposures to total fungi and to *Penicillium* species were associated with significant increases in unscheduled visits, even after controlling for outdoor fungal levels.[57] In NCICAS, children exposed and sensitized to cockroach had more days of wheeze, unscheduled doctor visits and hospitalizations compared to those children who were only exposed, only sensitized or neither exposed nor sensitized.[58] In Baltimore, Maryland, among those who were sensitized and exposed to both cockroach and mouse, mouse appeared to be the stronger driver of worse asthma.[59] Cat, cockroach, rodent and house dust mite exposure in children has been associated with asthma exacerbations in a dose dependent fashion.[58,60]

Asthma guidelines recommend reducing exposure to relevant allergens to reduce inflammation, symptoms and need for medication. A tailored, multifaceted approach to allergen avoidance in the home, based on skin test sensitivity, is emphasized because steps to reduce single allergens have been shown to be largely ineffective.[61–63] Environmental control represents a financial and practical burden for both patients and society. Successful approaches need to set realistic goals that account for limitations imposed by the inner city setting. Necessary resources may not be available for optimal environmental control. For example, only 38% of homes in NCICAS had functioning vacuum cleaners.[64] Third party payers do not reimburse for supplies and equipment needed by patients to reduce environmental triggers in their homes, nor are visiting homecare workers consistently trained in evaluating homes for triggers and educating patients about household allergen reduction.

OUTDOOR ENVIRONMENTAL EXPOSURES

Higher levels of ambient air pollutants are associated with increased asthma morbidity.[65,66] Particulate matter (<10 μm [PM_{10}] and <2.5 μm in aerodynamic diameter [$PM_{2.5}$]) is a collection of mostly inorganic pollutants that has been associated with adverse respiratory effects and exacerbations of asthma. $PM_{2.5}$ can penetrate deep into the lung. Increasing asthma morbidity has been observed during a period of declining air pollution. However, populations living in underserved urban communities remain at higher risk because improvement in ambient air quality is not equally distributed among all communities.[67]

Many children living in inner cities live in close proximity to highways and businesses that rely on high volumes of truck traffic. Using the elemental carbon (EC) portion of $PM_{2.5}$ as a marker of diesel exhaust emissions, Spira-Cohen et al found increasing risk of adverse respiratory outcomes with increasing exposures to EC concentrations in inner city children with asthma.[68] Using an in vitro model, Wu et al demonstrated that near-roadway PM produced greater inflammatory response than urban background PM. PM induced higher levels of inflammatory cytokines IL-6, IL-8 and TNF-α.[69]

OBESITY

There has been a parallel rise in the prevalence of obesity and asthma over the last few decades. Blacks and Hispanics experience higher rates of obesity than whites. Low SES is also associated with higher rates of obesity.[70] Epidemiologic studies show an association between obesity and asthma prevalence and severity. Over one third of children with asthma in a multicenter inner city study were obese compared to 17% of the general population of children in the USAs.[70,71] Obese children are not only more likely to develop asthma but are more likely to have increased severity resulting in greater healthcare utilization.[72] In a longitudinal study obesity was associated with poorer asthma control in females.[71] One study found that in an urban, predominantly African American population, the effects of indoor $PM_{2.5}$ and NO_2 exposure on asthma symptoms were greater in overweight and obese than normal-weight children and adolescents.[73]

Interventions

Many interventions have been developed and implemented in a variety of settings, including EDs, hospitals, clinics, schools and home. The approaches include educational interventions aimed at patients and their families or healthcare providers, case management, and environmental control strategies. The limitations of studies of interventions are that the majority have not been subjected to randomized controlled clinical trials, have small sample sizes, are not culturally sensitive or do not examine the cost-effectiveness. The importance of a proper study design to assess new interventions is underscored by the fact that there is a significant improvement in outcome in children with asthma enrolled in control arms of these trials.[74] Therefore caution needs to be exercised in concluding that an intervention is efficacious when using a pre-post study design.

THERAPY

Currently available medications for the management of asthma used according to published guidelines and with good adherence and follow-up are highly effective in controlling asthma symptoms in inner city children. A guideline-based approach improved asthma control in several studies enrolling moderate to severe asthmatics.[75,76] For example, Figure 33-2 demonstrates that adolescents in a control arm of a study receiving guideline-based care improved quickly and maintained control over the course of the 1-year treatment period. Of interest despite good control of symptoms, children and adolescents continue to experience exacerbations at a high rate, particularly during the fall months. A study by the NIAID Inner-City Asthma Consortium showed a reduction in the frequency of fall asthma exacerbations when omalizumab (an anti-IgE drug) was added to guidelines-directed treatment.[77] The cost of this treatment is high and studies are underway to determine if a shorter course of treatment initiated prior to returning to school prevents the fall exacerbations.

https://CafePezeshki.IR

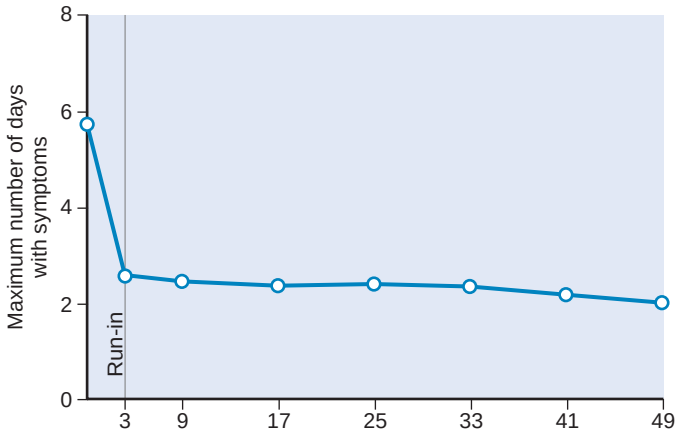

Figure 33-2 The response to guideline-based care. The graph shows symptom days per 2 weeks averaged over 1 year in adolescents in a control arm of a study given guideline-based care. *(Adapted from Szefler SJ, Mitchell H, Sorkness CA, et al. Management of asthma based on exhaled nitric oxide in addition to guideline-based treatment for inner-city adolescents and young adults: a randomised controlled trial. Lancet 2008;372(9643):1065–72.)*

EMERGENCY DEPARTMENT INTERVENTIONS

Utilization of the ED for children with asthma living in inner cities is high. Previous ED visits are strong predictors of subsequent ED visits.[78] Interventions targeting high-risk children might be expected to have an impact on asthma morbidity because these patients are likely to have severe asthma and poor asthma management skills. A number of strategies have been studied but the results have been conflicting.

A three-part ED-based intervention including asthma screening, viewing an educational video addressing beliefs and a mailed reminder did not improve follow-up or outcomes.[79] A randomized trial by Teach et al evaluated a single comprehensive follow-up visit after ED discharge that included education, initiating controller medications and scheduling a follow-up visit with a primary care provider.[80] The intervention improved asthma treatment adherence, symptom control, quality of life and healthcare use in this population of urban, largely disadvantaged, and minority children. It decreased the rate of unscheduled visits for asthma during the entire 6-month follow-up period. There was no effect of the intervention on follow-up with the primary care provider. A review of studies comparing usual care for asthma to more intensive educational programs concluded that asthma education aimed at children and their caregiver who present to the ED for acute exacerbations resulted in lower risk of future ED visits and hospital admission. It remained unclear as to what type, duration and intensity of educational packages were the most effective in reducing acute care utilization.[81] A Joint Task Force Report reviewing ED interventions recommended among other things that patients seen in the ED should have their asthma characterized and that a follow-up appointment with a primary care physician or asthma specialist be made before leaving the ED and if possible a telephone reminder.[82]

SCHOOL-BASED INTERVENTIONS

Various strategies have been used in school-based interventions but few have been subjected to randomized controlled clinical trials. Many programs have had trouble fully implementing their plans because school staff, healthcare providers and parents all find it difficult to commit sufficient time and effort to establish new patterns of cooperation. The success of school-based programs for asthma is dependent on a partnership with families and the healthcare system. Individual schools have different capabilities to deal with school health in general and with asthma in particular. The strategy to improve asthma outcomes that is most likely to succeed in a particular school will be dependent on the resources that each component of the partnership can contribute.[83]

Two randomized studies evaluated supervised asthma therapy in urban schools. Both provided medication at no cost. Gerald et al reported improved asthma control among urban school children.[84] In addition to administering medication in school, Halterman et al made guideline-based dosage adjustments and gave a home-based environmental tobacco smoke reduction program for smoke-exposed children.[85] Compared with usual care, the program improved asthma symptoms and decreased exacerbations.

Another strategy is to focus on self-management skills. Evans et al provided self-management education in inner city elementary school children.[86] The program emphasized the child's responsibility for recognizing symptoms and taking appropriate management steps. Children in treatment schools had increased management skills, fewer symptoms of asthma and improved school performance. A school-based intervention for adolescents used both group and tailored individual sessions and included education for their medical providers. Relative to control subjects, students in the intervention group reported more confidence to manage their asthma, taking more steps to prevent symptoms, greater use of controller medication, and fewer symptoms, acute care visits, hospitalizations and school absences due to asthma.[87]

Although not evaluated in controlled clinical trials, school-based mobile clinics have been used in several cities in the USA. The model attempts to reduce barriers to delivering effective care to underserved children with asthma. The mobile clinics are staffed by specialty trained asthma providers and integrate strategies for case identification, community outreach, continuity of care, structured healthcare encounters and patient tracking. Comparison of pre and post year data for subjects enrolled in the program for at least 1 year revealed reductions in the percentage of patients reporting ED visits, hospitalizations and missed school days.[88]

PROVIDER TARGETED INTERVENTIONS

Despite the findings that adherence to guidelines by providers is suboptimal, there are few rigorously designed trials of interventions aimed at providers in inner cities. A systematic review of provider interventions concluded that decision support tools, feedback and audit, and clinical pharmacy support were most likely to improve provider adherence to asthma guidelines, as measured through healthcare process outcomes.[89]

Training of staff in clinics providing care to inner city minority children coupled with administrative support for change in practice behavior increased the number of patients with asthma receiving continuing care and improved the quality of care they received compared to control clinics.[90] Health outcomes were not reported. The relative contributions of the training program and the strong organizational commitment by the

https://CafePezeshki.IR

local government health department to the outcomes could not be distinguished. Easy Breathing is a program instituted in primary care clinics serving inner city communities. The program had a positive effect on clinicians' knowledge and adherence to asthma guidelines as evaluated using a pre-post study design.[91]

The Inner City Asthma Study evaluated a decision support system with feedback to providers.[92] An automated computer program provided information to the child's primary care physician along with guideline-based treatment recommendations. The computerized algorithm analyzed each child's current level of symptoms, health care utilization and medication use and, on the basis of National Asthma Education and Prevention Program guidelines, recommended increased treatment, decreased treatment or no change. Children whose primary care physicians received these computerized letters had more follow-up care visits, received increased treatment more rapidly when warranted and had fewer ED visits.

ENVIRONMENTAL INTERVENTIONS

Asthma management guidelines emphasize the need for individualized environmental control measures in the treatment of asthma. In a small double-blind randomized trial in a low-income population, house dust mite mitigation intervention reduced dust mite levels and bronchial responsiveness but not symptoms or quality of life.[93] Attempts to reduce cockroach allergens in the home have had varied success.[94] Integrated pest management, which consists of filling holes with copper mesh, vacuuming and cleaning, and low-toxicity pesticides and traps, can control cockroach infestation. Reduction of cockroach allergen levels is feasible and can be maintained in some, but not all, multifamily dwellings in the inner city.[95,96]

Limitations in single allergen avoidance trials have directed attention to a multifaceted approach to allergen reduction. Krieger used community health workers to provide in-home environmental assessments, education, support for behavior change and resources.[97] The intervention reduced asthma symptom days and urgent health services use while improving caregiver quality-of-life score. Butz et al randomly assigned children with asthma residing with a smoker to interventions consisting of air cleaners only, air cleaners plus a health coach, or delayed air cleaner (control).[98] The use of air cleaners resulted in a reduction in indoor PM concentrations and an increase in symptom-free days. The intervention did not reduce exposure to secondhand smoke as measured by air nicotine or urine cotinine concentrations.

The Inner City Asthma Study (ICAS) reported on a multifaceted home-based environmental intervention for inner city children with asthma. Intervention was tailored to each patient's sensitization and environmental risk profile, utilizing a series of modules to reduce home allergen exposure.[99] Individuals who were randomized to environmental intervention demonstrated significantly fewer symptom days during the intervention year and during the year following intervention compared to individuals in the control group.[75] Cost of the intervention ranged from $750 to $1,000 per patient, estimated to cost $27 per symptom-free day.[100] In another multifaceted allergen avoidance study, Carter et al studied the effect of avoidance of dust and cockroach in a group of inner city children with asthma. While there was no overall improvement in the intervention group compared with control, significant reduction in acute visits for asthma was demonstrated for mite-allergic children who had a significant decrease in exposure to mite allergen.[101]

TECHNOLOGY-BASED INTERVENTIONS

There are few rigorously assessed computer-based interventions for asthma. These have had limited success. An educational software program did not produce greater improvement than occurred with review of traditional written materials.[102] A trial of a computer-assisted instructional (CAI) game on asthma symptoms was not effective in improving asthma symptoms.[103] In contrast, a small study found that computer-delivered self-management education used at home scored higher on prevention and treatment strategies and enhanced children's sense of self-efficacy.[104]

Emerging health information technologies designed to improve patient-physician communication can be used successfully in inner city populations. Among children and adolescents in a low-income, urban population, a text messaging intervention compared with usual care was associated with a modest improvement in the rate of influenza vaccination.[105] Smartphone applications to monitor peak flow or asthma symptoms are available but their use has not been evaluated in controlled clinical trials. The technologies are developing rapidly and have the potential of delivering targeted interventions to individuals.[106] An important barrier to overcome with interventions requiring daily monitoring or daily diaries is decreased compliance with monitoring over time that has been observed in inner city children with asthma.[107]

MULTIFACTORIAL INTERVENTIONS

The first phase of the NCICAS showed that a multitude of factors are responsible for asthma morbidity, including adherence, access to care and physician undertreatment. Other risk factors involve the living conditions, social welfare and mental health issues of the family. These risk factors may interfere with the ability of the family to give sufficient attention to the child's asthma. It also became apparent that asthma management was not the responsibility solely of the physician but of the family as well. For an intervention in the inner city to succeed, it must address a variety of risk factors, not all of which would be the same among individuals.

The asthma counselor intervention program developed by NCICAS used social workers to empower families to increase asthma self-management and to improve their communication with primary care providers. A risk profile was prepared for each child on the basis of assessments of skin test sensitivities, environmental exposures, psychosocial factors, difficulty accessing care, exposure to pets or smoking and other factors. The multifactorial intervention was tailored to each child using specific modules, each of which addressed specific risk factors. This tailored intervention approach was found to be highly effective in reducing asthma symptoms among the children.[108]

Home-based educational interventions may lead to modest short-term improvements in asthma outcomes among inner city children. A home-based intervention using asthma counselors modeled after the NCICAS intervention and culturally adapted for Puerto Rican families found no significant differences in symptom-free days between the intervention and control groups, although significant reductions were observed in symptom-free nights, ED visits and hospitalizations.[109]

https://CafePezeshki.IR

A randomized, parallel group, controlled trial found that asthma education led to improved adherence and decreased morbidity compared with usual care. The education consisted of five home visits by trained asthma educators reviewing medications, identifying barriers and discussing beliefs and concerns. Addition of feedback based on objective adherence data did not improve outcomes over education alone.[110] A nurse-led education program in Glasgow, Scotland, for children hospitalized for asthma who were predominantly of lower social class implemented home management training that incorporated written and verbal information and was reinforced with outpatient follow-up appointments and telephone advice.[111] A review suggested that culture-specific education programs for children from minority groups are effective in improving asthma-related outcomes of quality of life, asthma knowledge and rate of asthma exacerbations and asthma control. Thus asthma education programs for children from minority groups with asthma would be more likely to succeed if they were culture specific.[112]

One randomized controlled trial evaluated usual care versus 2-year asthma coach intervention for low-income, Medicaid-covered, African American children.[113] The coaches were two African American women with high school education residing in the same general neighborhoods as the participants. The coach intervention was designed to achieve standardization through a set of key behavioral objectives and a planned schedule of contacts as well as flexibility through a nondirective approach and individualization of key behavioral objectives. The asthma coach intervention achieved lower prevalence of hospitalizations. The intervention did not lead to a decrease in emergency visits that did not require hospitalization. A subsequent study assigned lay workers to coach parents to improve important aspects of care and reduce morbidity in a high-risk population.[114] Coaches were taught the pathogenesis, symptoms and management principles of asthma and how to communicate effectively, provide psychosocial support to parents during times of stress, assess parents' readiness to engage in targeted management strategies, and promote behavior change. Parental coaching increased asthma monitoring visits, including visits with documented controller medications, but these changes were not associated with fewer ED visits.

Walders et al used an interdisciplinary intervention consisting of a written asthma treatment plan, asthma education, an asthma risk assessment, problem-solving and access to a 24-hour nurse advice line.[115] The intervention group did not show evidence of reduced asthma symptoms or improved measures of quality of life beyond the changes demonstrated by the comparison group. However, the interdisciplinary intervention group had less frequent healthcare utilization for asthma over the course of the 1-year follow-up period.[115]

Community-Wide Asthma Coalitions

Community-wide asthma coalitions are collaborative efforts at the local level to achieve asthma control by bringing together diverse stakeholders that include healthcare providers, grassroots groups, voluntary and government agencies and business and industry who collectively implement strategies to improve asthma outcomes. The results are mixed.

Fisher et al evaluated a neighborhood asthma coalition in St. Louis. The coalition included educational programs for parents and children, promotional activities and individualized support provided by trained neighborhood residents. Acute care rates decreased for both the coalition and control groups from the year before intervention to the last year of intervention but with no significant differences between the coalition and control groups.[116]

Allies Against Asthma is a group of community-based coalitions working to improve asthma outcomes in vulnerable children. The evaluation of the program indicated that mobilizing diverse stakeholders and focusing on policy and system changes can generate significant reductions in healthcare use for vulnerable children with asthma.[117] What is evident is that results from the asthma coalitions are not instantaneous but become evident over the long term.

Conclusions

The management of asthma in inner cities presents a challenge that requires participation of multiple stakeholders. Major challenges to preventive asthma care are encountered by inner city children and include family and patient attitudes and beliefs, lack of access to quality medical care, psychosocial and environmental factors. The myriad factors contributing to morbidity are interdependent. It is clear that a 'one size fits all' approach is unlikely to be successful. There are lessons to be learned from the characteristics of successful interventions. It is important to assess individual risk factors. Programs require flexibility so that elements can be tailored to the individual. Guideline-based care will not succeed unless attention is paid to psychosocial and societal issues that are barriers to care. For example, a family with good asthma knowledge may not be able to overcome barriers such as no access to after-hours clinics or lack of insurance coverage for spacers.

The interventions outlined in this chapter demonstrate that positive outcomes can be achieved. However, translating research into practice is the ultimate goal and this presents another major challenge. An attempt to disseminate the NCICAS asthma counselor model at 22 sites across the country by the Centers for Disease Control exemplifies some of the difficulties. Implementation varied among sites. Retention was related to type and location of the sites, ease of obtaining written plans, language and ethnicity of asthma counselor and availability of on-site allergy testing.[118] A report from the Merck Childhood Asthma Network discussed the adaptation of evidence-based interventions at five sites and documented the site-to-site variations in fidelity to the original interventions.[119] More real world data on implementation and barriers are needed from those implementing community interventions in order to refine programs and reduce morbidity.[120]

Asthma in Older Children: Special Considerations

LEONARD B. BACHARIER | ROBERT C. STRUNK

KEY POINTS

- Failure of symptoms to respond to β-agonists and oral steroids should prompt consideration that the symptoms are not caused by asthma but by another process.
- Cough that persists despite treatment with bronchodilators and systemic corticosteroids is often not due to asthma. Consideration of other disorders, particularly sinusitis, is imperative.
- The Asthma Action Plan is the centerpiece of asthma education, focusing the child and parents on early warning signs, when to increase treatment and when to call for advice during more severe exacerbations. The action plan is directly relevant, focussing on action not theory. An understanding of theory may be helpful when the family can focus on these details.
- Pulmonary function measures may not accurately reflect asthma severity in children, who can have an FEV_1 in the normal range even when disease is severe. The FEV_1/FVC ratio is a much better indicator of severity of disease.
- Asthma is controllable in the vast majority of children. Even children with severe asthma can be expected fully to participate in activities. This is an important goal for children and their parents.

Asthma is the most common chronic disorder of childhood, affecting approximately 10.7% of children aged 5 to 14 years,[1,2] with 6.4% of children in this age group reporting an episode of asthma or an asthma attack in the preceding 12 months.[1,2] However, estimates of wheezing in this age group approach 20% or greater in some areas of the USA and in many industrialized countries, further magnifying the impact of wheezing disease on children.

Epidemiology and Etiology

PREVALENCE OF CHILDHOOD ASTHMA

In the USA from 1980 to 2010 asthma prevalence in the general population increased from 3.1% to 8.4%, with increases among 5- to14-year-old children from 4.4% in 1980 to 8.2% in 1995, 9.1% in 2004, and 10.7% in 2010.[1,2] Although the rise in asthma prevalence may reflect coding and classification issues, the influence of other factors, such as environmental exposures to allergens, infectious agents, endotoxin, vitamin D insufficiency and tobacco smoke, must also be considered. Place of residence appears to influence asthma prevalence.[3] Furthermore, there appears to be an effect of gender on asthma prevalence, as the male-to-female ratio for asthma is 1.8:1 among children aged 2 years and under, but by puberty, asthma becomes more prevalent amongst females (M:F ratio of 0.8:1). The change in gender ratio represents development of new cases of asthma in females during adolescence, not a decrease in males with asthma.[4]

FACTORS INFLUENCING THE ETIOLOGY OF ASTHMA

A general pattern of factors influencing development of asthma seems to be emerging, including family history/genetics, smoking, diet, obesity and inactivity, all of which seem to influence the development of asthma and disease outcomes (Table 34-1).

Socioeconomic Status

Many clinical or area studies have reported substantially higher rates of asthma prevalence, morbidity, hospitalization and mortality among racial and ethnic minorities. However, asthma is also most common among low socioeconomic groups regardless of race. While black children have higher rates of asthma than white children, most studies have found that black race is not a significant correlate of asthma after controlling for location of residence and socioeconomic status (SES). The basis for the effects of poverty and urban residence on asthma prevalence is not known. One potential factor is exposure and sensitization to allergens common in urban environments. Black children in inner city Atlanta are exposed to high levels of dust mite and cockroach allergen, and a high proportion of the children with asthma was sensitized to these allergens.[5] Litonjua et al also concluded that a large proportion of the racial/ethnic differences in asthma prevalence can be explained by factors related to income, area of residence and level of education.[6]

Income is a determinant of access to health care and frequently the quantity and quality of health care available. Persons who have low income, regardless of race or ethnicity, are more likely to be under- or uninsured, to encounter delays in receiving or be denied care, to rely on hospital clinics in emergency departments for health services and to receive substandard care. The usual socioeconomic indicators, education and personal or household income, serve only as surrogates for more complicated correlates of individuals within populations and multiple factors that can impact both on prevalence of asthma and adverse outcomes from the disease.

Genetics

The genetic basis of heritability has been extensively studied and while the genetic basis of asthma remains incompletely understood, studies are yielding some understanding[7,8] (see

https://CafePezeshki.IR

TABLE 34-1 Factors which Influence Disease Development and Severity

Factor	Disease Development	Disease Severity
Atopy	++++	++++

*While exercise is a common precipitant of asthma symptoms, improved physical conditioning can reduce asthma severity.
†Consider in the context of asthma, nasal polyposis and severe sinus disease.

Chapter 3). There is as of yet no established genetic pattern that predicts presence of asthma or defines its severity.

Allergy

Studies of school children in Melbourne, Australia by Williams and McNicol[9] have indicated increases in both the incidence of asthma and asthma severity with increases in number of positive skin tests and total serum IgE. The relationship between allergy and asthma has more recently been highlighted by the importance of aeroallergen sensitivity in the progression of frequent intermittent wheezing to persistent asthma in young children.[10] Several large epidemiological studies have clearly indicated the importance of aeroallergen sensitization in asthma development among populations at risk. Sensitization to house dust mite and mold was a predictor of asthma in rural Chinese individuals selected on the basis of having at least two siblings with physician-diagnosed asthma.[11] In a similar study, total serum IgE levels and positive skin tests to aeroallergens were correlated with current wheezing.[12] This association was present in children from nonatopic, asymptomatic probands, as well as in the expected atopic asthmatic probands, suggesting that much of the increase in asthma prevalence is associated with specific IgE sensitization and is occurring in persons previously considered to be at low risk for developing asthma or atopy.

Demographic and Environmental Factors

Studies comparing the populations of East and West Germany showed the prevalence of hay fever and asthma to be significantly higher in West German children, suggesting that environmental factors may explain the difference in prevalence in these ethnically similar populations.[13] Early exposure to infections (e.g. being in a daycare environment early in life) or exposure to endotoxin or other bacterial products (e.g. growing up on a farm with close exposure to the farm animals) is associated with a decreased prevalence of asthma. In contrast, growing up in an urban environment or generally with an increased standard of living is associated with an increased prevalence of asthma.[14] Such correlates are also present for atopic diseases other than asthma. In fact, Strachan, who noted that prevalence of hay fever was inversely related to family size, was the first to recognize the importance of early exposures on atopic disease.[15] In the USA, asthma is more prevalent in African-Americans and Puerto Ricans. These findings are not explained by the observations on the role of social class in European studies. Given the ethnic differences between African-Americans and whites, these studies may represent gene-environment interaction producing varied phenotypic outcomes.

Gene-Environment Interaction

Genetic factors alone cannot explain the rise in asthma prevalence, morbidity or mortality.[16] However, a small change in the prevalence of relevant environmental exposures could explain a significant rise in disease prevalence among genetically susceptible individuals. Gene-environment interaction, defined as the co-participation of genetic and environmental factors, is particularly relevant to the etiology of asthma morbidity, particularly in individuals who experience a disproportionate burden of environmental exposures,[17] and may exert its effect through epigenetic mechanisms.[18] Relevant exposures include smoking, stress, nutritional factors, infections, allergens and occupational exposures. In addition, racial/ethnic variability in the distribution of genetic polymorphisms can potentially modify the response to pharmacotherapeutic agents, such as the β_2-adrenergic agonists.[19]

Stress

Negative family characteristics such as family conflict and family dysfunction discriminated children who died of asthma from children with equally severe asthma who did not die.[20] Parenting difficulties have been associated with a higher risk for the development of asthma early in life.[21] In addition, children with the highest risk of developing early-onset asthma were those in families with both parenting problems and high stress. Evidence for a link between stress and asthma has been gained from temporal studies, as experiencing an acute negative life event increased children's risk for an asthma attack 4 to 6 weeks after the occurrence of the event.[22] Moreover, the combination of chronic and acute stress plays a role in the temporal association. Experiencing an acute life event among children who had ongoing chronic stress in their lives shortened the time frame in which they were at risk for an asthma attack to within 2 weeks of the acute event. The experience of daily life stressors is associated with same-day lower peak expiratory flow (PEF) rate and greater self-report of asthma symptoms. Further, high levels of stress have been associated with detrimental biological profiles, such as greater inflammatory responses after antigen challenge or in vitro stimulation of immune cells among children with or at risk for asthma.[23,24]

Children with asthma have been found to have higher rates of clinically significant family stress compared with healthy children.[25] Children whose families are more cohesive are more likely to have controlled, rather than uncontrolled, asthma.[26] Additionally, parenting difficulties early in a child's life, particularly during times of high stress, have been found to predict the

https://CafePezeshki.IR

onset of asthma in childhood.[21] Thus, strain in the family, both in terms of conflicts among family members and impact of illness on family relationships, could be associated with both increased asthma prevalence and poor asthma outcomes.

One psychological pathway that has been suggested to explain associations of SES with asthma is the differential experiences of stress faced by children of low and high SES. In healthy children, low SES has been associated with more frequent exposure to stressful life events, and children who live in low SES neighborhoods are more likely to report witnessing incidences of violence. Low SES also has been associated with more negative stress appraisals.[27]

Obesity

Obesity is linked with the development and severity of asthma in both children and adults, and weight reduction improves asthma severity and symptoms.[28,29] Similar to the results in industrialized countries, Celedon and colleagues found an association between overweight and presence of asthma or airway hyperresponsiveness among adults in China with either physician-diagnosed asthma or airway responsiveness to methacholine.[30] They also found an association between underweight (body mass index [BMI) 16 kg/m^2 or less) and asthma, which could be the result of an effect of asthma symptoms on nutrition or an effect of previous weight loss and development of asthma.

The relationship between obesity and asthma observed in adults has also been most often observed in adolescent females, but not in males. Girls who were overweight or obese at age 11 years were more likely to have current wheezing at ages 11 and 15 years, but not at ages 6 to 8 years. The relationship between obesity and asthma is strongest among females beginning puberty before age 11 years. Females who become overweight or obese between 6 and 11 years are seven times more likely to develop new asthma symptoms at age 11 and 13 years.[31] The mechanism of increased asthma with obesity is not clear. The strong gender differences observed[31,32] suggest that overweight status itself does not produce the asthma, as a direct effect of weight is not seen in both boys and girls. Longitudinal studies[31] suggest that there is a more fundamental relationship, as most of the asthma in obese adolescent girls was new-onset asthma. In a study of young adults with asthma,[33] a lower level of physical activity did not explain the association between the incidence of asthma and gain in weight. Poor asthma control in obese children with asthma may be overestimated since obesity is associated with enhanced perception of nonspecific symptoms such as dyspnea that results from altered mechanical properties of the chest wall.[34]

Infection

Viral respiratory infections are present in up to 85% of children with exacerbated asthma.[35] In addition to worsening asthma, there may be a more fundamental relationship between infection and the development of asthma. Such a relationship has been suggested by the finding of a higher than expected incidence of bronchial hyperresponsiveness in children who had whooping cough, croup or bronchiolitis in their early years of life.[36] Children hospitalized with respiratory syncytial virus bronchiolitis are at increased risk for asthma at school age,[37–39] and this risk appears to persist to early adulthood.[40] In addition, wheezing in the context of rhinovirus infection during the preschool years is also a significant risk factor for asthma at school age.[41]

The role of *Mycoplasma pneumoniae* or *Chlamydia pneumoniae* infections in the underlying pathogenesis of asthma has been suggested (see Chapter 31). A conclusive association between development of *C. pneumoniae* or *M. pneumoniae* infection and onset of asthma, or even an association between the presence of the organism and more severe disease, remains to be established in large prospective studies.

Diet

Several studies have identified relationships between maternal and infant diets and subsequent asthma risk.[42] Studies in birth cohorts have found that higher maternal intakes of vitamin D during pregnancy from both foods and supplements were associated with an almost 60% reduction of asthma and recurrent wheezing in 3- to 5-year-old children.[43,44] Other studies identified a relationship between a high dietary intake of vitamins C, A, and E with higher levels of lung function. A longitudinal analysis of decline in forced expiratory volume in 1 second (FEV_1) over a 9-year period in adults found the decline to be lower amongst those with a higher average vitamin C intake, but no relationship to magnesium or vitamins A or E.[45] The relationship between diet and atopy is not clearly understood, although there is some evidence for a relationship between concentrations of vitamin E and both allergen skin sensitization and IgE concentrations.[46]

Natural History of Asthma

PERSISTENCE AND PROGRESSION OF DISEASE INTO ADULTHOOD

The course of asthma through childhood and adolescence is variable. More severe asthma is likely to persist from childhood into adulthood without remission, with only 15% of children with severe asthma experiencing remission by age 50 years.[47] Another important tendency in the natural history is for symptoms to remit in adolescence only to return again in adulthood. In general, the amount of wheezing in early adolescence seems to be a guide for severity in early adult years, with 73% of those with few symptoms at age 14 years continuing to have little or no asthma at age 28 years.[48] Similarly, 68% of those with frequent wheezing at 14 years still experienced recurrent asthma at age 28 years. Most subjects with frequent wheezing at 21 years continued to have comparable asthma at 28 and 50 years. In addition to the importance of symptoms, the childhood degree of bronchial responsiveness combined with a low FEV_1 was also related to the outcome of asthma in adulthood.[49] While many children become asymptomatic in adolescence, pulmonary function deficits associated with asthma and wheeze increase throughout childhood,[50] and a significant proportion of children free of symptoms and with normal FEV_1 and even FEV_1/forced vital capacity (FVC) ratios, continue to have increases in bronchial reactivity.[51] This bronchial hyperresponsiveness is an independent risk factor for development of a low FEV_1 and associated symptoms in early adulthood.[52] What is perhaps most concerning about the persistence of childhood disease into adulthood is the development of chronic airflow obstruction, with loss of bronchodilator responsiveness[53] and a decline in FEV_1 over time, that is greater in adults with asthma than in asymptomatic peers.[54] These findings suggest that asthma, even uncomplicated by cigarette smoking, may be a precursor of a chronic obstructive pulmonary disease (COPD)-like syndrome in adults.

https://CafePezeshki.IR

DURATION OF DISEASE IS ASSOCIATED WITH DEGREE OF ABNORMALITY IN PULMONARY FUNCTION

Longer duration of asthma was associated with lower levels of lung function in children with mild-to-moderate asthma aged 5 to 12 years.[55] This association was independent of levels of atopy, presence of household allergens and prior use of anti-inflammatory medications. Duration of asthma was associated with lower levels of both pre- and post-bronchodilator values for FEV_1 and FEV_1/FVC ratio.[55] While the values for FEV_1 both pre- and post-bronchodilation were well within the normal range for children (93.9% predicted and 102.8% predicted, respectively), more than 50% of children with asthma had low FEV_1/FVC ratios, suggesting that airway obstruction is present and worsens even with relatively mild-to-moderate asthma. The degree of bronchial hyperresponsiveness in these children was also related to the duration of disease.[56] Since level of pulmonary function and degree of bronchial hyperresponsiveness are independent predictors of abnormal levels of lung function in adults who had childhood asthma, it is apparent that longer duration of disease in childhood and its associated abnormalities of lung function predispose adults to disease.

Morbidity and Mortality

In 2010, 6.4% of US children experienced a self-reported asthma attack, with no significant decrease in incidence since 1997[1,2] in spite of the much improved therapies available. Between 2001 and 2009, the rate of outpatient office visits remained relatively stable at 351 visits/10,000 population/year.[1,2]

Emergency department visits among children aged 5 to 14 years increased by approximately 8% from 2001 to 2009, with nearly 10% of children aged 5 to 14 years seeking emergency department care yearly.[12] Rates among blacks are almost 3-fold higher than rates for whites. Asthma is the leading admitting diagnosis to children's hospitals,[2] and blacks have greater than 3-fold more hospitalizations than whites. Rates of hospitalizations in 5- to 14-year-old children remained stable from 1980 to 2009, and were more than 3-fold lower than for younger children. A significant proportion of hospitalizations are repeat hospitalizations, with rehospitalizations accounting for 20% to 25% of hospitalizations in a signal year and up to 43% of hospitalizations in one urban children's hospital within a 5- to 10-year period.[57] A lifetime history of hospitalizations was associated with family impacts (greater family strain and family conflict, greater financial strain), as well as caregiver characteristics of greater personal strain and beliefs about not being able to manage one's child's asthma.[58] Individual characteristics of the caregiver (lower sense of mastery, being less emotionally concerned by asthma) predicted greater likelihood of future asthma hospitalizations.[58]

The rate of deaths due to asthma in 5- to 14-year-old children increased more than 2-fold from 1980 (1.8 per million) to 1995 (3.4 per million) before stabilizing through 2002 (2.4 per million) and then increasing in 2004 to 2.6 per million and 2.8 per million in 2009.[1,2] Blacks have many more deaths from asthma than whites (2.9-fold in 2009). While the death rate in children is relatively small compared to that in other age groups, physicians find that many, if not most, of these deaths are preventable, with the major reason for death being late arrival to health care associated with poor use of oral corticosteroids. Late arrival is often associated with psychological problems in the family or child, but can be associated with shortcomings in availability of medical care.

While there have been significant efforts toward understanding the reasons for the occurrence of fatal and near-fatal asthma episodes, the identification of patients at risk for dying remains an art with no single set of criteria able to identify all patients who will die. Prior history of severe events, especially respiratory failure requiring intubation, is an obvious risk factor. However, while as many as 25% of patients with a history of respiratory failure die in a 3- to 5-year follow-up, most patients who die have not had a previous episode of respiratory failure.[59] Most studies indicate that a high proportion of patients who have died have had severe asthma, but the number of patients with severe disease is large and only 1% to 3% will die over an extended follow-up period. The importance of psychological factors in poor outcomes from asthma[20] indicates that patient and family factors resulting in psychological dysfunction need to be identified as well.

There are certain time intervals when risk of fatality is increased. For example, patients may need extra care and communication in periods following hospitalization, as enhanced bronchial hyperresponsiveness persists after hospitalization much longer than abnormalities in spirometry, and oral steroids will be being weaned, further increasing risk. Hospitalizations that occur in spite of optimally prescribed therapy are of special concern.

Differential Diagnosis of Asthma

The differential diagnosis of cough and wheeze is extensively reviewed in Chapters 27, 32, and 37.

Evaluation

Figure 34-1 presents an algorithm for evaluation of a school-age child or adolescent who presents with chest symptoms of cough, wheeze, shortness of breath, chest tightness or chest pain.

HISTORY

Historical elements should include specific symptoms, their frequency and severity, triggering factors and response to therapy. Age of onset of symptoms is important, as 80% of patients with asthma experience symptoms within the first 5 years of life. Thus, the adolescent presenting with recent onset of symptoms without a prior history warrants further evaluation of alternative diagnoses. Since asthma is a disorder characterized by repeated episodes of at least partially reversible airflow obstruction, failure of symptoms to improve with treatment including bronchodilators and corticosteroids should prompt evaluation for other processes, either a nonasthma diagnosis or a co-morbid condition complicating underlying asthma.

A short series of questions focussing on recent symptom frequency is extremely informative in assessing the child with asthma. The Asthma Control Test (ACT) serves this purpose,[60,61] and when completed at each follow-up asthma visit, can serve as a rapid appraisal of asthma control over time.

Additional history should focus on identification of other co-morbid conditions that may worsen asthma severity, including allergen exposure, rhinitis, sinusitis and gastroesophageal reflux. Furthermore, an assessment of underlying psychosocial

https://CafePezeshki.IR

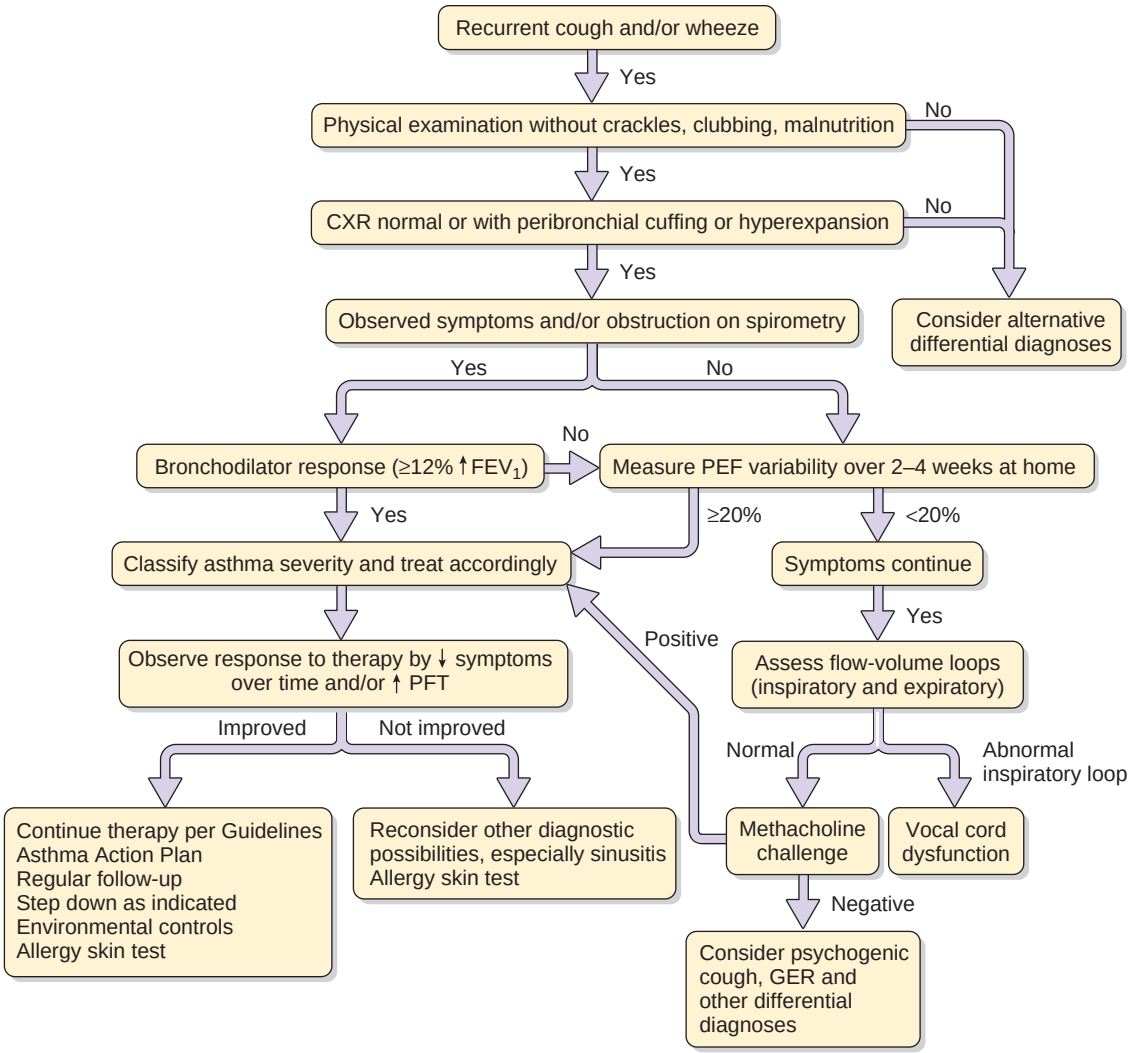

Figure 34-1 Algorithm for establishing diagnosis in children with recurrent cough and wheeze. *CXR* – chest x-ray, *FEV_1* –forced expiratory volume in 1 second, *PEF* – peak expiratory flow, *PFT* – pulmonary function test, *GER* – gastroesophageal reflux.

factors and adherence to the medical regimen may provide valuable clues as to barriers in delivery and receipt of asthma care.

PHYSICAL EXAMINATION

Findings may include an increased anteroposterior chest diameter in severe disease and expiratory wheezes and prolongation of the expiratory phase during exacerbation. Presence of nasal polyposis should prompt an evaluation for cystic fibrosis, regardless of the age of the child, as cystic fibrosis remains the leading cause of polyps in childhood. The primary focus of the exam should include careful evaluation to assure absence of findings suggestive of other diseases, such as the presence of crackles, digital clubbing and hypoxemia, as well as to uncover factors that worsen disease, including nasal and sinus disease.

LABORATORY EVALUATION

Peripheral blood eosinophilia and/or elevated serum IgE levels are often found in children with asthma and can be helpful in the evaluation of severe disease. Laboratory evaluation is helpful in excluding entities that comprise the differential diagnosis of asthma. Serum immunoglobulin levels (IgG, IgM and IgA) may be helpful in evaluating for defects in humoral immunity predisposing to recurrent lower respiratory tract illness. Sweat chloride analysis is required to exclude cystic fibrosis. Children with bronchiectasis along with chronic otitis media and sinusitis may warrant an evaluation of ciliary structure and function. A purified protein derivative (PPD) skin test is helpful in excluding mycobacterial infection.

ASSESSMENT FOR ALLERGIC SENSITIZATION

Evaluation for allergen-specific IgE, either by percutaneous skin testing or in vitro testing, should be part of the evaluation of all children with persistent asthma, as proper identification of allergic sensitivities and instruction in environmental control measures may provide significant clinical benefit.

RADIOLOGY

All children with recurrent episodes of cough and/or wheeze should have a chest radiograph (anteroposterior and lateral

https://CafePezeshki.IR

views) to aid in exclusion of other diagnostic entities. Radiographic findings that may be seen with asthma include hyperexpansion, increased anteroposterior diameter, peribronchial cuffing and/or areas of atelectasis (any lobe or subsegment can be involved). Findings of chronic changes, including bronchiectasis, should lead to further evaluation of alternate diagnoses.

PULMONARY FUNCTION TESTS

With the help of well-trained and experienced pulmonary function technicians, children as young as 4 to 5 years of age should be capable of performing spirometry. Spirometry measures FVC, FEV_1, the ratio of FEV_1/FVC, as well as other measures of airflow including the forced expiratory flow between 25% and 75% of FVC ($FEF_{25–75}$). The FEV_1 is the most commonly used and reproducible measure of pulmonary function, whereas the $FEF_{25–75}$ demonstrates much more intrapatient variability. Standards are widely available for most spirometric measures and allow for correction for patient age, gender, race and height. The FEV_1/FVC ratio is an indicator of airflow obstruction and may be more sensitive in identifying airflow abnormalities in asthma than the FEV_1, as most children with asthma have an FEV_1 within the normal range, even in the presence of severe disease (see section on Classification of asthma severity).

Asthma is characterized by airflow obstruction that is at least partially reversible by a bronchodilator. Thus, spirometry is often performed before and 20 minutes following administration of a bronchodilator such as albuterol. An increase in the FEV_1 of at least 12% is considered to represent a significant change and exceeds that seen in nonasthmatic individuals, although recent evidence suggests that lower levels of bronchodilator response (≥8–9%) may be more appropriate cut-offs in identifying asthma in children.[62,63]

Particular attention should be given to the inspiratory and expiratory flow-volume loops, as they are extremely helpful in excluding other patterns of airway obstruction.[64,65] For example, fixed airway obstruction (abnormalities on both the expiratory and inspiratory loops) can be seen with a mediastinal mass compressing a large airway or variable extrathoracic airway obstructive process (abnormalities just on the inspiratory loop) is seen with vocal cord dysfunction (VCD). Asthma produces variable intrathoracic obstruction (abnormalities on just the expiratory loop). Patients with VCD without asthma do not demonstrate intrathoracic airway obstruction, but may show blunting or truncation of the inspiratory loop consistent with variable extrathoracic obstruction. Variability between spirometric trials is not uncommon in patients with VCD, often consisting of normal and abnormal inspiratory loops during a single session.

In addition to spirometry, other tests of pulmonary function may aid in the evaluation of the child with asthma that is difficult to diagnose or control. Patients with asthma generally demonstrate normal total lung capacity (TLC) on lung volume testing by plethysmography, but may demonstrate evidence of air trapping as shown by elevated residual volumes (RV) and RV/TLC ratio. Measurement of diffusing capacity of carbon monoxide (DL_{CO}) is normal in patients with asthma, and abnormalities in DL_{CO} should prompt evaluation for interstitial lung diseases.

Fractional exhaled nitric oxide (FeNO) is a noninvasive marker related to asthmatic airway inflammation as reflected by bronchial wall inflammation,[66] sputum eosinophila[67] and airway hyperresponsiveness.[68] FeNO levels increase as asthma control deteriorates[69] and decrease with treatment with agents which reduce airway inflammation, including inhaled corticosteroids (ICSs)[70–72] and leukotriene receptor antagonists (LTRAs).[73–75]

CHALLENGE TESTING

Some children present with atypical features of asthma and may pose greater challenges in confirming an asthma diagnosis. Thus, use of bronchial challenges with agents that provoke bronchoconstriction may be helpful in the diagnosis and management of the child with atypical symptoms, poor response to asthma medications or lack of a response to a bronchodilator during spirometry. Agents used for bronchoprovocation challenges include methacholine, mannitol, histamine, adenosine, allergen, cold air and exercise. Methacholine challenge has been widely used in epidemiological and clinical trials of childhood asthma and has demonstrated an excellent safety record. Challenge studies should be performed in laboratories familiar with such procedures.

BRONCHOSCOPY

In children with particularly severe disease or with poor response to conventional therapy, direct visualization of the airways along with bronchoalveolar lavage (BAL) may provide important clinical information. Such examinations may reveal the presence of previously undiagnosed foreign body aspiration or other intrinsic airway mass, infection, extrinsic airway compression, evidence of chronic aspiration, as well as indicators of airway inflammation (such as eosinophilia or neutrophilia).

Evaluation and Management of Factors which Increase the Severity of Disease

OVERVIEW

The most common precipitating factors are respiratory infections and weather changes. Drawing attention to these factors can prompt patients to start increased treatment early in an exacerbation, as they will be looking for increasing symptoms that occur as an infection starts or as weather is changing rapidly. Exercise is also commonly identified as an exacerbating factor. Interestingly, although it is known that exposure to allergens and irritants can worsen asthma, such exposures are much less commonly recognized as important.

EXPOSURE TO INHALANT ALLERGENS

Exposure and allergic sensitization to cockroach allergen was associated with a significantly greater risk of asthma hospitalization and greater healthcare utilization among 476 children aged 4 to 9 years who participated in the National Cooperative Inner-City Asthma Study.[76] Allergic sensitization to the mold *Alternaria* has been identified as a significant allergen in terms of increasing airway hyperresponsiveness[77] and was associated with a nearly 200-fold increased risk of respiratory arrest due to asthma,[78] emphasizing the importance of determining

https://CafePezeshki.IR

underlying allergic sensitivities in patients with asthma and providing patients with accurate and practical advice on allergen avoidance techniques.

The Childhood Asthma Management Program, comprised of 1,041 children aged 5 to 12 with mild-to-moderate asthma, found that allergic sensitization to tree pollen, weed pollen, *Alternaria*, cat dander, dog dander or indoor molds was associated with greater airway hyperresponsiveness to methacholine, although only sensitivity to dog and cat dander and the outdoor fungus *Alternaria* had independently significant relationships.[79] A cross-sectional analysis of a birth cohort of 562 children studied at 11 years of age found that bronchial hyperresponsiveness significantly correlated with higher levels of total serum IgE.[80] Burrows and co-workers[81] found a close relationship between total serum IgE and both the severity and persistence of bronchial responsiveness in a longitudinal study of adolescents and adults. Together these findings further the importance of control of these allergens in attenuating asthma symptoms.

A number of studies have followed children with asthma through childhood and adolescence into adulthood. Conclusions from the study in Melbourne, Australia indicate that severity of asthma in adulthood is related to the presence of increased levels of atopy in childhood, with the presence of an atopic condition in childhood shifting the risk of asthma in later life toward more severe outcomes.[9]

There is a clear association between sensitization to pets and current wheezing and bronchial hyperresponsiveness.[82] Dharmage and co-workers found that a high level of cat allergen in floor dust was associated both with an increased risk of being sensitized to cats and the presence of current asthma.[82] In the Childhood Asthma Management Program (CAMP) population, children sensitized to dog and exposed to high levels of dog allergen and sensitized to cat and exposed to high levels of cat allergen had a clearly increased risk of nocturnal awakenings.[83]

In contrast, there is evidence of a lower risk of asthma among children exposed to pets in early life compared with unexposed children.[84] Other studies find that individuals living with a pet have significantly less asthma or less severe bronchial hyperresponsiveness.[85] Studies showing protection from pet ownership are confounded by the likelihood that subjects with less severe asthma can keep the pets, whereas subjects with more severe disease are unable to hold pets.

RHINITIS

Rhinitis is common in children with asthma, with estimates of up to 80% of patients with asthma reporting upper airway symptoms. Whereas most rhinitis that worsens asthma is allergic, perennial rhinitis in nonatopic subjects can be a risk factor for more severe asthma.[86] Topical nasal steroid therapy for allergic rhinitis has also been shown to attenuate the increase in bronchial hyperresponsiveness during the grass pollen season,[87] as well as decrease the risk of emergency department visits[88] or hospitalizations for asthma.[89] Thus, treatment plans for patients with asthma and allergic rhinitis should consist of optimal management of concomitant allergic rhinitis (see Chapter 24).

SINUSITIS

Sinusitis is often discovered in the search for factors responsible for an overall worsening of asthma unexplained by changes of environment or other obvious historical features. Although many patients present with symptoms of upper airway disease along with asthma, some have sinusitis as a significant contributor to difficult-to-control asthma but with a paucity of symptoms suggestive of sinusitis.

Radiographic examination of the paranasal sinuses in children hospitalized for acute asthma exacerbations is positive in 30% to 60% of children, partly depending upon the diagnostic technique used (Water's view radiograph or computed tomography of the sinuses). The effect of antibiotic treatment of bacterial sinusitis on asthma control has been examined in several clinical studies and shown to reduce asthma medication use, decrease asthma symptoms and improve bronchial hyperresponsiveness.[90,91] (see Chapter 26). Duration of antibiotic treatment should be individualized, but should continue until the patient is symptom-free for at least 7 days.

GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux (GER) is common among patients with asthma. In adults with asthma the estimated prevalence of GER approaching 80%.[92] Studies of the prevalence of GER in pediatric patients with asthma are limited, but a reported 64% incidence of a positive pH probe study in a group of 25 children with asthma[93] suggests that GER may also be common among children with asthma.

In our experience most young children and even adolescents with GER do not report symptoms classically associated with GER in adults, including heartburn, chest pain, dysphagia or hoarseness. In fact, children rarely complain of symptoms even in the presence of significant GER demonstrated by pH probe studies. Thus, a high level of suspicion of underlying GER is necessary in the evaluation of the child with severe asthma, especially uncontrolled asthma associated with nocturnal symptoms. However, a recent trial in children with persistent asthma without symptoms of GER did not demonstrate a benefit of gastric acid suppression with omeprazole in terms of asthma symptom control, even among children with evidence of GER by pH probe study.[94]

ENVIRONMENTAL EXPOSURES (INCLUDING TOBACCO SMOKE)

Passive exposure to tobacco smoke is a clear exacerbating factor in asthma, with increases in asthma prevalence and asthma severity among children exposed to parental smoking.[95] Maternal smoking is associated with small but statistically significant, and probably clinically important, deficits in pulmonary function among school children. Since most smokers begin smoking during the adolescent years, active personal tobacco smoke exposure must be considered in all adolescents with asthma, especially when the clinical course becomes more severe. Cigarette smoking has been reported to be associated with mild airway obstruction and slowed growth of lung function in adolescents without asthma.[96] Furthermore, asthma has been linked to an accelerated rate of decline in FEV_1 over time, and this rate is even greater among asthmatic individuals who smoke.[54]

Many patients report that their asthma is triggered by 'weather changes.' Weather changes may be accompanied by changes in airborne allergen exposures. However, multiple studies have failed to find a definitive link between airborne

https://CafePezeshki.IR

outdoor allergen levels (except for an occasional mold) and worsening asthma symptoms. Thus, the true link between weather changes and asthma attacks remains unknown. In addition to allergen exposure, epidemiological studies suggest an association between levels of air pollutants, including ozone, nitrogen oxides, carbon monoxide and sulfur dioxide, and symptoms or exacerbations of asthma.

VOCAL CORD DYSFUNCTION

Vocal cord dysfunction (VCD), a functional respiratory tract disorder resulting from paradoxical adduction of the vocal cords, complicates the diagnosis and management of common respiratory tract problems, including asthma.[97] The recognition of VCD in a patient with atypical or difficult-to-control asthma is critical in minimizing symptoms and potential side-effects associated with treatment of severe asthma. The symptoms of VCD are not unique to the disorder and include cough, wheeze, stridor, dyspnea, hoarseness and choking. Some patients report difficulty swallowing or tightness in the chest or throat. Patients with VCD often report difficulty 'getting air in' due to paradoxical adduction of the vocal cords during inspiration, in contrast to difficulty with exhalation as reported by asthmatics. However, patients with significant exacerbation of asthma do have diffuse airway narrowing and can have significant inspiratory limitation, which can dominate their perception of breathing difficulties. Cough is a common feature of VCD and must be differentiated from cough due to asthma or from post-nasal drainage due to rhinosinusitis. Patients with VCD frequently complain of tightness in the throat and/or chest and may speak in a hoarse voice. Nocturnal symptoms are uncommon in uncomplicated VCD, but may occur in patients with both VCD and asthma. Exercise is a frequent precipitant of both VCD and asthma.

Upon presentation in an emergency department, increased work of breathing and decreased aeration caused by VCD can be difficult to distinguish from asthma. A report provides evidence that a normal level of oxygen saturation can be a clue that the cause of the distress is VCD rather than asthma.[98]

Spirometry and inhaled provocation challenges assist in the differentiation between VCD and asthma. Asthma typically produces abnormalities in the expiratory phase of the flow-volume loop, whereas VCD results in inspiratory loop abnormalities, such as blunting or truncation of the inspiratory loop due to variable extrathoracic airflow obstruction. Respiratory impedance during inspiration, as assessed by impulse oscillometry, has been reported to differentiate between patients with VCD and normal controls.[99] Provocation challenges, either pharmacological (methacholine or histamine) or exercise, are helpful in determining the presence or absence of airways hyperresponsiveness, a feature characteristic of asthma. Exercise challenges frequently reproduce clinical symptoms and spirometric abnormalities consistent with VCD. If this approach fails to establish the diagnosis or if the patient does not respond to appropriate therapy, direct visualization of paradoxical vocal cord movement during symptomatic periods may be helpful in confirming the diagnosis of VCD. Characteristic findings include adduction of the true vocal cords during inspiration with a diamond-shaped opening at the posterior aspect of the glottis. Once the diagnosis of VCD has been established, attention should focus on reassurance, maneuvers directed at laryngeal relaxation (from speech therapy) and discovering underlying stress that is often involved in producing or exacerbating the problem (from psychology). In our experience, a combination of speech therapy and psychological evaluation is necessary for successful therapy for VCD. Maintenance therapy for VCD includes minimization of medication use for co-morbid conditions frequently confused with VCD (i.e. asthma).

PSYCHOLOGICAL FACTORS

Psychological factors may be as, or even more, important than medical factors in determining outcomes of asthma, particularly in children with more severe asthma. In a group of children with severe asthma, 50% had levels of fitness in the significantly abnormal range.[100] Psychological functioning as determined by structured interviews significantly correlated with cardiopulmonary function, but medical characteristics did not.[100] Similar to the findings in studies of fitness levels, school performance[101] and gross and fine motor coordination,[102] while generally in a normal range (in contrast to the findings of fitness), overall correlated with psychological functioning but not the medical characteristics of the asthma. Depression symptoms, cigarette smoking and cocaine use occurred more frequently in youth reporting current asthma than in youth without asthma.[103] These results indicate a need to screen adolescents with asthma for depression.

At the level of characteristics of the individual caregiver, the beliefs that parents hold about their ability to manage their child's asthma and the quality of life that they maintain while caring for a child with asthma may be associated with asthma hospitalizations.[104] A health education intervention study conducted to improve asthma management skills and to build family self-confidence in the ability to manage asthma found that families that participated in the intervention reported better attack management strategies and preventive strategies compared to a control group.[105] Adults with asthma who have greater confidence or trust in the care they receive from their doctor report having better controlled asthma and are more likely to have mild, as opposed to severe, asthma.[106] Thus, parents who believe strongly that they cannot adequately care for their child's asthma may be more likely to bring their child to the hospital repeatedly for acute episodes.

POOR ADHERENCE TO THE MEDICAL REGIMEN

Most patients receive suboptimal benefit from any given prescribed asthma regimen. This is often reflected as inadequate asthma control, and often leads to prescription of higher doses or additional controller medications based upon the assumption that the medication prescribed accurately reflects the medication the patient actually takes. However, since most patients miss substantial amounts of medications, even when participating in research studies examining medication adherence,[107] practitioners must focus on patient education regarding the importance of asthma medication use as directed and provision of a written plan of action which is practical for the patient. Complex regimens consisting of several medications given frequently during the day are less likely to be followed when compared to simple regimens with less frequent dosing requirements. When discussing asthma-related information and setting appropriate and achievable short- and long-term goals, excellence in communication and development of a partnership between healthcare providers and patients is essential in

https://CafePezeshki.IR

establishing the foundation for asthma care and adherence to the recommended treatment approach.

The developmental level of the child complicates adherence in the pediatric population. Children's understanding of their asthma and the steps necessary to control the disease evolve over time. Thus, the action plan for each child must be individualized based upon the child's developmental stage. While children begin to acquire basic asthma decision-making abilities by the ages of 8 years, they remain unable to manage their asthma independently until about 16 years of age.

OBESITY

Weight reduction in obese patients with asthma has been associated with improvement of lung function and other indicators of lung status.[108] Similar to the importance of monitoring height in children with asthma, both as an indicator of general wellness and the effects of medications used to treat asthma, comprehensive care in children with asthma includes monitoring weight acquisition and encouraging weight reduction. Recognition that obesity may produce respiratory symptoms that mimic but do not actually represent asthma is essential[34] to avoid inappropriate and unnecessary escalations of asthma therapy.

EXERCISE

Exercise-induced asthma (EIA) may lead to decreased participation in physical activities due to either exertional limitation or fear of symptom development. This may explain the finding that children with asthma are less physically fit than their non-asthmatic peers.[109] Despite these facts, asthma should not be perceived as a limitation on physical fitness, as evidenced by the prevalence of asthma among Olympic athletes approximating twice that of the general population.[110] Increased aerobic fitness decreases EIA, as better conditioned individuals require smaller increases in heart rate and ventilation for a given task.[109] Thus, although EIA may still occur, more physical work can be done before it begins (see Chapter 36).

Classification of Asthma Severity and Control

Asthma severity is currently classified as either intermittent or persistent disease (Table 34-2). While the distinction between intermittent and persistent disease, and even between the various levels of persistent disease, is arbitrary, it serves as a framework for severity classification and ultimately treatment recommendations. Asthma severity is most easily assessed in a patient not receiving long-term control therapy as this reflects the intrinsic intensity of the disease process. The assessment of asthma severity requires determination of morbidity in the domains of impairment and risk, where impairment reflects the frequency and intensity of symptoms and functional limitation experienced, and risk reflects the likelihood of asthma exacerbations. Four major features of asthma – daytime symptom frequency, nocturnal symptom frequency, interference with exercise and pulmonary function – define levels of severity in the impairment domain, and exacerbations requiring systemic corticosteroids define severity in the risk domain. Nocturnal symptoms are a particularly important marker of more severe disease.[111]

Although most previous national and international guidelines provide lung function measures that are suggested as those which correspond to each level of asthma severity, these parameters do not appear to be entirely appropriate for the classification of childhood asthma, since most children with persistent asthma, even severe asthma, have FEV_1 measures within the normal range (≥80% predicted).[112] Current guidelines have improved on this by including the FEV_1/FVC ratio as an additional lung function parameter to help assess asthma severity.[111] Thus, clinicians and researchers should focus upon a combination of symptom frequency and medication use in assigning a level of asthma severity rather than relying solely on isolated measures of lung function (either FEV_1 or PEF) as the primary determinants of asthma severity.

Once asthma therapy has been initiated, the ongoing assessment of asthma control becomes central to disease management. Asthma control is defined as the degree to which the manifestations of asthma are minimized by therapeutic intervention and the goals of therapy are met. Three levels of control (well-controlled, not well-controlled, and very poorly controlled) provide for gradations of control (Table 34-3) and emphasize the need to re-evaluate patients at every visit and adjust strategy if asthma is not well-controlled or is very poorly controlled. The concepts of impairment and risk are central in the determination of the level of control. Similar to the assessment of asthma severity, the impairment domain for control includes daytime symptom frequency, nocturnal symptom frequency, interference with exercise and pulmonary function, while the risk domain includes exacerbations requiring systemic corticosteroids, progressive loss of lung function or reduced lung growth, or risk of adverse effects of medications. The incorporation of the use of standardized and validated tools to assess asthma control, such as the Asthma Control Test[60,61] and Asthma Control Questionnaire,[113] can identify and monitor patients whose level of asthma control falls below the goals of therapy, prompting consideration of adjustment of therapy.

To maximize the outcome of asthma therapy, goals must be high and be clearly communicated to the child and family. Achievable goals for nearly all children with asthma are outlined in Box 34-1. Routine reassessment of patient attainment of these goals is a critical component of ongoing asthma care.

Perception of Bronchoconstriction

Presence of symptoms is an important determinant of severity determinations. Interpretation of symptom histories must be undertaken in the context of over-reporting in anxious individuals, under-reporting in children who do not want to be bothered by limitations that may be imposed if symptoms were fully reported, and under-reporting in children who do not perceive their level of bronchoconstriction, either acutely or chronically. The last of these possibilities is the most worrisome because patients with asthma who have difficulty perceiving significant airway obstruction appear to be at risk for severe outcomes, such as hospitalization or even death. Review of studies in the literature on this subject do not provide clear guidelines on which patients should be considered as possibly being unable to perceive bronchoconstriction, indicating that lung function should be measured at regular office visits and the relationship between level of lung function and current symptoms discussed. The finding of a discrepancy between the level of lung function and current symptoms can

BOX 34-1 GOALS OF ASTHMA TREATMENT

REDUCING IMPAIRMENT

- Prevent chronic and troublesome symptoms (e.g. coughing or breathlessness in the daytime, in the night or after exertion)
- Require infrequent use (≤2 days a week) of short-acting β2-agonist for quick relief of symptoms (not including prevention of exercise-induced bronchospasm)
- Maintain (near) normal pulmonary function
- Maintain normal activity levels (inducing exercise and other physical activity and attendance at work or school)
- Meet patients' and families' expectations of and satisfaction with care

REDUCING RISK

- Prevent recurrent exacerbations of asthma and minimize the need for emergency department visits or hospitalizations
- Prevent loss of lung function; for children, prevent reduced lung growth
- Minimal or no adverse effects of therapy

Adapted from Program NAEaP. Expert Panel Report III: Guidelines for the Diagnosis and Management of Asthma. Bethesda, MD: US Department of Health and Human Services; 2007.

be an important part of the education and planning for future exacerbations; a child with no symptoms but with low lung function needs to be aware that any symptoms might mean severe problems are present. Such a child is one who might benefit from regular use of a peak flow meter, not stopping measurements when well as most children tend to do.

Treatment of Childhood Asthma

Achieving optimal control of asthma requires a comprehensive approach that addresses the underlying pathophysiological disturbances. Thus, in addition to the pharmacological approach to asthma, one must minimize exposure to asthma triggers, including environmental allergens (see Chapter 22) and nonspecific airway irritants (such as tobacco smoke), and treat concomitant medical conditions which influence asthma severity (such as GER and rhinosinusitis). Equally important is providing asthma education and support for the child and family in the process of chronic disease management.

Severity-Based Asthma Management

Once asthma has been diagnosed and a level of severity based upon the algorithm assigned, attention should shift toward the development of a comprehensive treatment plan (see Table 34-3). A central element to any treatment regimen is a written action plan, which provides the child and family with a clearly defined approach towards asthma management, including medications for routine daily use and a rescue plan for exacerbations, including medication modifications and signs of asthma symptom progression which should prompt contact with the healthcare provider or seeking of emergency care.

Pharmacological Management

Currently, asthma medications are divided into two major categories – those that provide rapid relief of asthma symptoms (quick relievers) and those that serve to decrease airway inflammation and improve asthma on an ongoing basis (long-term controllers). The choice of medications for a given patient depends upon the level of asthma severity and control (Figure 34-2).

Intermittent asthma is managed with as needed use of short-acting β2-agonists by inhalation. However, all patients with persistent asthma should receive one, or potentially a combination of, controller medication(s) that possess anti-inflammatory properties.

Controller Medications

The inflammatory nature of persistent asthma supports the use of medications aimed at decreasing, and ideally eliminating, airway inflammation. Thus, agents with anti-inflammatory

https://CafePezeshki.IR

properties are essential in the treatment plan of all children with persistent asthma.

INHALED CORTICOSTEROIDS

Inhaled corticosteroids (ICSs) are the most effective long-term controller medication for asthma in childhood. ICS therapy leads to significant improvement in asthma control as reflected by reductions in asthma symptom frequency and severity, exacerbation rates, hospitalizations, asthma death, quality of life and airway hyperresponsiveness. Short-term studies of ICS therapy have reported improvements in measures of lung function and reduction in inflammatory cells and other markers of inflammation within the airways.

The CAMP, the largest and longest prospective clinical trial of ICS therapy in children, examined the effect of three treatment strategies in 1,041 children with mild-to-moderate asthma.[114] Children received either (1) an ICS (budesonide 200 μg bid), or (2) a nonsteroidal agent with anti-inflammatory properties (nedocromil sodium 4 mg bid) or (3) a matching placebo for an average of 4.3 years of continuous therapy. All children received albuterol as needed for symptoms, and oral steroids for exacerbations. The primary outcome of the study was the FEV_1 after bronchodilator following a mean of 4.3 years of therapy. Children treated with ICSs demonstrated an initial rise in FEV_1 over the first 6 to 12 months of the trial, but upon completion of the trial the ICS group and the placebo group did not differ in terms of FEV_1. Children who received ICS therapy experienced numerous clinical benefits not experienced by children who received placebo, including significant improvement in airway hyperresponsiveness, fewer asthma symptoms, less albuterol use, more days without an asthma episode, a longer time until need for oral corticosteroids for an asthma exacerbation, fewer courses of oral corticosteroids, fewer urgent care visits and hospitalizations, and less need for supplemental ICS therapy due to poor asthma control. The clinically meaningful improvements in control of asthma achieved during continuous treatment with ICSs do not persist after continuous treatment is discontinued.[72,115,116]

Guidelines for asthma management suggest that increasing levels of asthma severity or poor asthma control require increasing doses of ICSs to achieve disease control. Several studies support a dose-response relationship for ICSs. However, this relationship is nonlinear and is complicated by the dose-side-effect relationship. Low doses of ICSs (as low as 200 μg/day of budesonide[117] or 50 μg bid of fluticasone propionate[118]) have been demonstrated to be effective in controlling asthma in children with persistent asthma. Furthermore, each child is likely to demonstrate an individual ICS dose-response relationship, as demonstrated in adults.[119] In addition, the rates of improvement of individual measures of asthma control vary, with symptom control and peak flow measures generally responding to low-dose ICS therapy within 2 to 4 weeks,[117] while treatment with higher doses for longer periods of time are necessary to maximize the effect on airway hyperresponsiveness.[114] Thus, ICS dosing must be tailored to the individual patient's needs and response to therapy.

In general, ICS therapy is well-tolerated by the majority of patients. However, potential side-effects of ICS therapy include the effects of ICSs upon skeletal growth and bone density, alteration of the hypothalamic-pituitary-adrenal (HPA) axis and local side-effects including oral candidiasis and hoarseness.

The effect of ICS therapy on growth during childhood has been extensively studied. However, many of the conclusions from these investigations are difficult to fully appreciate, as many studies are of short-to-intermediate durations (generally ranging from 8 to 12 weeks to 1 year). ICS therapy has been shown to result in short-term reductions in rates of linear growth in children, an effect which is most evident in prepubertal children. These effects are dose- and drug-dependent, with no significant effect on growth when low doses (100–200 μg/day of fluticasone propionate) are used for up to 1 year.[72,120] CAMP demonstrated that children receiving ICS therapy for 4 to 6 years grew an average of 1.1 cm less than those receiving placebo. The growth effect was in the first year of treatment without additional effect as treatment continued. When adult height was predicted using standardized measures based upon current height, current age, bone age and age at first menses (for females), the ICS-treated children and the placebo-treated children had similar projected final heights.[114] However, the effect of ICS therapy on growth persisted 5 years after regular ICS therapy was discontinued, with evidence that the effect is more pronounced in girls than boys;[115] similar findings have been reported in other populations.[121–123] Follow-up of the CAMP population until achievement of adult height demonstrated that the initial decrease in attained height associated with the use of ICSs persisted as a reduction in final adult height, although the decrease was neither progressive nor cumulative.[124]

Numerous studies have examined the effect of ICS therapy on HPA axis function with conflicting results. While the available evidence suggests that low-to-moderate dose ICS therapy is generally not associated with alterations in HPA function,[125,126] the long-term effects of high-dose ICS therapy in growing children remain unclear. The interaction between ICS use and bone mineral density (BMD) was studied thoroughly in CAMP; ICS therapy has the potential to reduce bone mineral accretion in male children progressing through puberty, although the ability of ICS to reduce the need for oral corticosteroid therapy (and the attendant reduction in BMD) largely outweighs this small risk.[127] The effect of high-dose ICS therapy on BMD in growing children remains uncertain.

There has been some concern that ICSs may cause the course of chicken pox to worsen, based upon case reports of death from chicken pox in individuals on high doses of *oral* steroids. There have been no deaths with ICSs alone, but clinicians caring for children with persistent asthma should assure varicella immunity, either through prior natural infection or through vaccination, and be prepared to minimize ICS use and to add antiviral agents should chicken pox occur in individuals on ICSs.

LEUKOTRIENE MODIFIERS

The cysteinyl leukotrienes (LTC4/LTD4/LTE4) are mediators produced by eosinophils and mast cells and trigger many processes central to asthma – mucus secretion, bronchoconstriction and increased vascular permeability. The clinical effects of agents which modulate leukotriene activity confirm the role of these mediators in the pathophysiology of asthma. Clinical trials have demonstrated the positive effects of LT antagonism on pulmonary function and clinical outcomes in children with asthma.[128]

https://CafePezeshki.IR

Montelukast, a selective leukotriene receptor 1 antagonist, improved pulmonary function, reduced rescue albuterol use, improved quality of life and decreased peripheral blood eosinophil counts over an 8-week period in children aged 6 to 14 years with moderate asthma compared with placebo.[128] Montelukast has also been shown to inhibit exercise-induced bronchoconstriction in children with mild-to-moderate asthma.[129] In addition to having positive effects as monotherapy, leukotriene modifiers (LTMs) appear to have additive properties when given with ICSs.[130,131]

The inflammatory nature of asthma currently demands that controller medications possess anti-inflammatory properties. While the data regarding the anti-inflammatory attributes of LTMs is limited compared to those of ICSs, several studies strongly suggest that these agents decrease markers of allergic airway inflammation, including peripheral blood[128] and sputum eosinophils,[132] nitric oxide in exhaled air,[75,133] bronchial hyperreactivity[134] and cellular infiltrates in BAL fluid following segmental allergen challenge.[135]

While the long-term effects of antileukotriene therapy are unknown, these agents possess desirable clinical and biological properties and deserve consideration in children with all levels of persistent asthma. These agents have excellent safety records in children and the oral delivery system makes these agents easy to administer to children. Evidence supporting ICSs as the preferred maintenance therapy over montelukast in school-age children with mild persistent asthma (Step 2) has come from several sources. A multicenter, randomized, double-blind trial demonstrated that clinical outcomes, pulmonary responses and inflammatory biomarkers improved more with fluticasone 100 μg twice daily compared to daily montelukast in children aged 6 to 17 years with mild-to-moderate persistent asthma.[116] The Pediatric Asthma Controller Trial (PACT), a year-long, randomized, double-blind trial in children aged 6 to 14 years with mild-to-moderate persistent asthma also demonstrated the superiority of the ICS fluticasone over montelukast therapy for asthma control days, exacerbations, quality of life and pulmonary function.[72,136] Based upon these data, current guidelines support the use of LTRAs as an alternative to ICSs as monotherapy in mild persistent asthma as well as adjunctive therapy in moderate-to-severe asthma.[111]

LONG-ACTING β-AGONISTS

Two long-acting β_2-adrenergic agonists (LABAs), salmeterol and formoterol, have been demonstrated to be safe and effective agents in children, both in terms of bronchodilation and prevention of exercise-induced bronchospasm. Their onsets of action differ, with formoterol having an onset similar to that of albuterol (3 minutes), while salmeterol has a slower onset of action (10–20 minutes). Following administration of a single dose, both agents demonstrate durations of action of up to 12 hours. Following regular twice daily administration, bronchodilation remains effective; however, a level of tolerance (or tachyphylaxis) develops, manifested as a loss of bronchoprotective properties to stimuli such as exercise, methacholine and allergen, although the clinical relevance of these findings is unclear.

The complementary actions of ICSs and LABAs suggest that these agents should be effective when used in combination. Extensive data in adults confirm the superiority of the addition of a LABA to patients uncontrolled on ICSs compared to increasing the dose of the ICS alone.[137,138] The PACT trial also included a combination therapy arm consisting of fluticasone (100 μg once daily) plus the LABA salmeterol (50 μg twice daily).[72] This combination of once-daily ICS therapy plus a twice-daily LABA was associated with comparable asthma control to the twice-daily fluticasone approach in terms of the proportion of asthma control days and Asthma Control Questionnaire scores, but was inferior to fluticasone alone in terms of changes in lung function, airway hyperresponsiveness and exhaled nitric oxide levels. Among children with asthma inadequately controlled by an ICS alone, the addition of a LABA led to improved lung function and symptom control compared to placebo.[139] In contrast, one study found no advantage with the addition of salmeterol to low-dose ICS therapy compared with a doubling of the ICS dose in children with mild-to-moderate asthma.[140] Studies in adults also suggest that LABAs may facilitate ICS reduction in patients whose asthma is controlled on a moderate-to-high dose of ICS.[112,141] While the addition of a LABA to an ICS improves lung function, a recent Cochrane Review concluded that there is no evidence to date that the addition of a LABA to ICS therapy reduces significant asthma exacerbations in children.[142] However, in a recent trial among children aged 6 to 17 years with asthma not controlled with low-dose ICS monotherapy, the addition of the LABA salmeterol to low-dose ICS was more likely to provide a better response than the addition of an LTRA or doubling the dose of ICS,[138] and treatment with ICS + LABA was associated with the fewest exacerbations. The addition of LABA therapy may increase the risk of rare life-threatening or fatal asthma exacerbations, and thus should be carefully considered in children with asthma inadequately controlled with ICS therapy alone.[111] More clinical trials are necessary to fully determine the role of LABAs in the management of persistent asthma in childhood. However, the compelling evidence of the efficacy of ICS + LABA therapy in older children and adults has led to the recommendation of a combination of ICS and LABAs as the preferred therapy in children aged 5 years and older whose asthma severity and/or control indicate the need for Step 4 care (see Figure 34-2).[111]

CROMOLYN AND NEDOCROMIL

Cromolyn sodium and nedocromil sodium are inhaled agents that are alternatives to ICSs in the management of mild persistent asthma in children. Both drugs have been shown to possess anti-inflammatory properties through nonsteroidal mechanisms, although the exact mechanisms for their actions remain unclear. Both agents are effective in the short-term prevention of exercise-induced bronchospasm. Several clinical trials have suggested beneficial effects with regular administration of cromolyn, although a meta-analysis suggests that there is insufficient evidence to support the use of cromolyn as maintenance therapy for asthma.[143] Nedocromil (8 mg/day) therapy for approximately 4 years in children with mild-to-moderate asthma resulted in a reduction in oral corticosteroid use and urgent care visits for asthma compared to placebo/albuterol for symptoms only, but did not affect lung function or rescue albuterol use compared with placebo.[114] These agents are generally well-tolerated, with cough, sore throat and bronchoconstriction being the most common side-effects to cromolyn. Nedocromil

https://CafePezeshki.IR

is more commonly associated with bad taste, headache and nausea than cromolyn.

THEOPHYLLINE

Theophylline acts as an inhibitor of phosphodiesterase, although at therapeutic serum levels phosphodiesterase inhibition is weak yet bronchodilation occurs. Theophylline also inhibits the effects of adenosine, a molecule known to induce airway narrowing.

Theophylline is more effective than placebo in controlling asthma symptoms and pulmonary function, and is particularly effective in preventing nocturnal asthma symptoms. Current guidelines suggest theophylline as an alternative to ICSs in children with mild persistent asthma and as an add-on therapy with a low-dose ICS in children with moderate-to-severe asthma.[111] Patients may experience deterioration of asthma control following withdrawal of theophylline from their regimen.[144,145]

Theophylline has the potential for significant toxicity occurring with increasing serum concentrations. The benefits of theophylline may be recognized at lower serum levels than previously recommended (a target range of 5–15 μg/mL).[111] Serum drug level monitoring is needed with doses above 12 mg/kg or if side-effects occur. Theophylline metabolism is age dependent, with younger children having greater rates of metabolism than older children and adolescents. Drug interactions may lead to decreased theophylline metabolism, and thus increased serum levels (such as macrolide antibiotics [erythromycin, clairithromycin], cimetidine, ciprofloxacin) or increased theophylline metabolism, and thus lower serum levels (such as carbamazepine, phenobarbital, phenytoin, and rifampin). Febrile illnesses may result in decreased theophylline clearance, whereas tobacco and marijuana smoking result in accelerated clearance. Side-effects of theophylline are often dose dependent and include anorexia, nausea, emesis and headache. The effects of theophylline on psychomotor functioning and school performance have been examined and have generally shown no significant negative on learning or behavior.[146]

ALLERGEN IMMUNOTHERAPY

Specific immunotherapy (SIT) is the repetitive parenteral injection of allergen extracts to reduce the manifestations of allergy caused by natural exposure to those allergens.[147,148]

Allergen-specific immunotherapy has been demonstrated to have beneficial effects in the management of childhood asthma, including effects on symptom control, medication use and airway hyperresponsiveness.[149] A recent meta-analysis examining the efficacy of allergen-specific immunotherapy concluded that there is moderate strength evidence that subcutaneous immunotherapy improves asthma symptoms and high strength evidence that sublingual immunotherapy improves asthma symptoms.[150] Furthermore, the majority of studies demonstrating efficacy of subcutaneous immunotherapy involved single allergen immunotherapy, whereas most children with asthma are polysensitized.[151,152] Allergen immunotherapy should not be initiated in patients with asthma that is not stable to pharmacotherapy.[149]

SIT of monosensitized children may prevent the development of both additional sensitivities and asthma.[147] Specific immunotherapy to pollens in children aged 6 to 14 years with allergic rhinoconjunctivits without asthma led to fewer asthma symptoms after 3 years of therapy, suggesting that SIT can reduce the development of asthma in children with seasonal allergic rhinoconjuctivitis.[153]

OMALIZUMAB

A humanized monoclonal antibody directed against IgE (anti-IgE or omalizumab) rapidly and significantly reduces circulating levels of IgE. Repeated subcutaneous administration of omalizumab has been demonstrated to be safe[154] and effective in permitting reduction of ICS dosing while preventing asthma exacerbations in placebo-controlled trials in both adults[155] and children[156] with moderate-to-severe persistent allergic asthma receiving ICSs, as well as improving asthma-related quality of life.[157] Omalizumab is currently approved as an adjunctive therapy for children aged 12 years and older with moderate-to-severe persistent allergic asthma whose symptoms are inadequately controlled with ICS therapy, and the National Asthma Education and Prevention Program (NAEPP) Guidelines support its use when Step 5 or 6 care is indicated.[111]

Quick Reliever Medications

β2-ADRENERGIC AGONISTS

Rapid acting inhaled β_2-adrenergic receptor agonists are the most effective bronchodilator agents currently available and serve as the preferred treatment for acute symptoms and exacerbations of asthma as well as the prevention of exercise-induced asthma. These agents stimulate the β_2-adrenergic receptors located on bronchial smooth muscle and trigger a signaling cascade culminating in the generation of intracellular cyclic adenosine monophosphate (cAMP). In addition to relaxation of airway smooth muscle, β_2-agonists stimulate mucocilliary transport, modulate the release of mast cell mediators and decrease edema formation.

β_2-Agonists are available for inhalation (by metered dose inhalers and nebulizers), oral administration (syrup and sustained-release tablets) and parenteral (subcutaneous and intravenous) administration. Inhalation is the preferred route of delivery as it maximizes efficacy and minimizes side-effects. Several different β_2-agonists are currently available, and have comparable efficacy and safety properties. The single isomer preparation of albuterol, levalbuterol, has the theoretical advantage of possessing bronchodilatory properties (*R*-isomer of albuterol) without the presence of the nonbronchodilatory isomer (*S*-albuterol). Clinical trials with this agent demonstrate minimal clinically relevant differences in bronchodilation or side-effects related to β-adrenergic receptor stimulation, such as tachycardia, tremor and decreases in serum potassium levels, compared to racemic albuterol.[158]

ANTICHOLINERGIC AGENTS

Potential mechanisms by which cholinergic pathways contribute to asthma pathophysiology include bronchoconstriction through increased vagal tone, increased reflex bronchoconstriction due to stimulation of airway sensory receptors, and increased acetylcholine release induced by inflammatory mediators.[159] Patients with asthma experience lesser degrees of

https://CafePezeshki.IR

bronchodilation with anticholinergic agents (such as atropine and ipratropium bromide) than with β2-agonists. There is presently no indication for anticholinergic agents as a component for long-term asthma control. Evidence supports the use of ipratropium bromide in conjunction with inhaled β2-agonists in the emergency department during moderate-to-severe acute exacerbations of asthma in children.[160,161] This effect is most evident in patients with very severe exacerbations. Addition of ipratropium has been shown to decrease rates of hospitalization[160] and duration of time in the emergency department.[161]

SYSTEMIC CORTICOSTEROIDS

Systemic steroids are valuable in gaining control of asthma symptoms in patients under poor control. Although the onset of action of systemic corticosteroids is slower than that of inhaled bronchodilators, there is evidence that corticosteroids have a faster onset of action than that suggested by their primary mechanisms of action, namely inhibiting the function of inflammatory cells and the secretion of cytokines, chemokines and other proinflammatory mediators. Corticosteroids rapidly up-regulate β_2-adrenoreceptor number and improve receptor function, likely leading to clinical improvement within 4 hours of administration.

Systemic corticosteroids hasten the resolution of acute exacerbations of asthma. Corticosteroid administration in the emergency department decreases admission rates for asthma[162] and shortens the length of stay in hospital. Dosing recommendations for acute asthma range from 1 to 2 mg/kg of body weight per day of prednisone. There is no significant difference in the efficacy of oral or parenteral corticosteroids in acute asthma,[163] unless the child is unable to tolerate oral medications due to vomiting. Given the well-described side-effect profile of repeated or continuous use of systemic corticosteroids, dosing should always be minimized. Rare patients with severe asthma may require regular corticosteroid therapy to gain or maintain disease control. In these situations, alternate-day dosing is associated with fewer adverse effects, but a very small percentage of patients with severe disease may still require daily steroid administration. Side-effects associated with chronic corticosteroid use in severe asthma include hypertension, cushingoid features, decreased morning serum cortisol levels, osteopenia, growth suppression, obesity, hypercholesterolemia and cataracts.[164] There is no evidence for clinically significant HPA axis suppression following short 'bursts' of systemic corticosteroids for acute exacerbations of asthma, and tapering is not required with courses of 10 to 14 days or less in duration. Furthermore, there is no evidence for increased susceptibility to common acute infections.[165]

Management of Acute Asthma Episodes

Asthma exacerbations occur frequently and may occur even in the context of regular use of long-term controller therapy. Most exacerbations, especially those which are mild in nature, can generally be managed without difficulty at home. However, success in outpatient care of acute asthma demands excellent preparation, including a written set of instructions to help guide the patient and his/her family. The Asthma Action Plan is the central component for home asthma management. Patients must be instructed as to the early and accurate recognition of changes in asthma status, as early intervention is likely to lessen the severity and rate of progression of the episode. An algorithm which serves as the basis for the action plan and allows for telephone triage and recommendations is shown in Figure 34-3.

At the onset of asthma symptoms, including cough, chest tightness, wheeze, shortness of breath, or with a decline in PEF below 80% of personal best, initial therapy should include administration of a rapid-acting bronchodilator such as albuterol, either via a metered dose inhaler (with a spacer device) or nebulizer. This treatment may be repeated up to three times in the first hour, with PEF measured before and after each albuterol administration. Patients who demonstrate rapid improvement following this intervention should be closely followed over the ensuing hours and days for signs of recurrence of symptoms, with a particular attention to nocturnal awakenings. Given the potential for progression of symptoms, addition (or increasing the dose) of an ICS is often recommended. Increased use is continued until baseline status is achieved and then for an additional 7 to 10 days because of the time needed for resolution of the increased inflammation produced during the exacerbation. Failure of this rescue approach to markedly reduce symptoms and improve PEF to >80% of personal best should lead to institution of systemic corticosteroids. Several protocols for administration of oral corticosteroids are commonly used. One such approach is to give prednisone, 2 mg/kg/day (up to 60 mg) for 5 days. The approach used in the CAMP trial, 2 mg/kg/day (up to 60 mg) for 2 days followed by 1 mg/kg/day (up to 30 mg) for 2 days,[166] decreased overall steroid exposure and was very effective in resolving exacerbations in patients with mild-to-moderate asthma. This should be accompanied by frequent reassessment of clinical status and PEF as well as albuterol every 4 to 6 hours, more frequently if needed. Patients who do not improve with this approach are experiencing moderate-to-severe exacerbation and may need further evaluation and intervention, generally in the physician's office or in the emergency department. Signs of worsening respiratory distress should prompt emergent evaluation and therapy.

Conclusions and Summary

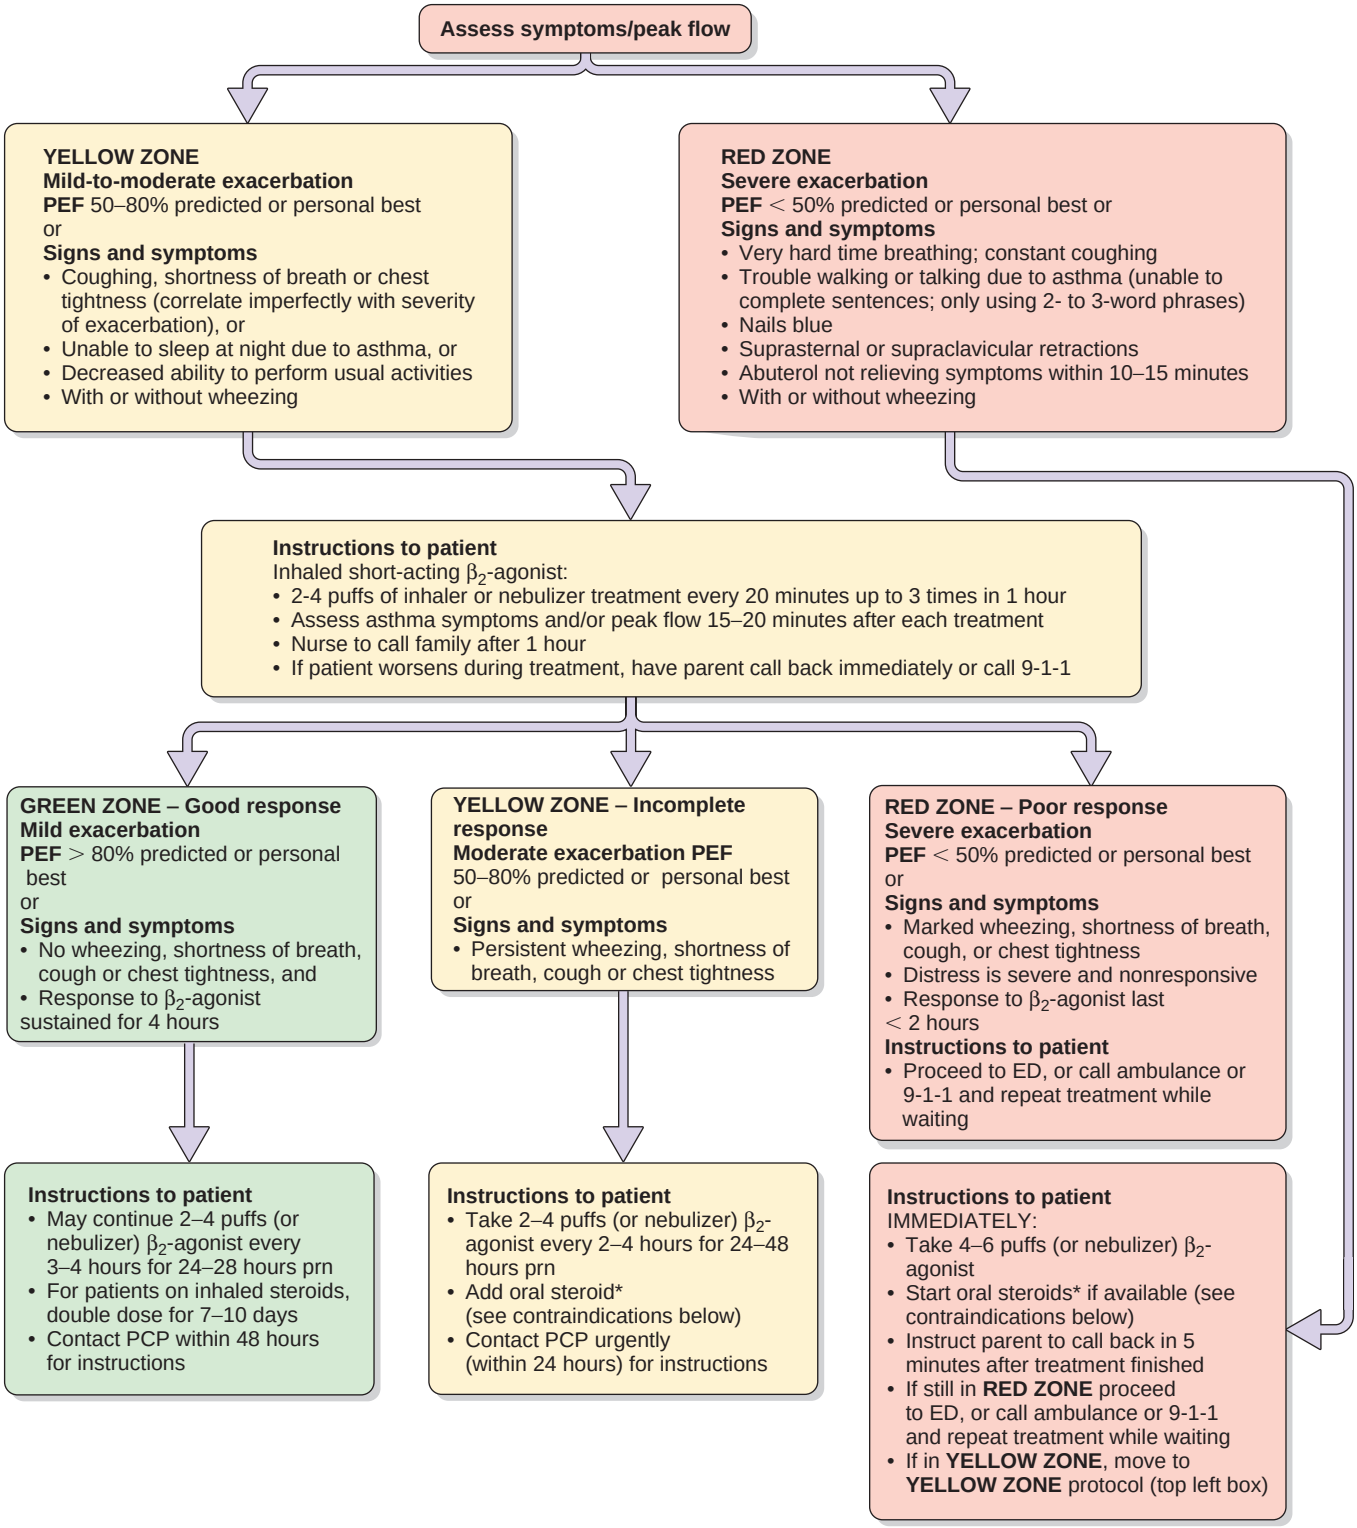
Asthma can significantly impact on the quality of life of both children and their families. Careful attention to the details of determining severity and applying an appropriate therapeutic regimen can control asthma symptoms in almost all children (see Key Concepts). In determining severity and applying the appropriate regimen, it is essential to establish good communication about the goals of therapy and to understand the family dynamics to assure the family can adhere to the therapeutic regimen prescribed. Ongoing evaluation based on communication of current symptoms, with regular assessment of the family's ability to adhere to therapeutic recommendations and the appropriateness of recommendations, is necessary for long-term control of the disease and minimization of side-effects of medications. Review of actions to take during exacerbation, using the Asthma Action Plan as the central mechanism of communication, is part of regular visits for asthma.

The complete reference list can be found on the companion Expert Consult website at http://www.expertconsult.inkling.com.

https://CafePezeshki.IR

Follow this plan for After Hours patients only. Nurse may decide not to follow this home management plan if:
- Parent does not seem comfortable with or capable of following plan
- Nurse is not comfortable with this plan, based on situation and judgment
- Nurse's time does not allow for callbacks

In all cases, tell parent to call 9-1-1 if signs of respiratory distress occur during the episode
NOTE: If action plan has already been attempted without success, go to "RED ZONE - poor response" or "YELLOW ZONE - incomplete response" as symptoms indicate.



Documentation faxed or given to PCP within 24 hours; phone or verbal contact sooner as indicated.

* Ask patient about preexisting conditions that may be contraindications to oral steroids (including type 1 diabetes, active chicken pox, chicken pox exposure or varicella vaccine within 21 days, MMR within 14 days). If so, nurse to contact PCP before initiating steroids. Oral steroid dosages: Child: 2 mg/kg/day, maximum 60 mg/day, for 5 days.

35 School-Centered Asthma Programs

LISA CICUTTO

KEY POINTS

- High rates of school absenteeism affect a child's ability to learn. Every school day in the USA 36,000 children and youth miss school because of asthma.
- Asthma has the potential to affect academic performance, starting at a young age.
- Several school-centered models have been evaluated and demonstrated benefits in asthma-related outcomes. Evaluated activities include asthma screening, asthma case identification, supervised administration of maintenance asthma medication, case management, care coordination among students, families, healthcare providers and schools, self-management asthma education programs, creating asthma friendly and supportive schools, and asthma care programs delivered through school-based health clinics.
- Asthma management at schools is important for pediatric pulmonologists and allergists, pediatricians, family care providers, and healthcare professionals providing quality asthma care. The variability of asthma care practices makes it necessary for clinicians to learn what is happening at their patients' schools and to advocate for appropriate services.

Introduction

Asthma is a common chronic childhood condition associated with significant morbidity, high rates of school absenteeism, and excessive costs for the individual and society. Every school day in the USA 36,000 children and youths miss school because of asthma.[1] High rates of school absenteeism affect a child's ability to learn. A healthy student with well-controlled asthma is a student ready to learn and to be a full participant in the school experience, including physical activity and sports.

The history of asthma programs in schools dates back about 30 years; thus, a significant body of literature exists that has evaluated a variety of strategies directed at improving overall asthma management in order to reduce asthma-associated morbidity. The purpose of this chapter is to review the literature in terms of the rationale for school-centered interventions, barriers identified in school settings, strategies implemented and evaluated, strengths and limitations of the literature, future directions for research and how asthma care providers can be effective team players.

Why Center on Schools?

As mentioned, asthma is a leading cause of school absenteeism, but this is not equally distributed among those with asthma.[2] School absenteeism is associated with family income. Recent research highlights that students attending schools with the highest proportions of low-income students were more likely to miss school because of asthma.[3] Additional risk factors for high absenteeism rates included younger age, frequent experience of asthma symptoms and/or using asthma medications.

Asthma has the potential to affect academic performance, starting at a young age. A prospective cohort study in New Zealand observed that entering school with asthma was associated with low academic achievement.[4] Entering school with asthma reliably predicted low reading level achievement independent of known co-variates such as high absenteeism, minority status, male gender, single-parent family, low socioeconomic status and poor academic skills at school entry. Data from the U.S. National Interview Survey noted that children with asthma missed three times more school and had a 1.7 times greater risk of having a learning disability compared to well children.[5]

Basch[6] expanded our understanding of this area with a systematic review that identified that asthma directly and indirectly affects academic achievement of school-aged youth. The results of this study indicated that asthma affects the student's motivation to learn. Identified causal pathways that could affect academic achievement included cognition, high absenteeism, school connectedness and dropping out.[6] Asthma and the causal pathways have interactive and synergistic effects that represent a complex situation that must be addressed collectively through a coordinated and partnered approach. Taken together, this work suggests the need for school-level interventions to decrease asthma-related absenteeism, especially in schools with a high proportion of low-income families.

Partnering with schools provides opportunities to reach most children with asthma and those at the highest-risk of asthma burden in need of assistance. Because schools provide reliable access for reaching large numbers of children with asthma, they have become a targeted setting for quality asthma care programs and initiatives. In addition, schools are often the only setting of affordable health care for low income and ethnic minority youth because of limited access to medical care. Schools are often advocated as the ideal setting for health education, health services and the development of supportive networks and collaborations. Accordingly, school settings are ideal settings for reaching high-risk children and youth with asthma and for reducing asthma health disparities. Several school-centered models have been evaluated and have included a variety and combination of activities: asthma screening, asthma case identification, supervised administration of maintenance asthma medication, case management, care coordination among students, families, healthcare providers and schools, self-management asthma education programs, creating asthma friendly and supportive schools, and asthma care programs delivered through school-based health clinics.

Asthma Management Challenges in Schools

INSUFFICIENT HEALTH TEAM STAFFING AT SCHOOLS

Although school settings have several advantages over clinic settings in providing asthma care, there are several distinct challenges that must be considered. Given the prevalence of asthma and the shortage of health personnel in schools, it is not surprising that once students are identified as having asthma, schools lack the facilities for appropriate evaluation and treatment. A US national survey conducted as part of the School Health Policies and Programs Study revealed that only 36% of schools had a full-time school nurse and that only 19% of health coordinators in the school setting received professional development for asthma care,[7] suggesting that not only do schools have a shortage of health personnel, but that these personnel also have significant knowledge gaps in asthma care. A survey of parents confirmed that learning gaps exist for school personnel and parents expressed a desire for teachers and staff to have higher levels of knowledge and understanding to support their children.[8]

POOR COMMUNICATION

A major obstacle to successful asthma management in schools is poor communication among students, families, healthcare providers and schools. Surveys and interviews with school nurses, school personnel, parents and healthcare providers identified communication as the greatest challenge.[9,10] Most parents of students with asthma never speak to the school nurse and too often school nurses learn of a student's diagnosis of asthma when he/she presents to the office with asthma symptoms and informs the nurse of the diagnosis.[9] Although all parties recognize that students require individualized instructions and information to support asthma management at school, this is not happening.[10] School nurses also identified the lack of parental support and involvement as a significant barrier to successful management. Often there is also role confusion and unclear policies and practices for managing asthma at schools that could be addressed through clearer communication by schools of existing policies and protocols. If asthma management is to improve, it is crucial that improvements in communication occur among these parties.

School Asthma Care Plans and Easily Accessible Rescue Therapy

Two key elements for successful asthma management in school settings are (1) beginning the school year with a completed school asthma care plan and (2) an on-site quick relief inhaler that is preferably carried by the student. The purpose of the written asthma care plan is to outline asthma management steps at schools and to serve as a type of medical order for schools. It is required so that students experiencing symptoms can use their quick-acting inhaler kept at school to relieve symptoms quickly, thus enabling them to return to class and avoid having to leave the school for treatment or to wait in the nurse's office while a family member brings in the inhaler. Asthma care plans for schools differ from asthma action plans for home use in several ways and therefore home plans may not be acceptable or sufficient for the school setting. Common problems of home-based asthma action plans are that they often lack a release for sharing health information among school personnel and the student's healthcare providers, and lack the signed indication from a parent/guardian and healthcare provider for self-carrying the inhaler or the need for assistance with medication administration. Additionally, because the action plan is seen as a medical order in schools, the inclusion of the use of maintenance asthma medication (typically containing an inhaled steroid) is problematic, as it is interpreted that the school nurse is required to administer the medication daily (often twice daily). This latter issue creates additional problems for the school in that it has insufficient personnel for daily, supervised, administration of maintenance asthma medications for all students with asthma and it requires reliance on families to supply schools with maintenance asthma medications as schools do not have funds to supply these medications. Often families have insufficient funds to purchase asthma maintenance medications for home use let alone funds to purchase extra medication to be kept at school; a steroid inhaler can cost hundreds of dollars.

Several studies highlight that these two crucial elements to successful asthma management in schools are not being fulfilled.[11,12] A recent study involving five Alabama school districts observed that not one student with physician-confirmed asthma had a complete school asthma care plan/action plan on file at the school. Reported rates of students with asthma having a quick-relief inhaler at school ranged from 14% to 39% of students with asthma.[12,13] This work suggests that the gap between policy and practice is dramatic and potentially life threatening. Federal laws exist and many states and school districts have legislation and policies in place permitting students to possess quick-relief inhalers and/or to receive support from school personnel in the storage and administration of the medication.[14] However, school district policies typically require completion of an asthma care plan for school or standard forms and authorizing signatures of students' parents/guardians and physicians/healthcare providers. A study in Minnesota developed and implemented a secure portal designed for the electronic exchange of an asthma action care plan between providers and schools. School nurses reported that this initiative resulted in more efficient asthma management and school nurse self-confidence in managing an individual student's asthma.[15] This type of intervention deserves additional investigation.

Physical Activity at School

Most students with asthma report experiencing symptoms during physical activity at school, prompting them to initiate the self-care activities of sitting out the activity, visiting the school nurse and/or drinking water.[16] Barriers reported by students to participating in physical activity include the lack of a school asthma care plan or action plan detailing asthma management steps for physical activity, such as pretreatment, lack of accessible quick-relief inhalers, poor asthma control, and stigma associated with symptoms caused by physical activity and with using asthma inhalers.[16] Most work in the area has been limited to describing the issue with little attention focused on increasing participation in physical activity in schools.

https://CafePezeshki.IR

School-Centered Implemented and Evaluated Strategies

Poor and minority children experience the greatest asthma morbidity and are also least likely to receive adequate asthma care.[2] As a way to target these high-risk children, school-centered asthma care management programs have been evaluated, mainly in inner cities. A variety of strategies have been evaluated and typically involve some degree of partnership among school personnel, community health providers and families. The types of direct services implemented and evaluated vary in strategy, targeted audiences for intervention and human resources for staffing the intervention. The focus of these interventions was to increase the quality of asthma care, but the process to achieve this goal varied from direct asthma service provision, case management and care coordination to asthma self-management educational programs and creating supportive school environments.

HUMAN RESOURCE SUPPLEMENTATION OF THE SCHOOL HEALTH TEAM

To address the shortage of trained health professionals on site at schools, strategies evaluated have included adding physicians and other community healthcare providers, and extending the hours of school nurses to full-time. Although not evaluated through a controlled study, it was observed that a program that provided a consulting physician a half day per week to work with school nurses increased the delivery of quick-relief medications at school instead of home, which led to reductions in the number of students leaving school or requiring a 911 call for urgent care, thus keeping them engaged in school activities.[17] In a similar non-randomized controlled study, the same trend for a reduction in sending students home because of asthma was reported, although the difference was very small (13.8% vs 12.6%).[18] Similarly, in a quasi-experimental study, adding a full-time school nurse versus a part-time nurse (often 1 day/week) to care for students with asthma, improvements were noted: a decrease in absenteeism, fewer emergency department visits and cost savings.[19] Healthcare provider support can also be brought into the school through school-based health centers. These centers provide on-site care delivered by physicians, physician assistants or nurse practitioners for students at school. Two studies focusing on improving asthma care through school-based health clinics demonstrated improvements in the need for emergency department visits, hospitalizations and school absenteeism.[20,21] Bringing a mobile health clinic to the school to provide healthcare staff, diagnostics and regularly scheduled visits is an alternative strategy to improve asthma outcomes, again leading to improvements in reducing hospitalizations, emergency department visits, asthma symptoms, rescue inhaler use and school absenteeism.[22–24]

DIRECTLY OBSERVED THERAPY

Several small and larger randomized controlled studies have evaluated the benefits of directly observed asthma maintenance therapy (primarily inhaled corticosteroids) by school nurses that involved the partnership and coordination of care among school nurses, primary care providers and families. The approach involved identifying students requiring daily maintenance asthma therapy, review and agreement of therapy and dosages by both study physicians and students' physicians, and school nurse provision of daily maintenance controller therapy on school days. Because adherence to asthma medications is typically below 50%, it is an important factor in achieving asthma control. These studies have typically observed improvements in medication adherence and asthma-related outcomes such as symptoms-free days, asthma control, reduced number of exacerbations and school absenteeism.[25–27] In one of the larger randomized controlled studies, the improvements observed were marginal and not as consistent as in the other studies.[27] Similarly, one study only noted improvements in those not exposed to second-hand smoke.[25] An important consideration when determining the generalizability and application of this work is that the success of this intervention may be related to the study physicians supporting asthma guideline-recommended care and that supervised medication use may not have the desired benefit if the level of treatment is not consistent with the level of asthma control.

CASE MANAGEMENT AND CARE COORDINATION

Case management involves spending time contacting and then patiently and persistently working with the family to build a trusting relationship. Care coordination services ensure timely, coordinated care to provide appropriate levels of health, psychosocial and support services, and continuity of care through ongoing assessment of the client's and family members' needs. Care coordination and case management activities include: an initial assessment of service needs; development of a comprehensive, individualized plan; coordination of services required to implement the plan; monitoring of the client and family to assess the plan's effectiveness; and re-evaluation and revision of the plan as necessary. Case management strategies applied through schools to higher risk students with asthma hold promise. Many of the school-centered interventions evaluated have included case management as an element of the intervention.[13,19,22–31] The case management activity most frequently reported was working with the family followed by contacting healthcare providers. Extensive care coordination and case management services are typically only needed by students who continue to experience poorly controlled asthma despite having the usual support systems. Benefits observed included improved asthma control, reduced use of healthcare services related to asthma exacerbations and reduced school absenteeism.[13,19,22–31] However, many of the studies highlighted that a great deal of effort is needed to engage the community asthma care providers.

Information Technology Infrastructure

Information technology that permits data sharing is an important component of an infrastructure to promote coordination of care across schools, families and healthcare providers to achieve successful asthma management. A project in the Charlotte Mecklenburg Schools suggests that databases maintained by nurses, asthma program staff and school personnel can be successfully integrated into a single asthma program evaluation database. Benefits reported as a result of their shared database included an ability to identify students with an elevated level of

https://CafePezeshki.IR

need in order to receive priority care status from the asthma education program, and an ability to evaluate program outcomes that were not possible before such as academic performance, school attendance, school behavior and quality of life.[32] Others have focussed on developing a web-based system to make previously evaluated effective programs that require intense study staff participation potentially sustainable and transferable because web-based systems are viewed as less expensive and more accessible. However, work is needed to determine if these assumptions are valid. A study in Denver Public Schools is currently underway to evaluate an asthma-specific tab as part of the district's electronic academic platform. This system includes monitoring receipt of a school asthma care/action plan, availability of an on-site quick-relief rescue inhaler, monitoring of at-risk asthma status, monitoring of school absenteeism, calculating the percentage of school absenteeism, tracking visits to the school health office for asthma, and 911 calls for asthma.[30,33] Studies are needed to evaluate the effectiveness and added value of information technology platforms that are intended to improve communication and coordination of care among schools, families and healthcare providers, provide asthma care support to school nurses and promote sustainability, while reducing costs.

Interventions to Improve Asthma Self-Management Skills

The National Heart, Lung and Blood Institute Expert Panel Guidelines for the Diagnosis and Management of Asthma stress the need for asthma education and the development of asthma management skills to achieve successful disease control.[34] A number of studies have assessed the effectiveness of providing asthma education in schools.[31,35–45] These educational programs incorporate health education theories and asthma practice guidelines. Most school-based educational programs have focussed on building skills for elementary school-aged children and have demonstrated improvements in asthma knowledge, confidence/self-efficacy, asthma management skills and associated asthma morbidity outcomes, such as improved quality of life, and reduced symptoms, emergency department visits, urgent care visits, hospitalizations and school absenteeism.[31,35–45] Some studies have extended these benefits to improvements in school grades and academic performance.[37,38,44,45]

Recently, school-centered asthma education efforts have targeted adolescents of low income living in urban settings.[46–50] Studies in adolescents, an identified difficult-to-reach group, have demonstrated acceptance, involvement and retention by this age group: over 75% of those eligible participated and over 70% were retained.[46,47] Benefits observed included improved self-confidence in asthma management skills, appropriate use of controller and quick-relief asthma medications, fewer days with symptoms and activity limitation, fewer interrupted nights due to asthma, decreased hospitalizations, emergency department visits, and school absenteeism, and improved quality of life.[29,46–50] Interventions are starting to address the complexity of and co-morbidities associated with asthma. A pilot study completed in Chicago high schools combined asthma management and nutrition and weight management for all students with asthma, regardless of weight.[50] The program consisted of nutrition and weight management, asthma education, a family education event, and two-monthly reinforcement visits with behavioral counseling provided by a nurse and dietetic intern to increase asthma and nutrition knowledge, asthma and nutritional self-efficacy, asthma control and quality of life. Web-based asthma self-management programs have also been developed to attract and educate adolescents with asthma.[29] Puff City, a web-based tailored asthma intervention with a case manager, led to improved symptoms, restricted days and school absences; however, improvements in medical care were not observed. With the exception of a few studies,[29,48,49] this work was completed through non-randomized, controlled study designs with relatively short follow-up periods. This area is worthy of studies using more rigorous study designs.

Synthesizing findings in this area is difficult due to the heterogeneity of interventions, age of students, interventional populations and outcomes assessed. For instance, interventions varied in educational components, number and duration of sessions and personnel type. Target populations included exclusively students with asthma or these students in combination with one or more of the following groups: parents/guardians, healthcare providers, classmates and school personnel. Study personnel providing the intervention ranged from certified asthma educators to school nurses to health professional students to lay providers. Teaching modalities also varied from individualized one-on-one teaching to group teaching to computer-based programs. Although several randomized controlled trials have been conducted, limitations remain: studies do not clearly describe usual care; several studies included students with mild asthma and did not perform subgroup analyses to determine if asthma severity, asthma control, age, race/ethnicity, socioeconomic status or location (inner-city, suburban, city, rural) predicted interventional response; studies were often limited in their ability to draw conclusions about differences between comparison groups due to a lack of power with smaller sample sizes; and studies did not include a follow-up period to determine if improvements continue, are sustained or regress. Although results across studies have not been consistent, systematic reviews suggest that school-centered asthma education has positive clinical, humanistic, health, economic and academic outcomes.[44,45]

Creating Asthma Friendly Schools

Asthma friendly schools are those that make the effort to create safe and supportive learning environments for students with asthma. Schools can create asthma friendly and supportive environments for learning and healthy development through the implementation of policies and protocols. Table 35-1 identifies eight core elements and implementation tips for creating asthma friendly and supportive schools, taken from the work of several groups and organizations.[11,51–56]

In the USA, school nurse teams deliver most asthma care, although only one third of schools have a full-time nurse and one third have a full-time health paraprofessional. In the absence of health service staff, main office staff and teachers are required to manage flare-ups and medication administration. Deaths from asthma in schools may be attributed to delays in school personnel providing assistance.[57] Previous studies highlight inadequate asthma management practices in schools and asthma knowledge and skill gaps of school personnel.[11,36,58–60] Despite the importance of intervention from school staff, few interventions have targeted this important group.

https://CafePezeshki.IR

TABLE 35-1 Elements for Creating Asthma Friendly and Supportive Schools

Elements for Supportive Schools	Implementation Tips
Identify and know which students have asthma	School health registration forms should ask explicitly about whether or not the student has asthma and uses asthma medications Parents/guardians and students need to let schools know they are affected by asthma School-wide screening to identify new cases of asthma is discouraged
Provide easy access to quick-relief asthma inhalers	Most schools do not stock quick-relief inhalers for students' use, even for emergency use Families need to ensure that their children with asthma have a quick-relief inhaler at school at all times. Even when schools encourage self-carrying of inhalers, as few as 14% of students have access to a quick-relief inhaler at school[27] Know the school district form(s) that need to be completed and returned to ensure the student has easy access to his/her inhaler Ensure students with asthma know how to correctly use the inhaler, the importance of not sharing their inhaler and the responsibilities associated with self-carrying their inhaler
Ensure that school staff are prepared to identify and handle worsening asthma and asthma emergencies	Each student with asthma needs a completed and submitted up-to-date asthma care plan or action plan appropriate for his/her school district Schools should have a written protocol or plan for school staff to follow for identifying and responding to worsening asthma
Reduce exposure to environmental asthma triggers	Report asthma triggers on the individualized asthma care plan/action plan for school Develop and implement Indoor Air Quality Management program for schools (www.epa.gov/iaq/schools/): • Schools and grounds are smoke free at all times • Low scent and green products (cleaning, art supplies, etc.) are used • Integrated pest management practices are followed
Facilitate full participation of students with asthma in all activities, including physical activity and play	Asthma should not be an excuse for not participating in gym class, sports or play during school recesses School asthma care plans/action plans typically have a section dedicated to delineating steps to take for supporting participation in physical activity and recess Clinicians need to ensure that students clearly understand the steps to take and that the plan is clearly communicated to the school to permit the student to be a full participant
Provide learning opportunities for students, parents/guardians and school staff	At least annual staff trainings are needed to review how to identify and respond to worsening asthma, accurately use asthma medications and manage asthma triggers in a school setting School nurse health teams often have 'teachable moment' opportunities during office visits for worsening asthma or pretreatment sessions to reinforce the same asthma control messages as the asthma care provider, and for assessing and coaching for accurate technique along with other asthma management education topics and skills Healthcare providers play an important role in providing educational opportunities for the school community including students, school personnel and parents
Coordinate and work with students, parents/guardians, healthcare professionals and community organizations to successfully manage asthma	A system exists for schools, families affected by asthma and healthcare providers to share information for keeping all parties informed. This system may be paper-based or electronic. Examples of system elements include: asthma care plans/action plans, alerts to healthcare providers and families when high rates of absenteeism have occurred, notifications to the family and healthcare provider related to excessive use of a rescue inhaler, and sharing discharge summaries with school nurses for urgent/emergency department visits and hospitalizations

Training school staff (administrators, secretaries, teachers, etc.) in the recognition of and appropriate response to worsening asthma and in asthma medications led to improvements in asthma knowledge and practice.[36,61] A randomized controlled study in 130 elementary schools evaluated a multifaceted intervention, 'The Creating Asthma Friendly Schools Resource Kit', which involved education of the entire school community, support for policy changes and resources for asthma friendly schools, and reported improvements in school practices that created supportive and asthma friendly school environments. Improvements were noted for asthma knowledge and skills of school personnel and students, the percentage of school staff that knew the students with asthma, the provision of easy access to inhalers with increases in students self-carrying their quick-relief inhaler, the existence and use of a school-wide process for managing worsening asthma, the implementation of strategies to reduce exposure to triggers and to permit students to be full participants at school, and the use of strategies to support communication among families, schools and asthma care providers.[36] This work suggests that the potential benefit of interventions targets the whole school community; however, additional work to determine the effectiveness of such interventions is needed.

Cost-Effectiveness of Strategies

Few school-centered studies have determined the cost-effectiveness of these types of interventions. A study by Noyes et al[62] demonstrated that their school-based supervised maintenance asthma therapy program could be economically effective for children aged 3–10 years in inner city schools: $10 per one extra symptom-free day. The reported cost of the program was $4,822 per 100 children, which included personnel costs. The program resulted in about $3,000 in savings to schools and the healthcare system. They noted that limiting the program to students having the most persistent asthma symptoms increased the cost-effectiveness. Another study looking at cost-effectiveness of a school-based health center program noted that

https://CafePezeshki.IR

medical savings alone could not offset the costs of implementing and sustaining an asthma prevention program. However, when savings due to reduction in parent opportunity costs and premature child deaths were considered, the benefits of the program far exceeded the costs.[63] As noted above, several studies in the school setting have demonstrated that case management, self-management and educational programs are effective. However, these programs cost money to implement and often result in higher medication costs owing to increased use of more expensive maintenance asthma inhalers, and more physician/healthcare provider visits for monitoring and follow-up. Information on the cost-effectiveness of school-centered interventions is severely limited, and requires additional study and reporting.

How can Community Asthma Care Providers Be an Essential Part of the Team?

Asthma management at schools is important for pediatricians, family care providers, pediatric pulmonologists and allergists, and healthcare staff working with physicians to provide quality asthma care. The variability of asthma care services and programs that may or may not be provided in schools across the USA makes it necessary for clinicians to learn what is happening at their patients' schools and to advocate for appropriate services.

Asthma morbidity for children and youth can be significantly reduced through the coordinated efforts of asthma care providers, families and schools. Asthma care providers play a vital role in preparing and supporting children and youth with asthma and their families to manage asthma at school as part of the overall goal of achieving successful asthma control. Time is often limited for asthma care providers so it is important to know which actions will have the greatest benefits. Table 35-2 summarizes the literature reviewed and existing resources to provide a list of 'best practice' action items and Box 35-1 provide existing resources for busy asthma care providers.[64–67]

Summary

Second to their home, youths spend the largest portions of their day at school and during the school year, the largest portion of their wakeful hours. The Centers for Disease Control (CDC) and multiple studies highlight the need for schools, youths with asthma and their families, and asthma care providers to work together to control asthma through school-centered health services and education. If asthma is well controlled, students will experience fewer school absences and be more productive and engaged in school.

What can school-centered programs accomplish? Several studies and systematic reviews have demonstrated that these programs improve student asthma knowledge, confidence in and actual practice of asthma management skills, regular use of preventive asthma medications, school absenteeism, school performance and urgent and emergent asthma care. However, not all studies demonstrated improvements in asthma outcomes. There are several potential reasons why benefits were not observed and possibly diluted: several interventions were provided to all students with asthma and it may be that students with more moderate to severe or poorly controlled asthma reap larger benefits than students with intermittent or well-controlled asthma. Although self-management behaviors improve, students have little control over environmental exposures and asthma medications prescribed for their use. Many of these studies occurred in inner cities that are known for significant trigger exposures. Research by Halterman et al[25] revealed that only those not living in a home with a smoker benefited from intervention. Lastly, students with asthma can only take their asthma control so far on their own as they must rely on and work with their asthma care provider. If their provider does not assess asthma control, prescribe the right medications, complete the necessary school forms and provide reinforced asthma messaging, the student loses the benefits. Many of the programs described a lack of cooperation with community asthma care providers at several levels. A review by Wheeler et al[64] noted that the most important lesson learned from school-centered asthma programs was the need to establish strong links to the asthma care providers of students. Collectively, research demonstrates that programs that either provide asthma care directly at school or ensure adequate links between the school and the student's asthma care provider have successfully reduced asthma morbidity.[64] Schools absolutely need the involvement and cooperation of asthma care providers to help students successfully manage their asthma. Efforts of asthma care providers and schools, individually and collectively, should address the medical, psychosocial and educational needs of the child/youth. The synergy created by each party playing an active role in asthma management assists students and their families to achieve asthma control and reduce associated morbidity.

Models of asthma care that place schools at the center or core of the model are applicable nationwide and may serve as a model for managing other chronic illnesses.

TABLE 35-2 Actions for Clinicians Caring for Students with Asthma

Actions	Comments
Complete and share asthma care plans or action plans for schools	If your local school district has a standardized form, make sure this form is completed and returned to the school. As discussed above, the action plan used for home may not be suitable for the school setting. This form will allow the school health team to provide individualized care
Schedule a summer tune-up asthma visit	This visit is extremely important for having the student start school 'ready to go'. At this visit, assess asthma control, prescribe a second quick-relief inhaler for school use, and complete and review the asthma care/action plan for school use
Ensure students have a quick-relief inhaler for school use	Asthma flare-ups are often unexpected so it is key to have a quick-relief inhaler easily accessible at school. This typically involves having a second quick-relief inhaler for school use that is kept in the main office or on the student, so providing a back-up prescription is often necessary. Review the responsible use of the inhaler at school and assess and coach for accurate inhaler use
Encourage parents and students to share with the school community that the student has asthma	Schools are unable to support students to reach their full potential if they are not aware that a student has asthma. Explain to families the importance of letting the school know that the child/youth has asthma in the case of an asthma attack and the ability to use a quick relief inhaler to relieve symptoms
Request extra support for case management and care coordination for patients with poorly controlled asthma	Obtain written parental permission to send information to the school, to discuss the child's/youth's asthma condition with the school and to receive information from the school as required by FERPA (Family Educational Rights and Privacy Act). Contact the school nurse to discuss additional support that may be provided during school hours to support attainment of asthma control and to learn about and discuss previous exacerbations, use of the quick-relief inhaler, school absenteeism and participation level in school activities (gym class, recess, etc.)
Investigate what asthma resources exist at your local schools	If you have never worked directly with schools, check out valuable information at the following websites: American Academy of Pediatrics School Health (www.schoolhealth.org) and Schooled in Asthma (www.aap.org/schooledinasthma)
Know your state laws and local school policies concerning asthma	At a federal level, under Individuals with Disabilities Act, Section 504 of the Rehabilitation Act of 1973 and Title II of the Americans with Disabilities Act, students with asthma are able to have access to life-saving medications and care. Several states have their own legislation regarding asthma medications and school districts may have their own specific asthma care policies, protocols and forms. At a minimum, for those without a specific asthma policy, most school districts require completion and submission of a school medication administration form to permit inhalers to be carried by the student or stored at school
Partner with a local school nurse to hold an asthma education session	Get to know your local school nurses. They welcome support in providing education to other school nurses, school personnel, students with asthma and their families
Advocate for creating supportive school environments	Offer to help develop, revise and review asthma policies and protocols in schools, such as the guidelines or protocol for how to recognize and respond to worsening asthma. Consider becoming active on a school board or the school's health and wellness committee

36 Exercise-Induced Asthma: Strategies to Improve Performance

J. TOD OLIN

KEY POINTS

- Prevalence of exercise-induced bronchoconstriction (with or without baseline asthma) may be as high as 20% of the population of casual exercisers, and much higher in specific risk groups.
- Initiating events in exercise-induced asthma include an osmotic insult to airway epithelial cells.
- Multiple indirect challenge tests are becoming available as surrogates for clinic-based exercise challenges.
- While novel therapeutics have not been developed for exercise-induced asthma, there is emerging data that dietary changes may offer therapeutic benefit.
- In patients requiring several medications for exercise-induced asthma, practitioners should consider alternative diagnoses including upper airway obstruction.

Introduction

The ability to exercise comfortably is of central importance in the lives of patients of all ages. Exercise-induced bronchoconstriction (EIB) and exercise-induced asthma (EIA) are two similar conditions which can significantly impair this ability. EIB is defined as transient airflow obstruction in response to an exercise stimulus. In patients with previously diagnosed asthma, the term EIA describes the same phenomenon.

These conditions are important for several reasons. From a public health standpoint, in an age when guidelines from several health oversight committees strongly advocate frequent and vigorous exercise, the most important impact of bronchospasm is its tendency to make exercise uncomfortable, decreasing the frequency, intensity and duration of exercise bouts in children and adults. Additionally, from a performance standpoint, bronchospasm may impair performance through either ventilatory limitation or dyspnea.

Our understanding of the pathophysiology of bronchospasm is evolving in an age of improved biometric analyses. This insight has led to improved diagnostic strategies and may continue to do so among different groups of patients across different ages and performance requirements. It may also lead to therapeutic advances and more personalized strategies.

This chapter focuses mainly on the clinical features, pathophysiology, diagnostic strategies and treatments for EIA. When appropriate, the chapter makes specific reference to data applicable to isolated EIB. A section is devoted to specific groups of patients and athletes that require more individualized considerations. For completeness, it briefly reviews the epidemiology and impact of EIA as well as the differential diagnosis of exertional dyspnea.

Epidemiology

The number of people that suffer from EIA is staggering. In 2010, in the USA alone, over 25 million people were estimated to have asthma.[1] Worldwide, an estimated 300 million people are affected.[2] Specific high-risk groups include people of Puerto Rican, African American, and multiple race heritage as well as those living in urban areas or born to low-income parents.[1,3,4] The majority of these patients with baseline asthma describe characteristic symptoms associated with EIA.[5]

In addition to isolated asthma patients, the preterm birthrate is nearly 12% in the USA and the rate of associated chronic lung disease varies inversely with gestational age.[6] Patients with chronic lung disease of prematurity are much more likely than controls to experience EIA.[7]

Prevalence estimates for isolated EIB vary, but may be as high as 20% of casual adult exercisers.[8] Among athletes, this number can be much higher, depending on the specific sport studied and testing methodology employed.[9,10] Excellent summaries of EIB prevalence studies among athletes have been published.[11]

Children are also affected by EIA, and prevalence varies by location and methodology from 4% to 20% in different studies.[12,13] There is debate as to the existence of isolated EIB in young children because airway hyperreactivity is such a strong predictor of asthma onset at a future date, although many children diagnosed with EIA do not show signs of respiratory disease outside of exercise.[14]

Impact

The burden of EIA takes many forms, including mortality and quantified morbidity. Death due to EIA is exceedingly rare, but has been reported.[15] From the public health perspective, exercise avoidance due to EIA may be the most important burden on health. Children with untreated asthma have been shown to be less fit than age-matched controls.[16] Moreover, asthma has been identified as a barrier to activity in children with measured inactivity, although this finding has not been replicated in all populations.[17–19] The causal relationships between asthma and obesity are not fully understood, although both appear to affect each other. Moreover, there is reasonable fear that increased sedentary time in response to an asthma diagnosis or symptoms could lead to future increases in obesity, cardiovascular disease and death.[20] From a cognitive perspective, in addition to asthma being a barrier to activity, EIA is associated with a decreased health-related quality of life.[21]

https://CafePezeshki.IR

The effect of untreated or undertreated EIA on performance is somewhat more difficult to quantify for ethical reasons. It is common for patients to complain of symptoms related to exercise and performance, but the effect of the bronchoconstriction that causes symptoms likely has variable effects on specific task performance. Possible causes of decreased performance related to bronchoconstriction include ventilatory limitation, increased work of breathing leading to decreased substrate delivery to performance muscles (without observed ventilatory limitation), and performance limitation due to dyspnea.

Treated EIB seems to have minimal impact on performance. In Olympic competition, using medals as the outcome of performance, there are no important differences between patients that carry a diagnosis of active asthma and nonasthmatic athletes.[22]

Pathophysiology

There has been considerable debate regarding the mechanisms leading to EIA in the last four decades. It is possible that there is no unifying theory explaining all laboratory and clinical observations in EIA, but rather multiple phenotypes of disease which may vary across ages, exposures and characteristics of the underlying asthma. It is recognized that the central event in EIB is rapid airway epithelial water loss extending to smaller generations of airways due to an inability of the upper airway to adequately condition inspired air. EIB can be largely blunted simply by inspiring warm humid air. Two competing, but not mutually exclusive, hypotheses explain many of the downstream clinical phenomena observed in EIB: the osmotic hypothesis and the thermal hypothesis.

According to the osmotic hypothesis, the airway epithelial water loss leads to an increased osmolarity of the airway surface lining fluid. In response to this change, water then flows from epithelial and subepithelial cells in order to maintain equilibrium. This secondary flow of water causes intracellular changes and leads to the release of mediators which ultimately lead to bronchoconstriction. In 2014, it appears that experimental evidence favors this osmotic hypothesis over the thermal hypothesis.

According to the thermal hypothesis, airway cooling and subsequent bronchial vasoconstriction are followed by a reactive hyperemia. This vascular engorgement is considered to cause airway narrowing. Among other evidence consistent with this hypothesis are the interesting findings that inhalation of cold dry air or norepinephrine after exercise can attenuate EIB.[23] It is important to note that airway warming and cooling are not required to trigger bronchospasm, an observation which has called into question the role of thermal change in EIA.

In addition to osmotic and thermal changes, the hyperpnea associated with exercise exposes the epithelium to increased mechanical stress as well as increased exposure to noxious agents. Airway desquamation is known to occur in response to exercise challenge in patients with EIA, although controls may also exhibit this phenomenon.[24,25] There is evidence the oxidative stress at an epithelial level may be somewhat higher in patients that suffer from EIA.[26] Through mechanisms that are not entirely elucidated, it is felt that dysfunctional injury repair mechanisms may predispose patients to both the acute and chronic changes seen in EIA. This is, in part, supported by observations that exercise challenges in patients with EIA, compared to controls, increase epithelial-derived 15S-hydroxyeicosatetranoic acid (proinflammatory) and decrease epithelial-derived prostaglandin E_2 (PGE_2) (anti-inflammatory).[24,27]

The osmotic, thermal, and mechanical stresses that occur during exercise indirectly cause bronchospasm via a complex and incompletely understood cascade involving multiple effector cells and mediators (Figure 36-1). In addition to epithelial sources, key mediators of bronchospasm have been linked to increased numbers of mast cells and eosinophils.[24,28] A possible link between epithelial stress and effector cells is a combination of interleukin 33 (IL-33) and thymic stromal lymphopoietin, epithelial-derived mediators which affect mast cell differentiation and release of cysteinyl leukotrienes (cysLTs) and PGD_2.[29]

cysLTs, derived from mast cells and eosinophils, have been strongly implicated in the pathogenesis of EIB, although their actions do not explain all observed bronchospasm. They have been detected in increased amounts in both exhaled breath condensate and sputum of patients with EIA.[30,31] Clinical trials using leukotriene receptor antagonists (LTRAs) and leukotriene synthesis inhibitors for prevention of bronchoconstriction consistently demonstrate incomplete inhibition of bronchospasm.[32,33]

Histamine is also implicated in EIA. Released primarily from mast cells in response to an exercise stimulus, it is thought to mediate the initial events in EIA.[34] Antagonism seems to prevent bronchospasm in response to surrogate challenge, but has not consistently shown clinical benefit in exercise challenges.[35]

There are mediators which may play protective roles in EIA, although much remains to be studied in this area. Lipoxin A4 levels appear to decrease in patients with notable EIA compared to controls.[36] Prostaglandins may play a role in EIA, as suggested by antagonism studies using cyclooxygenase inhibitors as well as in primary studies of the airway in EIA, but mechanisms are poorly understood.[24,37] Prostaglandins have been most convincingly implicated by their role in modulating refractoriness to repeated exercise challenges (a phenomenon which will be described later), although the precise mechanisms are far from clear.[37]

Our understanding of the roles of sensory nerves and parasympathetic efferents is evolving. Neurokinins are released from sensory nerve fibers in response to a variety of stimuli, including hyperosmolar stimuli. Among other functions, neurokinins can stimulate secretion of mucin 5AC.[38] Parasympathetic innervation, known to be involved in asthmatic responses due to the tendency for patients with asthma to demonstrate bronchoconstriction in response to methacholine, likely plays a more variable role in EIA across patients (as has been shown for decades).[39] Some of the variability may be a result of differences in baseline vagal tone across subjects.[40,41]

It is plausible to consider potential constitutive or induced differences in airway smooth muscle as predisposing factors to developing EIA for a variety of reasons, but there is a paucity of data regarding causal links in the area (especially in pure EIB).[42] In addition to presumed mass-bronchoconstriction force mechanisms, the muscle itself may act to secrete mediators perpetuating inflammatory responses. Future research is needed in this area to clarify these possibilities as well as their relative importance to the overall clinical phenotype of EIA.

Refractoriness to EIA, the phenomenon in which repeated exercise challenge elicit a decremental bronchospastic response over a period of hours, may involve mediators other than those described above (although a precise mechanism is unknown).

https://CafePezeshki.IR

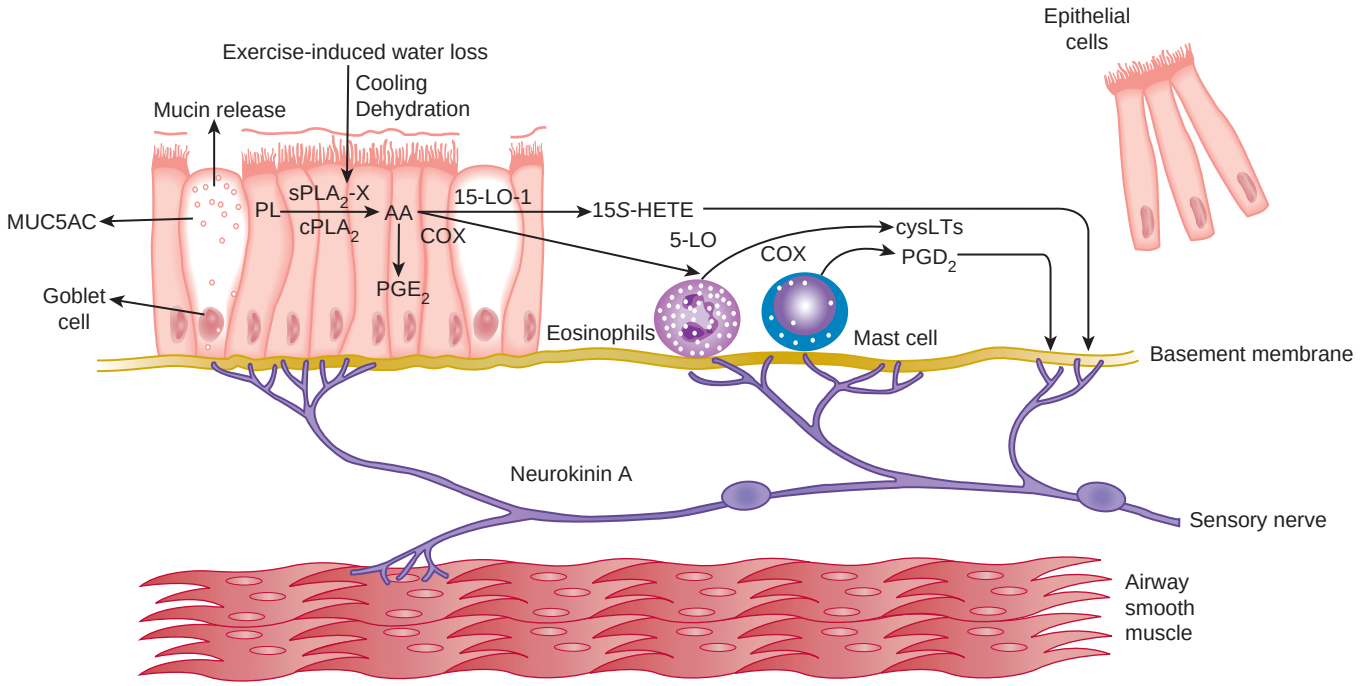

Figure 36-1 Disease model of exercise-induced bronchoconstriction (EIB) pathogenesis. Asthmatics with EIB have increased concentrations of shed epithelial cells, cysteinyl leukotrienes (cysLTs) and cysLT-to-prostaglandin E_2 (PGE_2) ratio in induced sputum. Exercise challenge initiates the production of cysLTs, PGD_2, and 15S-hydroxyeicosatetraenoic acid (15S-HETE), and a reduction in PGE_2. An increase in secreted phospholipase A_2 group X ($sPLA_2$-X) may increase the release of arachidonic acid (AA) by the epithelium or by adjacent inflammatory cells. Contraction of the airway smooth muscle and mucin release occurs in part through retrograde axonal transmission in sensory nerves that release neurokinin A. *15-LO-1* – 15-lipoxygenase-1; *5-LO* – 5-lipoxygenase; *COX* – cyclooxygenase; *cPLA*$_2$ – cytosolic phospholipase A_2; *MUC5AC* – mucin 5AC; *PL* – phospholipids. *(From Hallstrand TS, Henderson WR. Role of leukotrienes in exercise-induced bronchoconstriction. Curr Allergy Asthma Rep 2009;9:18–25. Copyright © 2009 by Current Medicine Group LLC, reproduced with permission.)*

The mediators are likely similar to those induced by other indirect airway challenges as cross-refractoriness is known to occur between hyperventilation and exercise as well as mannitol and exercise. However, refractoriness does not necessarily exist between indirect and direct challenges. Catecholamine release, while initially suspected, is not thought to play an important role.[43] Prostaglandin release in response to indirect stimuli (implicated due to the ability of indomethacin to eliminate refractoriness) and tachyphylaxis of cysLT receptors are the most widely accepted mechanisms of refractoriness at this time.[37,44]

Characteristic Clinical Features

Patients describe EIA in terms of a variety of symptoms. Cough is generally the most common in study settings. Wheeze, chest tightness, disproportionate dyspnea for a given task and increased mucus production are also common symptoms.[45] Symptoms generally occur after at least 8 to 10 minutes of exercise and persist for 30 to 45 minutes. At times, patients describe a phenomenon in which symptoms improve after continued exercise (the spirometric physiology of which is detailed below). Symptoms may vary in terms of frequency and severity with multiple environmental and exercise-associated factors, specifically worsening in cold, dry environments with high allergen or pollutant content. Activities with high ventilatory requirements (e.g. cross country skiing) are more likely to trigger symptoms than activities with low ventilatory requirements (e.g. golf). Generally, patients do not describe loud, audible breathing, severe distress or cyanosis (although fatal events are rarely documented in the literature). Generally, chest pain, pallor and syncope are not features of the disease.

On physical examination, patients generally appear normal in a clinic setting. Given the high proportion of patients that suffer from baseline asthma and atopy, stigmata of asthma and atopic disease may be present. Cyanosis, an extreme barrel chest, auscultated crackles and clubbing are not features of EIA and suggest alternative diagnoses.

In terms of diagnostic testing commonly available in the clinic setting, findings are often completely normal, but like the physical exam, may suggest baseline asthma and atopy. Resting spirometry may be normal or suggest obstruction. Bronchodilator response above resting spirometry may be present as well. Skin testing and exhaled nitric oxide testing are often positive. Chest radiography is generally normal, but may demonstrate hyperinflation. Definitive provocative testing is described in a later section.

The classic spirometric pattern demonstrated with bouts of exercise is one in which airflow may increase slightly during and immediately after exercise, decline to nadir values roughly 10–15 minutes after exercise and spontaneously resolve to near-baseline levels within 60 minutes. For unclear reasons, young children may demonstrate a slightly different pattern, with an earlier onset of measurable bronchoconstriction associated with a more depressed nadir.[46]

One feature of EIA that is distinct from most other causes of dyspnea is refractoriness. Patients often describe this as the ability to 'run through asthma'. Many patients with EIA, following an initial airway stress (which may or may not cause measured airway obstruction), can exercise without the degree of

https://CafePezeshki.IR

bronchoconstriction typically experienced for a given task.[47] As noted above, the mechanisms behind this phenomenon are unclear and are likely similar across multiple indirect airway challenges.

The existence of a second phase in EIA is controversial and will not be reviewed in this chapter.

Groups Requiring Special Consideration

Several individual groups of patients with EIA require special consideration due to the frequency and severity of symptoms. Winter sport athletes who participate in activities requiring high ventilation are particularly susceptible to EIA and isolated EIB.[10] Warm weather endurance athletes suffer EIA and EIB at a somewhat lower rate.[48] The reasons for this are likely related to the magnitude of osmotic stress induced by the activities involved.

In addition to endurance exercise and cold weather exercise, exercise in environments with a high degree of particulate pollution is associated with high rates of EIA.[49] This may particularly affect those who exercise in an urban area and those who exercise at indoor facilities cleaned or serviced by machines that emit particulate matter, including ice polishers.

Swimmers, while experiencing warm humid air while exercising, are exposed to high levels of a variety of compounds formed by the interaction of nitrogen-containing compounds and chlorine. In terms of acute bronchospasm, a high proportion of competitive swimmers suffer from symptoms.[9] Chronic effects are less clear, with some authors suggesting a role for chlorine as a causative agent for asthmatic phenotypes later in life.[50]

There are some young children who demonstrate severe EIA once old enough to perform spirometry. This seems to be associated or predicted by airflow limitation detected during (rather than after) exercise bouts, a phenomenon described as 'breakthrough EIB.' The mechanisms behind this severe decline are unclear. It is possible that the small airway caliber of children is to blame. It is also possible that large airway dysfunction plays a more important role than in older populations.[51]

Differential Diagnosis

The differential diagnosis of EIA is quite broad, although several competing causes of exertional dyspnea are quite rare, especially in younger populations.

It cannot be overstated that the most important diagnosis to consider in a patient with known or suspected EIA or EIB is poorly-treated baseline asthma, especially in younger populations. Bronchial hyperresponsiveness is strongly suggestive of asthma and predictive of the development of asthma.[52]

Inducible laryngeal obstruction at the glottic and supraglottic level should be strongly considered in patients that do not respond to inhaled bronchodilators. This is an umbrella term that includes paradoxical vocal fold motion as well as prolapse of the arytenoid cartilages. Clinically, patients with these conditions often describe rapid onset and resolution of symptoms when compared to typical cases of EIA. Rather than describe a typical refractory period, patients often describe worsening dyspnea with repetitive exercise. Symptoms often are associated with a high degree of distress as opposed to the mild discomfort typically associated with EIA. Inspiratory stridor can be present, but is not seen in all cases as it is likely a function of both the degree of obstruction and the instantaneous air flow rate. Regardless of stridor, hypoxemia is rare. The gold standard for diagnosis of these conditions is direct laryngoscopic visualization, but the intermittent nature of the condition can present challenges. Some highly-specialized centers advocate the use of continuous laryngoscopy during exercise.[53]

Hypoxemia can be the cause of exertional dyspnea and performance limitation in the absence of overt distress. It can be normal for well-trained athletes to achieve mild hypoxemia (from the high 80s to low 90s) even at sea level.[54] Generally, more important hypoxemia is associated with a degree of cyanosis. Intrapulmonary shunts have been described as a potential cause of hypoxemia. In younger populations, undiagnosed conditions leading to this degree of hypoxemia are rare (largely because cyanotic heart disease is detected at earlier ages).

Dysrhythmias have been described as a cause of exertional dyspnea. Generally, they should not be associated with cyanosis or hypoxemia. Rarely, muscle disease can manifest as dyspnea out of proportion to work rate.

The deconditioned patient presents challenges from a diagnostic perspective. There are no widely accepted criteria to quantitatively diagnose deconditioning. Moreover, a diagnosis of deconditioning does not exclude other causes of dyspnea.

Diagnostics

There are several diagnostic strategies used to confirm a diagnosis of EIA. Each has benefits and drawbacks when considering sensitivity, specificity, feasibility and cost.

In select cases, clinical history alone may be an option. It is clear that this is not an ideal option in patients capable of performing more specific testing because history alone is associated with both over- and under-diagnosis of EIB.[45] However, for young patients with developmental or musculoskeletal conditions that prevent exercise testing or centers without the infrastructure for specialized testing, this must be considered. In this context, empirical trials of bronchodilators before exercise aid in the diagnosis.

Exercise challenges are another option that should be considered in patients complaining of exertional dyspnea. In order to confirm a diagnosis, clinicians should observe a decline in the forced expiratory volume in one second (FEV_1) of 10% to 15% after exercise. Receiver-operator curves have demonstrated optimal threshold values for positive and negative test interpretation, although individual considerations and testing conditions must enter the diagnostic equation.[55] Recent consensus guidelines recommend the use of a 10% decline in adults and a 12% decline in children as threshold values.[56]

There are several benefits to formal exercise testing. Exercise intensity, a variable which has been clearly demonstrated to affect the likelihood of triggering EIA, can be closely monitored in a laboratory setting. The availability of measurement equipment is also an advantage. Additionally, patients can conceptualize the challenge and accept the results as the challenge is more conceptually familiar than the other indirect airway challenges mentioned below.

The drawbacks of exercise challenges include the fact that ambient conditions are often not conducive to triggering bronchospasm because laboratories offer warm and relatively humid environments. Additionally, standard exercise protocols may

https://CafePezeshki.IR

not be sufficient to trigger bronchospasm in all patients. The time course of achieving higher work rates and thus high ventilatory rates as well as the duration of exercise challenge can both affect the sensitivity of the test. Challenges which are either too short or too long in duration may not result in a positive test. The mode of exercise also affects the sensitivity of the test in patients that have different ventilatory rates across different modes of exercise at the highest sustainable work rate.

As an alternative to laboratory testing, field testing has been advocated by several authors.[57] When compared with laboratory-based testing, field testing offers the advantages of cold, dry environments and exercise scenarios that are comparable to everyday activities. Drawbacks include the inability of the tester to closely monitor exercise intensity as well as of performing the challenge tests in close proximity to measurement equipment.

Outside of exercise, there are multiple inhaled challenges that can confirm a diagnosis of EIA. Methacholine challenge is a direct airway challenge, which can quantify the degree of airway hyperresponsiveness. Its benefits include broad availability as well as decades of use in hospital settings. However, methacholine causes bronchoconstriction through mechanisms not necessarily present in EIA. For this reason, overlap between patients with methacholine-induced airways hyperresponsiveness and pure EIB is not perfect.[58]

Eucapnic voluntary hyperventilation is a challenge that mimics the high ventilatory rates associated with exercise.[59] In this challenge, the patient attempts to maintain maximum voluntary ventilation while breathing from a circuit which offers 5% carbon dioxide. Its benefits include its lack of dependence on environmental conditions because the breathing circuit is isolated from the laboratory environment. Additionally, it bypasses the need for exercise equipment in the laboratory. Its drawbacks include its somewhat limited availability.

Hyperosmolar challenge with inhaled mannitol offers another means of assessing airways hyperresponsiveness.[60] Mannitol offers an indirect challenge and is thought to cause the same fluid shifts from the submucosal tissue to the airways surface lining fluid. Its benefits include its relatively high concordance with properly-conducted exercise challenge and drawbacks include its somewhat limited availability.

Therapeutics

There are several available therapeutic agents for EIA, which target a number of mediators and effector cells. Of interest, there is no single therapy that has been universally successful. The differences between patients with regard to treatment response may suggest that multiple physiological phenotypes of EIB exist, each with an ideal individualized therapy. There are multiple published guidelines to assist practitioners with decision-making regarding medications.[56,61] The guidelines for EIA treatment are generally compatible with treatment of underlying asthma, although there are some notable areas of conflict which the practitioner should be aware of.

The title of this chapter implies that these therapies can improve performance. While this is presumably true in concept, the vast majority of clinical trials in the area of EIB do not assess performance directly. Moreover performance as an outcome will presumably vary in terms of assessment from sport to sport. For the purposes of this section, the reader can assume that medication efficacy is defined by its ability to preserve lung function measured as a post-exercise or post-surrogate challenge FEV_1.

Since the last edition of this text, most progress with regards to asthma therapies has been with biological agents. These agents are not currently being studied for their effects on prevention of EIB, mainly due to their cost as well as the cost and feasibility of the challenges associated with using exercise testing as a clinical trials outcome measure. While there have been rare case reports of successful therapy of exercise-induced anaphylaxis with omalizumab, it will likely be several years before we understand the full effect of biologicals on EIA.[62] One can hope that, through improving underlying inflammation in patients with baseline asthma, the impact of EIA will be lessened through novel asthma therapies.

Most new therapeutic insights in EIA and EIB have been made in the area of adjunctive therapies, including dietary modifications (e.g. omega-3 fatty acids and low salt diets). A review of the available medications will precede discussion of behavioral strategies (Table 36-1).

Short-acting β-agonists (SABAs) have long been the mainstay of prevention and treatment of EIA. Target receptors for these medications are present on mast cells and airway smooth muscle. In patients with recurrent symptoms, their use is recommended 15 minutes before activity and their effects persist for about 3 hours.[63] They are effective in the majority of patients, but do not provide complete protection in roughly 20% of patients. Despite their efficacy, a consideration with these medications is the development of physiological tolerance to the medications.[64] With this phenomenon in mind, it is recommended that patients with frequent need for SABAs also use controller agents.

Inhaled steroids provide a small degree of acute protection against EIB, but are utilized mainly as a daily controller in baseline asthma.

LTRAs are known to decrease EIB when compared with placebo, increasing the nadir lung function after exercise challenge by as much as 8% to 10%. They have been strongly recommended for patients incompletely controlled on SABAs alone or for those who use daily SABAs.[56] While clearly not as effective as SABAs, LTRAs remain equally effective after 1 month of therapy, avoiding problems of medication tolerance.

Long-acting β-agonists (LABAs) provide protection against EIB that lasts for several hours. Similar to their short-acting analogs however, they induce tachyphylaxis.[65] Baseline asthma guidelines strongly advocate against LABA monotherapy and EIB guidelines are similar in this regard.[52,56] There is strong evidence to suggest that LABAs are effective in patients with asthma that is poorly controlled on inhaled steroids alone.[52] EIA

TABLE 36-1 Available Treatments for Exercise-Induced Asthma

Pharmacologic	Non-Pharmacologic and Dietary
Short-acting β-agonists	Warm-up period
Inhaled corticosteroids	Face and inspirate warming
Leukotriene receptor antagonists	Omega-3 fatty acid supplementation
Anticholinergics	Low salt diet
Long-acting β-agonists	
Mast cell stabilizing agents	

https://CafePezeshki.IR

guidelines have avoided specifically making recommendations about LABA use in patients who are poorly controlled at baseline with respect to underlying asthma on inhaled steroids alone. Given the evidence that LTRAs are effective as adjuncts to inhaled steroids (when compared to LABAs), practitioners should strongly consider LTRAs before LABAs as add-on agents in patients for whom EIB has notably high impact.[66]

Mast cell stabilizing agents (MCSAs) have been demonstrated to prevent EIB. While their use has fallen out of favor as a controller for baseline asthma, they remain a mainstay in many parts of the world for EIA. As with LTRAs, these medications are recommended in EIA that is not controlled on SABAs alone.[56] Despite their efficacy, limited availability in the USA makes acquisition by patients a huge challenge.

Anticholinergics have long been used to prevent EIA and EIB. They are particularly recommended for use in patients with increased baseline vagal tone. Since this assessment is not readily available in clinical settings, and since elite athletes are considered to have increased vagal tone, it may be reasonable to strongly consider these medications in highly competitive athletes. One advantage is the widespread availability of these medications, including combination preparations with SABAs.

For reasons related to the feasibility of conducting clinical trials, there may never be definitive evidence for the preferred medication for EIA (LTRA, MCSA or anticholinergics) in patients failing SABAs and inhaled steroids. One can imagine the challenge and expense of trying to find a sufficient number of patients failing these medications as documented by exercise or surrogate challenge to participate in a four-treatment (including placebo) cross-over trial. With this in mind, practitioners must rely on judgment to sequentially select medications empirically. One therapeutic strategy was presented in the 2012 American Thoracic Society Clinical Practice Guideline on EIA (Figure 36-2).[56]

In addition to medications which blunt EIA, there are a number of behavioral and dietary interventions that may be employed to improve performance. While each of these interventions comes at low financial cost, the decision to use these strategies should be based on comparisons between the burden of symptoms and the burden of treatment.

The refractory period has been used for decades to improve athletic performance and decrease symptoms. Given our evolving knowledge about cross-refractoriness, it may not be necessary to actually exercise in order to induce refractoriness (and voluntary hyperventilation could be used as an alternative). In practice, however, exercise is still the most widely-used method to induce refractoriness. Generally, patients perform a vigorous warm up that is sufficient to induce high rates of ventilation 45

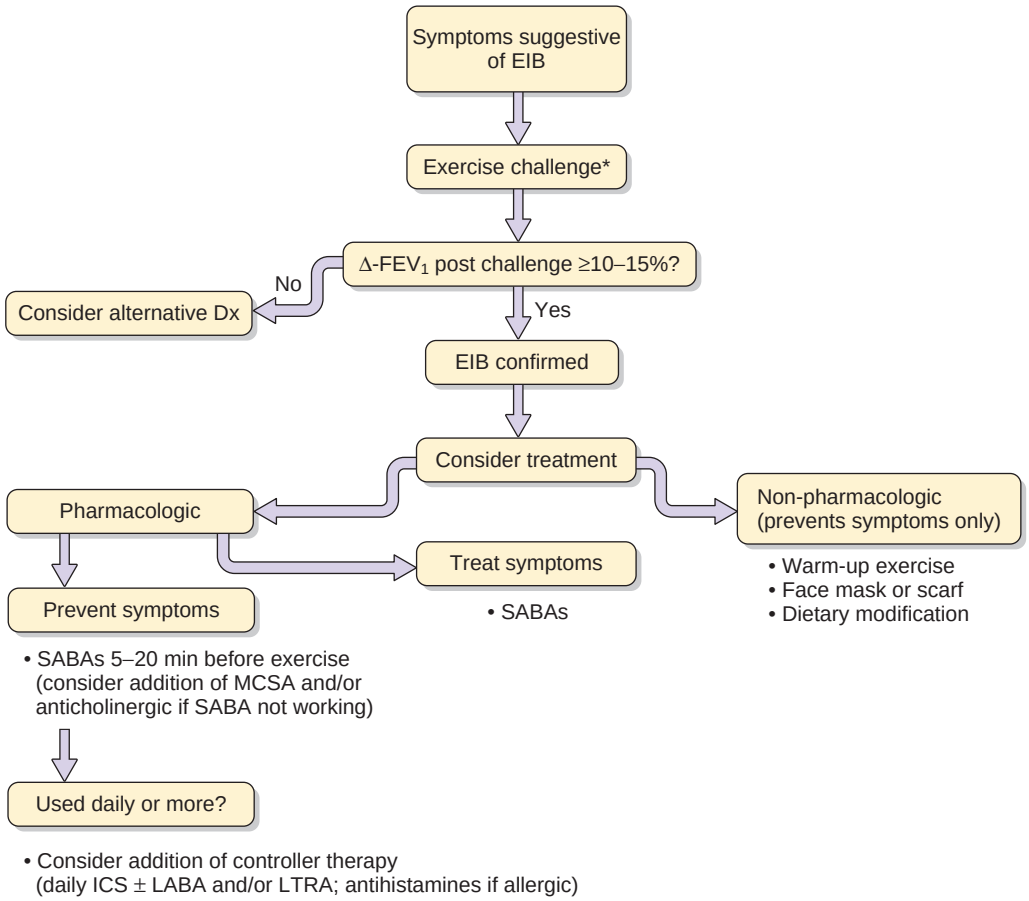

Figure 36-2 Diagnostic and treatment algorithm for exercise-induced bronchoconstriction (EIB). *LABA* – long-acting β_2-agonist; *LTRA* – leukotriene receptor antagonist; *MCSA* – mast cell stabilizing agent; *SABA* – short-acting β-agonist; *Dx* – diagnosis; *FEV_1* – forced expiratory volume in 1 second. *Or surrogate challenge, e.g. hyperpnea or mannitol. *(From Parsons JP, Hallstrand TS, Mastronarde JG, Kaminsky DA, Rundell KW, Hull JH et al. Copyright © 2013 by the American Thoracic Society, reproduced.)*

https://CafePezeshki.IR

to 60 minutes prior to participation in the event of interest. Since bronchospasm is not required to induce refractoriness, SABAs (which generally maintain efficacy for 3 hours) may be used prior to the warm up. Many specific strategies have been employed for the warm up (including 6-minute jogs at speeds sufficient to produce a heart rate in the 140–150 range, as well as interval sprints). For the most part, patients can fully recover from a fatigue standpoint before the event of interest. Patients are often asked to trial a number of strategies in order to optimize performance.

Masks and headgear which can warm the face and inspired air as well as humidify inspired air can be helpful. This strategy presumably works by decreasing the osmotic stimulus of exercise in cold conditions, but may also work through blunting vagal stimuli as well.

Dietary changes, including increased omega-3 fatty acids, low salt diets, and high vitamin C have been proposed as adjunctive therapies for EIA. Omega-3 acids demonstrate efficacy in blunting EIA, as does a low salt diet (which appeared to demonstrate a dose-dependent effect).[67,68] There is also some limited evidence to suggest that vitamin C can help blunt EIB.[69]

In summary, many therapies exist for EIA, but guidelines recommending specific preferred medications in patients failing SABAs and inhaled corticosteroids are unlikely in the near future. Despite the number of available medications, practitioners should remember that only rare patients require more than a few of these medications to control EIA. As the number of medications used increases, so should the tendency to search for alternative diagnoses.

Areas for Future Research

As EIA is an intermittent phenomenon, it presents challenges to researchers. However, as molecular research techniques improve, so should our understanding of EIA. Several fundamental questions about the nature of EIA remain unanswered.[70] Among these are:

- Is EIA one disease or many? Can we phenotype different groups of patients with EIB based on clinical or inflammatory features?
- Assuming that the ventilation associated with vigorous exercise induces epithelial stress, why do some athletes develop EIB and others do not? Can genetic studies help answer this question?
- What is the role of lipid mediators in EIA and refractoriness?
- What are the anatomical, epithelial or inflammatory causes for the severe EIA in certain children?
- Can environmental modification with regard to chemical exposure during swimming improve EIA?
- Can therapeutic strategies targeted toward the epithelium offer benefit in EIA?

Summary

Bronchospasm is a common phenomenon in patients with and without underlying asthma. It is a particular problem in winter sport athletes, swimmers and children. It can have considerable impact on exercise performance and may affect the likelihood that casual exercisers will participate in cardiovascular activities. Bronchospasm occurs after osmotic and other epithelial stress trigger a cascade of mediators, including cysLTs. It is a condition that can be commonly confused with other causes of dyspnea, most notably paradoxical vocal fold motion. Diagnosis depends on measurement of inducible expiratory airflow limitation and surrogate challenges are becoming increasingly available for exercise. Several therapeutic options exist, but short-acting β-agonists prior to exercise and control of underlying asthma remain the mainstays of therapy. Improved molecular research techniques will hopefully improve patient quality of life through the development of improved diagnostic and therapeutic tools.

37 Refractory Childhood Asthma: Assessment and Management

ANDREW BUSH

KEY POINTS

- Problematic, severe asthma comprises wrong diagnosis ('not asthma at all'), asthma with co-morbidities ('asthma plus'), difficult asthma and true severe, therapy-resistant asthma. These patients should undergo a detailed, protocolized series of investigations.
- More than 50% of children referred to tertiary centers with problematic severe asthma in fact will be well controlled if basic management is optimal; they do not require therapy with 'beyond guidelines' medications.
- Invasive investigation should be considered in children with apparent severe, therapy-resistant asthma to determine whether there is discordance between symptoms and inflammation; whether there is an unusual pattern of inflammation; whether the child is steroid responsive and to what extent; and whether there is fixed airflow limitation.
- Unlike adult severe asthma, pediatric severe, therapy-resistant asthma is characterized by marked atopy and airway eosinophilia not neutrophilia, but without classic Th2 signature cytokine expression; the optimal monitoring strategy is unclear; sputum cellularity is much more variable over time and titrating treatment against sputum eosinophil count is not useful.
- There is little or no evidence base for 'beyond guidelines' therapy in children who fail standard therapies including omalizumab.

Introduction

Refractory asthma is rare in childhood and probably accounts for less than 5% of all pediatric asthma.[1] It may be becoming less common over time, possibly because of more effective modern treatments.[2] However, this group accounts for an enormous amount of morbidity and healthcare costs, and even mortality, and so although rare, it is a very important topic. This chapter describes the assessment of children aged 6 years and older using the Royal Brompton Hospital approach to apparent refractory asthma. This personal practice is described as no evidence-driven approach exists. The reader is invited to judge the value of these protocols, as well as referring to a recent ERS/ATS guideline.[3] Finally, recent research advances are briefly summarized. Severe preschool wheeze is not discussed here.

Refractory Asthma: Basic Principles

The cardinal sin in asthma management is to continue to escalate and intensify asthma therapy in a child who is not responding to treatment, without posing the question, why is the prescribed treatment not working? We know that most children with asthma will respond very well to low-dose inhaled corticosteroids (ICSs) when properly administered, sometimes in combination with a second controller such as long-acting β_2 agonists (LABAs) or leukotriene receptor antagonists (LTRAs).[4] So, when faced with a child with apparently refractory asthma, the pediatrician should not reach again for the prescription pad, but go through a rigorous protocol to determine what it is about the child and his/her asthma that means the anticipated response is not happening.

Nomenclature

We use the term '*problematic severe asthma*' to describe children who, despite apparently optimal asthma management, have ongoing symptoms (Table 37-1).[5–8] It should be noted that this definition is arbitrary and not evidence based. Problematic severe asthma itself comprises four categories, the management of each of which is entirely different (Table 37-2).

The overall aim of these protocols is to determine if the individual child is truly a candidate for 'beyond guidelines' therapy or can be better managed by standard approaches.

An overlapping approach which is also a useful conceptual framework is to define risk by considering domains of asthma severity. These are:

1. Level of prescribed treatment
2. Level of baseline asthma control over the previous month
3. Burden and nature of exacerbations over the previous 6 to 12 months
4. Risk of future complications, including failure of normal airway growth (for which there is increasing evidence), risk of future loss of control and/or exacerbations; risk of medication side-effects.

Approach to the Child with Problematic Severe Asthma

The first step is as always a full history and physical examination. Close attention should be paid to the nature of the symptoms. In particular, the word 'wheeze' is used very imprecisely, including being applied to crackling noises, upper airway noises and even stridor.[9–13] The possibility that the child does not in fact wheeze should be considered unless and until a physician has heard wheeze with a stethoscope.[14] Cough-variant asthma is a popular diagnosis, but most children who cough do not have asthma or indeed any other disease.[15] The decision as to whether to investigate further, and what tests to perform, is driven by findings on history and examination. The two classical errors are failure to document physician-heard wheeze and failure to document airflow obstruction which changes over

https://CafePezeshki.IR

TABLE 37-1 Criteria for 'Problematic Severe Asthma'. More than One of These Scenarios May be Encountered in the Same Child

- *Chronic symptoms*: (defined as the use of short-acting β_2 agonists (SABAs) on at least 3 days a week for at least 3 months) despite inhaled corticosteroid (ICS_ (beclomethasone equivalent [BDP] 800 µg/day) and the use of any combinations of long-acting β_2-agonists (LABAs),leukotriene receptor antagonists (LTRAs) and low-dose theophylline (or failed trials of at least two of these add-on therapies)
- *Severe asthma attacks*: any or all of: one admission to pediatric intensive care, the need for more than two intravenous treatments in the previous year, and the use of two or more prednisolone bursts in the previous year. This exacerbating pattern is not inevitably associated with poor background control
- *Airflow limitation*: FEV_1 of <80% after SABA withhold, or an FEV_1 of <80% despite a trial of systemic steroids and acute administration of SABA (persistent airflow limitation [PAL])
- *Disconnect of symptoms*: strictly, the child presenting with a multitude of symptoms with no objective evidence of uncontrolled disease may belong in a separate disease category, and certainly is not placed in severe asthma guidelines. Since the means of addressing this scenario are so very similar, inclusion in this group is pragmatically justified. The reverse scenario, underreporting of symptoms, is also considered

TABLE 37-2 Differential Diagnosis of 'Problematic Severe Asthma'

1. *Not asthma at all*: the diagnosis is wrong
2. *Asthma plus*: there are associated co-morbidities which need to be addressed
3. *Difficult asthma*: accounts for about 50% of those in whom the first two categories have been excluded. This diagnosis comprises children who in fact need to get the basic steps of asthma management correct
4. *Severe, therapy-resistant asthma*: these children appear to have ongoing problems with asthma despite the optimization of all the basic steps of asthma management; such children are candidates for 'beyond guidelines' therapy

time or with treatment. There has been an increased interest in the diagnostic use of measurements of airway inflammation such as exhaled nitric oxide (FeNO), usually measured at a flow rate of 50 mL/s ($FeNO_{50}$) and induced sputum cytospin. Although evidence of airway inflammation is not a mandatory diagnostic test for asthma, and in particular a child already on treatment with ICS may be inflammation free, absence of any evidence of airway inflammation in a child apparently symptomatic for asthma should prompt a diagnostic review. Finally, the diagnostic process should not end at this stage; the possibility of a wrong diagnosis should be at the forefront throughout, and further testing considered in the presence of a surprising finding such as airway neutrophilia (see below).

DOES THE CHILD ACTUALLY HAVE ASTHMA?

Numerous conditions may mimic asthma (Table 37-3). The likelihood of particular diagnoses will vary across the world. Important clues to an alternative diagnosis include neonatal onset of symptoms; chronic productive cough for many sequential weeks; and evidence of systemic disease. The nonatopic child

TABLE 37-3 Differential Diagnoses of Severe Asthma

Class of Diagnosis	Examples
Local immunodeficiency	Cystic fibrosis, primary ciliary dyskinesia, persistent bacterial bronchitis
Systemic immunodeficiency	Any, including B cell and T cell dysfunction
Intraluminal bronchial obstruction	Foreign body, carcinoid, other tumor
Intramural bronchial obstruction	Bronchomalacia, complete cartilage rings, intramural tumor
Extraluminal bronchial obstruction	Vascular ring, pulmonary artery sling, congenital lung cyst, enlarged lymph nodes due to tumor or tuberculosis, other mediastinal masses
Direct aspiration	Bulbar or pseudobulbar palsy; laryngeal cleft
Aspiration by direct contamination	H-type fistula
Aspiration secondary to reflux	Any cause of gastroesophageal reflux, including hiatus hernia and esophageal dysmotility
Complications of prematurity	Bronchomalacia, structuring secondary to intubation, vocal cord palsy secondary to surgery for patent arterial duct
Congenital heart disease	Bronchial compression from enlarged cardiac chambers or great vessels; pulmonary edema
Interstitial lung disease	Any not presenting with neonatal respiratory failure
Dysfunctional breathing	Vocal cord dysfunction, hyperventilation syndromes

with apparently severe asthma should always be carefully assessed, since most such children have multiple positive skin prick tests and specific IgE, as well as a raised total IgE. A review of diagnostic testing for all the conditions listed in the Table 37-3 is beyond the scope of this chapter, but as a principle, testing should be focussed rather than take a scattergun approach.

ARE THERE SIGNIFICANT CO-MORBIDITIES WHICH NEED ADDRESSING?

A co-morbidity may not be easy to treat (e.g. obesity), but it is difficult to argue that potentially toxic biologicals are appropriate for a child who is not being supported by his/her family to lose weight. Co-morbidities have recently been reviewed in detail.[16]

Gastroesophageal Reflux

The possible relationships between asthma and respiratory symptoms, and gastroesophageal reflux are complex. Reflux can cause symptoms either by direct contamination of the lower airway or indirectly by an esophagobronchial reflex;[17–19] respiratory disease can cause reflux, including via mechanisms secondary to abnormal pleural pressure swings or configuration of the diaphragm; and reflux may be an asymptomatic fellow-traveler. The best evidence is that, irrespective of any symptoms suggestive of reflux, therapy with, for example, a proton pump inhibitor does not improve severe asthma;[20–22] and that has certainly

https://CafePezeshki.IR

been our experience, despite hitherto performing pH-metry as part of our work-up for severe asthma.

Rhinosinusitis

Upper airway disease worsens quality of life, and should be treated on its own merits in any context.[23–25] There is increasing evidence that treating rhinosinusitis may be beneficial at least in mild to moderate asthma.[26] The mechanisms of any benefit remain conjectural.[27] In our series, significant rhinosinusitis is unusual in severe asthma.

Obesity

There are complex potential interactions between asthma and obesity. Obesity may cause breathlessness and 'wheeze' without evidence of asthma, leading to inappropriate treatment. Obesity may be associated with a pauci-inflammatory form of asthma, at least in adults, although it is sometimes unclear whether this is true asthma[28]; asthma with an eosinophilic phenotype on airway wall biopsy with raised sputum interleukin 5 (IL-5)[29]; and steroid resistance.[30] Obesity is a proinflammatory state,[31] as is obstructive sleep apnea (OSA) (see below).[32] Asthma (via reduced exercise performance) and its treatment (prednisolone bursts or long-term therapy) may cause or contribute to obesity. Hence, particular care is necessary before escalating therapy for 'asthma' in the obese child with respiratory symptoms. Weight reduction is always beneficial in the obese child, but is difficult to achieve.

Upper Airway Obstruction/ Sleep Disordered Breathing

There is an increasing literature on asthma and OSA.[33] Although the literature reports associations in at least mild to moderate asthma, in our patients OSA is very rare in severe asthma, except in the presence of concomitant obesity (see above). We do not routinely perform polysomnography on children with severe asthma who are not obese. OSA was reported to cause sputum neutrophilia rather than eosinophilia in one study;[34] this inflammatory pattern rarely if ever occurs in true severe, therapy-resistant asthma, and if seen, should prompt a diagnostic re-evaluation.

Dysfunctional Breathing

Vocal cord dysfunction and other forms of dysfunctional breathing are common in asthma,[35] although not all groups report this[36] and the symptoms are frequently misattributed to asthma, with inappropriate escalation of therapy. There is much less work in children than in adults.[37–39] Fifteen percent of children investigated following our protocol had evidence of dysfunctional breathing,[40] including hyperventilation and vocal cord dysfunction. Clues include the absence of symptoms at night, and often stridor rather than expiratory noises. An experienced respiratory physiotherapist should be asked to assess breathing pattern, and to treat an abnormal breathing pattern with a training program, although currently there is no randomized controlled trial evidence of benefit.[35] Parental video-recording of an attack may be illuminating. In older children, direct laryngoscopy during an exercise test enables direct demonstration of the problem. Dyspnea perception has been little studied in severe pediatric asthma,[39] but adults with severe asthma do not become as dyspneic as those with mild asthma during bronchoconstriction.[41] The possibility of poor symptom perception as a cause of an apparent sudden catastrophic deterioration should be borne in mind.

Food Allergy

Atopy is almost inevitable in severe pediatric asthma, but patients with asthma and food allergy are over-represented in such cohorts.[42,43] Whether food allergy is causative of the problem or a marker is unclear; certainly anaphylaxis at rest and on exercise enters the differential diagnosis of acute severe asthma, and should always be considered because it is treatable. Food allergy should always be properly documented if exclusion diets are proposed; blind dietary exclusions are frequently tried and in our experience are of no benefit.

NEXT STEPS: IS TRUE SEVERE, THERAPY-RESISTANT ASTHMA LIKELY?

Once it is clear that the diagnosis is almost certainly asthma, and co-morbidities have been excluded or identified, we proceed with a more detailed evaluation, led by the specialist asthma nurse and often involving the clinical psychologist and respiratory physiotherapist. The assessment will include both a hospital outpatient visit and a nurse-led community assessment, with the nurse arranging a visit to the family home and making contact with the school.[40]

Hospital Visit

Details of the hospital visit are given in Table 37-4. We evaluate allergic sensitization by both skin prick tests (SPTs) and sIgE tests, because there is imperfect concordance (76–83%) between them.[44,45] This includes fungal sensitization[44]; because severe asthma with fungal sensitization [SAFS] (Table 37-5) has different treatment options (see below), we do not routinely perform double-blind food challenges. FeNO is measured ideally at multiple flow rates as an indirect assessment of proximal (J_{NO}) and distal (C_{ALV}) airway inflammation.[46] Although there is evidence that distal inflammation may be important in severe asthma (below), variable-flow FeNO has not been evaluated as a clinical tool to guide therapy in an individual child, so this is largely a research technique.

TABLE 37-4 Assessments Performed at the Nurse-Led Hospital Visit

Issue to be Addressed	Tests Performed
Symptom pattern	Asthma control test, prednisolone bursts, unscheduled visits
Psychosocial factors	Questionnaires
Lung function	Spirometry before and after bronchodilator
Allergic sensitization	Skin prick tests, specific IgE
Aeroallergens	Grass and tree pollen, house dust mite, cockroach, cat and dog, and any others suggested by the clinical history
Food allergens	Peanut, milk, egg and any others suggested by the clinical history
Fungi (see Table 37-5)	Fungi Table 37-3
Airway inflammation	$FeNO_{50}$, multiple flow rates Induced sputum if FEV_1 is >70% predicted
Tobacco exposure	Urine or salivary cotinine
Medication adherence	Serum prednisolone and theophylline levels if prescribed; serum inhaled corticosteroid levels if available

TABLE 37-5 Diagnostic Criteria for Severe Asthma with Fungal Sensitization (SAFS)

Adult Criteria	Proposed Pediatric Criteria*
Treatment with 500 µg fluticasone/day or continuous oral corticosteroids, or four prednisolone bursts in the previous 12 months or 12 in the previous 24 months, *and*	Meets criteria for problematic severe asthma (above)
IgE <1000 (exclude ABPA)	No IgE exclusion
Negative IgG precipitins to *Aspergillus fumigatus*	No IgG exclusion
Sensitization (SPT, sIgE) to at least one of *Aspergillus fumigatus, Alternaria alternata, Cladosporium herbarum, Penicillium chrysogenum, Candida albicans, Trichophyton mentagrophytes* and *Botrytis cinerea*	As adult criteria

*There is no agreed definition in children, but given the rarity of allergic bronchopulmonary aspergillosis (ABPA) in children with asthma, we have proposed to eliminate the total IgE and IgG criteria, from the diagnostic criteria.

It should be remembered that children are not mini-adults. In particular, it should be noted that the interpretation of spirometry and imaging has a developmental perspective.

Spirometry, Bronchodilator Responsiveness and Bronchial Challenge Testing. Unlike in adults, spirometry is poorly discriminatory between asthma of different severities in children.[47–49] Spirometry is of course useful as part of the definition of an exacerbation, and to monitor progression of lung growth over time in epidemiological studies. Epidemiological evidence is that, *for groups*, spirometry in severe asthma tracks over decades,[50–54] but the pattern of lung growth may be abnormal in really severe asthma; for example, the Melbourne study showed a failure of the adolescent airway growth spurt.[54] There is other worrying evidence from studies showing that individuals with apparently good control of symptoms with ICSs may have abnormal airway growth over time.[55–57] One post hoc analysis suggested that this was related to the exacerbating phenotype, but only in patients not treated with ICSs.[58] This study requires prospective confirmation, but is in line with studies of other airway diseases showing so-called 'exacerbations' lead to a worse overall long-term outlook.[59–63] Bronchodilator responsiveness may be used diagnostically and to define persistent airflow limitation (PAL). Little has been written about bronchial challenge testing as a clinical tool in children with severe asthma. In many, it will be too hazardous because of poor baseline spirometry and/or extreme bronchial hyperreactivity. There is one situation in which direct airway challenge usually is useful in the diagnostic work-up, namely in a child with normal spirometry but reported severe symptoms, and in whom a negative challenge would make uncontrolled asthma unlikely. In such children, a combined protocol of hypertonic saline challenge and sputum induction[64] may be useful; in genuine severe asthma, the need for albuterol pretreatment before sputum induction as a safety measure precludes this approach. The role of challenge testing in children with PAL or obliterative bronchiolitis (OB), as part of confirmation that further escalation of therapy is not useful, is not clear; in all probability, a systemic steroid trial would be preferred.

High-Resolution Computed Tomographic (HRCT) Scanning. HRCT is not a routine part of our protocol, and there is no pediatric evidence to suggest the need for it. HRCT may be performed as part of the diagnostic work-up if, for example, the patient is nonatopic or bronchiectasis is suspected. However, in adult studies, bronchial wall dilatation is common in severe asthma,[65,66] and it is important not to over-diagnose bronchiectasis in children, in whom minor degrees of airway dilatation may be reversible, even when related to an immunodeficiency. It is essential to note that HRCT scans may be unable to distinguish severe asthma from OB.[67] In adults, but not in children, there is evidence that HRCT scans may be a useful biomarker of asthma severity.[68,69] In children, HRCT changes consistent with asthma are less apparent (and also less well defined) than in adults,[70] and bronchial wall thickening has no or only the weakest correlation with reticular basement membrane (RBM) thickening and forced expiratory volume in 1 second (FEV_1).[71–73] Air trapping on HRCT may allow an estimate of distal airway disease,[74,75] but in severe asthma has not been compared with sophisticated tests of distal airway function such as lung clearance index.[76–78] There are no studies on the usefulness or otherwise of HRCT scans as a monitoring mechanism for severe pediatric asthma, and the radiation risk of even low-dose HRCT, especially in young children, is not a trivial consideration.

Home Visit

The nurse-led home visit is a key part of the work-up of problematic, severe asthma.[40] Professors sitting in the clinic know little to nothing of what is really happening at home. Five areas are explored: adherence, tobacco smoke, allergens, psychosocial issues and asthma education. If the patient has been referred from a distant center, the home visit may be performed by a local specialist nurse after discussion with our own team. This approach may not be feasible everywhere, but in our hands, allows the identification of significant and potentially reversible factors in more than half of those referred with problematic severe asthma. It is certain that relying purely on a hospital-based assessment by a pediatrician will lead to many mistakes.

Adherence. This is discussed in detail in chapter 38. It was found that less than half of patients had picked up more than 80% of the required prescriptions, and nearly one third had picked up less than 50%.[40] We also enumerated the collection of excessive prescriptions of short-acting β2-agonists (SABAs); collecting ≥6 prescriptions/year is associated with a poor outcome.[79]

It was common to find that medication was past its expiry date; in 25% of cases a complete set of in-date medications could not be produced when the nurse visited. Other issues were total inaccessibility of any medications, and medications unopened in their original wrapping, neither of which inspired confidence that medications were actually being taken.[40]

Parental Supervision. In one study, even young children (20% of 7-year olds, 50% of 11-year olds) were left to take asthma medications unsupervised.[80] Often parents think they are supervising treatment, but do not in fact actually witness their child take the therapy, instead merely calling out reminders to their child who is in a different room in the home. This situation requires sensitive exploration.

Use of Inhaler Devices. These are often wrongly used and regular instruction in their use may lead to improvements.[81,82] However, even multiple teaching sessions are not enough to ensure good inhaler technique; all the children in our series had

https://CafePezeshki.IR

had repeated instruction in specialized centers, and yet still had a poor technique. A common issue is using pressurized metered dose inhalers without spacers, because spacers are considered babyish; this omission guarantees minimal airway deposition of medications.

Environmental Tobacco Smoke and Other Irritants. Active smoking by adults with asthma causes steroid resistance,[83–86] and it seems likely that passive smoke exposure has the same effect. Passive smoke exposure is common in children with asthma;[87–89] the prevalence of active smoking is unknown, but unlikely to be low. We found that 25% of children with problematic, severe asthma were exposed to tobacco smoke.[38]

The mechanisms of tobacco smoke-induced steroid resistance have been researched mainly in adults;[90] the phenotype is neutrophilic. In a study of children with severe, therapy-resistant asthma,[91] we found that parental smoking reduced histone deacetylase protein expression and activity, and reduced the in vitro inhibitory effects of dexamethasone on tumor necrosis factor-α-induced IL-8 release from alveolar macrophages. Bronchoalveolar lavage (BAL) showed higher IL-8 concentrations and neutrophil counts and the children had lower asthma control test (ACT) scores compared with non-passive smoke-exposed children; these findings are supported by adult data. Additionally, it is also likely that symptoms are exacerbated by a direct irritant effect of smoke.

Other environmental irritants sometimes encountered include incense or joss sticks, and the extensive use of air fresheners and other aerosol sprays. Environmental pollution is also important, but difficult to modulate except at the level of public health.

Allergen Exposure. This is discussed in detail elsewhere. Allergen exposure in the home combined with evidence of sensitization has been clearly implicated in the etiology of viral-induced asthma attacks.[92]

In our study,[38] 17 of 30 children who owned furry pets were sensitized to that pet on skin prick testing; only two had any allergen avoidance precautions in place. Thirty-one children were thought to have clinically significant house dust mite (HDM) exposure; five were using comprehensive allergen avoidance measures, 15 partial and 11 none. Reduction of mold exposure may be particularly important if SAFS (see above) is suspected. Allergen exposure in school may also be important, but this is an even more difficult area in which to intervene.

Psychosocial Issues. Acute and chronic stress may trigger asthma exacerbations;[93–95] there may be quite complex time relationships between the two. Stress has been shown to amplify the airway eosinophilic response to allergen challenge.[96] In our study,[38] psychosocial issues were common, especially anxiety and depression, a finding reported by others.[97] Most issues only emerged during discussions in the home. Altogether, about half the families were referred to clinical psychology for a more detailed assessment. It is not productive to try to determine whether anxiety and depression are the cause or result of severe asthma; both are treated on their individual merits.

Asthma Education. Some adherence issues relate to basic misunderstandings of the purpose of treatment, and these are also addressed. If the child does not have a detailed asthma plan, this is put in place and communicated to the school. It is to be hoped that all this will have been done previously, but any gaps are sought and closed.

Lesson Learned the Hard Way

School Visit. Despite the best efforts of my specialist respiratory nurses, I have made many mistakes. The importance of contact with the school cannot be overemphasized. Teachers are an important resource; they are experienced in assessing children and spend many hours each day with them. If there is any suspicion that symptoms are being overcalled by the parents, talk to the teacher. In one particularly egregious case (details modified to preserve patient confidentiality) a girl with so-called severe asthma was in fact the captain of field hockey, had the nickname of 'the Greyhound' and her teachers did not know that she even had asthma, let alone that a reserve supply of SABA was kept for her!

Management of Exacerbations. In theory, the treatment of an asthma attack is based on objective evidence of present symptoms. In practice, the previous history is influential. When assessing the child with apparent multiple severe exacerbations, it is essential to determine what (if any) objective assessments were carried out before instituting treatment, and whether or not the level of treatment was objectively justified. One child under our care was actually started on intravenous albuterol despite being fully saturated on room air!

Parental Doublespeak. The basic tenet of pediatrics is to believe the parents. On occasion, parents not telling the truth may be the underlying problem, and this is very difficult to detect. This is distinct from the effect of a very understandable parental anxiety leading to exaggeration of symptoms. Motivation for the former may include access to financial and other benefits as a result of having a 'sick' child, right up to deliberate fabrication of symptoms (Munchausen by proxy). Unfortunately the result is often a long delay in diagnosis.

MULTIDISCIPLINARY TEAM DISCUSSION

The assessment generates a mass of detailed information, and this is next assessed in a dedicated, multidisciplinary team meeting. We aim to determine whether the child has difficult asthma for which the basic management steps need to be addressed, or potentially severe, therapy-resistant asthma, which justifies further invasive investigations.

Does the Child Have 'Difficult Asthma' or Severe, Therapy-Resistant Asthma?

In more than half of the children, no further investigations are undertaken, or at least, invasive testing is deferred pending other interventions. This unfortunately does not mean the problem is necessarily solved; for example, it is one thing to identify poor adherence as an issue, but quite another to address it. Often, the child's poor adherence to medication has not been appreciated by the parents, and identification of the problem leads to them finding a solution. Adherence may be addressed by giving the child an inhaler with a microchip to record when medication is taken. We never attempt deception, and always tell the child and family that a recording is being made. If the inhaler is used and the child improves, this is gratifying. However, it is still illuminating if the inhaler is not used and asthma symptoms continue unabated. We have sometimes used directly observed therapy at school, on the basis that 5 days of treatment a week is better than

https://CafePezeshki.IR

none; if this is put in place, it is essential to check that the seemingly obvious, namely that therapy is directly observed, is actually happening. One child told us that the school nurse was always working at a desk with her back to the child when supposedly directly observing therapy!

Deferring investigations for psychological intervention are common. Psychological interventions may be effective.[98] In general, individualized plans work best.[99–101] Of course, these may be combined with the other interventions outlined above, and also with invasive investigations.

Addressing allergen exposure in the home is notoriously difficult, especially if the allergen concerned originates from a much-loved family pet (the English disease). Frequently, the cat will be sent away for a short time and then allowed to return because the child's asthma has not improved; however, at least a year's separation is necessary substantially to reduce the allergen load. We do not prescribe omalizumab to any child unless every effort to reduce the environmental allergen burden has been made.

The fact that many children with apparent severe asthma just need to get basic management right has been reported by others, and has been the bugbear of intervention study design; those with apparently severe asthma tend to melt away when proper, protocol-driven management is put in place.

The remainder of the children continue in the protocol as outlined in the next section.

Is the Distinction Between 'Difficult Asthma' and 'Severe, Therapy-Resistant Asthma' Meaningful? We have published follow-up data for 78 children.[102] Those assigned to the difficult asthma group were able to reduce their prescribed dose of ICS (although perhaps in reality they were actually taking it for the first time) while increasing their FEV_1 and having fewer prednisolone bursts than the children with severe, therapy-resistant asthma. This is in accord with the multifaceted intervention studies reported in those with less severe asthma.[103,104] The severe, therapy-resistant group had smaller increases in FEV_1 but were unable to reduce treatment. We concluded that the groups behaved differently, and the distinction was useful. We also assessed whether or not the two groups could be distinguished from basic measurements; however, although children with severe, therapy-resistant asthma had a lower FEV_1% predicted, more bronchodilator reversibility and a higher $FeNO_{50}$ than those with difficult asthma, the overlap between the groups made placing all individuals into the correct category an impossibility. A similar result was reported by the Severe Asthma Research Program (SARP) group, namely statistically significant but clinically unreliable differences between severe and moderate asthma in terms of FEV_1 and $FeNO_{50}$.[105]

Research Implications. The categorization into difficult and severe, therapy-resistant asthma has important implications for the interpretation of research studies, such as genetic association studies. Cohorts of children with 'severe asthma' who have not gone through a detailed filtering process will be diluted by at least 50% with children for whom the basics have simply not been addressed, and therefore may not be comparable to those with truly therapy-resistant asthma.

INVASIVE TESTING

Typically children with severe, therapy-resistant asthma have very major problems with asthma (Table 37-6), thus justifying an invasive approach.[106] There are a number of differences between the typical child with severe, therapy-resistant asthma and the adult with this diagnosis. In children, there is no female predominance, but a strong atopic history was common[102,106] (85% atopic with a total median IgE of 386 [115–1286]). The children are also not obese. Although we have published a number of research papers based on our bronchoscopic studies, the aim of testing is primarily clinical to answer four key questions (Table 37-7). An individualized treatment plan is devised on the basis of the answers to these questions.

TABLE 37-6 Characteristics of Children with Severe, Therapy-Resistant Asthma

Parameter	Mean Result (range)
Symptoms (ACT)	13/25 (9–17)
Symptom duration (years)	10.1 (9.3–12.7)
Number intubated	11/53 or 21%
FEV_1 %predicted	69 (55–87)
Acute FEV_1 response to 1 mg of albuterol (%)	15.6 (5.5–23.4)
$FeNO_{50}$ (ppb)	50 (29–70)
Mean sputum eosinophils (%)	7.5 (3.2–30.4)

TABLE 37-7 Four Key Questions Answered by Invasive Investigation of Children with Severe, Therapy-Resistant Asthma

1. Is there phenotype discordance: a disconnect between symptoms and airway inflammation? Anti-inflammatory medication is not escalated if the airway is not inflamed, and is intensified in an exacerbating child if there is airway inflammation when the child is asymptomatic
2. Is the airway inflamed at all, and if so, what is the pattern of inflammation?
3. Is the child partially or totally steroid responsive, or steroid resistant?
4. Does the child have persistent airflow limitation? Therapy for airflow obstruction is not escalated if the child has reached the plateau of the dose-response curve

Protocol: Invasive Investigation of Severe, Therapy-Resistant Asthma

The child is assessed invasively and noninvasively on the same day. Noninvasive investigations are symptom assessment, spirometry and acute response to bronchodilator, sputum induction and FeNO measurement, as performed in the initial assessment. The child then undergoes a bronchoscopy under a general anesthetic, with performance of BAL and endobronchial biopsy, and often bronchial brushings as a research procedure, as described in detail elsewhere.[106] At the end of the procedure, we administer a single dose of intramuscular triamcinolone (40–80 mg depending on the size of the child). The child is kept in hospital overnight, even if a pH study is not to be performed. The child is then seen again 4 weeks later, and all the noninvasive measurements are repeated.

The key requirement for the safe performance of bronchoscopy in these children is a skilled anesthetist. The child may be premedicated with SABAs. Adverse events are very rare. We have seen acute severe bronchospasm on one occasion, which rapidly responded to treatment. Close post-procedure monitoring of the child is essential.

https://CafePezeshki.IR

Assessment of Airway Inflammation. We do not see neutrophilic inflammation in children with severe asthma,[106] which is in marked contrast to what is seen in adults. Instead, induced sputum, BAL and endobronchial biopsy are eosinophil dominated, although there are marked variations between individuals in the extent of eosinophilia. Hence, a neutrophilic phenotype should prompt reconsideration of the diagnosis. There tends to be agreement between induced sputum and BAL, but discordance between these luminal compartments and the airway wall histology.[107] It is not clear which is most relevant to disease pathophysiology. The relationship between FeNO and airway eosinophilia is discussed below.

Given the marked eosinophilic phenotype, a Th2 cytokine profile would be expected, but two pediatric severe asthma studies have failed to confirm this. We studied induced sputum supernatant, BAL using both the Luminex and CBA platforms, and performed immunohistochemistry on endobronchial biopsies, and found scant evidence of the Th2 signature cytokines IL-4, IL-5 and IL-13.[106] The SARP group also failed to find evidence of Th2-driven inflammation.[108] They compared severe, therapy-resistant asthma with mild-moderate disease and showed that the cytokines which best discriminated between the two groups were GRO (CXCL1), RANTES (CCL5), IL-12, interferon-gamma (IFN-γ) and IL-10. They concluded that pediatric severe, therapy-resistant asthma was neither a Th1- nor a Th2-driven disease. Gene expression studies of the sort that have generated the Th2 high and low groups in adults have so far not been performed in children.[109] Whether those few children in whom Th2 cytokines are detectable (see above) are in fact Th2 high remains to be seen. In this context it should be noted that periostin, a useful serum biomarker in adults for the Th2 high phenotype, is not useful in children because it is released from growing bone.

The findings of these two large studies described above do not necessarily show that Th2 cytokines are unimportant in the pathophysiology of severe asthma. All children with severe, therapy-resistant asthma are by definition prescribed high-dose ICS, and it may be that the Th2 component of their disease is abrogated by this therapy. What these studies do suggest is that the factors driving ongoing disease are different from those in adults. Attention is shifting to the epithelial-derived cytokines (IL-25, IL-33, thymic stromal lymphopoietin [TSLP]) as possible candidates, perhaps interacting with innate lymphoid cells.[110] We have shown that IL-33 promoted collagen synthesis by fibroblasts from pediatric patients with severe asthma.[111] We also showed that increased cellular expression of IL-33, but not IL-13, was associated with increased reticular basement membrane thickness in endobronchial biopsies. IL-33 also stained strongly in the endobronchial biopsies. The results were supported by animal data. Also, a recent study of a monoclonal antibody (AMG 157), which prevents TSLP interacting with its receptor, led to marked attenuation of both the early and late phase allergen response in adults with mild asthma,[112] a surprising finding given that only a single cytokine was blocked.[113]

The Th17 pathway has been considered another candidate, at least in adults, but it possibly more likely drives a neutrophilic phenotype, and thus is an unlikely candidate in children. However, eosinophil chemoattraction by IL-17 has been reported, at least in animal models.[114,115] Furthermore, a recent trial of the monoclonal anti-IL-17 receptor antibody brodalumab in adults showed disappointing results.[116] Further work is clearly needed in order to delineate the proinflammatory mechanisms driving pediatric severe, therapy-resistant asthma.

There is an important implication of the above findings. An increasing number of studies of anti-Th2 cytokine strategies, such as mepolizumab (anti-IL-5,[117] lebrikizumab (anti-IL-13)[118] and dopilumab (IL-4 receptor alpha chain)[119] have recruited children aged 12 years and older, although they are largely dominated by adult participants. It is essential that the promising results in these trials are not uncritically extrapolated to children. It may be justified to perform a therapeutic n-of-1 trial in a child doing badly on all therapies, but further trials in children are needed, including measurements of Th2 cytokines, before Th2 cytokine strategies can be widely recommended in pediatric severe, therapy-resistant asthma.

Assessment of Steroid Responsiveness. It is likely that steroid responsiveness is a continuum; true steroid unresponsiveness is likely confined to rare cases of mutations in the corticosteroid receptor. The widely accepted adult definition of steroid response[120,121] is ≥15% predicted increase in FEV_1 in patients with bronchodilator reversibility (BDR) of ≥12% from baseline and an abnormal FEV_1 (≤80%) prior to the trial. There is no accepted definition in children, and the adult definition cannot be applied to around half of our pediatric patients with severe, therapy-resistant asthma, mainly because their baseline spirometry is not sufficiently abnormal prior to the trial,[106] and also because spirometry is often a poor reflection of asthma severity in children (see above). Furthermore, there is no consensus on the dose and duration of corticosteroids for the trial. We opted to use triamcinolone intramuscularly to ensure adherence. We use a multimodality definition of steroid responsiveness (Table 37-8).[122] Most children are partial responders, about 10% are total nonresponders and 10% completely responsive in all domains (complete responders). Some children who were nonresponsive according to the adult definition were partial responders in the multidomain assessment. We have also shown that additional doses of triamcinolone do not change the category of responsiveness (unpublished observations). While the clinical utility of this approach has yet to be confirmed, it might serve as a useful template for current research; so, for example, an intervention with an anti-inflammatory medication might be expected primarily to affect the inflammatory domain.

Assessment of PAL. The definition of PAL is relatively easy; FEV_1 <80% (or better, −1.96 Z [standard deviation] scores) despite a trial of systemic steroids and acute administration of SABAs. However, the dose, duration and route of administration of steroids has still to be agreed, as has the dose of SABAs. We have shown that neither 40 mg of prednisolone for 2 weeks[123] nor a single dose of triamcinolone combined with 1 mg albuterol inhaled from a large volume spacer[124] is adequate

TABLE 37-8 Domains and Definition of Steroid Responsiveness

Modality	Response
Symptoms	ACT >19/25 or 50% increase
Spirometry	FEV_1 > 80% predicted or 15% increase
$FeNO_{50}$	Falls to <24 ppb
Sputum eosinophils	Falls to <2.5%

https://CafePezeshki.IR

to determine whether the child has PAL, but it is doubtful that a higher or longer duration of systemic steroids can be justified. Thus, we have taken the pragmatic decision that PAL should be at least provisionally diagnosed after a single dose of triamcinolone and albuterol as above.

Treatment of Pediatric Severe, Therapy-Resistant Asthma

The treatment options, with the exception of the use of omalizumab, are largely anecdotally based.[125] The following scheme is suggested.

1. *Is omalizumab indicated?* Much of the evidence for omalizumab is inevitably in less severe asthma,[126–135] but if the child meets national guidelines for asthma *and* has been assessed in detail as above and found to have persistent eosinophilic airway inflammation on bronchoscopy, *and* every effort has been made to reduce the allergen burden in his/her environment, then we recommend a 16-week trial of omalizumab, with detailed monitoring of the response. Although guidelines mandate aeroallergen sensitization, omalizumab may be trialed in the rare nonatopic child with IgE in the range for which omalizumab is indicated.[136] If after 16 weeks there is no benefit, we discontinue therapy.
2. *Should standard medications be used in novel ways?* Options are high-dose ICSs, fine particle ICSs, oral prednisolone and intramuscular triamcinolone; the SMART regimen (a single combination ICS and LABA device, usually a Symbicort Turbohaler™); and low-dose theophylline (anti-inflammatory dose) if not already used prior to referral. For all but the SMART regimen, demonstration of ongoing eosinophilic airway inflammation is essential. Steroid total nonresponders who have eosinophilic inflammation should only be considered for low-dose theophylline and not the steroid based regimens.
   - High-dose ICS: for most children, the plateau of the ICS dose response curve is 100 μg twice daily of fluticasone,[4] and escalation of dosing risks increased side-effects. However a small minority of children with asthma may benefit from increasing the dose to as high as 2000 μg/day.[137] However, if there is no response to dose escalation, it is essential that the ICS is promptly stepped down to the lowest possible dose.
   - Fine particle ICS: there is evidence from adult studies that some patients with asthma may have very distal inflammation on transbronchial biopsy (TBB).[138–140] These studies have not been performed in children because of fears of the risks of TBB. There is also physiological evidence from alveolar NO concentration (C_{alv}) measurements of distal airway inflammation in adults with asthma, with response both symptomatically and physiologically to fine particle ICS or systemic steroids.[141,142] There is too much variability in C_{alv} for it to be used as a biomarker in individual children,[46] and there is no evidence for this approach in severe, therapy-resistant asthma. However, a trial of fine particle ICS may be worth considering, with its discontinuation if there is no benefit. Finally, it is interesting to speculate whether or not the distal airway inflammation is related to poor peripheral deposition of ICS, and might respond to low-dose oral prednisolone, delivering steroid by the blood-borne rather than the airborne route.
   - Oral prednisolone: the non-evidence-based starting dose is 0.5 mg/kg, tapering down to the lowest dose needed to control the disease. If this comes at the price of unacceptable side-effects, then a steroid-sparing agent (see below) should be considered.
   - Intramuscular triamcinolone: there is no evidence that this offers any advantage other than in assuring adherence, which is an insufficient reason for using it other than for a steroid trial (see above). Indeed, if it is used as a 'quick fix' for nonadherence, there is a risk that the child will continue to use it long term with the risk of severe steroid side-effects.
   - SMART regimen:[143–145] we use this simple approach particularly in adolescents, and also consider it in the child with symptoms and ongoing peak flow variability but without evidence of eosinophilic airway inflammation. It could be argued that a LABA as a single inhaler added to the child's base medications would be more logical, but given the risks of a LABA as a single agent, we prefer the compromise of the additional ICS. The risk of this strategy is that it relies on adequate symptom perception, which may not always be the case in children with severe asthma (see above).
   - Low-dose theophylline: there is laboratory evidence, and data from adult studies, that theophylline in a dose aimed at serum levels of 5–10 μg/mL may have significant anti-inflammatory effects and restore steroid responsiveness, the latter making it particularly attractive in steroid complete nonresponders.[146–153] The lower serum levels reduce but do not eliminate the risk of drug interactions and other side-effects. Despite the strong theoretical background, this approach has rarely been successful in our hands.
3. *Does the child meet criteria for SAFS?* The definition of SAFS is given in Table 37-5. The results of trials of itraconazole in adults are conflicting ,[154] but voriconazole has shown benefit.[155] Fungal sensitization in children may be associated with a more severe phenotype,[156] but there are no randomized controlled trials of treatment. Our approach is first to minimize environmental fungal exposure in the home, including checking any nebulizer the child may have for fungal contamination, and banning visits to stables (by analogy with management of allergic bronchopulmonary aspergillosis in cystic fibrosis). If antifungals are to be used, it is essential to remember that these interact with ICSs, such that iatrogenic Cushing's syndrome may be seen.[157–160] Anecdotally, antifungals have been successful in some children.
4. *Should nonstandard medications be used?* The possible approaches are macrolide antibiotics, immunosuppressants, intravenous immunoglobulin as an immunomodulator, and a continuous subcutaneous infusion of terbutaline.
   - Macrolide antibiotics are the safest option, and may be indicated for the rare child with a neutrophilic phenotype, or if an atypical infection is suspected.[161,162] One study comparing azithromycin with montelukast as add-on therapy ended in futility,[163] as only 55 of the 292 who were symptomatic while prescribed ICSs and LABAs could be randomized; most of the rest were

https://CafePezeshki.IR

nonadherent or did not have asthma at all, underscoring the need for detailed evaluation of these patients before uncritical acceptance of the diagnosis 'severe asthma'. However, in the small group who were actually studied, the results were not encouraging.

- Immunoglobulin infusions: the evidence is scanty in adults, and anecdotal and conflicting in children.[164–167] As with immunosuppressants, immunoglobulin infusions are used only in children with evidence of ongoing airway inflammation which is either steroid resistant or only responsive at the cost of major side-effects. One small study in teenagers with steroid-dependent asthma showed a reduction in maintenance oral steroids, steroid bursts and hospitalizations for asthma. The authors suggested that the mechanism may be a synergistic interaction with dexamethasone in suppressing lymphocyte activation and also significant improvement in the glucocorticoid receptor-binding affinity.[168]
- Immunosuppressants are used in children on the basis of small case series (methotrexate,[169,170] cyclosporine[171]) or no published evidence (azathioprine). Nebulized cyclosporine may be an attractive way of deriving benefits while avoiding systemic toxicity, but has only been used after lung transplantation
- Subcutaneous terbutaline infusions may be considered in children with ongoing documented labile airflow obstruction and no underlying airway inflammation.[172] This is a rare group, and the evidence base is a small case series. We now perform a double blind n-of-1 therapeutic trial, but rarely find any benefit.

5. *What about other biological agents?* The differences in pathophysiology between childhood and adult severe asthma have been highlighted above. Nonetheless, in a child who has persistent eosinophilic inflammation with ongoing symptoms, either totally steroid responsive or suffering major steroid side-effects, and particularly in the rare case of documented Th2 activation, a trial of one of the monoclonal Th2 strategies (see above) could be justified on compassionate grounds.
6. *Physical methods?* There is no evidence to recommend bronchial thermoplasty in children, and indeed the potential long-term consequences of this procedure on the growing airway are a concern.

A DIFFICULT SPECIFIC PROBLEM: TREATMENT OF THE EXACERBATING PHENOTYPE

Acute asthma exacerbations cause considerable morbidity, sometimes death, but are fortunately not a feature of all children with asthma. Exacerbations cannot be abolished completely. Exacerbation and loss of baseline control are not the same thing; loss of baseline control is characterized by wide diurnal peak expiratory flow variation and acute exacerbation by a steep decline in peak flow, with no increased variability.[173] Children may have good control, but still show exacerbations,[174] and increasing the doses of preventer and controller medications taken between exacerbations merely increases the risk side-effects. However, poor control[175] and previous severe exacerbations[175,176] both predict future acute exacerbations.

In older children, the combination of respiratory viral infection and both sensitization and exposure in the home to high allergen levels is strongly predictive of exacerbation.[92] These patients are typically characterized by mixed eosinophilic and neutrophilic, or pure neutrophilic inflammation.[177–179] At the other extreme, very high allergen exposure can cause acute exacerbations (e.g. thunderstorm asthma[180] and the Barcelona soya bean epidemic asthma[179]) and thunderstorm asthma at least is characterized by airway eosinophilia.[181]

In school-age children with multiple exacerbations, we aim to increase the baseline dose of ICS to abolish interval sputum eosinophilia, the effects of which are best shown through the proof of concept anti-IL5 studies.[182,183] LABAs also reduce exacerbations.[184–186] Allergen sensitization is identified and avoidance measures advised. High-dose ICS[187] or LTRAs[188] may be considered at the first sign of a viral exacerbation. However, none of these measures will completely obviate the need for oral corticosteroids. Finally, if exacerbations are of very sudden onset, with rapid deterioration over minutes, we provide the child with a source of injectable epinephrine (Epipen™). The hospital treatment of acute exacerbations is beyond the scope of this chapter.

Monitoring the Child with Severe, Therapy-Resistant Asthma on Treatment

MONITORING TREATMENT BENEFIT

It might be thought on the basis of research in adults with asthma that monitoring therapy in the inflammatory phenotypes would be beneficial in children.[189,190] However, the only trial in children with severe, therapy-resistant asthma using induced sputum every 3 months to guide the dose of inhaled corticosteroids was negative.[191] While a post hoc analysis did suggest a reduction in acute asthma attacks in the month after the sputum measurement in children who were monitored using the sputum strategy, there is currently insufficient evidence to recommend induced sputum or $FeNO_{50}$ to monitor severe asthma. Two studies may help explain why this is the case. In the first of these, the variability of sputum phenotype longitudinally was determined in children with either mild/moderate or severe asthma, and spontaneous phenotype changes were common in both groups and not predictable. This is in marked contradistinction to results in adults who appear to be much more stable over time.[192] The second study reported the relationship between sputum eosinophil count and $FeNO_{50}$ in severe therapy-resistant asthma: 148 samples were concordant (eosinophil positive, $FeNO_{50}$ positive = 77; both negative = 71) and 49 (25%) were discordant (eosinophil positive, $FeNO_{50}$ negative = 25; eosinophil negative, $FeNO_{50}$ positive = 24). Fifty-nine children produced at least two sputum samples. Of these, 31 (53%) were consistently concordant, 24 (41%) were discordant in one sample but concordant on at least one other occasion (one showed discordance in both directions and concordance in a third sample) and only four (7%) demonstrated consistently discordant levels.[193] Thus, these two markers cannot be used interchangeably, and neither can currently be recommended for monitoring children with acute severe asthma.[194]

MONITORING SIDE-EFFECTS

In addition to standard monitoring for both asthma and systemic steroid therapy, the question of adrenal insufficiency must be considered. Clearly, adrenal suppression is inevitable if

https://CafePezeshki.IR

the child is on any but the lowest dose of oral steroids. Most recommend a synacthen test for children on high-dose ICSs, but the dose of adrenal corticotrophin, the sampling protocol and the frequency at which the test is performed are still controversial. Our current recommendation is for an annual standard synacthen test.

ROLE OF AN ANNUAL ASSESSMENT?

There is a strong case to be made for a structured annual assessment in all children with severe, therapy-resistant asthma. This should include a re-evaluation of adherence (see above) and allergen exposure, as well as screening questionnaires at least for psychological morbidity. Spirometry and acute bronchodilator responsiveness, sputum induction and $FeNO_{50}$ should also be part of the evaluation. The annual assessment also provides the opportunity to evaluate side-effects with measurements of height and weight, blood pressure, urinalysis and the performance of a short synacthen test. Following this reassessment, a multidisciplinary planning meeting is held.

Recent Advances in Pathophysiology

Very little is known about the pathophysiology of severe, therapy-resistant asthma in children. This section summarizes the findings of some recent studies. However, there is no definitive evidence in this field.

GENETICS

Most genetic association studies have been in mild to moderate asthma, which is often very poorly phenotyped – 'doctor diagnosed asthma'. Very few studies have performed the sort of detailed assessments described above.

Genetic and other studies suggest that PDCD4 is important in inflammatory responses in severe asthma, with multiple plausible mechanisms.[195,196]

RESPONSE TO VIRAL INFECTIONS

We compared children with severe, therapy-resistant asthma with non-allergic healthy controls,[197] and showed that, as in adults,[198–201] an impaired innate antiviral response to rhinovirus is a feature of severe, therapy-resistant asthma.

VITAMIN D

Vitamin D, once thought to be of importance just in bone health, is now known to have many immunomodulatory properties. Importantly, 'normal' ranges for serum vitamin D levels are based on bone health; the optimal values for immunological function are unknown and may not be the same.

We showed a stepwise relationship between asthma and 25(OH)D(3) levels: lowest in severe, therapy-resistant asthma and intermediate in mild/moderate asthma.[202] There was a positive relationship between 25(OH)D(3) levels and percentage predicted FEV_1. 25(OH)D(3) levels were positively associated with ACT and inversely associated with exacerbations and ICS dose. Airway smooth muscle mass, but not epithelial shedding or reticular basement membrane thickness, was inversely related to 25(OH)D(3) levels and there was the expected positive correlation between smooth muscle mass and bronchodilator reversibility. However, the real pathophysiological significance of vitamin D deficiency remains in doubt for two reasons. First, cross-sectional studies cannot disentangle cause from effect and it is entirely possible that low vitamin D results from immobility and lack of sunlight exposure due to severe asthma. Second, treatment effects are confounding as, for obvious reasons, studies have not included untreated patients with severe, therapy-resistant asthma. However, it would seem reasonable to give vitamin D supplements to children with severe, therapy-resistant asthma who have suboptimal serum levels.

LESSONS FROM PEDIATRIC SARP

The key findings of the pediatric studies within this large study are:

- Cluster analysis identified four asthma clusters, with severe asthma being present in all four. The clusters were (1) relatively normal lung function and less atopic; (2) slightly worse lung function, more atopic and increased symptoms and medication use; (3) more co-morbidity, increased bronchial responsiveness and lower lung function; and (4) lowest lung function and greatest symptoms and medication use.[203] Worryingly, children with severe asthma had progressive airflow obstruction, but it was unclear whether this was the result of progression of remodeling or impaired lung growth.[204]
- Breath condensate pH was the same in children with severe and milder asthma,[205] but breath condensate formate concentration was significantly higher in those with severe asthma, possibly related to increased catabolism of endogenous S-nitrosothiols.[206]
- Children with severe asthma may have dysregulated macrophage function, manifest by decreased phagocytic function and increased apoptosis.[207] Dysregulated glutathione metabolism was associated with increased oxidative stress[208] and impacted alveolar macrophage function in severe compared to milder asthma.[209]

Severe, Therapy-Resistant Asthma: The Future?

Prevention is always better than treatment. We need to be smarter at understanding and preventing nonadherence, and also detecting it. Internet technology is the key way forward with alerts to remind patients to take therapy, and using devices that detect correct activation and not just whether the device has been activated. Perhaps adherence issues with teenagers would disappear if their smartphones were automatically inactivated whenever they did not take their medications!

The planning of treatment for severe, therapy-resistant asthma will improve. The term 'severe asthma' will become as obsolete as the unqualified terms 'severe anemia' or 'severe arthritis'. Crude planning on the basis of a single cell type measured on a single occasion will surely be replaced by sophisticated analyses of gene up- and down-regulation, using induced sputum or upper airway cells,[210] or exhaled breath analysis with devices such as the electronic nose.[211] We will follow the example of oncologists, who are now looking for tumor gene expression signatures and matching these to medications which reverse these changes. This approach has identified sodium valproate as a possible treatment for triple negative breast cancer,[212] not

https://CafePezeshki.IR

an immediately obvious compound in this context. Of course, this innovative approach risks reversing what is a protective change, but must surely replace putting steroids in the tap water to control asthma.

Will pharmacogenomics deliver personalized therapy? It is likely that something more sophisticated than just looking at DNA will be needed. The complexities of gene-environment interactions have shown that the effect of CD14 polymorphisms is dependent on whether environmental lipopolysaccharide levels are high or low.[213] It seems likely that these gene-environment interactions, probably also involving epigenetic influences, may also influence individual medication responses.

So, promising improvements can be expected in the near future for those with very severe asthma, with the ability to identify those who respond to properly administered treatment, and a truly personalized program of therapy for those with severe, therapy-resistant asthma.

Summary and Conclusions

Severe asthma is one of the great challenges of pediatric pulmonology. Mismanagement may result in a dead child. This chapter has proposed a systematic approach to treatment. It is essential to optimize basic management, and this is not achievable without a skilled multidisciplinary team. We still do not really understand the underlying pathophysiology of very severe asthma and hence have no targeted treatments. It is not safe to assume that adult and pediatric severe asthma is the same disease; compared with adults, in children with severe asthma, atopy is much more prominent, there is no gender difference or increased prevalence of obesity, and eosinophilic not neutrophilic airway inflammation is the rule. Furthermore, eosinophilic asthma is in the main not Th2 driven, meaning that the successful use of anti-Th2 strategies in adults may not be replicated in children. There is a great need for mechanistic studies and randomized controlled trials of treatment in well-characterized groups of children with severe asthma, but these will only be possible once there is multination and multicenter cooperation in adopting standardized assessment protocols.

Promoting Adherence and Effective Self-Management in Patients with Asthma

BRUCE G. BENDER

KEY POINTS

- Patients often take less than half of their prescribed controller medication, and surprisingly many stop taking their controller medication altogether after an initial filling at their pharmacy.
- Decreasing adherence contributes to poor control and increased exacerbation risk, in turn driving up health-care costs.
- Complex and time-consuming adherence interventions are difficult to integrate into everyday clinical practice.
- Evidence-based, time-efficient strategies can be adopted by most providers to increase patient adherence.
- Successful strategies utilize principles of patient-centered care and effective communication, including collaboration on treatment goals and plans.

Nonadherence Undermines Treatment

Patient adherence with asthma self-management plans, as with all chronic medical conditions, is often poor. Adherence to daily medication regimens averages about 50% or less for chronic conditions in general,[1] including patients with asthma.[2,3] *Adherence* as defined in these studies means that about half of the prescribed medication was taken, although it does not necessarily signify that it was taken in the appropriate manner. In addition, the report of 50% medication adherence reflects the average of groups of patients studied but does not translate into a uniform pattern of taking every other dose of medication. Individual adherence patterns include widely varying behaviors, with some patients taking close to all their medications at the appropriate time and others taking almost no medication.[3] Individual adherence fluctuates greatly over time, often with periods of time during which patients take no medication for varying periods, often for days or weeks at a time.[4] Further, asthma medication adherence may be on the decline. A 1993 review of ten published studies found that adherence had averaged 48%.[5] Recently published studies have reported mean inhaled corticosteroids (ICS) adherence at 34% in adults[6] and 40% in children.[7] Other studies have shown alarmingly high rates of medication abandonment, reflected in refill nonpersistence, a problem not unique to asthma. For example, large administrative and pharmacy database studies have revealed that 59% of patients with asthma,[8] 39% of patients with hypertension[9] and 86% of patients with chronic obstructive pulmonary disease (COPD) ceased refilling their medication and did not return to fill again within a year.[10] Decreasing ICS adherence is followed by worsening asthma symptoms in children.[11] Because most adherence research is conducted on patients who volunteer to participate in studies and know that their adherence is being monitored, these numbers may be inflated. One medication refill study, reflecting the behavior of 5,500 adult and pediatric patients using a national pharmacy chain, found mean ICS adherence of 22.2% over 12 months.[8]

Impact of Nonadherence

Depending on the duration of action and the drug side-effects profile, periods of nonadherence may have several potential consequences, including waning drug action, hazardous rebound effects when administration stops abruptly, and overdose effects when administration of full-strength drugs suddenly resumes.[4] In studies of metered-dose inhaler (MDI) use among children with asthma, inhalers were not used on 48% of study days and abandonment of medication typically occurred for several consecutive days.[12] The consequences of such start-and-stop adherence patterns are unknown. Time to onset of the effectiveness of ICS in the treatment of mild-to-moderate asthma is about 3 weeks, with faster impact (3 days) reflected on morning peak expiratory flow values in patients with severe asthma.[13] It remains to be determined how varying patterns of adherence translate into asthma control and whether, for example, control in patients with relatively high adherence who fail to use their medication for 1 week or longer is poorer than in patients who use less total medication but with better regularity.[14]

While the assumption that underuse of asthma controller medication can result in less control over the disorder is accurate, conclusions about the amount of medication required by any individual child are difficult to establish largely because of individual variations in disease characteristics, medication requirements and drug metabolism rates. The prevailing standard, as reflected by the US National Asthma Education and Prevention Program (NAEPP) guidelines for the diagnosis and management of asthma, is that increased medication administration is the correct response to inadequate symptom control.[15] The potential benefit of medication escalation on the part of the physician is realized only if the patient responds by adhering to the new regimen. Although some studies have defined nonadherence as less than 75% of medication taken, it is impossible to establish a minimum level of adherence that is sufficient for

https://CafePezeshki.IR

all patients. Evidence exists that ICS are highly effective in controlling asthma, that some benefit persists even at relatively low dosing frequency, and that a dose-response relationship exists between degree of adherence and degree of benefit. Suissa et al,[16] for example, conducted a nested case-control study of patients with severe asthma and found that decreasing number of ICS pharmacy refills was associated with increasing risk of death from asthma. As few as three ICS canisters per year reduced risk by one half, with increasing protection gained as refills increased up to a full adherence level of 12 canisters per year. Clearly, as adherence levels drop, asthma becomes less controlled. For example, in a 3-month study, children with a median ICS adherence of 14% had asthma exacerbations requiring urgent office visits and oral steroid bursts, whereas those with adherence levels of 68% remained medically stable.[17] Even children with relatively mild asthma demonstrated increased asthma symptoms as adherence declined.[11] Nonadherent adults with asthma had more airway obstruction than adherent patients.[18] In large studies of managed care populations, decreasing use of ICS has been linked to increased risk of hospitalization.[19] Children who did not adhere to their asthma treatment regimen had poorer asthma control and required more urgent-care visits, steroid bursts and hospitalizations.[17,20,21] In a recent study of 18,456 Medicaid children with asthma, increasing adherence to controller medication was associated with higher cost but also decreasing odds of an ED visit.[22] Tragically, nonadherence has been associated with asthma-related deaths in children, particularly where psychologic dysfunction was observed in the patient or the patient's family.[23]

Strategies to Change Patient Behavior

Numerous strategies to improve patient adherence have been tested, many in carefully conducted randomized clinical trials. While most of these interventions have been able to change patient or parent behavior, changes are often small and difficult to sustain. Further, effective interventions are often costly and require large amounts of healthcare provider time or supplementary staff. A Cochrane Collection meta-analysis of 69 randomized trials of adherence interventions, covering a large range of ages and diseases, reported that 40% produced an effect on both adherence and at least one clinical outcome. All involved complex interventions combining components such as information giving, reminders, self-monitoring, reinforcement, counseling, psychological therapy, crisis intervention and telephone follow-up.[24] A meta-analysis of 70 controlled studies of interventions to improve adherence across various chronic pediatric conditions, including asthma, diabetes, cystic fibrosis, cancer, sickle cell disease and gastrointestinal disorders, revealed moderate effect size in multicomponent behavioral interventions and small effect size from interventions limited to education and instruction.[25] Multicomponent behavioral programs again included a variety of interventions such as behavioral reinforcement, social support, computer and technology-based components, homework assignments and family and individual psychological counseling. Other promising strategies include the use of patient advocates or navigators[26] and introduction of innovative web-based technology into school-based clinics to improve care coordination and adherence.[27]

A recent consensus report from a group of 20 internationally recognized experts on adherence emphasized the essential importance of identifying simple, brief interventions that could be delivered by healthcare providers during the course of routine office care.[28] The challenge, then, becomes one of identifying interventions that are not costly, do not require a large amount of healthcare provider time and can be implemented during routine office visits. Do such interventions exist, and are they evidence based? A considerable amount of evidence indicates that key communication strategies exist that can change parent and patient behavior and are evidence-based, time-efficient and teachable to busy healthcare providers.

Five Communication Strategies for Changing Patient Behavior

Behavioral scientists have long adopted a translational research approach to understanding and changing health behaviors. Much like 'bench' research, the process begins with studies that document frequencies, predictors and moderators of health behaviors. This information is used to build models, or theories, that explain health behaviors. Such models of behavior change are used, in turn, to translate theory to the 'bedside' by allowing behavioral scientists to develop and test interventions that change people's health behavior.[29] Strategies to change patient behavior have been rooted in a number of health behavior change frameworks. These include *patient-centered care*, *motivational interviewing*, *readiness to change* and *shared decision-making*. Each has produced evidence of the effectiveness of very specific communication strategies. These strategies are discussed below, along with evidence from each model that supports its use. The collective group of five strategies are presented here as an integrated program that can guide provider behavior during patient visits to increase treatment effectiveness and outcomes. Further, these strategies can enhance satisfaction from the encounter for both the family and the healthcare provider.

1. BUILD A RELATIONSHIP

Promoting strong adherence begins with the development of patient trust in the provider-patient relationship. Patients and parents are more likely to increase and accurately report their adherence levels, and to express satisfaction with their care, where healthcare providers demonstrate thorough information sharing, interpersonal sensitivity and partnership-building.[30] *Patient-centered care* embraces the concept that trust is established where the provider demonstrates genuine interest in and concern about the patient and considers the family's cultural traditions, personal preferences and values, current situations and lifestyle.[31] Trust begins with communication, including listening and exploring concerns. The first moment of interaction when the provider and patient come together sets the tone for the communication that will follow. Consensus recommendations indicate that very basic elements of communication that establish this foundation include adopting a friendly tone, greeting the family with a smile, and being aware of tone, pace, eye contact and other elements of nonverbal communication that establish genuine interest in the patient (Box 38-1).[32] Further, patients will be more adherent when physicians provide more information and are nonjudgmental, supportive and understanding.[33] Patient-centered care has been shown to

https://CafePezeshki.IR

BOX 38-1 KEY ELEMENTS OF THE INITIAL VISIT THAT HELP BUILD A POSITIVE RELATIONSHIP

- A warm smile moves mountains
- Greet and express interest in your patient
- Use tone, pace, eye contact and posture to show care and concern
- Use simple language and basic concepts
- Don't overload the patient or parent
- Be sensitive to cultural differences

Bayer-Fetzer Conference on Physician-Patient Communication in Medical Education. Essential elements of communication in medical encounters: the Kalamazoo Consensus Statement. Acad Med 2001;76:390–93.

BOX 38-2 EXAMPLES OF QUESTIONS THAT HELP TO SET THE STAGE FOR PATIENT-CENTERED CARE

- What worries you about your child's asthma?
- What do you want to accomplish at this visit?
- What do you want to be able to do that you can't do now because of your asthma?
- What do you expect from treatment?
- What medicines have you tried?
- What other questions do you have for me today?

NAEPP Guidelines for the diagnosis and management of asthma. Expert Panel Report 2007;3.

improve health outcomes for a number of disorders including diabetes,[34] hypertension,[35] obesity[36] and asthma.[37]

Demonstration of interest and concern includes asking questions that allow the patient or parent to tell the physician about their worries, symptoms and hopes for the visit. In a survey study, 865 patients from three primary care practices completed a questionnaire inquiring about what the patient desired in a consultation with their physician. Factor analysis of the results identified three primary domains: (1) *communication*, which included listening, exploring concerns and providing information with clear explanations; (2) *partnership*, which included discussion with the physician to achieve common ground and mutual agreement about the problem and treatment; and (3) *health promotion*, which included information and encouragement to maintain health and reduce risks of future illness.[38] A systematic review of relevant literature revealed that physician questioning is an important part of effective communication that can exert positive influence on the patient's emotional wellbeing, symptom resolution and functional and physiologic improvement.[39] This approach has advantages for both the family and the provider. Taking the time to ask and answer patient questions is associated with greater physician job satisfaction and higher rates of adherence to medical treatment[40] and lower rates of medical errors.[41]

The NAEPP guidelines for the diagnosis and management of asthma[15] provide examples of questions that can be asked in the initial visit and help set the stage for positive communication (Box 38-2).

2. FOCUS ON LISTENING

Healthcare providers who want to be helpful to their patients by sharing important information about an illness, test results and treatment plans are often well-practiced at giving information, but may not always be as cognizant of the importance of listening. Time pressures add to the sense that the encounter must be brief and efficient, a tendency to ask questions that can be answered 'yes' or 'no' to limit discussion, and a desire to move briskly toward completion of the visit. The result may be that the family's concerns are not heard. The family's unheard concerns often undermine adherence.

In the context of the Health Beliefs Model, the parent's decision about whether or not to follow a treatment plan is largely influenced by their perception of the risks associated with the disease, and the risks and benefits introduced by the treatment.[42] For patients or parents of patients with asthma, concerns often include fears about medication side-effects, a perception that the medication is not helping, concerns about long-term dependence on the medication and the cost of the medication.[43] In a study of parents of 67 children with asthma, increased concerns about risks of taking asthma medications were associated with lower adherence; fewer concerns combined with a perception of benefit from the child's medication were associated with higher adherence.[44] When the patient or parent voices their concerns, the healthcare provider has an opportunity to discuss these concerns and perceptions, to provide more information and to discuss treatment options. When the discussion leads to a shift in the family's perception of the relative benefits of the medication over its risks, increased adherence is likely to follow.[44,45]

Patients who do not perceive a positive benefit-to-risk advantage to their treatment are likely to be ambivalent and uncommitted to a daily treatment regimen. Evidence of this ambivalence is seen in the finding that over half of 5,500 patients who filled an ICS prescription once did not return to refill within 12 months.[8] The technique of *motivational interviewing* is designed to increase patient and parent motivation by strategically helping to overcome ambivalence while avoiding confronting or lecturing the patient.[46] At the core of this technique are four important listening strategies: open-ended questions, affirmations, reflective listening and summary statements.[47]

Open-ended questions allow the patient and parent to 'tell their story', and contrast with closed-ended questions, which force the family into a yes-no response (e.g. 'Tell me about how you are using the asthma medication' rather than 'Are you taking your medication?').

Affirmations are positive statements that help to build rapport and encourage behavior change (e.g. 'I can see that you are really trying to get your child's asthma under control').

Reflective listening, arguably the most challenging of these listening skills, involves stating back to the patient and parent what the healthcare provider believes they have heard from the family. Reflective listening helps to ensure that the provider understands the patient's perspective while emphasizing positive statements about change. The seven types of reflective listening, from simplest to most complex, are listed in Table 38-1.

Summary statements are longer summaries of what the provider has heard from the patient or parent, and serve the purpose of providing a recap of key points, highlighting

https://CafePezeshki.IR

TABLE 38-1 Types of Reflections Used in Motivational Interviewing

1. Repeating Use to diffuse resistance	**Patient** 'I don't want to take my medication.'	**Healthcare Provider** 'You don't want to take your medication.'
2. Rephrasing Slightly alter what the patient says to provide the patient with a different point of view	**Patient** 'I want to take my medication, but I have trouble fitting it into my day.'	**Healthcare Provider** 'Taking your medication is important to you.'
3. Empathic reflection Provide understanding for the patient's situation	**Patient** 'You've probably never had to deal with anything like this.'	**Healthcare Provider** 'It's hard to imagine how I could possibly understand.'
4. Reframing Help the patient think about his or her situation differently	**Patient** 'I've tried to take my medication consistently, but I just can't seem to pull it off.'	**Healthcare Provider** 'You are persistent, even in the face of discouragement. Controlling your asthma is really important to you.'
5. Feeling reflection Reflect the emotional undertones of the conversation	**Patient** 'I know that not taking medication is bad for my asthma.'	**Healthcare Provider** 'You're worried about your asthma getting worse.'
6. Amplified reflection Reflect what the client has said in an exaggerated way. This encourages the client to argue less and can elicit the other side of the client's ambivalence	**Patient** 'My mom is totally exaggerating my symptoms. My asthma isn't that bad.'	**Healthcare Provider** 'There's no reason to be concerned about your asthma.' (said without sarcasm)
7. Double-sided reflection Acknowledge both sides of the patient's ambivalence	**Patient** 'Taking medications just takes away my freedom. It's such a hassle.'	**Healthcare Provider** 'On the one hand, you find that medication takes away your freedom. On the other hand, you said that your asthma symptoms limit your freedom by preventing you from doing things you enjoy. What do you make of this?'

Reprinted with permission, J Allergy Clin Immunol 2007;120(5).

the family's ambivalence and gently moving the patient toward a positive change (e.g. 'You'd like to really get your child's asthma under better control, and you think this medication is helping, but you are not convinced that this medication is safe enough to take for a long period of time'). Both reflective listening and summary statements help to crystallize where a behavior change is needed, and help to transition the discussion toward action.

3. COLLABORATE ON THE TREATMENT PLAN

Patient-centered care presumes that the provider is willing to put aside a paternalistic approach in which the patient is told what is wrong with them and what they need to do, and instead work toward a partnership in which the patient is heard, a discussion occurs and the two parties agree both on the goals of treatment as well as the treatment itself.[48] To accomplish this partnership, the provider must engage and listen to the patient and parent, showing sensitivity, interest, concern and comprehension of the family's message. Differences in goals and expectations must be discussed and resolved before the treatment plan is finalized. The partnership approach is favored by many patients. For example, a survey of patients following a consultation showed increased satisfaction where physicians were 'interested in what I think the problem is', 'interested in what treatment I want' and would 'discuss and agree with me on treatment'.[38] The NAEPP guidelines emphasize the importance of this relationship and provide recommendations on establishing a partnership with the patient and family (Box 38-3).

Establishing a partnership between the provider and family necessarily reflects a shift of authority within which the physician takes into account patients' concerns and preferences before making treatment recommendations. The degree to which the provider defers to the patient or parent will depend on both the physician and family. Many physicians are most comfortable maintaining control of the treatment plan, and may do so while still adopting a sensitive patient-centered focus. Other physicians may be comfortable taking the partnership a step further, allowing the patient more control over the choice of treatment plan. This approach is adopted in the *shared decision-making* model, a communication approach that

BOX 38-3 STEPS TO DEVELOP AN ACTIVE PARTNERSHIP WITH THE PATIENT AND FAMILY

- Establish open communications
- Identify and address patient and family concerns about asthma and asthma treatment
- Identify patient/parent/child treatment preferences regarding treatment and barriers to its implementation
- Develop treatment goals together with patient and family
- Encourage active self-assessment and self-management of asthma
- Encourage adherence by:
  - choosing a treatment regimen that achieves outcomes and addresses preferences that are important to the patient/parent (Evidence B)
  - reviewing the success of the treatment plan with the patient/parent at each visit and making adjustments as needed (Evidence B)
- Tailor the asthma self-management teaching approach to the needs of each patient
- Maintain sensitivity to cultural beliefs and ethnocultural practices (Evidence C)

NAEPP Guidelines for the diagnosis and management of asthma. Expert Panel Report 2007;3.

https://CafePezeshki.IR

attempts to increase concordance about treatment choices and goals by promoting greater involvement of the individual patient in deliberations about treatment options.[49,50] One study evaluated the effectiveness of shared decision-making in improving outcomes in adults aged 18 to 70 years with poorly controlled, mild to moderate persistent asthma. Healthcare providers were randomly assigned to one of three training conditions: (1) usual care (no training), (2) management by guidelines (training in following the evidence-based guidelines), and (3) shared decision-making (training in guidelines combined with shared decision-making). In the group of 170 patients of providers trained in shared decision-making, controller medication adherence improved from 40% at baseline to 70% following the intervention, significantly more than for the 331 patients in the other two conditions.[51] In another study, 808 women with asthma were interviewed about their healthcare experiences. Those who reported that their provider had entered into a negotiated treatment plan with the patient reported greater adherence and lower oral steroid use at follow-up.[52] Not all patients may prefer a shared decision-making approach. In a study where patients evaluated videos of two different types of consultations with a physician, one shared decision and one in which the physician was more directive, the directed approach was often preferred by older patients while the shared decision approach was often preferred by younger patients and those with higher education levels.[53]

4. MANAGE TIME

With limitations in insurance reimbursement and a consequent need to see larger numbers of patients, physicians often experience significant pressure to limit the time they spend with each patient. Discussions about changing patient health behavior, therefore, are sometimes greeted with the concern that improved communication will mean large increases in time for each patient encounter. However, strategic time management and adoption of brief but effective communication strategies often results in meaningful changes in patient and parent motivation without increased encounter time. For example, a large randomized trial tested the effectiveness of educating primary care pediatricians in two interactive seminars that provided training in asthma management guidelines and communication skills. Half of the 100 pediatricians received the training. Compared to the control pediatricians, patients of the trained group reported more discussion about personal concerns and goals for treatment during office visits, and experienced fewer symptom days and emergency department visits over the ensuing year. Assessments of time spent with the family revealed that those pediatricians who had received the training spent no more time than control physicians during the initial visit, acute asthma visits or well-child visits.[54]

Effective time management begins with setting the agenda at the beginning of the visit. This includes asking the patient what they hope to accomplish ('What brings you here today?'; 'What are you hoping I might be able to do to help?'). The 'patient agenda' may differ from the 'physician agenda'.[48] Patients and parents may be reluctant to voice their agenda, feeling intimidated or worried about how their concerns will be heard by the physician.[48] However, when physicians proceed with their own presumed agenda and fail to elicit the family's agenda, outcomes are often less successful.[55] Asking families to voice their agenda does not carry with it a presumption that the provider can address all concerns in the allotted time. Simply listening to and acknowledging the patient's concerns often provides an emotional relief to the patient. The provider must establish priorities with the patient or parent for this visit ('What is at the top of your list?'), consider the time available and make a plan that may include data collection and a follow-up visit.[56] It may be helpful for the provider to establish explicitly the boundaries for the visit and remind the patient of the time available:[57,58] 'We have about 15 minutes today, so let's decide together what is most important to accomplish. Then I'll order some tests and we'll have you schedule a follow-up visit. Would that be OK?'. Establishing interest in and concern for the patient does not mean giving unlimited time for the visit. Employing the techniques of reflective listening allows a means for the physician to summarize the information or concerns expressed by the patient or parent and move toward completion of the visit.

An additional communication strategy that is helpful both to managing time and assuring that the patient or parent understands what the provider means to communicate is the 'teach back' method.[59] This method consists of asking the patient to repeat in their own words what has been decided and what they need to do when they leave the office, and allows the provider to check the understanding of all plans and instructions ('I want to see if I have done a good job of explaining all of this to you. Can you tell me what we decided today, and what you're going to do about your child's asthma this week?').

5. FOLLOW-UP

Providers have limited opportunity to influence the behavior of patients once they leave the office. However, if strong communication in the office has set the stage for motivating health-promoting behavior, follow-up contact can reinforce this motivation. Follow-up interventions may include return visits to the clinic, telephone calls and other media-based interventions.

NAEPP guidelines recommend follow-up visits at 2 to 6 weeks after the initiation of controller medication therapy, and intervals of 1 to 6 months for asthma well care visits. Because a large number of patients are almost immediately nonadherent following initial controller therapy prescription,[8] investment of efforts to increase adherence at the point of initiation of controller treatment may yield greatest return. Each follow-up visit provides an opportunity for discussion of the family's perceptions and concerns about treatment and, if necessary, renegotiation of the treatment plan. NAEPP guidelines include recommendations for questions that can be asked at follow-up visits that invite increased communication, provider-patient collaboration and treatment adherence (Box 38-4).

Recent evidence indicates strong potential for the employment of telecommunication technology to reach out to patients and encourage adherence. The rapid uptake of telecommunication technology has penetrated every demographic subgroup of the American public, which in turn means that there is the interest and opportunity to use technology to engage patients. Evidence is mounting to support adherence-enhancing strategies that include leveraging email,[60,61] text messaging[62] and interactive voice recognition technology[63,64] to activate patients and encourage better disease self-management. In a randomized study of a computerized speech recognition program designed to call patients with asthma to inquire about disease

https://CafePezeshki.IR

BOX 38-4 MONITORING PATIENT-PROVIDER COMMUNICATION AND PATIENT SATISFACTION

- 'What questions have you had about your child's asthma daily self-management plan and action plan?'
- 'What problems have you had following the daily self-management plan? The action plan?'
- 'How do you feel about making your own decisions about therapy?'
- 'Has anything prevented you from getting the treatment you need for your asthma from me or anyone else?'
- 'Have the costs of your child's asthma treatment interfered with your ability to get asthma care?'
- 'How satisfied are you with your asthma care?'
- 'How can we improve your asthma care?'

NAEPP Guidelines for the diagnosis and management of asthma. Expert Panel Report 2007;3.

control and promote adherence, patients who received the calls were significantly more likely to use their ICS and to have a routine asthma follow-up visit.[64] A similar system has been developed to promote diabetes self-management.[65]

Conclusions

A large proportion of patients with asthma take less than half of their prescribed controller medication, and surprisingly many stop taking their controller medication altogether after an initial filling at their pharmacy. Decreasing use of inhaled corticosteroids has been linked to worsening asthma symptoms and increased risk of hospitalization and death. Many interventions to improve patient adherence have been tested in controlled clinical trials; while some interventions increase adherence, many are complex, costly, time consuming and nearly impossible to adopt in independent primary care and allergy practices. Nonetheless, four decades of behavioral research and modeling have produced a number of communication strategies that may be used by healthcare providers to effectively change health behavior. From these, five key communication strategies with significant empirical support have been extracted and are presented here. These are: (1) build a relationship, (2) focus on listening, (3) collaborate on the treatment plan, (4) manage time, and (5) follow up. These communications strategies do not require a large amount of healthcare provider time, can be implemented during routine office visits and can change patient behavior. Realistically, these strategies will not transform every nonadherent patient into an effective illness self-manager, but employment of these strategies will improve adherence in many families. Furthermore, they can be used to effect change in other health behaviors, such as smoking cessation or weight loss. Finally, beyond behavior change, enhanced communication has been repeatedly shown to improve satisfaction in the interaction for both the family and the provider.

New Directions in Asthma Management: A Tale of Two Cities

STANLEY J. SZEFLER

KEY POINTS

- Recent statistics show that asthma deaths and hospitalizations are decreasing, but there are still health disparities in that the African American/black population bears a heavier burden of the disease.
- There is a need to *standardize* and *harmonize* our approach to asthma care; a continuing need for *communication* among the various stakeholders; and also a need for *collaboration* in order to address the health disparities in asthma care.
- In managing asthma today the focus is on achieving asthma control through an effort to minimize asthma impairment, specifically factors that affect day-to-day symptoms, and risk for future asthma events, such as asthma exacerbations, progression and adverse effects of medications.
- New medications have been developed and the positive responses to them have been linked to certain biomarkers, e.g. sputum or blood eosinophil count with anti-IL-5 therapy and serum periostin with anti-IL-13 therapy.
- There is emerging concern regarding the potential for overlap of asthma and COPD in certain patients, called the 'asthma-COPD overlap syndrome', and growing interest in preventing this phenomenon.

Introduction

'It was the best of times, it was the worst of times.' This well-known quote opens Charles Dickens' popular novel 'A Tale of Two Cities.' Charles Dickens characterized the bleak times of an industrializing country having personally experienced many trials and tribulations while growing up and then reflecting on the bad and good times as an adult. While painting a very depressing picture of strife and struggle, there are threads of optimism throughout his work and even glimmers of humor. His writing and public speaking brought attention to the problems and ultimately had impact on changing society. However, he did not live long enough to see the changes that followed.

In many ways analogies can be made between the situation described by Dickens and the healthcare system. The poor seek help. The system is complicated. There is a growing concern that two levels of care are emerging. This situation is of great concern worldwide, but especially in the USA, where the economy is strong yet the healthcare system is in apparent disarray. A careful examination of various national healthcare systems reveals that each has its benefits and limitations.[1]

Certainly, asthma provides a good model for the healthcare situation generally. There continues to be a high burden of asthma among the poor. On the other hand, scientific advancements are being made regarding the use of patient characteristics, biomarkers and genetics to assist in individualizing care. New medications are being developed but there are financial limits to their application.

The review on new directions in asthma management in the previous edition of this book concentrated on the understanding of the therapeutic interventions at the time and the possibilities for improving asthma management and perhaps halting the progression of the disease.[2] It also emphasized an integrated approach to patient care. At the time, there were serious deficiencies in the healthcare system that influenced access to health care. The reported decline in asthma mortality and morbidity was encouraging, but it was pointed out that this could be deceptive since the decline did not encompass all racial/ethnic groups. Recent statistics have shown that asthma deaths and hospitalizations are indeed decreasing, but there are still health disparities in that the African American/black population bears a heavier burden of the disease (Figure 39-1).[3]

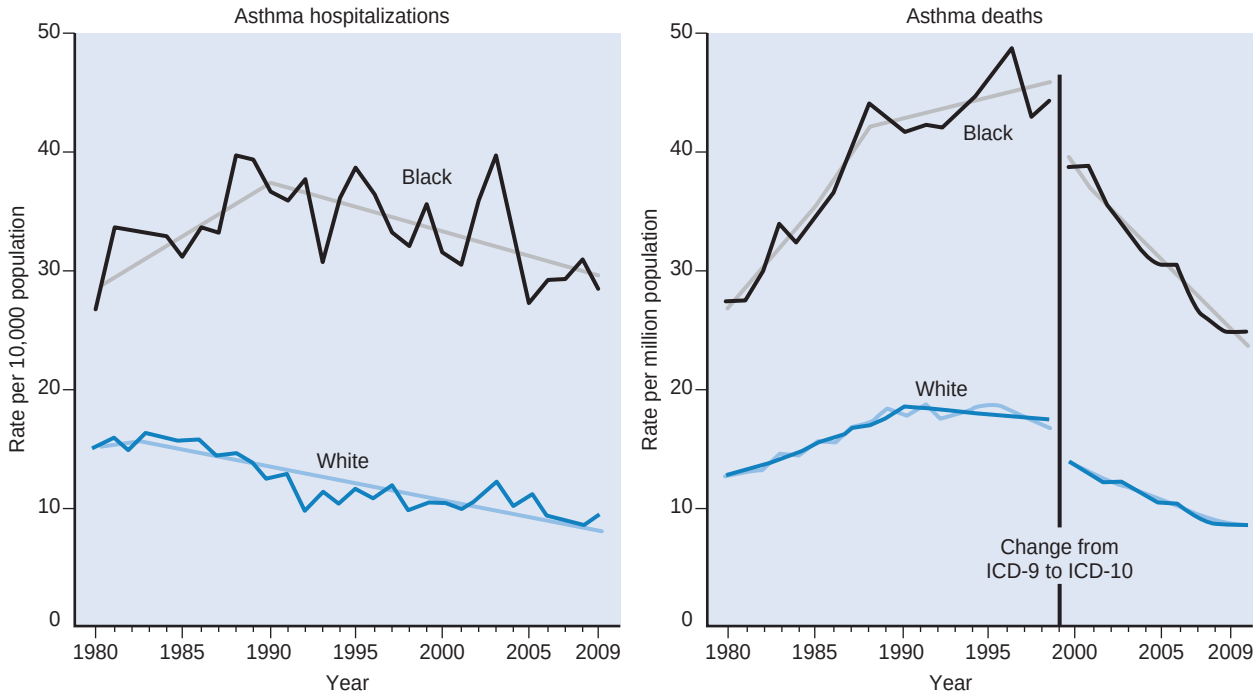
Concerted efforts are now being directed toward understanding this phenomenon and recommendations are being made to integrate the various national resources available to improve outcomes of asthma care for children in the USA. The application of electronic medical records and additional methods of surveying disease management should prompt improvements in medical care.

This chapter will describe the current state of asthma care, using some quotes from Dickens' writing to highlight the important points. Perhaps this will inspire a reflection on the past to help set a vision for the future. The key message is that there is a need to *standardize* and *harmonize* our approach to asthma care; a continuing need for *communication* among the various stakeholders; and a need for *collaboration* in order to address health disparities in asthma care.

Asthma: Past, Present and Future

In the Christmas Carol, Dickens wrote 'It is a fair, even-handed, noble adjustment of things, that while there is infection in disease and sorrow, there is nothing in the world so irresistibly contagious as laughter and good humor.' In the past, asthma was treated as an episodic disease, primarily with bronchodilators (Figure 39-2). As it began to be realized that asthma has an inflammatory component, inhaled corticosteroids became the cornerstone of asthma management. Advances in extending the duration and specificity of the bronchodilator led to the development of the long-acting ß-adrenergic agonists and their combination with inhaled corticosteroids. Additional medications

https://CafePezeshki.IR



Notes: Population-based rates are age adjusted to the 2000 standard population. Light blue and gray lines show the modeled trend estimated by Joinpoint. Inflection points respresent a change in the annual percent change.

Figure 39-1 Asthma hospitalization rates and asthma death rates (population-based) by race: United States, 1980–2009. *(From Moorman JE, Akinbami LJ, Bailey CM, National Surveillance of Asthma, et al.[3])*

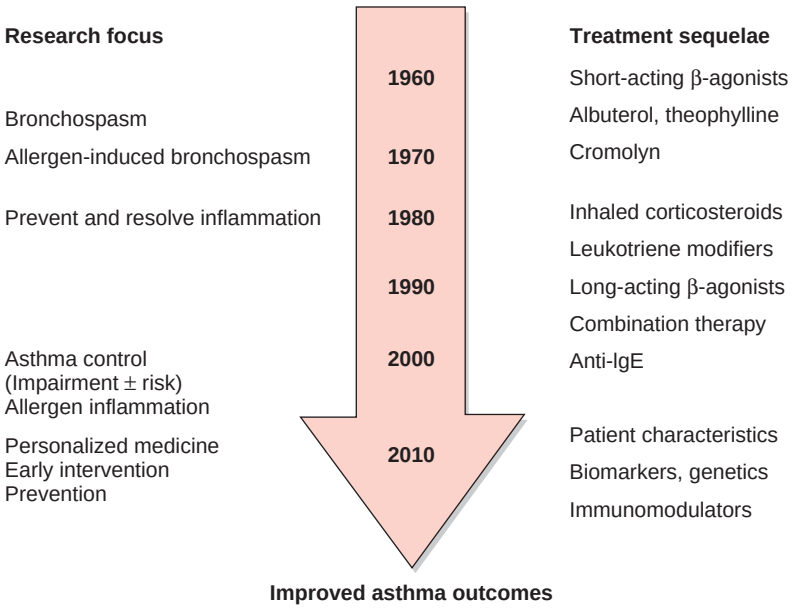


Figure 39-2 Timeline of advances in asthma care showing the interaction of research focus and development of new medications.

introduced in the last 20 years included leukotriene modifiers and anti-IgE therapy. Asthma guidelines were also introduced and revised over the past 30 years and helped to standardize and harmonize asthma care.

Currently, we have the Global Initiative for Asthma[4] as a template global strategy for managing asthma. This strategy is updated regularly and the latest version was released in May 2014. Many countries have their own specific guidelines, such as the National Asthma Education and Prevention Program *Guidelines for the Diagnosis and Management of Asthma* in the USA.[5] These guidelines were last released in 2007 and placed an emphasis on asthma control. They are currently being reviewed for revision and there are several areas that need to be updated to integrate recent studies that impact asthma management.[6] The importance of guidelines in asthma management is addressed by Allan Becker in Chapter 29.

In managing asthma today the focus is on achieving asthma control through an effort to minimize asthma impairment, specifically factors that affect day-to-day symptoms, and risk for future asthma events, such as asthma exacerbations,

https://CafePezeshki.IR

progression and adverse effects of medications. The issues for current management in young and older children include asthma worsening due to exercise, infection and living in the inner city, as well as severe asthma are comprehensively addressed in Chapters 31–34, 36 and 37.[7,8] Up to date information related to immunology and pulmonary physiology have been summarized (see Chapters 28 and 30). Information is also provided on methods to improve asthma management by improving medication adherence (see Chapter 38), as well as supporting students with asthma through school-centered asthma programs (see Chapter 35).

Some key observations have been made that can be useful in designing strategies for future asthma management, including the variability in response to medications, the association of a positive response to certain biomarkers and patient characteristics, and the potential to utilize intermittent inhaled corticosteroid therapy in place of or in addition to daily administration of inhaled corticosteroids. There is growing concern about the management of patients with difficult-to-control asthma. Of interest, new medications have been developed and the positive response to them have been linked to certain biomarkers, e.g. sputum or blood eosinophil count with anti-IL 4 therapy and serum periostin with anti-IL13 therapy.[7,8]

For the future, there is emerging concern regarding the potential for overlap of asthma and chronic obstructive pulmonary disease (COPD) in certain patients, called the 'asthma-COPD overlap syndrome', and growing interest in preventing this phenomenon.[4] There is also a growing need to address the special needs of children and asthma management must be viewed across the ages. Of great interest is the development of strategies to prevent asthma.[9,10]

Key Steps in Moving Asthma Care Forward

MANAGED CARE TO ORGANIZED CARE

The USA is gradually moving from a system of managed care to one of more collaborative care. In the managed care system, the care of the patient is directed toward the medical home where the primary care physician oversees the direction of care and is responsible for a number of individuals and their ongoing care, including referral to specialty care when needed. The reimbursement system is changing from a fee per service to a certain cost per individual. However, the specialist still is largely paid on a fee per service basis for medical consultations and procedures. The next step is to integrate the specialist into the system and creating what is called a medical neighborhood in order to provide comprehensive care and reimbursement; this is called bundled care. However, it will be a challenge for each specialty area to determine where it fits in this system of care.[11] For example, for asthma care, specialty areas include allergy and immunology and also pulmonary medicine. In this setting, either specialty or both working together could oversee the care of patients with asthma within a certain medical system. That is, the specialist or preferably a multidisciplinary team would monitor the care of all asthma patients within the medical system, including those seen personally. This requires careful analysis of data regarding patient visits, medical costs and urgent care utilization within a system. These are all indicators of asthma control for individual patients and within a medical system.

PERSONALIZED MEDICINE

Over the past 15 years, only one new medication has been introduced for asthma therapy, namely anti-IgE and specifically omalizumab. The use of this medication is linked to having a certain level of serum IgE as well as demonstration of specific allergen sensitivity. On the horizon is the imminent approval of a set of new medications that are directed toward blocking key cytokines related to asthma. Of interest, the response to these medications has been linked to the level of the identified biomarkers. For example, the use of lebrikizumab, an anti-IL-13 antibody, has been linked to a high level of periostin or exhaled nitric oxide, while the response to anti-IL4 and anti-IL5, e.g. dupilumab and mepolizumab, has been linked to a certain level of sputum or blood eosinophils.[12,13] These observations have brought attention to the use of biomarkers to predict response to asthma therapy. Since these medications are likely to be expensive, at least initially, there is a need to develop criteria to allow the careful selection of patients for their use, and also to realize that the cost of the medication may greatly outweigh the anticipated savings for medical care. A potential benefit, however, is that perhaps one of these medications when used early in treatment may actually alter the course of the disease. This would represent lifetime cost savings rather than immediate cost savings related to reducing costs of hospitalizations over a short-term period, such as a year or two. This will raise questions regarding reapportioning the costs of care.

In the interim, it will be important to maximize the use of available medications before considering these more expensive alternatives, including improved methods to enhance adherence to conventional therapy. To do this, we will need to standardize and harmonize medical care, while improving communication and setting up systems of collaboration.

SUPPORT SYSTEMS FOR MEDICAL CARE

Chapter 35 on school-centered asthma programs raises a number of issues around asthma care. Schools can be a source of support for the medical system in monitoring asthma control, education of children regarding the management of chronic disease and reporting back to the clinician certain observations related to the child's medical care.

In order to do this successfully, we must *standardize* medical forms of communication, such as the so-called asthma action plan that is designed for administering medications in the school setting as prevention for exercise-induced asthma, as well as administering rescue therapy for symptoms. Some experts prefer to call this form the school asthma care plan. This differs from the comprehensive treatment plan that the patient receives from the clinician and could be called the home asthma treatment plan. In order to appreciate and support the medical treatment plan, it would be useful for the school, particularly the school nurse and the medical support team in the school setting, to see both treatment plans. The school treatment plan gives the directions for school-administered medications in the school setting, e.g. by the nurse or a designated assistant. Access to the home treatment plan would allow the school nurse to see the whole management plan in order to assess adherence to the plan in the school setting and support appropriate medication inhaler technique and asthma knowledge. Standardizing the name for each treatment plan as well as standardizing the

https://CafePezeshki.IR

format for these two communication documents is necessary and will help in communication electronically.

In addition, it would be useful if the electronic medical record systems could alert clinicians to potential risk factors for loss of control, e.g. a certain constellation of symptom clusters, seasonal exacerbations, or biologic risk factors, that could help predict an asthma exacerbation in order to take steps to prevent it. Systems must continue to be standardized as we gain more knowledge about risk factors for exacerbations, as well as progression and even onset of disease.

In order to effectively communicate within the system and co-manage patients, we must also improve methods to *harmonize* asthma care. Asthma guidelines have helped in designing a uniform approach to management. Asthma guidelines are available for individual countries and are sometimes modified for regional application. The Global Initiative for Asthma has helped to present a global strategy for asthma care.[4] In regards to a harmonized implementation effort, the Easy Breathing program is a cost-effective, evidence-based, asthma management program for healthcare providers that includes training and tools to improve the recognition and management of childhood asthma.[14,15] The program has led to improvements for inner city children with asthma in reducing hospitalizations, outpatient visits and asthma-specific emergency department visits, which have varied among black and Hispanic children. [15] Additional information about the Easy Breathing program can be obtained from their website at http://www.connecticutchildrens.org/community-child-health/easy-breathing-asthma/.

The asthma specialist is in a unique position and has the expertise to provide guidance and oversight for asthma care in the medical system, including the support of school-centered asthma programs. It is important for the specialist to encourage *harmonization* of the approach to asthma care by applying an evidence-based guidelines approach to asthma care. This will lead to consistency across the community and less confusion. There is also a need for ongoing bidirectional *communication* between community asthma care providers and the schools, which should prompt a spirit of *collaboration* and *coordination* in managing asthma among schools, healthcare providers and families. We must also improve electronic communication between asthma specialists and primary care providers within medical systems and across medical systems. Key stakeholders in this coordinated effort include students, families, school nurses (central role for the school), school administration, school personnel (teachers, coaches, etc.), clinicians including primary care physicians and specialist care, and payers (families' ability to acquire multiple quick relief inhalers, reimbursement for disease management, case management and care coordination efforts). A concerted effort should result in better asthma control with reduced costs from urgent care utilization.

Our own experience with a collaborative program being implemented and evaluated in Denver, Colorado and Hartford, Connecticut, 'Building Bridges for Asthma Care', is an attempt to improve communication between schools and medical care providers. The Building Bridges school-centered asthma program incorporates many of the effective components described above, including case management according to the asthma risk level for the individual student, use of school asthma care plans, onsite quick relief inhalers, asthma education for students, families and school staff, and the build out and optimization of existing information technology platforms in schools (see Chapter 35). This program is the first to combine a multifaceted school-centered program and a multifaceted asthma care provider program, while identifying barriers to overcome and the potential synergies to be realized. Models of asthma care that place schools at the center or core of the model and coordinate evidence-based asthma care are applicable nationwide and may serve as a model for managing other chronic illnesses.

Our Building Bridges program seeks to utilize school nurses to identify students with asthma based on parent history, assess their level of severity based on a set of key questions, monitor their school absence, physical activity and ongoing asthma control as well as school performance, and communicate this information to their parents and healthcare provider. It is hoped that this level of communication will be useful in better preparing students for school and also preventing seasonal exacerbations. Communication between the provider and the school may also help to support the overall school and home asthma care plan. In certain situations, directly observed therapy is needed to assure adherence to the treatment schedule.[16] An important feature of any school-centered asthma program is finding sustainability mechanisms. This may come through reorganization of school staffing or some unique mechanisms of payment to supplement schools that are struggling with budget appropriations. Indeed, communication and collaboration among key stakeholders are essential in providing students with the necessary assistance in managing their asthma in the school setting to improve school attendance and academic performance, and to encourage physical activity to reduce the health risks of obesity. It is also our hope that national medical and nursing societies will support these efforts and make them ongoing community engagement and quality improvement features of their continuing education and maintenance of certification programs.

Addressing Asthma Mortality, Morbidity and Origins

Another quote from Charles Dickens, this time from 'Great Expectations' is, 'Suffering has been stronger than all other teaching, and has taught me to understand what your heart used to be. I have been bent and broken, but – I hope – into a better shape.' Indeed, we have learned a lot from past suffering related to asthma, and we now look to a brighter future. Effective treatments have now been developed not only to relieve but also to prevent symptoms including exacerbations. However, much has still to be learned if the progression of the disease is to be altered and eventually its onset prevented. The tools to accomplish this task are being developed.

There are reasons for optimism that overall management of asthma can improve. For example, there are devices that can effectively measure adherence to asthma therapy. Prompts can then be included in order to remind the patient to take his/her medication and the clinician can use motivational techniques to encourage better self-care. Telemedicine is being developed in order to facilitate communication between clinicians at a distance and also for patients from the home or school setting to their own clinician.

In relation to the science around asthma care, a systems biology approach is being developed to understand better ways to predict response to medications and also to monitor disease

https://CafePezeshki.IR

activity. However, such approaches will not only add to the cost of medical care but will lead to the implementation of medications, such as immunomodulators, that may be more costly than conventional therapy. The benefits and risks of such an approach will need to be carefully assessed in terms of lifetime benefits. The pharmaceutical industry has responded by developing these new medications, and partnerships with academic centers and providers will be necessary in order to advance this area of discovery in order to meet regulatory requirements and assess cost-benefit. This will involve use of such medications at the early stage of disease onset or perhaps even before it occurs if indicated by a certain risk profile. Hopefully, this new form of treatment for childhood asthma coupled with preventative measures, such as reduction in tobacco smoke exposure and smoking avoidance, will lead to an improved quality of life and reduced risk of chronic obstructive airway disease as children reach adulthood. If executed effectively, this effort should have a marked impact on reducing the prevalence of lung disease in the future and the consequent burden of respiratory illness on society.

40 Mucosal Immunology: An Overview

M. CECILIA BERIN | MIRNA CHEHADE

KEY POINTS

- The gastrointestinal associated lymphoid tissue protects the vast surface of the gastrointestinal tract from pathogens while remaining tolerant to antigens from food and commensal microbiota.
- Several specialized antigen uptake mechanisms exist for the sampling of luminal contents by antigen-presenting cells in the Peyer's patch and lamina propria.
- Antigen-presenting cells of the gastrointestinal tract, including dendritic cells and macrophages, maintain immune tolerance to antigens from food and commensal microbiota by generating regulatory T cells.
- Immune homeostasis is regulated by factors in the diet and by the microbiota.
- Secretory IgA provides an immune barrier by excluding antigens from uptake, but antibodies including IgA, IgG and IgE can function as antigen uptake mechanisms across the intestinal epithelium.

Introduction

The gastrointestinal (GI) tract is the largest immunologic organ in the body. The small intestine itself has the largest surface area in the GI tract due to structural features including villi and microvilli. The purpose of this extensive surface is to facilitate nutrient absorption from ingested foods. From the stomach to the rectum, a single layer of columnar epithelial cells separates the external environment of the gastrointestinal lumen from the body proper. The lumen contains a myriad of microorganisms and dietary proteins. The challenge from an immune perspective is to guard the extensive surface area of the GI tract from breaches by microorganisms, in particular pathogenic microorganisms. In the small intestine, the main antigenic load is from ingested food. Along the proximal to distal axis, the food antigen load decreases as it is digested and absorbed, but the microbial load increases. In the large intestine, there are 10^{10}–10^{12} organisms per gram of dry luminal contents.[1] The intestinal immune system must remain nonreactive or tolerant to antigens from food or commensal flora, yet retain the ability to mount a protective immune response to enteropathogens. This function is accomplished by the gastrointestinal associated lymphoid tissue (GALT) that has adapted to its unique environment.

Structure of the Gastrointestinal Associated Lymphoid Tissue (GALT)

The gastrointestinal tract has several types of organized lymphoid tissue comprising the GALT. Underlying the intestinal epithelial layer is a loose connective tissue stroma called the lamina propria (LP), containing a resident population of CD4 and CD8 T lymphocytes, plasma cells, macrophages, dendritic cells (DCs), eosinophils and innate lymphoid cells (ILCs). The LP of the small and large intestine is drained via lymphatics that empty into the mesenteric lymph nodes (MLN). Migratory DCs capture antigens in the LP and deliver those antigens to the MLN. The MLN is a typical secondary lymph node with organized B cell follicles and paracortical T cell areas. Peyer's patches (PP) are lymph nodes found within the mucosal wall and have direct access to the intestinal lumen. PP are large and visible by eye as bulges on the serosal surface of the intestine. In addition to PPs, the intestine contains smaller structures called isolated lymphoid follicles (ILF), each containing a single B cell follicle with an overlying follicular epithelium. Mouse intestine contains an abundance of these small organized structures.[2,3] The precursor of the ILF is the cryptopatch, comprised of clusters of lymphoid tissue inducer cells.[4] Bacterial signals promote the enlargement of the ILFs through the recruitment of B cells.[5,6] The MLN, PP and ILF comprise the inductive sites in the gastrointestinal tract. In addition, T lymphocytes are normally found between epithelial cells (intraepithelial lymphocytes, or IELs). IELs are predominantly $CD8^+$ T cells in the small intestine and have an oligoclonal repertoire. The immune cells of the LP and the IELs comprise the effector cells of the GALT and are responsible for both the maintenance of tolerance to harmless antigens and immunity against pathogens. Figure 40-1 shows a schematic of the structure of the GALT.

Mechanisms of Antigen Sampling in the Intestinal Mucosa

Food protein antigens are digested by a combination of gastric acid, pancreatic proteases and brush border peptidases, resulting in a mixture of amino acids and di- and tri-peptides, which are then absorbed by the intestinal epithelial cells. Dietary antigens that escape proteolysis in the lumen can be taken up by the intestine in various ways. Soluble antigens are taken up by enterocytes via fluid phase endocytosis by the microvillous membrane, transported in small vesicles and larger phagosomes, and then digested when lysosomes combine to form phagolysosomes. Intact molecules that remain after digestion are deposited in the extracellular space by exocytosis.[7] As a result, approximately 2% of intact proteins reach the intestinal lymph and portal circulation under physiologic conditions.[8] Goblet cells have also been identified as portals of uptake of soluble antigens, delivering these antigens to subepithelial DCs.[9]

Particulate antigens are poorly sampled by enterocytes, where the glycocalyx provides a barrier to even relatively small particles.[10] PPs are overlaid by specialized epithelial cells, referred to as membranous or microfold (M) cells.[11] M cells that

https://CafePezeshki.IR

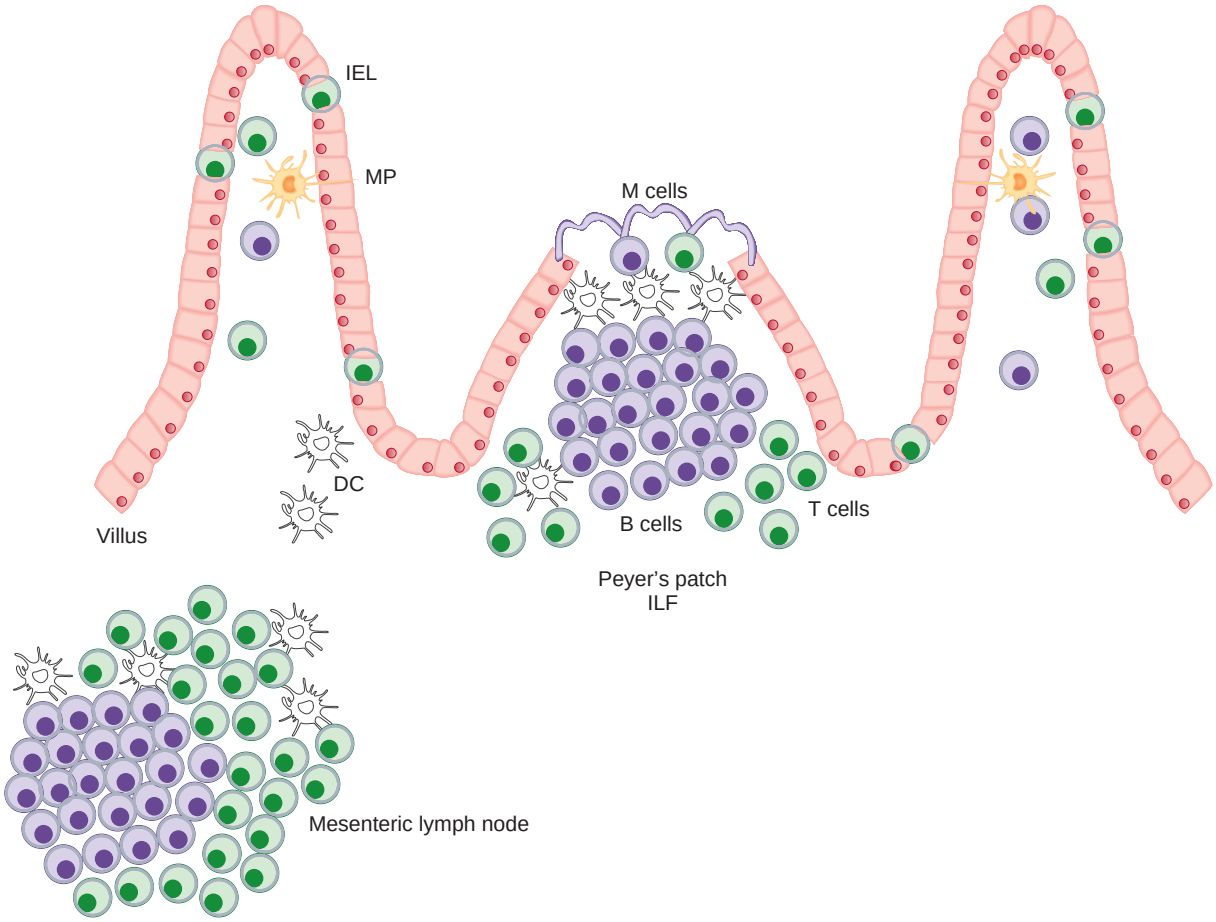

Figure 40-1 Structure of the GALT. Organized lymphoid structures in the gastrointestinal tract include the mesenteric lymph node (*MLN*) that drains the mucosa via the lymphatics. Peyer's patches and isolated lymphoid follicles (*ILF*) are present within the mucosal wall and are covered by specialized antigen sampling cells called M cells. Dendritic cells (*DC*) continuously migrate from the lamina propria into the MLN to present antigen. Organized lymphoid structures contain B cell follicles surrounded by T cell areas. Within the lamina propria are scattered T cells, B cells, macrophages (*MP*) and DCs. A population of intraepithelial lymphocytes (*IEL*) is also found through the gastrointestinal tract. A single layer of columnar epithelium separates the mucosal immune system from the luminal contents.

overlay PPs have a reduced glycocalyx layer and shortened microvilli that allow for binding of particles that cannot adhere to enterocytes.[10] In addition, they have a sparse flattened cytoplasm and enhanced endocytic activity, allowing rapid antigen delivery into the subepithelial dome region of the Peyer's patch. The subepithelial dome is rich in DCs that process and present antigen to T lymphocytes or transfer antigen to B lymphocytes.

The intestinal mucosa is densely populated with a network of DCs that function to acquire antigen, migrate to T cell areas of lymph nodes, and present antigen to naïve T cells. They can acquire this antigen after it has been transcytosed across enterocytes, M cells or goblet cells as outlined above. In addition, mononuclear phagocytes with dendritic morphology have been shown to extend dendrites between enterocytes into the intestinal lumen.[12,13] These dendrites are functional, as antigen sampling extensions can acquire luminal bacteria.[12,13] This mononuclear phagocyte subset is more similar to macrophages than DCs by transcriptional profiling[14] and does not migrate to the lymph nodes under steady-state conditions.[15] These antigen-sampling resident macrophages provide antigen to DCs, which are the cells that carry antigen to the draining lymph nodes and can prime naïve T cells.[16] Figure 40-2 outlines these major pathways of antigen uptake.

Antigen transport across the intestinal barrier has been shown to be altered by immunization or allergic sensitization, either enhancing[17,18] or inhibiting[19] uptake. As discussed in detail later, IgA-, IgG- and IgE-facilitated antigen sampling have been documented in the intestinal mucosa.

Normal Immune Response to Sampled Antigens in the Intestine

Food contains a diverse mix of antigens that are capable of stimulating immune responses if administered by other routes. Administration of antigens by the oral route is one of the most effective means of inducing tolerance. The process of oral tolerance was first defined experimentally in laboratory rodents that displayed systemic unresponsiveness to immunization with antigens to which they had previously been fed. Tolerance can be transferred to a naïve animal by transferring T lymphocytes,[20,21] demonstrating that this is an active immune-mediated process. Oral tolerance has also been demonstrated in humans

https://CafePezeshki.IR

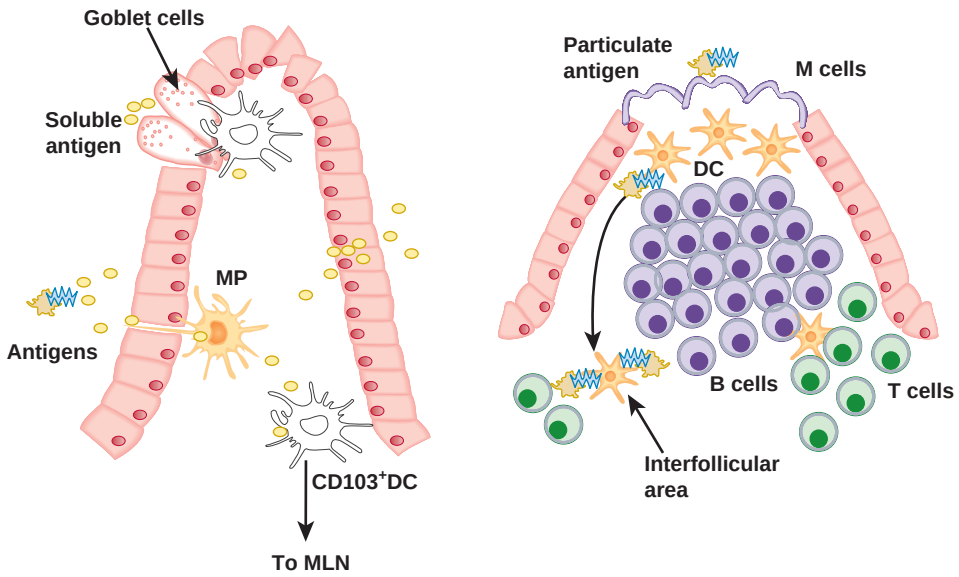

Figure 40-2 Antigen uptake in the intestine. In the intestinal villus (left), antigen can reach subepithelial dendritic cells (*DCs*) by several routes. Macrophages (*MP*) can send extensions between enterocytes to sample particulate antigens directly from the lumen and transfer these antigens to DCs. Alternatively, soluble antigens can be taken up by fluid phase endocytosis by enterocytes and be deposited in the lamina propria for uptake by macrophages or DCs. Goblet cells can also function as conduits for delivery of antigen to DCs. DCs migrate from the lamina propria to the mesenteric lymph node (*MLN*), where antigen can be presented to naïve T cells. In the Peyer's patch (right), M cells are specialized for uptake of particulate antigens that are delivered to DCs in the subepithelial space. These DCs can then traffic to the interfollicular areas of the Peyer's patch for presentation to T cells (green) or interaction with B cells (blue).

by feeding a neo-antigen prior to immunization with that antigen.[22,23]

Several different phenotypes of regulatory T cells have been shown to contribute to oral tolerance induction to fed antigens, including $CD8^+$ T_{REGS},[24] and different subsets of $CD4^+$ T_{REGS}.[20,21] Of the $CD4^+$ T_{REGS}, T helper 3 (Th3) cells and $Foxp3^+CD25^+$ cells have been described as contributing to oral tolerance to fed antigens. Th3 cells produce TGF-β together with IL-4 and IL-10, can be identified by surface expression of latency-associated peptide (LAP), and were first described using myelin basic protein (MBP)-specific $CD4^+$ T cell clones from the mesenteric lymph nodes of MBP-fed mice. Adoptive transfer of these cells from MBP-fed mice suppressed experimental allergic encephalomyelitis, an experimental model of multiple sclerosis.[25] Inhibition of TGF-β with neutralizing antibodies can abrogate tolerance responses in this model.[26,27] $CD25^+Foxp3^+$ T_{REGS} include both thymic-derived natural T_{REGS} (nT_{REGS}) and induced T_{REGS} (iT_{REGS}) generated in the periphery. There are data both for and against a role for nT_{REGS} in oral tolerance.[26,28] Feeding mice induces a population of antigen-specific T regulatory cells that express similar markers as natural T regulatory cells ($CD25^+$, $Foxp3^+$ and CTLA-4) and mediate regulatory responses via TGF-β but not IL-10.[26] Specific depletion of all $Foxp3^+$ T cells, followed by a rest period to allow nT_{REGS} to rebound, provides supporting evidence that iT_{REGS} are the most critical regulatory population mediating oral tolerance.[29] Tr1 cells are another regulatory subset that secrete IL-10. Although several studies indicate that IL-10 is dispensable for the induction of oral tolerance to foods, IL-10 is critical for the suppression of inflammatory responses initiated by the intestinal microbiota.[30]

Naïve T cells must be instructed to become regulatory in phenotype rather than becoming effector Th1, Th2 or Th17 cells. There is growing evidence that the milieu in which food antigens are presented to the naïve T cells by DCs is a critical factor promoting the development of regulatory T cells in the intestine.

The Role of Intestinal Dendritic Cells in Tolerance and Immunity

An abundant network of DCs surrounds the epithelium and fills the lamina propria. The role of DCs in both tolerance and immunity in the intestinal mucosa was first explored using the growth factor FMS-like tyrosine kinase 3 ligand (Flt3L) to expand the DC population in mice. Flt3L treatment enhanced tolerance responses to an innocuous antigen when it was delivered orally.[31] In addition, when antigen was administered with adjuvant to elicit protective immunity, DC expansion also enhanced that response.[32] These studies show that, like elsewhere in the body, DCs are essential for the initiation of an active $CD4^+$ T cell response, whether regulatory, or effector Th1, Th2 or Th17 in nature.

In the lamina propria, DCs bearing the marker CD103 are derived from DC progenitors and constitutively express CCR7, a chemokine receptor required for lymph node homing.[33] These $CD103^+$ DCs are required for the generation of oral tolerance.[15,34] $CD103^+$ DCs from the mesenteric lymph node preferentially induce the development of $Foxp3^+$ regulatory T cells that express chemokine receptors and adhesion molecules that support homing back to the intestine. This resulting phenotype is induced by release of retinoic acid and expression of TGF-β by the DCs.[35,36] The regulatory activity of these DCs is modified by environmental factors. Local tissue factors, including the cytokine GM-CSF[37] and mucins produced by the epithelium,[38] enhance the regulatory function of $CD103^+$ DCs. In contrast, administration of the mucosal adjuvant cholera toxin can

https://CafePezeshki.IR

modify these CD103$^+$ DCs into immunogenic rather than tolerogenic DCs.[39]

Macrophages Have a Regulatory Phenotype in the Intestine

Macrophages are the most abundant phagocytic cells resident in the small and large intestinal LP. They form a band of cells directly beneath the surface epithelium distinct from the localization of DCs.[40] Like DCs, macrophages can take up antigen and present it to T lymphocytes; however macrophages are not migratory, and do not reach lymph nodes for interaction with naïve T cells. Macrophages from the human intestine are adept at both phagocytosis and killing of microbes after uptake.[41,42] Therefore, they function as a secondary barrier after the epithelium in preventing the influx of microbes from the gut lumen into the body proper. Macrophages from the intestinal mucosa of mouse and human are nonresponsive to microbial stimuli compared to monocytes or macrophages from other sites.[42,43] This was shown to be due to TGF-β released from the intestinal stroma in humans[42] or autocrine effects of IL-10 in the mouse.[43] IL-10 is clearly important for immune homeostasis in the intestine because mice lacking IL-10 develop spontaneous colitis,[44] as do mice lacking IL-10 receptor specifically in macrophages.[45] Although resident macrophages do not have access to naïve T cells to initiate tolerance to fed antigens, they play an important role in the expansion of T_{REGS} during the generation of tolerance.[29] CX_3CR1^+ macrophages extend dendrites across the epithelium to interact with luminal contents. In mice genetically deficient in CX_3CR1, these dendrites cannot form, and oral tolerance to fed antigens is impaired. The role of gastrointestinal DCs and macrophages in the generation of tolerance and immunity is outlined in Figure 40-3.

Homing of Lymphocytes to the Intestine

Lymphocytes that differentiate in the inductive sites of the GALT into effector or regulatory T cells or IgA-producing B cells home preferentially to the intestinal lamina propria to carry out their function.[46,47] Targeted homing of lymphocytes is determined by expression of specific adhesion molecules and chemokine receptors.[48] Homing to the intestine is mediated by the adhesion molecule α4β7 binding to MAdCAM on high endothelial venules.[49] In addition, the chemokine receptor CCR9 promotes migration to the small intestine where constitutive expression of the ligand CCL25 is found.[50,51] Migration to the large intestine is promoted by the chemokine receptor CCR10 binding to its ligand CCL28.[52,53] The intestinal migratory phenotype is imprinted on lymphocytes by stromal cells,[54] as well as the CD103$^+$ population of DCs in the MLN,[35,55] via a retinoic-acid dependent mechanism.

Microbial Regulation of Mucosal Immunity

The gastrointestinal mucosa is often described as being in a state of 'physiologic inflammation'. In mice, the genetic deletion of a wide range of immunoregulatory genes results in colitis, a phenotype that is commonly absent if the mice are raised in germ-free conditions.[56] Although microbial signals can induce inflammation and tissue damage if not appropriately controlled, these signals are also necessary for the health of the organism. Our intestinal microbiota contributes locally to the digestion of nutrients, regulates the epithelial barrier, and is essential for maturation of the mucosal immune system in addition to having systemic effects on metabolism and the neuroendocrine system.[57]

Mice reared under germ-free conditions have poorly developed lymphoid structures in the gastrointestinal tract, and colonization with a single strain of bacteria is sufficient to induce significant changes in gene expression in the intestinal epithelium and maturation of the mucosal immune system.[58] Different organisms have differing effects on the development of effector and regulatory responses in the gastrointestinal tract. Segmented filamentous bacteria that are in intimate contact with mouse intestinal epithelium promote the development of Th17 responses in the gastrointestinal tract.[59] *Bacteroides fragilis* and several Clostridia strains promote the development of regulatory T cells.[60,61] Humoral immunity is also significantly regulated by the commensal microbiota. Germ-free mice have

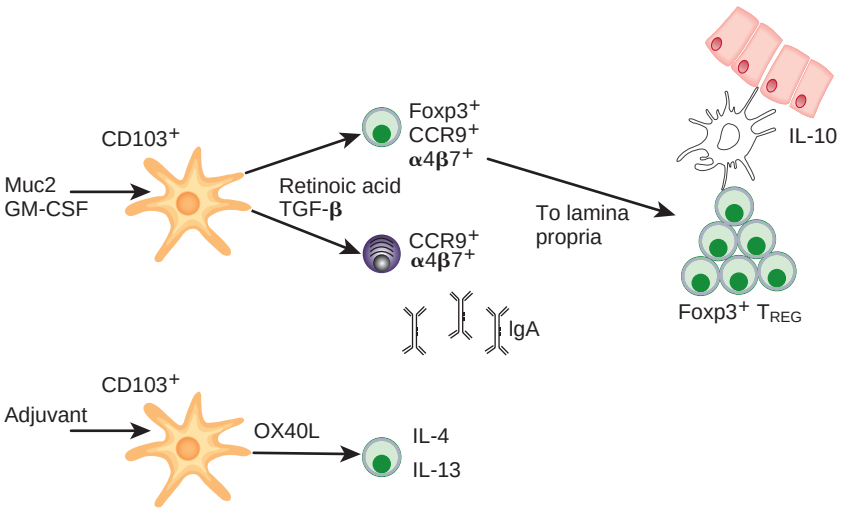

Figure 40-3 Function of antigen presenting cells in the intestine. A subset of DCs in the lamina propria express the marker CD103. These are migratory DCs that acquire antigen and traffic to the MLN. In normal conditions, CD103$^+$ DCs prime naïve T cells and B cells to generate a gut-homing phenotype expressing CCR9 and α4β7. CD103$^+$ DCs promote the generation of regulatory T cells expressing Foxp3, and promote IgA secretion from B cells. The T_{REGS} migrate to the lamina propria, where they interact with IL-10-$^+$expressing CX_3CR1^+ macrophages and are expanded in response to antigen. Mucosal factors such as GM-CSF and mucins (Muc2) promote the regulatory phenotype of DCs, while the presence of the mucosal adjuvant cholera toxin induces CD103$^+$ DCs to up-regulate OX40L and induce Th2 skewing from responder T cells.

https://CafePezeshki.IR

reduced levels of all isotypes of antibodies with the exception of IgE, which is uniquely elevated.[62] IgA production is carefully regulated by the commensal microbiota, and the specificity of the IgA response adapts to respond to changes in intestinal microbial populations.[63]

Cellular and humoral immune responses in the gastrointestinal tract are influenced by the commensal microbiota, and it is therefore not surprising that the microbiota is a key factor in the development of tolerance or allergy in the gastrointestinal tract. Germ-free mice have a reduced capacity for the generation of oral tolerance, and conversely show increased susceptibility to allergic sensitization through the oral route.[64] Colonization with normal microbiota, or with Clostridia strains, results in the expansion of regulatory T cells and the suppression of allergic sensitization.[64] Toll-like receptor (TLR)2, TLR4 and TLR9 are host receptors that have been shown to contribute to tolerogenic effects of the intestinal microbiota.[65–67] Metabolic products of the microbiota, such as short chain fatty acids, also promote a tolerogenic tone in the intestine.[68] Although the microbiota has generally been shown to be tolerogenic, susceptibility to food allergy has been shown to be transmissible in mice,[69] suggesting that there may be pro-allergenic bacterial strains as well as pro-tolerogenic strains, although these have yet to be identified.

Influence of Diet on Mucosal Immunity

Diet and the microbiota are the two factors with the strongest impact on the mucosal immune system, although we are only beginning to gain an understanding of the impact of diet on immunity. The microbiota is significantly altered by changes in diet,[70] demonstrating an indirect mechanism of dietary regulation of the mucosal immune system. Dietary components can also have direct effects on the mucosal immune system. The vitamin A metabolite retinoic acid is best known for promoting the generation of regulatory T cells as outlined above, although the impact of retinoic acid is not always regulatory. In the presence of the inflammatory cytokine IL-15, retinoic acid can amplify inflammatory responses and in this way has been shown to contribute to intestinal damage in a murine model of celiac disease.[71] Vitamin D promotes homing of lymphocytes to the gastrointestinal tissue and suppresses IL-17 production,[72] and vitamin D insufficiency results in significant reduction of a unique population of regulatory intraepithelial lymphocytes bearing the marker CD8αα.[73] Aryl hydrocarbon receptor ligands (AHR ligands) that are found in the diet are also regulatory[74] and promote the development of immune tolerance to foods.[75] In contrast to these regulatory elements of the diet, a high fat diet can have proinflammatory effects by altering cytokines from innate lymphoid cells that regulate epithelial barrier function.[76]

Humoral Immune Responses in the Intestine

The intestinal mucosa is a rich site of antibody production, particularly secretory IgA. Naïve B cells in the MLN and PP are activated by binding to their antigen, proliferate, and with T cell help differentiate into antibody-secreting cells or memory B cells. GALT DCs promote the differentiation of B cells into IgA-secreting cells, as well as up-regulating CCR9 and α4β7 on B cells to promote homing of cells to the lamina propria.[46] CCR10 is also expressed on a subset of antibody-secreting cells and contributes to homing to the large intestinal mucosa.[52,77] Immunoglobulins play an important role in neutralization of pathogens, and also function together with epithelial-expressed receptors as specific antigen-sampling mechanisms in the intestinal mucosa. IgA is the most abundant immunoglobulin produced within the intestinal mucosa, but there is also evidence for a significant contribution of IgG to host defense against enteropathogens. In the context of food allergy, IgE and its receptor CD23 also come into play as an antigen-sampling mechanism and inducer of inflammatory reactions in the intestine. Figure 40-4 shows the function of these immunoglobulin receptors in the intestine.

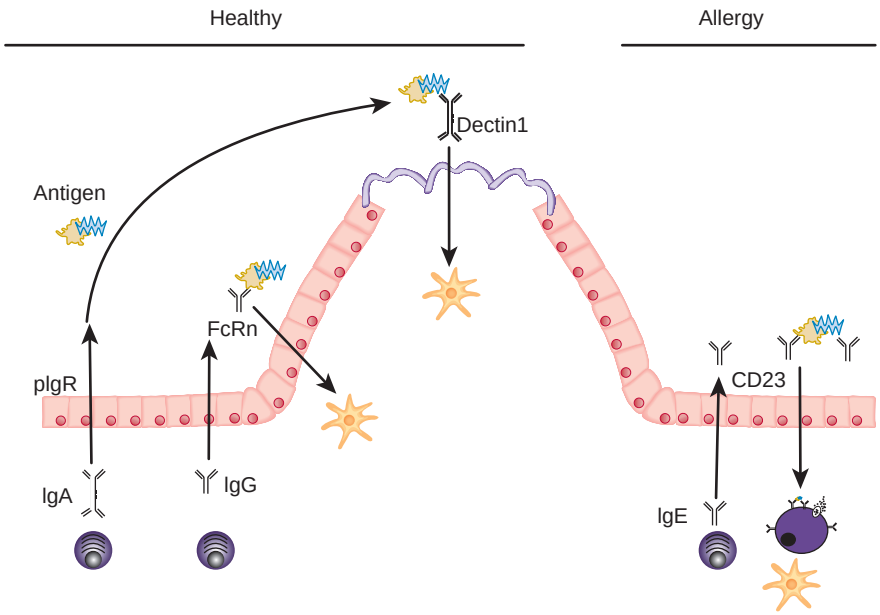

Figure 40-4 Immunoglobulin secretion and antibody-facilitated antigen uptake in the intestine. Epithelial cells express receptors for IgA (pIgR), IgG (FcRn) and IgE (CD23). All three receptors can facilitate the secretion of their respective immunoglobulins in a basal-to-apical direction. IgA can facilitate uptake of antigen by M cells through Dectin-1. FcRn captures IgG-antigen complexes for delivery to dendritic cells (DCs) and promotes the generation of tolerance to foods or immunity to pathogens. When allergen-specific IgE is produced and secreted (i.e. during food allergy), IgE-allergen complexes can be captured from the apical side by CD23 and transported to the basal side of the epithelium. IgE-allergen complexes can then degranulate effector cells or induce the migration of DCs through epithelial-derived chemokines.

https://CafePezeshki.IR

IgA/pIgR

Eighty percent of IgA-secreting cells are found in the gastrointestinal mucosa, and daily production of IgA outpaces that of all other immunoglobulin isotypes combined.[78] IgA in plasma occurs primarily as monomers, but IgA in mucosal secretions is comprised of polymeric IgA (2–4 molecules) joined at the Fc region by a joining 'J' chain and secretory component that is a fragment of the polymeric Ig receptor (pIgR). There are two IgA subclasses, IgA1 and IgA2, that differ in their resistance to intestinal proteases (IgA2 being more resistant than IgA1). pIgR is expressed on the intestinal epithelium and transports polymeric IgA from the basolateral face into the intestinal lumen. Pentameric IgM is also transported into the lumen via the pIgR. Binding of dimeric IgA and pentameric IgM to pIgR occurs through the J chain that connects the Ig subunits. Each molecule of pIgR can only perform one transport of Ig, as the extracellular portion is cleaved to form the secretory component.

Secretory IgA has been shown to selectively bind to M cells via the interaction of constant domains[79] with Dectin-1.[80] Antigens tagged to IgA are taken up by M cells and delivered to DCs in the PP[81] where they induce an immunoglobulin response. Thus IgA may selectively allow for controlled entry of antigens into the PP while preventing broad access to the remaining intestinal mucosa.

IgG/FcRn

Like IgA, IgG is also found in intestinal secretions in significant quantities. In rodents, the neonatal Fc receptor for IgG (FcRn) is expressed in the intestine prior to weaning and facilitates the transfer of passive immunity from the mother via colostrum. In humans, passive immunity is delivered via the placenta, but FcRn is expressed in the intestine and is maintained throughout adult life.[82] This suggests a function for FcRn beyond transfer of passive immunity. In vitro systems have shown that FcRn functions as a bi-directional transporter of IgG.[83] The development of transgenic mice expressing human FcRn into adulthood has uncovered a critical role for FcRn as an antigen-sampling mechanism in vivo. IgG is secreted into the intestinal lumen via FcRn, where it binds to its antigens and can be recaptured by FcRn and transported into the intestinal LP.[84] Antigen is then delivered to subepithelial DCs that can generate a functional T cell response. This pathway was shown to promote clearance of the murine enteric pathogen *Citrobacter rodentium*.[85] Induction of tolerance in the neonate by antigen exposure via IgG-containing breast milk has also been shown to be mediated via FcRn-facilitated uptake and delivery to DCs.[86]

IgE/CD23

IgE is not generally thought of as a secretory immunoglobulin, but it can be detected in the intestinal secretions and stool of subjects with food allergy.[87,88] The low-affinity IgE receptor CD23 is constitutively expressed by human intestinal epithelial cells.[89,90] Similar to studies with FcRn, CD23 has been shown to function as a bi-directional transporter of IgE across gastrointestinal as well as respiratory epithelial cells.[89,91]

Conclusions

The mucosal immune system is tightly regulated to prevent inappropriate immune reactions to food antigens or the commensal flora, and is responsible for guarding a vast surface area against pathogenic entry. Antigens can gain access to the mucosal immune system by a number of different mechanisms including direct DC uptake and antibody-facilitated antigen uptake. The normal response to food antigens is an active tolerance response mediated by regulatory T cells and induced by gastrointestinal DCs and macrophages. Microbiota and diet are critical factors in the maintenance of gastrointestinal immune homeostasis.

41 Evaluation of Food Allergy

S. ALLAN BOCK | HUGH A. SAMPSON

KEY POINTS

- A *food allergy* is an adverse health effect arising from an immune response that occurs reproducibly on exposure to a given food, whereas a *food intolerance* is an adverse effect due to a nonimmunologic response, e.g. metabolic, pharmacologic or toxic.
- Food allergies may be 'immediate' (IgE-mediated) or 'delayed' (non-IgE-mediated) in onset and induce a variety of symptoms involving the skin, respiratory or gastrointestinal tracts and/or cardiovascular system.
- A thorough and detailed history is the most important part of the evaluation and determines which laboratory tests should be ordered, which food challenges and treatments may be required, and the education that will be needed regarding the results.
- Prick skin tests and food-specific IgE levels confirm sensitization and provide some evidence on the probability of clinical allergy, but alone are never adequate to make the diagnosis of food allergy.
- The oral food challenge remains the 'gold standard' for diagnosing food allergy.

Introduction

It is now 40 years since the first double-blind placebo-controlled food challenges were performed and demonstrated that histories of adverse food reactions could be objectively confirmed or refuted.[1] Recently, new diagnostic tools have become available that may decrease the number of challenges required for accurate diagnosis and management. In addition, treatments for food allergy are being developed and studied, and while they are not quite ready for clinical use, these developments are exciting and offer hope that one day a treatment will end the impact of food allergy on patients' quality of life.[2]

The definitions of terms in this discussion are derived from and consistent with the 2010 Guidelines for the Diagnosis and Management of Food Allergy in the United States: summary of the NIAID Sponsored Expert Panel Report, and the recent Practice Parameter Update.[3,4]

'*Food allergy* is defined as an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food.'[3] These immune responses may be IgE-mediated, non-IgE-mediated or an apparent mixture of multiple mechanisms. The term *food intolerance* is used to designate a nonimmune mediated reaction that may include metabolic, pharmacologic or toxic mechanisms. Another important term is *sensitization*, which indicates that individuals may have demonstrable IgE or other antibodies or antigen-reactive cells in the absence of clinical symptoms. An immune-mediated food allergy requires both the presence of sensitization and clinical responsiveness when the food is ingested.

Prevalence

Current literature suggests that food allergy may affect up to 10% of the population, but probably not more than that percentage. Studies of prevalence have certain limitations, making them difficult to compare. In children, a 2009–2010 study estimated that 8% of the study population of children have food allergy.[5] In a Canadian study,[6] after adjusting for improbable reports of food allergy, it was estimated that 6.7% of the overall population, 7.1% of children and 6.6% of adults, had food allergy. Since these conclusions were based upon self-reporting, it is clear that they are estimates at best. McGowan et al[7] used the National Health and Nutrition Examination Study (NHANES) 2007–2010 data based upon specific food allergen IgE measurements and a specific set of definitions to arrive at an estimated prevalence of food allergy among children of 6.5%.

IgE-Mediated Symptoms (Box 41-1)

CUTANEOUS SYMPTOMS

Food allergy-induced skin symptoms generally fall into two main categories: atopic dermatitis and urticaria. Urticaria typically begins promptly after the ingestion of a known food allergen, is usually diagnosed early and the culprit food determined. Chronic urticaria is rarely due to a food allergen. Rarely, food additives have been reported to cause chronic urticaria in adults, but there are no systematically confirmed reports in children.

Atopic dermatitis has been shown to be exacerbated by food allergies in numerous, carefully controlled studies using double-blind, placebo-controlled food challenges. Food allergic reactions may trigger an eczematous rash in 30–40% of children with moderate-to-severe atopic dermatitis. In some situations, the onset of symptoms is subtle and somewhat delayed, with irritability and then itching being the first symptoms to appear, followed by erythema and/or urticaria preceding the more typical erythema and morbilliform eruption that may be most prominent the day after the offending food is consumed. There does not appear to be a single pattern of presentation, but careful observations by families can often make the connection, especially when parents are instructed on the typical presentation. The mechanisms of these reactions are considered in detail in Chapter 47.[8–10]

https://CafePezeshki.IR

BOX 41-1 DIFFERENTIAL DIAGNOSIS OF ADVERSE REACTIONS TO FOODS: IMMUNE

IgE-MEDIATED

- Immediate (gastrointestinal, respiratory, cutaneous, ocular, cardiovascular, anaphylactic)
- Immediate and late-phase (atopic dermatitis, allergic gastrointestinal disorders)
- Oral allergy syndrome or pollen-food allergy syndrome

NON-IgE IMMUNE-MEDIATED

- Celiac disease, dermatitis herpetiformis
- Food protein-induced gastrointestinal illnesses
  - Food protein-induced enterocolitis
  - Eosinophilic esophagitis, gastroenteritis (allergic)
  - Allergic colitis/proctocolitis
  - Food protein-induced enteropathy (milk, soy, others)
- Food-induced pulmonary hemosiderosis (Heiner's syndrome)

NON-IMMUNE-MEDIATED

- Toxic reactions
- Toxic reactions (food poisoning, e.g. scombroid fish poisoning)
- Non-toxic reactions
- Intolerances
  - Carbohydrate malabsorption (e.g. lactase deficiency, fructose deficiency, sucrase-isomaltase deficiency)
- Psychological reactions (strongly held beliefs)

RESPIRATORY SYMPTOMS

Respiratory symptoms of a food allergic reaction include those in the upper respiratory tract – sneezing, nasal pruritus, rhinorrhea and congestion, and periocular pruritus and tearing. In the lower respiratory tract, symptoms and signs include stridor, hoarse voice, cough, dyspnea and wheezing. It is important to note that a hacking staccato cough may be a sign of impending laryngeal obstruction without other symptoms and may lead to abrupt airway closure. Asthma is infrequently the sole manifestation of an allergic reaction to food. However when a patient with asthma has symptoms that are not responding in the usual fashion to treatment, a food reaction should be considered and the treatment approach altered to include injected epinephrine. Food allergy in individuals with asthma may predispose them to more severe episodes and may be a risk factor for more severe and fatal asthma.[11–19]

GASTROINTESTINAL SYMPTOMS

Immediate-onset gastrointestinal symptoms include nausea, abdominal pain and cramps, vomiting and diarrhea. Nausea and vomiting are often immediate – while the food is being consumed, raising the suspicion of food allergy, especially in an individual with a known food allergy. In individuals without known food allergy, these symptoms should raise the suspicion of a food allergy as often as 'food poisoning' is suspected. It should be noted that the gastrointestinal symptoms may not be accompanied by skin manifestations. Rapid resolution of gastrointestinal symptoms and return of appetite are frequently noted after a gastrointestinal food reaction. Diarrhea may occur immediately or be delayed for a few hours.

The issue of colic as a gastrointestinal food allergic reaction in infants remains controversial. With newer feeding guidelines suggesting that delaying food introduction may increase food allergy, it is often difficult to determine whether or not to try elimination diets.[20] However, when infants and families are under significant distress, a brief trial of dietary elimination may be warranted.[21–25]

Pollen/Food Allergy Syndrome (also see Chapter 46)

Pollen-food allergy syndrome (oral allergy syndrome) is a common disorder in which oral symptoms, itching of the throat and occasionally mild oral edema occur immediately upon the ingestion of certain foods, most commonly raw fruits and vegetables, but also certain nuts, e.g. hazelnuts and peanuts can trigger these symptoms. These complaints are due to specific IgE antibodies directed to aeroallergens that cross-react with certain food proteins. It is often useful to perform skin tests with fresh fruits and vegetables to confirm the diagnosis, and component protein testing for hazelnut (Cor a 9 and 14) and peanut (Ara h 8) will identify IgE to the birch pollen cross-reactive protein, Bet v 1. This constellation of symptoms is often present in children, but it is often unrecognized unless patients with pollen allergy (and/or their parents) are specifically queried about the presence of oral symptoms with certain foods.[26–29]

Chronic Constipation

A few controlled trials suggest that this is worth considering in youngsters having persistent constipation issues, but this remains controversial.[30]

Eosinophilic Esophagitis (see Chapter 45 and below)

Many children with eosinophilic esophagitis (EoE) have an IgE-mediated food allergy and atopy, but the underlying immunopathogenic mechanism of EoE is not IgE-mediated and routine allergy tests are generally not helpful in identifying foods provoking symptoms.

CARDIOVASCULAR SYMPTOMS

Allergic reactions to foods that involve the cardiovascular system in children usually appear as respiratory compromise first and then progress to a drop in blood pressure and shock, as contrasted with adults who may have the sudden onset of cardiovascular symptoms before any other symptoms occur.

ANAPHYLAXIS (see also Chapter 58)

The working definition of anaphylaxis is 'a serious allergic reaction that is rapid in onset and may cause death.'[31] The clinical criteria for diagnosing anaphylaxis are outlined in Chapter 58. Acceptance and use of these criteria should aid emergency responders in the rapid identification of anaphylaxis and prompt the institution of resuscitative measures, as validated in recent studies.[32,33]

Non-IgE Immune-Mediated Reactions to Food

Celiac disease is an autoimmune process that occurs when antibodies directed to gluten cross-react with epithelial cells in the gastrointestinal tract. When gluten-containing foods are

https://CafePezeshki.IR

removed from the diet, the gastrointestinal lesion resolves. An associated but less common condition is dermatitis herpetiformis that is often mistaken for atopic dermatitis. Virtually all individuals with celiac disease exhibit HLA-DQ2 or DQ8 genetic haplotypes.[34]

The eosinophilic gastrointestinal disorders (see Chapter 45), especially EoE, appear to be increasing. In the majority of children, food allergy is a significant trigger; however, it is not IgE-mediated and therefore current diagnostic methods for detection of IgE (skin tests and specific serum antibody measurements) are generally not helpful. A careful and detailed history may be the most important means of raising suspicion of the disease and prompting referral of the youngster for endoscopy. A pattern of seasonal exacerbation in some individuals raises the possibility of swallowed aeroallergens as triggers. It is often difficult to monitor the effectiveness of food elimination diets because there are no noninvasive tests to examine the esophagus for a response.

Another gastrointestinal syndrome that is immunologically mediated is food protein-induced enterocolitis syndrome (FPIES; see also Chapter 44). A careful history elicits a pattern of repetitive vomiting that is delayed by about 2 hours after the ingestion of culprit foods. Characteristics of FPIES that distinguish it from IgE-mediated gastrointestinal reactions are the delayed onset of symptoms, the lack of immediate recovery after the vomiting, and the continuous pattern of vomiting, pallor and hypotension in about 15% of cases. There is a helpful website for both parents and providers (fpies.org).[35,36] Food protein-induced proctocolitis is characterized by gross or occult blood in the stools with an otherwise healthy appearing infant (see Chapter 44).

Non-Immunologic Reactions

TOXIC REACTIONS

A number of toxic reactions have been described that could be confused with allergic reactions to food. Food poisoning due to bacterial contamination commonly provokes nausea, abdominal pain and often profuse diarrhea. Scombroid fish poisoning, due to histamine in poorly prepared histidine-containing fish, is less common and can more easily mimic an allergic reaction, including triggering skin changes that are not caused by bacterial food poisoning. These skin changes may include flushing, urticaria and angioedema. Respiratory symptoms may occur due to the large amount of histamine present.

NON-TOXIC REACTIONS

Auriculotemporal syndrome (Frey's syndrome) is triggered when foods that increase salivation cause a flushing reflex through the auriculotemporal branch of the trigeminal nerve resulting in a 'strap-like' rash on both sides of the face.[37] Gustatory rhinitis triggers rhinorrhea due to the ingestion of spicy foods.[38]

Lactose intolerance due to lactase deficiency is the most common carbohydrate malabsorption condition. When there is insufficient lactase in the intestinal mucosa, diarrhea and bloating ensue, and the condition may be confused with milk allergy. Depending upon the degree of lactase deficiency, some patients may tolerate small quantities of milk products without symptoms. Chronic diarrhea in young children may be due to carbohydrate malabsorption caused by fructose in fruit and especially fruit juice. The diarrhea, which often has an acrid smell, may be accompanied by a scalded skin appearance in the perianal and diaper area in the youngest children.

Psychological Reactions

Some parents harbor strongly held beliefs about specific foods that trigger various symptoms in their children, including behavioral changes. These beliefs are usually imposed on children by their parents and may lead to food aversions. Clinicians must be vigilant to ensure these beliefs and dietary restrictions do not lead to malnutrition or deficiency in specific nutrients. Occasionally, Münchausen syndrome by proxy must be considered, most often related to behavioral changes or other subjective symptoms.[39]

Evaluation

HISTORY

A thorough and detailed history is the most important part of the evaluation and will determine which specific laboratory tests to order, which food challenges and treatments may be required, and the education that will be needed regarding the results and avoidance of food triggers. The details to be ascertained include a detailed description of the following: symptoms that have been observed including the sequence of those symptoms; timing from onset of symptoms to their resolution; number of events that have occurred for each suspected food; possible ingestion of the food without symptoms; quantity of food eliciting symptoms, including the least amount (threshold) that has triggered symptoms if there has been more than one event; and associated factors such as exercise (in food-dependent exercise-induced anaphylaxis), medication (especially antireflux medication) and alcohol ingestion accompanying the suspected food.[2–4]

A history of anaphylaxis or a severe reaction increases the need for accurate details that include getting the ingredients of a meal from the facility (restaurant, home or school) where the reaction occurred. This may lead to suspicions about less obvious culprits, especially spices. Emergency department records may be helpful. It is also important in situations where wheezing has been part of the reaction, to inquire if the asthma symptoms responded in the usual manner for that individual. If not then a food might have been the trigger.

PHYSICAL EXAMINATION

A complete physical examination should be done in children with a history of a food allergic reaction; however, the exam is usually normal unless the reaction is occurring acutely. The major exception is atopic dermatitis, which is a chronic condition that may exacerbate during the acute reaction. Other stigmata to observe include a possible abnormal abdominal examination, signs of malnutrition, or significant failure to thrive in young children placed on a restricted diet.

LABORATORY STUDIES

Skin Testing

Skin testing by the prick/puncture technique is an easy to perform, cost-effective method for identifying sensitization to

https://CafePezeshki.IR

a food and for determining the probability that a food challenge is likely to be helpful.[40] Food allergens eliciting wheal diameters of at least 3 mm or larger than the negative control are considered positive test results. Negative skin tests have a high negative predictive accuracy, thus usually excluding food allergy to common foods. The negative predictive accuracy for children younger than 3 or 4 years of age tends to be lower than for older children.[2–4]

Food extracts that elicit a positive result in the absence of a strong history of clinical reactivity typically have a positive predictive accuracy of less than 50% and cannot be considered diagnostic of symptomatic food allergy. Some studies suggest that larger skin tests (≥ 8-mm wheals for some foods) correlate better with symptomatic food allergy, but there is no correlation between skin test size and severity of reactions.[41] If there is a history of a convincing allergic reaction to a food and the skin test is positive, the test may be viewed as diagnostic. There have been rare reports of adverse reactions to intracutaneous skin tests.[42]

Skin test outcomes can be variable depending on a few factors: reagents and devices used for testing, experience of the testing personnel and the interpretation of the test results. A strongly positive history incriminating a specific food in the face of a negative skin test must be evaluated further, e.g. food-specific serum IgE determination and/or physician-supervised oral food challenge.

Skin tests must be selected judiciously based upon the history rather than performing 'panels of food skin tests'. Selection of numerous foods to be eliminated from the diet based on large numbers of poorly selected skin tests may lead to diets that are difficult for families to follow and may eliminate foods that are clearly tolerated, making adherence to the diet poor.[43] In rare instances these diets can be so strict as to be nutritionally inadequate.[39,44]

Commercial skin test extracts vary considerably in allergen content. It is often very useful to use fresh fruits and vegetables for skin testing by the technique referred to as 'prick to prick'. In this technique the fresh food is 'pricked with the skin test device and then the skin is pricked immediately'. The results of these tests are very helpful when positive, but less so when negative.[45–47]

Limitations of skin testing include a number of variables: (1) commercially prepared extracts often lack labile proteins responsible for IgE-mediated sensitization to most fruits and vegetables (as noted above); (2) skin testing on skin surfaces that have been treated with topical steroids may induce smaller wheals than those measured on untreated skin; (3) negative prick skin tests with commercial extracts that do not confirm convincing histories of food reactions should be repeated with the fresh food before concluding that IgE is absent; and (4) long-term, high-dose systemic steroid therapy may reduce allergen wheal size.

Intradermal skin testing for food is not recommended because of its high false positive rate and its occasional association with systemic reactions. However, intradermal skin tests have been found to the useful in reactions to beef, pork and lamb due to reactivity to the meat proteins and galactose-α-1, 3-galactose.[48]

In Vitro Testing

Numerous studies have shown that specific serum antibody levels correlate well with the outcome of oral food challenges, especially for peanut, egg, milk and tree nuts, but there is less information on fish, shellfish and a few other foods. As with skin testing, detectable antibody in an immunoassay gives probability information on the likelihood of a reaction to a suspected food, but the history and food challenge remain crucial. Two early studies established 'cut-off values' giving 95% decision points, which suggested that values exceeding these levels obviated the need for a food challenge.[49,50] Since then, numerous other studies have been performed in various populations and with children of various ages.[40,51–55] Recent studies suggest that longitudinal monitoring of specific serum antibody levels may be useful in deciding when a child may have outgrown a particular food allergy and when a challenge is likely to be helpful in identifying the resolution of a food allergy. The rate of fall of specific serum antibody levels may be a useful predictor of the resolution of a food allergy. These decision points have also been used as 'cut-off' values to determine a reasonable level for doing food challenges based on the likelihood of resolution of a food allergy.[56] Two recent studies have formulated predictive curves for the probability of resolution of egg and milk allergy in young children.[57,58]

In vitro measurements are preferred in a number of situations: (1) patients with extensive dermatographism; (2) patients with extensive skin disease (atopic dermatitis or urticaria); (3) patients who cannot discontinue antihistamines; and more recently (4) use by nonspecialists who do not perform skin testing to evaluate children for potential food allergy.

There is no consensus on whether skin tests or specific serum antibody levels are most sensitive. However, at least one study has found that prick/puncture skin tests and immunoassays have similar sensitivities and specificities when compared with double-blind, placebo-controlled food challenges.[59] At present, most allergists use the two tests together to decide whether or not to do challenges (see below), and the probability of the challenge being positive for a particular food (Table 41-1).

A new and potentially important advance in in vitro diagnosis is the availability of component-resolved diagnostics for evaluation of food allergy (see Chapter 18). However, at this time only a limited number of food component proteins have been demonstrated to correlate well with clinical reactivity to food, e.g. peanut (Ara h 1, 2, 3, 6 and 8) and hazelnut (Cor a 1, 9 and 14).[60–63] As with other diagnostic tests, care needs to be taken when using component measurements to ensure that patients are not told a food is safe when it is not.[64]

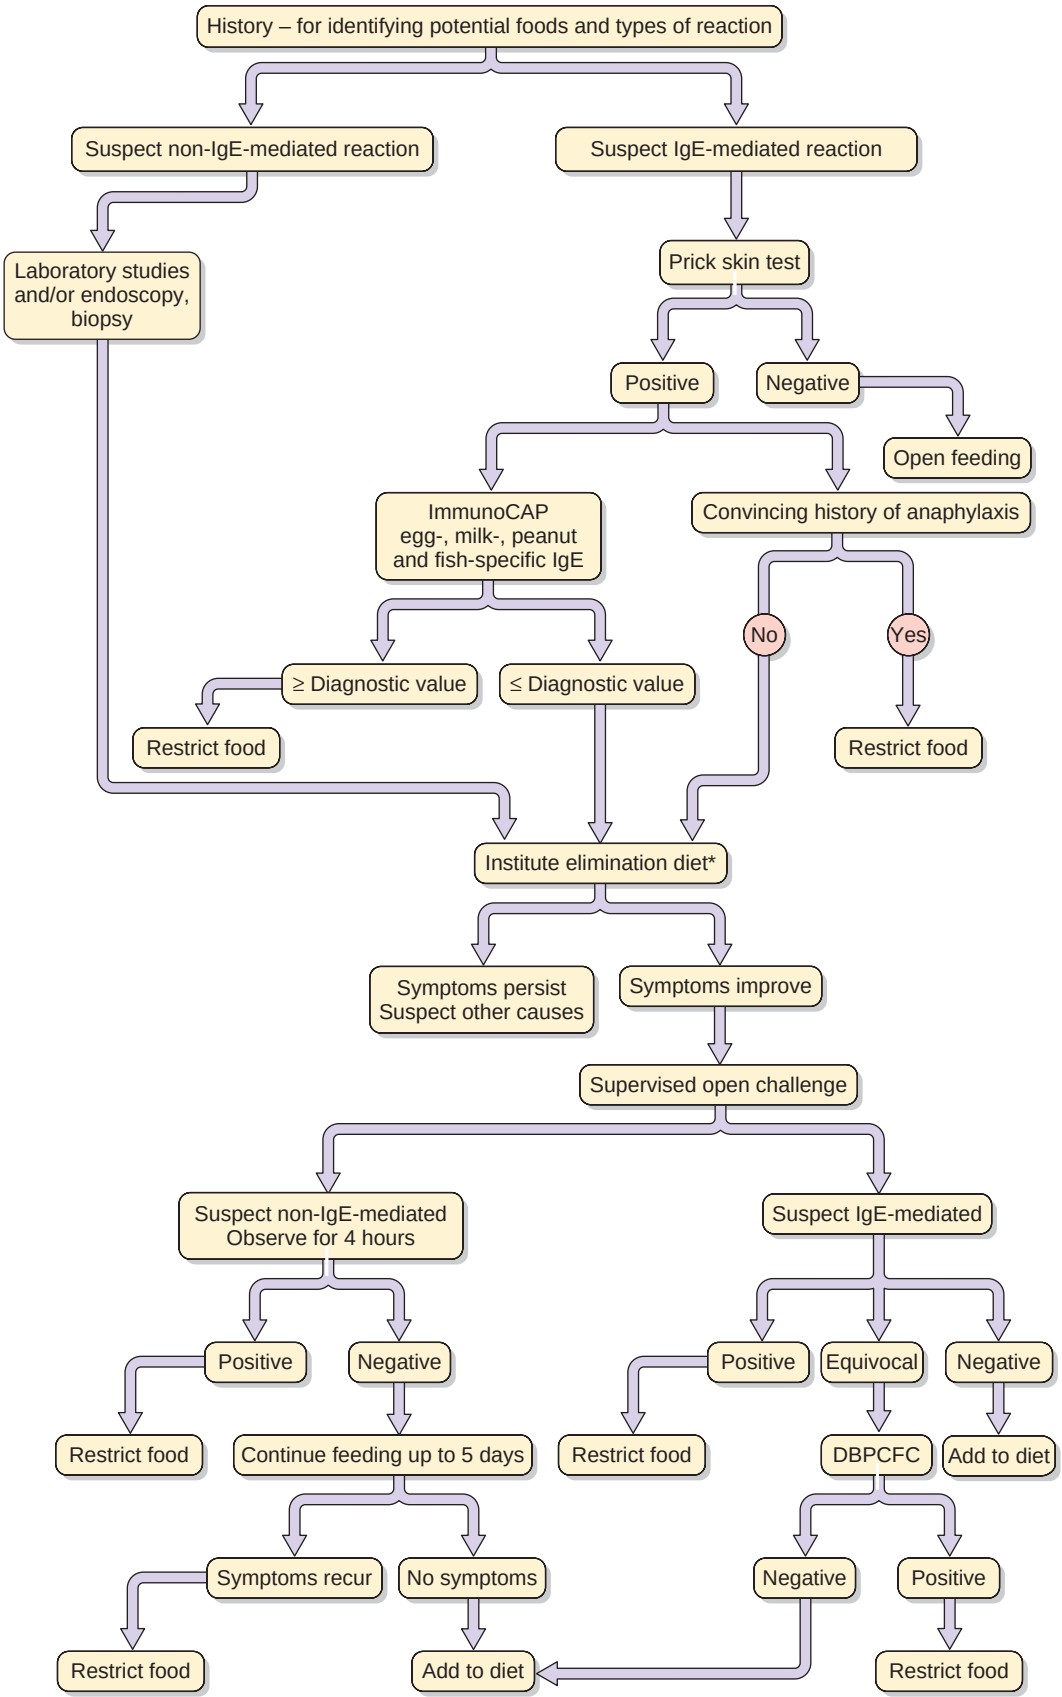
TABLE 41-1 Predictive Value of Food-Specific IgE

Allergen	Decision Point (kU_A/L)	Rechallenge Value (kU_A/L)
Egg	≥7.0	≤1.5
≤2 years old	≥2.0	
Milk	≥15.0	≤7.0
≤2 years old	≥5.0	
Peanut	≥14.0	≤5.0
Fish	≥20.0	
Tree nuts	≥15.0	<2

Adapted from Sampson HA.[50]

Note: Patients with food-specific IgE values less than the listed diagnostic values may experience an allergic reaction following challenge. Unless history strongly suggests tolerance, a physician-supervised food challenge should be performed to determine if the child can ingest the food safely.

https://CafePezeshki.IR



* Up to 2 weeks for IgE-mediated reactions; up to 8 weeks for non-IgE-mediated food hypersensitivity.

Figure 41-1 Algorithm diagnosing food hypersensitivity. *IgE* – Immunoglobulin E, *DBPCFC,* – double-blind, placebo-controlled food challenge.

https://CafePezeshki.IR

It has also been found that patients with antibodies to sequential (linear) epitopes in egg and milk, as compared to conformational epitopes to these foods, are more likely to exhibit persistent food allergy. Extensive heating (baking) of milk and egg changes conformational epitopes that are recognized by the majority of youngsters, allowing them to tolerate baked milk- and egg-containing products. Peptide microarray technology is characterizing patient heterogeneity and may more accurately predict clinically significant food allergy as opposed to just allergen sensitization.[65–78]

Serum IgG levels to foods have not been found to have clinical utility. All individuals with a normal immune system will produce some IgG antibodies to many food proteins.[79]

'Atopy patch tests' have not been found to be consistently useful for detection of clinically significant food allergy.[3,4,80]

FOOD CHALLENGES

The double-blind, placebo-controlled food challenge (DBPCFC) is the gold standard for precise diagnosis of allergic reactions to foods, and has provided a standard by which to evaluate other tests. All food challenges are designed to confirm or refute patient histories with the double-blind technique being the most precise, but also the most cumbersome. Recently, an attempt has been made to establish standard protocols. Challenges that use both active and placebo foods may generally be given on two separate days or one set (active or placebo) in the morning and the other set (placebo or active) after lunch.[81–91]

Unless a specific protocol is being used as part of a study, the quantity of food used in the challenge and the interval between portions is determined by the history elicited from the patient/parents. One approach is to start with an amount about one half of that thought to be lower than the amount previously triggering symptoms. Another approach is to make up the entire challenge and then give a certain percentage at the prescribed intervals. The time between portions should allow for the possibility of symptoms to occur before the next portion is ingested (as suggested by the history). When the challenge is negative or passed, up to approximately 8–10 g of dried foods or 60–100 g of wet food in a single portion, the challenge ends. A negative or passed challenge is not considered negative until the food is actually in the patient's diet in usual and customary portions on multiple occasions.

Single blind food challenges are useful in situations in which an objective result from the patient is important, such as a history of subjective symptoms, but it is less important for the individual providing the challenge to be blinded. The protocols may be the same or similar to those used for DBPCFC. This procedure may be useful when an open challenge (see below) is not likely to be accurate but the rigor of DBPCFC is not needed.

In the clinical setting, open food challenges are very useful for refuting food allergy histories and may be useful when the challenge is positive with objective symptoms that recapitulate symptoms that have been reported in the history. Open challenges are also useful for determining if there are foods that have never been ingested but for which there is a positive diagnostic test with low likelihood. For example a youngster with egg allergy who has never ingested peanut but who has a small positive skin test or a low level of specific antibody may be challenged under observation using an open challenge.

SUMMARY OF APPROACH

Figure 41-1 outlines a summary of the approach for the evaluation of children with a history of adverse reactions to food. A detailed history is followed by selection of skin tests and in vitro tests to be performed. The results of these tests allow selection of foods to be challenged under observation or reintroduced at home. Care must always be taken to be certain that any possible food culprit is introduced under observation.

42 Approach to Feeding Problems in the Infant and Young Child

ARNE HØST | SUSANNE HALKEN

KEY POINTS

- Infants most often develop food allergies in the order of exposure (e.g. milk, egg, fish, vegetables, etc.).
- The majority of infants and young children with food allergies have symptoms that affect at least two organs (cutaneous, gastrointestinal or respiratory).
- The most frequent allergic gastrointestinal reactions to food in infants and young children include colic, vomiting, diarrhea and failure to thrive. None of these is pathognomonic for allergy and may be caused by many other conditions.
- Food allergy should be suspected in cases of persistent severe symptoms, symptoms related to food intake, two or more different symptoms, two or more organ systems involved and allergic predisposition.
- Among children presenting with symptoms suggestive of food allergy, the diagnosis can be confirmed by controlled elimination/food challenge procedures in only about one third.

For the past decades, an increasing awareness of food allergy has emerged in western industrialized societies where confirmed food allergy seems to affect around 3% to 7% of young children and 3% to 5% of adults depending on population, methods and diagnostic criteria.[1,2] However, the public perceives food allergy to be much more common.[2–4] Given the public's frequent misperception that various mild symptoms are caused by food-induced allergic reactions, performing a careful evaluation and correct diagnostic procedures is imperative to avoid over-diagnosis, which may lead to malnutrition, eating disorders and psychosocial problems, as well as family disruption.[1,5] In contrast, under-diagnosis may result in unnecessary symptoms, growth failure and physical impairment.

True food allergies (i.e. immune-mediated reactions) are most often immunoglobulin E (IgE)-mediated reactions. However, non-IgE-mediated reactions may play a major role in delayed reactions.[1,5] It is evident that a correct classification of an adverse reaction to foods will depend on the extent and the quality of the diagnostic tests and procedures performed.

No single laboratory test is diagnostic of food allergy. Therefore, the diagnosis has to be based on strict, well-defined food elimination and oral challenge procedures, preferably double-blind, placebo-controlled food challenges (DBPCFCs) in children older than 2–3 years and in cases of subjective symptoms.[5–7] In infants, open, controlled challenges have been shown to be reliable when performed under professional observation in a hospital setting or a clinic.[8,9] Food allergy is primarily a problem in infancy and early childhood. Most often the infants develop food allergies in the same order as the introduction of foods into the diet. Thus, the prevalence of reactions to different foods depends in part on the eating habits of a given population.[10,11]

This review concentrates on gastrointestinal symptoms, which may cause suspicion of food allergy in early childhood, focussing on indications for food allergy evaluation. Specific disease entities, such as enterocolitis, proctocolitis, enteropathies and allergic eosinophilic esophagitis/gastroenterocolitis, are discussed in Chapters 44 and 45.

Frequency

In prospective studies, the incidence of cow's milk protein allergy (CMPA) during the first year of life has been estimated to be about 2% to 3% based on strict diagnostic criteria, as reviewed by Høst.[12] Other common food allergens in children are egg, peanuts, tree nuts, soy, fish and cereal grains.[11] The total cumulated incidence of food protein allergy during the first 3 to 5 years of life has been found to be about 4% to 7%.[2,13,14] In a prospective birth cohort study, the point prevalence of food allergy at 3 years was 2.3%.[4]

Adverse reactions to *food additives* have been demonstrated to affect less than 1% of unselected school children when using DBPCFCs.[15] The most common positive reaction was worsening of atopic eczema and urticaria in atopic children. Among children with atopic symptoms referred to hospital allergy clinics,[16] 23% were suspected of food additive intolerance. However, only 7% reacted to food additives on open challenge and only 2% had reproducible reactions when DBPCFCs were performed. Another study indicates that artificial colors and/or preservatives (sodium benzoate) in the diet may result in a dose-dependent increased hyperactivity in 3-year-old and 8–9-year-old children in the general population.[17]

In children with symptoms suggestive of food allergy, it has been possible to confirm the diagnosis in only about one third by means of controlled elimination/challenge procedures.[2,3,5,12,14]

Age at Onset of Symptoms

The age at which symptoms start depends on the time of introduction of the foods; infants frequently develop food allergies in the same order as that in which the foods have been introduced into the diet. Many prospective studies have demonstrated that symptoms in CMPA develop in early infancy, rarely after 12 months of age.[12] The onset of disease is, in most cases, closely related to the time of introduction of cow's milk-based formula. Allergy to hen's egg is also more common in younger children, whereas allergies against peanut, tree nuts, fish and

https://CafePezeshki.IR

TABLE 42-1 Age at Onset of Food Allergy Against Different Foods

Age (Years)	Food
0–1	Milk, eggs
1–2	Peanuts, fish in Scandinavian countries
>2	Fruits, legumes, vegetables
>3	Pollen-related cross-reactivities (oral allergy syndrome)

TABLE 42-2 Clinical Features of Food Allergy in Children and Their Most Frequent Mechanisms

CUTANEOUS REACTIONS	
IgE mediated	Urticaria, acute or chronic (rare) Angioedema Atopic dermatitis
Non-IgE mediated	Atopic dermatitis Contact rash (e.g. perioral flare due to benzoic acid in citrus fruits)
GASTROINTESTINAL REACTIONS	
IgE-mediated	Immediate gastrointestinal hypersensitivity (e.g. nausea, vomiting, diarrhea) Oral allergy syndrome Colic
Non-IgE-mediated	Allergic eosinophilic esophagitis, gastritis or gastroenterocolitis Enterocolitis syndrome Dietary protein colitis Dietary protein enteropathy
RESPIRATORY REACTIONS	
IgE-mediated	Rhinoconjunctivitis Asthma (wheezing, cough) Laryngeal edema Food-dependent exercise-induced asthma
Non-IgE-mediated	Pulmonary hemosiderosis (Heiner's syndrome [rare])
SYSTEMIC ANAPHYLAXIS	
IgE-mediated	Anaphylaxis Food-dependent exercise-induced anaphylaxis
OTHER REACTIONS	
IgE-mediated	Otitis media (secondary to allergic rhinitis and Eustachian tube dysfunction or an allergic middle ear inflammation)
Unknown mechanisms	Migraine (rare), arthritis (rare), Henoch-Schönlein purpura (rare)

shellfish, fruit and fruit juice often have a later age of onset.[11,14] In a Spanish study,[10] this relationship between the age of introduction of various foods into the child's diet and allergy to these foods was demonstrated (Table 42-1).

Clinical Features

The clinical features of food allergy in childhood are shown in Table 42-2. In early infancy the most common food allergy is to cow's milk protein. Similar to other food allergies, the majority have at least two symptoms and symptoms that affect at least two organ systems. About 50% to 70% have cutaneous symptoms; 50% to 60% gastrointestinal symptoms and about 20% to 30% respiratory symptoms.[8] Also, approximately 0.5% of exclusively breastfed infants may react to food protein in their mother's milk,[12] and in these infants severe atopic eczema is the predominant symptom.

Symptoms occurring within a few minutes to 2 hours after food exposure (i.e. 'immediate reactions') are mostly IgE-mediated, whereas symptoms occurring more than 2 hours after food intake are classified as delayed reactions and are typically not IgE-mediated. Late reactions may occur after many hours even up to a few days, such as in allergic eosinophilic gastroenteritis. Delayed reactions are mostly non-IgE mediated. Anaphylaxis has been reported with varying frequencies, reflecting differences in patient selection. It is clear that patterns of reactions to foods may vary due to different exposure levels and different time intervals between exposures, as well as different thresholds of reaction.

Immediate IgE-mediated reactions to foods often involve two or more target organs, such as the gastrointestinal tract, the skin and the lungs, and may result in a variety of symptoms, including life-threatening reactions such as exacerbations of asthma, laryngeal edema and anaphylaxis with cardiovascular collapse. An exception is the *food-pollen allergy*, or *oral allergy syndrome* (OAS), a mucosal equivalent of urticaria, which is described in Chapter 46. OAS is associated with allergic rhinoconjunctivitis and allergy to specific pollen, e.g. birch, ragweed and mugwort pollens, and is most often elicited by specific foods with pollen IgE cross-reacting with homologous proteins in fresh fruits or vegetables. After ingestion, pruritus and swelling in the mouth and oropharynx occurs, which may prompt the child to refuse the offending foods. However, in some cases OAS may progress to more severe reactions.[18]

Gastrointestinal Problems in Early Childhood

Gastrointestinal manifestations of food allergy can be classified as a continuum from clearly IgE-mediated to mixed reactions dominated by eosinophilic granulocytes, to clearly non-IgE-mediated reactions.[19,20] Immediate gastrointestinal hypersensitivity and oral allergy symptoms are mainly IgE-mediated; allergic eosinophilic esophagitis, allergic eosinophilic gastritis, and allergic eosinophilic gastroenterocolitis are mixed-IgE and non-IgE-mediated reactions, and food protein-induced enterocolitis, proctocolitis and enteropathy, and celiac disease are non-IgE mediated. The most frequent adverse reactions to food in the infant and young child are immediate IgE-mediated reactions with manifestations such as nausea, abdominal pain (colic) and vomiting within 1 to 2 hours after food intake, and diarrhea within 1 to 6 hours. The frequency of presenting gastrointestinal symptoms in infants with CMPA is shown in Table 42-3.

Among non-IgE-mediated disorders, food protein-induced enterocolitis and proctocolitis typically have their onset in early infancy, up to 6 to 18 months of age. Mixed IgE- and cell-mediated reactions, allergic eosinophilic esophagitis and allergic eosinophilic gastroenterocolitis may present between early infancy and adolescence. Dietary protein enteropathy and celiac disease occur in early childhood, depending on the age of exposure to the antigen involved. The mixed-IgE- and non-IgE-mediated disorders are discussed in detail in Chapters 44 and 45.

The symptoms provoked by immediate gastrointestinal allergy typically develop within minutes to 2 hours after food

https://CafePezeshki.IR

TABLE 42-3 Presenting Gastrointestinal Symptoms in Infants with Cow's Milk Protein Allergy

intake. None of the symptoms is pathognomonic for allergy and may be caused by many other factors or diseases. Symptoms like colic, vomiting and diarrhea may be chronic or intermittent. Frequently, the children have a poor appetite, poor weight gain, intermittent abdominal pain and failure to thrive. Children who show concomitant symptoms in other organ systems like urticaria or atopic dermatitis or respiratory symptoms may easily be suspected of having a food allergy. When symptoms from other organ systems are lacking, the cause of the symptoms may remain undiagnosed for prolonged periods. A family history of atopic disease in such cases should give a clue to the diagnosis of possible food allergy. A variety of feeding problems in young infants may be associated with food allergy. Allergic gastrointestinal motility disorders such as gastroesophageal reflux disease (GERD), constipation and colic are among the most common disorders in infancy and early childhood. In a subset of infants with these functional disorders, a relation with food allergy has been reported following controlled food elimination and challenge procedures.[26]

INFANTILE COLIC

Infantile colic has often been related to food allergy,[18] especially CMPA, and high frequencies of food allergy of up to 71% have been in children with colic.[27] In that and another study,[28] the infants with colic due to cow's milk protein only rarely showed other features of CMPA. Although infantile colic is a common symptom of CMPA, it is almost always seen in combination with other features of CMPA.[8,29]

GASTROESOPHAGEAL REFLUX DISEASE

It has been reported that nearly half of the cases of GERD in infants younger than 1 year of age are not only CMPA associated but also CMPA induced.[18,30,31] GERD is a common disease, affecting up to 10% of infants in the first year of life. It is related to esophagitis but may be present without visible or histologic inflammation of the esophagus. Typical symptoms of GERD include vomiting with weight loss and symptoms of esophagitis (dysphagia, vomiting, abdominal pain, sleep disturbance), as well as respiratory symptoms (Box 42-1). Proteins other than cow's milk protein have been implicated in allergic eosinophilic esophagitis, such as wheat, soy, peanut and egg; often multiple antigens. Most cases in young infants resolve in less than 1 year. Some studies suggest that a portion of patients have both CMPA and GERD, particularly infants and children with severe GERD.[32] Given possible selection bias in previously reported studies, more population-based studies on this subject are warranted to evaluate the significance of this possible causal relationship.

BOX 42-1 SYMPTOMS OF GASTROESOPHAGEAL REFLUX DISEASE

- Regurgitation
  - Failure to thrive
- Esophagitis
  - Feeding problems
  - Signs of pain, especially with meals
  - Anemia, hematemesis
  - Stricture symptoms
- Respiratory symptoms
  - Wheezing
  - Recurrent pneumonia
  - Apnea, cyanotic episodes
  - Laryngospasm
- Neurologic symptoms
  - Sandifer's syndrome

CONSTIPATION

Constipation is a common clinical problem affecting up to 10% of infants and children,[33] and in a population-based study from Italy, 1.8% (91/5113) of children up to 12 years of age fulfilled the criteria for chronic constipation with the highest frequency (3.3%) among children aged 6 months to 6 years.[34] Chronic constipation may cause blood in the stools as well as symptoms of colitis and recurrent abdominal pain in older children. Some reports[35–37] describe chronic constipation as a manifestation of CMPA. In a recent study, the prevalence of atopy among children with chronic constipation was similar to that in the general

https://CafePezeshki.IR

population.[34] Thus, food allergy should be considered in severe cases of chronic constipation, but constipation does not appear to be a common manifestation of food allergy.

DIARRHEA

Diarrhea is often reported as a symptom of food allergy in young infancy. On the other hand, diarrhea is also a very common symptom due to 'normal reactions' caused by inappropriate or excessive intake of certain foods, such as raisins, carrots, legumes and other fruit – toddler's diarrhea. Transient or secondary lactase deficiency may occur in response to gastrointestinal infections, which are very common in infancy. This intolerance to lactose often lasts only a few days, after which there is a complete recovery.[38]

SPITTING UP/VOMITING

Symptoms of spitting up and vomiting may be very normal in young infants. The most common cause of vomiting is overfeeding. Such infants show normal growth and development, in contrast to infants with underlying gastrointestinal disease.[19] In some cases, nonorganic causes, e.g. behavioral causes, should be considered.[39]

FAILURE TO THRIVE

Failure to thrive may be caused by immediate gastrointestinal food allergy but is more often due to mixed-IgE- and non-IgE-mediated disorders of the gastrointestinal tract causing malabsorption, severe vomiting or diarrhea.[18,19] In some children with failure to thrive, organic causes cannot be demonstrated and it may be very difficult to confirm nonorganic causes. A report indicated the relevance of 'behavioral causes' such as food refusal, food fixation, abnormal parental feeding practices and onset after a specific trigger.[39]

BOX 42-2 DIFFERENTIAL DIAGNOSES OF FOOD ALLERGY

INFANT

- Upper gastrointestinal symptoms
  - Infection
  - Colic*
  - Gastroesophageal reflux*
  - Pyloric stenosis (defined age group)
  - Hiatal hernia
  - Tracheoesophageal fistula
- Lower gastrointestinal symptoms
  - Enzyme deficiency
  - Disaccharidase deficiencies (lactase, sucrase-isomaltase)
  - Glucose-galactose malabsorption
  - Galactosemia
  - Phenylketonuria
  - Infection
  - Constipation*
  - Hirschsprung's disease

TODDLER

- Infection
- Toddler's diarrhea
- Gastroesophageal reflux*
- Constipation*
- Lactose intolerance
- Malabsorption (celiac disease, cystic fibrosis)
- Bizarre diets

SCHOOL-AGE CHILD

- Infection
- Recurrent abdominal pain
- Lactose intolerance
- Malabsorption (celiac disease, cystic fibrosis, Schwachman syndrome)
- Inflammatory bowel disease
- Eosinophilic gastroenteritis*
- Other causes (immunodeficiency, Henoch-Schönlein disease)

*Could be caused by food allergy.

Differential Diagnoses

The differential diagnostic considerations of possible food-related symptoms are age dependent and include, for example, chronic gastrointestinal infections, nonspecific diarrhea of childhood, irritable bowel syndrome and recurrent abdominal pain, as described in Box 42-2. Some differential diagnoses of food allergy are mainly related to the upper gastrointestinal tract whereas others are associated with diseases in the lower gastrointestinal tract.

NONENTERAL INFECTIONS

Commonly seen in all ages, although most frequent in early infancy, are the nonenteral infections that may cause gastrointestinal upset, regardless of the focus of the infection; 'secondary dyspepsia'. Such sequelae after acute or chronic gastrointestinal infection should always be ruled out before evaluation of food allergy.

LACTOSE INTOLERANCE

Lactose intolerance is an important differential to consider in the diagnosis of food allergy, especially cow's milk allergy. Lactose constitutes a majority of the carbohydrate content of human and cow's milk and is an important part of the energy supply for infants in particular. Lactose is degraded in the gastrointestinal mucosa by the enzyme lactase. Lactose intolerance in the newborn is extremely rare and is caused by congenital deficiency of lactase. Acquired or adult-type lactase deficiency usually appears at the age of 3 to 5 years. Adult-type lactase deficiency is very common in those of African and Asian descent. It is less common in whites, especially in some groups such as the Scandinavian populations; in Denmark, only 3% of adults are affected.

Secondary lactase deficiency is temporary and may occur in response to malnutrition or gastrointestinal infections, which cause temporary damage to the villi of the small intestine, where the enzyme lactase is produced. This sensitivity to lactose often lasts only a few days, followed by complete recovery.

Lactase deficiency (lactose malabsorption) may or may not be associated with gastrointestinal symptoms, depending on many factors and co-existing conditions. Lactose intolerance is defined as a condition with gastrointestinal symptoms after ingestion of lactose in a person with lactase deficiency.[38]

Lactose intolerance may be diagnosed by oral lactose challenge tests and measurements of increased breath hydrogen, by glucose measurements or by direct enzyme measurements within a duodenal biopsy. A genetic test to diagnose the adult

https://CafePezeshki.IR

type of lactase deficiency was found to be valid, especially in older children.[38,40] Recently, it has been proposed that such tests should be followed by a blinded single-dose challenge of ingested lactose.[38]

Adult-type or primary lactase deficiency is a lifelong condition. The treatment of lactose intolerance is reduced ingestion of milk and dairy products with lactose. Avoidance does not need to be complete, such as for children with CMPA. A firm diagnosis of lactose intolerance and the threshold for development of symptoms should be established because the sensitivity to lactose is variable. In most lactose-intolerant individuals, considerable amounts of lactose – usually up to 250 mL of milk – may be ingested before symptoms develop. Lactase enzyme replacement is another treatment option.[38]

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) or recurrent abdominal pain in children is a clinical syndrome with a variable pathogenic background, including psychosomatic reactions, lactose intolerance, food allergy and inflammatory conditions such as gastritis or inflammatory bowel disease. It has been concluded that food reactions are unlikely to be major determinants in the pathogenesis of IBS and that double-blind, placebo-controlled food challenges are mandatory for investigation of this possible causal relationship.[41,42]

TODDLER'S DIARRHEA

To avoid unnecessary investigations for food allergy, it is important to pay attention to this very common 'disorder'. Many infants and young children have a high intake of dietary fiber and fruit sugar from high amounts of fruits, legumes, vegetables, raisins and great volumes of fruit juice. This is a normal cause of loose stools and diarrhea, often resulting in referrals to allergists for investigation of food allergy, which is unnecessary when children have normal growth and development. Laypersons, especially parents, need more information and knowledge about 'normal' reactions to foods in children. The simple advice is to reduce the intake of such foods.

MÜNCHHAUSEN'S SYNDROME BY PROXY

During the past decades, many infants and young children have been investigated for food allergy without a convincing indication for such, often comprehensive, diagnostic procedures. In cases where there is a lack of obvious possible allergic symptoms, physicians should abstain from unnecessary and potentially harmful investigations of healthy children with parent-, often mother-, induced or imaginary symptoms.[43]

Evaluation and Management

In infants and young children, food allergy should be suspected if severe symptoms persist, especially if there is more than one symptom and if relevant differential diagnoses have been excluded (Boxes 42-3 and 42-4).

Gastrointestinal symptoms in food allergy are often chronic or acute vomiting, diarrhea and colic. Colic appears to be a common symptom,[18] but as already mentioned nearly always occurs in combination with other symptoms.[8,12,29] Since most of these gastrointestinal symptoms are nonspecific and may be caused by other conditions, a careful evaluation for other causes is important at an early stage.

BOX 42-3 KEY CONCEPTS

Characteristics of Food Allergy

- Persistent symptoms
- Symptoms related to food intake
- Two or more different symptoms
- Symptoms in two or more different organs
- Allergic predisposition

BOX 42-4 THERAPEUTIC PRINCIPLES

General Approach to Evaluation of Food Allergy in Children with Gastrointestinal Problems

CONSIDER EVALUATION IN CASE OF:

Persistent symptoms in infant/young child with vomiting, diarrhea, colic or failure to thrive, and
Other common differential diagnoses are excluded, especially gastroenteritis and lactose intolerance
Particularly in cases where:
  History of symptoms exacerbated by particular foods or
  Other coexisting atopic manifestations, especially
    Atopic eczema/urticaria
    Allergic rhinitis
Initial screen
Careful case history and physical examination
Skin prick test/specific IgE to implicated foods
  Extra suspicion for 'history-positive' foods
  Extra suspicion for common food allergens (milk, hen's egg, wheat, soy, peanut, tree nut, fish, shellfish)
Consider elimination diet for a sufficient period to eliminate symptoms
Consider controlled oral challenges to exclude/confirm food allergy

None of the symptoms related to immunologically or non-immunologically mediated adverse reactions to foods is pathognomonic, although some characteristics should be suggestive of food allergy (Box 42-3).

No laboratory test is diagnostic of food allergy.[1,6,9,20] Therefore, the diagnosis has to be based on a careful case history and on strict, well-defined food elimination and challenge procedures establishing a causal relation between the ingestion of a particular food (or food protein) and a subsequent obvious clinical reaction[1,6,9,19,20] (see also Chapter 41). Possible helpful diagnostic tests include skin prick tests or determinations of serum allergen-specific IgE levels. These tests are often useful in choosing the elimination diet and the challenge procedure for the classification of the disorder and for determining the prognosis.

Conclusions

Food allergy is most frequently a problem in infancy and early childhood. Children with food allergy may experience a variety of symptoms affecting different organ systems and leading to feeding disorders. The disease manifestations often are localized to the gastrointestinal tract, but food allergy may also cause local symptoms in the skin and the respiratory tract. About

https://CafePezeshki.IR

50% to 70% of food allergic infants show cutaneous symptoms, 50% to 60% gastrointestinal symptoms and about 20% to 30% respiratory symptoms. Among young children with cow's milk allergy, the majority have two or more symptoms, and symptoms generally affect two or more organ systems. Mostly, the symptoms occur within a few minutes after food exposure (immediate reactions), but delayed reactions involving the skin, gastrointestinal tract and lungs may also occur. Among children presenting with symptoms suggestive of food allergy, the diagnosis can be confirmed by controlled elimination/challenge procedures in only about one third of individuals.

To avoid unnecessary diets and stigmatization, it is important to rule-out 'normal reactions' to foods and relevant differential diagnoses before undertaking specific comprehensive diagnostic procedures for food allergy. To avoid unnecessary diets, malnutrition and severe reactions such as anaphylaxis, it is important to make the proper diagnosis in case of suspected food allergy.

43 Prevention and Natural History of Food Allergy

SUSAN PRESCOTT | KATRINA ALLEN

KEY POINTS

- The rise in food allergy is more rapid than genetic deviation would allow and the current consensus is that environmental factors integrally linked to the 'modern lifestyle' are likely to be key drivers of this phenomenon. The concept that these factors might be potentially modifiable is supported by studies demonstrating that food allergy is more common in developed than developing countries, and migrants appear to acquire the incident risk of allergy of their adopted country.
- There is emerging evidence that the early immunomodulatory effects of microbial exposure (including through indoor pet ownership and siblings) and nutritional patterns (including breast or formula feeding, exposure to allergenic solids and specific nutrient optimization such as vitamin D) are both important determinants of the risk of early-onset inflammatory diseases such as allergic disease, including food allergy.
- At present there is no clear evidence that prebiotics, probiotics or synbiotics prevent food allergy and mixed evidence regarding hydrolyzed formula. Although 'breast is best,' there are insufficient data currently to support the hypothesis that breastfeeding is protective.
- Food allergy is most commonly acquired during the first year of life, with peak incidence of 5% to 10% occurring at 1 year of age. The prevalence falls until late childhood, where it plateaus at about 3.5% through adulthood.
- Whereas milk and egg allergies are most frequently outgrown in childhood, peanut allergy most commonly remains a lifelong issue. Tree nut, fish and shellfish allergy are also much more likely to continue into adulthood than are egg and cow's milk allergy.

Introduction

Allergic diseases have become the most common chronic diseases of childhood as part of a shifting profile of disease in modern societies. Even more recently, an epidemic of food allergy has emerged, particularly in the last 10 to 15 years. For good reason, we have described this as the 'second wave' of the allergy epidemic.[1] This phenomenon appears to still be evolving in many regions, and it is still unclear why it has occurred decades after the 'first wave' of asthma and respiratory allergy reached a peak in industrialized countries.

There is concern that this growing early predisposition for the allergic phenotype may portend a greater burden of later-onset allergic diseases such as asthma and allergic rhinitis, and contribute to an escalating burden of inflammatory disease in this new generation.[2] The parallel increase in many other immune diseases and inflammatory noncommunicable diseases (NCDs) strongly suggests broader immunologic effects of modern risk factors on human health.[2] In this context, allergy may be regarded as the most common and earliest manifestation of the vulnerability of the immune system to modern environmental change. Strategies to improve early 'immune health' may therefore not only prevent allergic disease but also ultimately reduce the burden of other inflammatory diseases.

Because the rise in food allergy is more rapid than genetic deviation would allow, the current consensus is that environmental factors integrally linked to the 'modern lifestyle' are likely to be key drivers of this phenomenon. The concept that these factors might be potentially modifiable is supported by studies demonstrating that food allergy is more common in developed than developing countries, and migrants appear to acquire the incident risk of allergy of their adopted country.[3]

Factors associated with a 'modern lifestyle' include a myriad of changes to our level of public health including improved sanitation, secure water supplies (with associated decreased prevalence of *Helicobacter pylori* infection), widespread use of antibiotics and increasing rates of immunization, improved nutrition, decreased helminthic infestation, improved food quality (and presumably less microbial load in the food chain) as well as generally improved nutrition and associated obesity. These factors might work individually or in concert to effect a failure in the development of oral immune tolerance in the first year of life when development of IgE-mediated food allergy is most likely to occur. In addition there is likely to be at least some component of gene-environment interaction. That is to say, lifestyle factors may have a differential effect depending on genetic status of the individual.[4]

The Importance and Timing of Early Intervention

This new epidemic of food allergy is most striking in preschool children, particularly in the first year of life. In high-income countries such as Australia, more than 20% of 1-year-old infants now have evidence of food sensitization and more than 10% now have challenge-proven IgE-mediated food allergy.[5] However it is not yet clear whether intervention measures need to be targeted prenatally or will be equally effective if administered postnatally. There is certainly evidence that an atopic predisposition has declared itself by the time of birth in at least some infants although, since food allergy phenotypes cannot be declared until postnatally, it is difficult to tease out whether interventions may still be effective in the postnatal period.

https://CafePezeshki.IR

ANTENATAL INTERVENTION

During pregnancy, there is close immunologic interaction between the mother and her offspring providing enormous opportunities to influence fetal immune development. The placenta and the fetus are vulnerable to a wide range of exogenous and endogenous maternal influences. Contrary to traditional concepts, human fetal T cells are responsive as early as 22 weeks' gestation.[6] We have shown emergent differences in immune function at birth in newborns destined to develop allergy[7,8] indicating that 'the scene is set' to some extent by birth. This highlights the importance of considering a broad range of immunomodulatory factors that may begin to have their effects much earlier in pregnancy than previously suspected. Notably, most of the environmental factors implicated in the development of allergic disease (including microbial exposure, dietary factors, cigarette smoke and other pollutants) have been shown to influence fetal immune function and contribute to an increased risk of subsequent allergic disease (reviewed in references 9 and 10). Moreover, there is also preliminary evidence that each of these has been associated with epigenetic effects, including activation or silencing of immune-related genes through epigenetic modifications.[9,10]

POSTNATAL INTERVENTION

The early postnatal period also appears to be a critical period in the development of oral tolerance. Events in the gastrointestinal tract are vitally important for normal immune maturation. After birth we encounter a vast array of new antigenic proteins in relatively high 'doses'. Most of this foreign antigenic load is derived from colonizing commensal bacteria and food components. We have to learn very quickly to distinguish 'friend' from 'foe' on a large scale. To prevent inflammatory responses to largely harmless antigens, the gastrointestinal associated lymphoid tissue (GALT) has evolved complex mechanisms to promote tolerance as a default response (reviewed in reference 11). The human intestines harbor between 10 and 100 trillion resident microbiota, and this vast and complex ecosystem forms gradually over the first years of life. The collective genetic material of these bacteria (called the 'microbiome') is estimated to contain 150 times more genes than our human genome.[12] Through co-evolution and established 'mutualism' the microbiota play an essential role in homeostasis of multiple interconnected host metabolic and immune functions.[13]

The success of oral tolerance appears to depend on a number of oral exposures. Although the best known of these is breast milk, 'optimal' microbial diversity (still an ill-defined concept) and other dietary immunomodulatory factors including prebiotics (soluble fiber), fat soluble vitamins (including vitamin D) and polyunsaturated fatty acids (PUFAs) may all have important antiinflammatory effects (reviewed in reference 14). There is also some evidence to suggest that both the gastric acid milieu[15] and a possible 'window of opportunity' of optimal allergenic solids introduction between 4 and 6 months of age[16,17] are potential factors for oral tolerance development (see below).

Immunomodulatory Strategies

There is now emerging evidence that the early immunomodulatory effects of microbial exposure (including through indoor pet ownership and siblings[18]) and nutritional patterns (including breast or formula feeding, exposure to allergenic solids and specific nutrient optimization such as vitamin D) are both important determinants of the risk of early-onset inflammatory diseases such as allergic disease, including food allergy, although the interplay between these two sets of risk factors has not been formally evaluated.

INFANT FEEDING

Breast Milk

It is universally agreed that human milk should be the first and most important source of nutrition for the infant. It contains a vast array of bioactive factors including hormones, growth factors, neuropeptides and antiinflammatory and immunomodulatory agents that influence many physiologic systems and promote normal gut colonization for both short-term and long-term benefits.[19]

Allergens are normally secreted in breast milk and appear to be an important early source of exposure.[20–22] This may actually be important in initiating, maintaining and reinforcing normal tolerance to foods and even inhaled allergens.[23,24] While this has been demonstrated in animals, human evidence is more limited because randomized controlled trials are not possible. Systematic analysis of observational studies on the protective effect of breastfeeding has shown conflicting results, and many of the studies included were conducted decades ago when food allergy was uncommon and methods of assessment were limited.[25] An early review by Muraro et al[26] including 15 observational and 14 interventional studies concluded that breastfeeding for at least 4 months was associated with a reduced cumulative risk of cow's milk allergy in high-risk infants over 18 months of age. None of these studies was either randomized or prospective, and most systematic reviews since have failed to find a specific beneficial effect on food allergy.[27,28] Several cohort studies suggested that extended *exclusive* breastfeeding may increase the likelihood of sensitization or food allergy[29,30] in infants at high risk (reviewed in reference 28). This may relate to the timing of first complementary foods rather than the effects of breast milk per se (below). In this regard there is some, albeit limited, evidence that continued breastfeeding during the period when complementary foods are initiated may promote tolerance and have protective effects.[31] Even so, many expert bodies recommend that breastfeeding should continue while solids are introduced into the diet[32,33] although strong scientific evidence that it plays a role in the prevention of allergic disease is both lacking and unlikely to be available due to the unethical aspects of randomization trials that would need to include a 'no breastfeeding' arm.[34]

Formula Feeding

There has been significant interest in the use of modified infant formulas – especially partially (PHF) and extensively hydrolyzed cow's milk formula (EHF) – for prevention of early childhood allergic disease. Intense expectations from families with a history of allergy seeking readily available primary prevention interventions have been responded to by industry with the development of a range of 'allergy prevention' formulae. Furthermore expert bodies have felt the need to provide recommendations regarding the use of formula for prevention of allergies. Current infant feeding guidelines in Europe,[33] the USA[32] and Australia all recommend that hydrolyzed formula can be considered as primary prevention therapy for allergic

https://CafePezeshki.IR

diseases. These guidelines have been informed by the Cochrane review, the last update of which occurred in 2009.[35] This review supports the use of hydrolyzed formula for the prevention of allergy especially in high-risk infants who are unable to be completely breastfed although the authors themselves recommend further larger trials because of the methodological concerns and inconsistency of the findings of the studies included in the review. It should be noted that the findings of this review are heavily influenced by the reported benefits of PHF during the first six years of life demonstrated by the largest study of the review, the German Infant Nutritional Intervention (GINI) study. We have recently demonstrated that the Cochrane review suffers from small-study publication bias (scarcity of small negative studies),[36] and thus is likely to have overestimated the beneficial effect of PHF. Since the last update of this review, new evidence from a large intervention trial of high-risk infants (the Melbourne Atopic Cohort Study; MACS) has emerged challenging the effectiveness of PHF.[37] Additionally, while the GINI study outcomes up until the 6-year follow-up were promising, subsequent results have shown little evidence of an ongoing preventive effect between the ages of 7 and 10 years.[38] These more recent findings have also not yet been incorporated into the Cochrane review.[35] GINI and MACS are the two largest trials conducted to evaluate the effectiveness of PHF and both were industry supported through the provision of formulae. Interestingly, although there is significant debate around the role of PHF for the prevention of allergic disease,[39,40] both show similar results when the findings of the intention to treat analysis (ITT) are compared. Although both have substantial strengths, each has limitations. As it would be unethical to mandate one type of feeding – breastfeeding exclusively or fully over complementary formula feeding – it is not surprising that both studies are complicated by the impact of parental choice during the feeding intervention. Irrespective of the strengths and limitations of each study, even in the best case scenario, the number of high-risk children who would need to be fed with partially hydrolyzed formula to prevent one child from developing allergic disease in the first year of life is as high as 80[41] provided infant feeding patterns in GINI were replicated.

It is interesting that most recent recommendations from GINI suggest that casein-predominant EHF might be expected to have a more profound biologic effect because the formula is more extensively modified.[42] However most guidelines' recommendations are based on the fact that PHF is both cheaper and more palatable than EHF and therefore should be considered in place of EHF. Certainly in some countries EHF can only be medically prescribed, which significantly increases costs to the healthcare system. Added to the fact that a large number of infants would require treatment for a beneficial effect, the data suggest that recommendation of modified formula as a prevention measure for allergic disease may be premature.

Timing of First Solids

Infant diet has long been thought to affect the risk of developing food allergies. In the 1960s infants were typically given solid foods in the first 3 months of life, but the 1970s saw the introduction of guidelines recommending delayed introduction of solids until after 4 months of age because of a perceived link between early introduction of gluten and celiac disease.[43] By the late 1990s, expert bodies had begun to recommend delaying solids until after 6 months of age, with further delay in the introduction of allergenic foods such as egg and nuts until at least 2 years of age recommended for infants with a family history of allergy.[44] This did not, however, appear to have the desired effect of reducing the prevalence of food allergy and in 2008 lack of evidence of a protective effect led to the removal of advice to delay the introduction of any foods beyond 4 to 6 months of age with current guidelines outlined below.

A systematic review of the relationship between early introduction of solid foods, defined as introduction before 4 months of age, and allergy, conducted in 2005, identified only one cohort study investigating the relationship between early introduction of solids and food allergy.[45] The one included study, a birth cohort of 135 infants with atopic parents, found that early introduction of solid foods was associated with an increased risk of having reported symptoms of food allergy by 1 year of age. However, no difference was seen in food challenge confirmed allergy and there was also no difference in allergy to milk, egg or wheat, diagnosed by history and skin prick test, at 5 years of age.

In a recent large observational cohort study in Melbourne, Australia, we found no relationship between timing of introduction of solid foods and challenge-confirmed egg allergy at 1 year of age.[17] Solid foods in this cohort were predominantly introduced between 4 and 6 months of age, with only 4% introducing solids before age 4 months and 5% after 6 months, thus an effect of very early or late introduction of solids cannot be ruled out.

Exposure to Allergenic Foods

Early intervention studies primarily investigated the impact of combined maternal and infant allergen avoidance on the prevalence of food sensitization and allergy among 'high-risk' infants with a family history of allergy. Not surprisingly, the initial reports from these studies showed lower rates of food sensitization and allergy in infants avoiding allergenic foods, indicating that allergic symptoms did not develop in the absence of exposure to these foods. However, protection did not appear to be maintained after the introduction of allergenic foods into the diet. Later follow-up of the study population in early childhood showed no reduction in the prevalence of food sensitization and allergy among those with early allergen avoidance, suggesting that these strategies were ineffective in promoting the development of tolerance.[46]

More recently, large observational studies have attempted to untangle the impact of timing of introduction of specific foods (such as peanut, egg or cow's milk) and development of allergy to those foods. The relationship between age at introduction of cow's milk products and cow's milk sensitization at age 2 was investigated in the Dutch birth cohort study described previously.[47] Although there was a trend for a decreased risk of sensitization with delayed introduction of cow's milk, this did not reach statistical significance. This analysis was also limited by the low percentage of the cohort for which sensitization data were available and by the lack of a clinically relevant outcome (symptomatic cow's milk allergy). A study of 12,234 newborn infants in Israel with 0.5% prevalence of IgE-mediated cow's milk allergy found that infants exposed to cow's milk in the first 14 days of life were less likely to be cow's milk allergic compared to those first exposed to cow's milk after 14 days,[48] although this was not controlled for family history of cow's milk allergy.

Two birth cohort studies designed to investigate risk factors for type 1 diabetes investigated the relationship between timing of food introduction and food sensitization or allergy.[49,50] Both

https://CafePezeshki.IR

studies contained only infants with a family history or personal genetic risk of diabetes. Poole and colleagues found that introduction of wheat after 6 months of age was associated with an increased risk of parent-reported wheat allergy.[49] This finding was based on 16 children with parent-reported wheat allergy, only four of whom had detectable levels of wheat-specific IgE on blood testing. The authors also failed to control for a history of eczema in the child, which is likely to be associated with both dietary modifications and an increased risk of food sensitization. The second study found that introduction of egg after 10.5 months was associated with an increased risk of sensitization to egg at age 5.[50] The relevance of this finding is questionable as neither history of early allergic symptoms in the child nor family history of food allergy or eczema were considered in the analysis, both of which are likely to be important confounders. A recent Turkish study of 1015 infants found no association between age at introduction of egg and egg sensitization,[51] however the study was relatively underpowered with only 19 egg sensitized infants and, as for the above studies, did not use objectively confirmed food allergy as the outcome.

A landmark study by Du Toit et al compared the prevalence of peanut allergy among Jewish school children in Israel and the UK.[52] Although the study found that Israel had a lower prevalence of peanut allergy in school aged children and that in general peanuts were introduced earlier into the diet of infants in that country compared to the UK, the study design did not allow a direct link between age at first peanut consumption and peanut allergy on the individual level. Furthermore, the study was unable to eliminate other environmental factors as the cause of the differing prevalence of peanut allergy, a possibility that is consistent with the study finding a higher prevalence of other food allergies such as egg, tree nut and cow's milk allergy in the UK as well as a difference in prevalence of eczema, a co-associated condition. Interestingly, although there was a higher prevalence of egg allergy in the UK, this was not accompanied by a statistically significant difference in age at introduction of egg.

By contrast, the Healthnuts study in Australia found that, compared with introduction at 4 to 6 months, introducing egg into the diet later was associated with higher rates of egg allergy (adjusted odds ratio 3.4 [95% CI 1.8 to 6.5] for introduction after 12 months). Most interestingly, introduction of cooked egg such as scrambled, baked or fried was more protective than simply introducing egg in baked goods, with those who had been introduced to cooked egg at 4 to 6 months being five times less likely to develop egg allergy than those waiting until the normally recommended time of 10 to 12 months of age, even after adjusting for confounding factors. There was no protective effect among infants who were first introduced to baked egg in their diet between 4 and 6 months, presumably because a lower dose exposure does not provide protection. No other factors such as maternal food allergen avoidance or prolonged breastfeeding were associated with altered risk of egg allergy after adjusting for confounders.[17]

Together these studies provide reasonable evidence that delaying the introduction of solids in general or allergenic solids in particular is unlikely to reduce the risk of food allergy and may even paradoxically increase the risk. This is reflected in current guidelines in Australia, Europe and the USA, which no longer provide any recommendations on the best time to introduce these foods, citing a lack of evidence base for the prevention of food allergy.

TABLE 43-1 Modified and Updated Summary of Data, with Regard to Infant Diet and the Primary Prevention of Food Allergy

Interventions	Summary
Pregnancy diet	No evidence of effectiveness
Lactation diet	Maternal antigen avoidance does not prevent atopic disease with the possible exception of atopic dermatitis. More data needed
Breastfeeding	Evidence exists that exclusive breastfeeding for at least 4 months vs feeding with cow's milk formula decreases cumulative incidence of atopic dermatitis and cow's milk allergy in the first 2 years of life Evidence exists that exclusive breastfeeding for at least 3 months protects against wheezing in early life, but there is not convincing evidence that exclusive breastfeeding in high-risk infants protects against allergic asthma beyond 6 years of age
Soy formula	No convincing evidence exists for the use of soy formula for allergy prevention
Protein hydrolyzate formula	Mixed evidence exists that atopic dermatitis may be delayed or prevented by the use of an extensively or partially hydrolyzed formula as compared to cow's milk formula in high-risk infants who are not breastfed exclusively for 4 to 6 months although more recent studies suggest a null effect. Not all hydrolyzed formulas have the same protective benefit. Cost must be considered in any decision-making process
Delayed introduction of solid foods	No convincing current evidence exists that delaying the introduction of solid food, including fish, egg and peanut, beyond 4 to 6 months protects against the development of allergic disease. There is emerging evidence that introduction of solids between 4 and 6 months may even be protective

Data from Greer FR, et al. Pediatrics 2008;121:183–91. Copyright © by the American Academy of Pediatrics, all rights reserved.

The most recent American Academy of Pediatrics guidelines (Table 43-1) state that there is insufficient evidence to recommend maternal dietary restrictions during pregnancy or breastfeeding. For infants at high risk of atopic disease, there is some evidence that exclusive breastfeeding for at least 4 months is protective against cow milk allergy in the first 2 years of life. However, there is no evidence that delaying the introduction of solids, including allergenic foods, until after 4 to 6 months is protective.[32]

Restoring More Traditional PUFA Status

Declining consumption of antiinflammatory n-3 polyunsaturated fatty acids (PUFA) has been another significant dietary change with increasing urbanization. This has been replaced by increasing intakes of proinflammatory saturated fat and synthetic and n-6 PUFA. In many western diets, the ratio of n-6 to n-3 fatty acids ranges from approximately 20 to 30 : 1 instead of the traditional range of 1 to 2 : 1.[53] Changes in the diets of

https://CafePezeshki.IR

Australian women are also reflected in the changing content of breast milk, which has similarly shown falling n-3 PUFA content and increasing n-6 PUFA levels.[54] This has led to falling intake of antiinflammatory n-3 PUFA in early life during the critical period of immune maturation.

Based on this, n-3 PUFA rich fish oils have been logical interventions for prevention and treatment of a number of inflammatory conditions. In one of the earliest randomized controlled trial (RCT) intervention studies for allergy prevention, we supplemented allergic women with fish oil from 20 weeks' gestation and demonstrated a range of immunomodulatory effects in their neonates.[55–57] We also saw preliminary evidence of reduced food (egg) sensitization and eczema severity at 1 year of age[55] although food allergy itself was not assessed. In a much larger subsequent RCT in 706 pregnant women, we again observed that fish oil supplementation significantly reduced egg sensitization at 12 months of age in high-risk infants.[58] Atopic eczema was also less common in the fish oil group. At the 3-year follow-up, eczema was still less common in the fish oil group although this was no longer statistically significant.[59] These observed reductions may still be important given the cost and burden of allergic disease. In a separate study, we also examined the effects of early postnatal fish oil supplementation in high-risk infants ($N = 420$) for the first 6 months of life. We observed that increased infant n-3 PUFA levels were associated with lowered allergen-specific Th2 responses and elevated polyclonal Th1 responses.[60] Although n-3 PUFA levels at 6 months were associated with lower risk of eczema and recurrent wheeze, there was no effect of the intervention per se on the primary study outcomes.[61]

The results from these and other n-3 long-chain PUFA supplementation RCTs suggest that the dose, timing and duration of n-3 long-chain PUFA supplementation may influence sensitization and allergic disease outcomes. It has been proposed that a combination of measures to ensure more traditional PUFA status throughout the pre- and postnatal period, during important periods of immune development and maturation, may be most efficacious.[62] Notably, early interventions using fish oil for allergy prevention in early childhood[60,61,63] have also shown benefits for metabolic programming,[64] oxidative stress[56] and reducing cardiovascular risk.[65,66] Furthermore, in addition to immunomodulation[55,60] and allergy reduction,[55,58] we have also seen beneficial effects on aspects of neurodevelopment after both prenatal[67] and early postnatal[68] fish oil supplementation. In summary, restoring the higher n-3 PUFA levels seen in more traditional diets provides a clear example of an early immunomodulatory intervention with potential multisystem benefits.

Vitamin D

The recent hypothesis that low vitamin D may increase the risk of food allergy[69] is supported by two lines of ecologic inquiry. First, there is a strong latitudinal prevalence gradient, with those countries further from the Equator (and thus lower ambient ultraviolet radiation) recording more admissions to hospital for food allergy-related events[70] and more prescriptions for epinephrine autoinjectors for the treatment of anaphylaxis.[70,71] These findings appear to be independent of longitude, physician density or socioeconomic status. Second, season of birth may play a role: children attending emergency departments in Boston with a food-related acute allergic reaction were more likely to be born in autumn/winter, when vitamin D levels reach their nadir, than in spring/summer[72] and there are similar links to birth seasonality in the southern hemisphere.[71]

We have recently confirmed that Melbourne, the most southern major city in Australia, has the highest reported prevalence of documented infantile food allergy in the world, with more than 10% of a population sample of 1-year-old infants having challenge-proven IgE-mediated food allergy.[5] In a separate study, we have shown that, compared to the northern states, children residing in Australia's southern states are six times more likely to have peanut allergy at age 6 years and twice as likely to have egg allergy than those in the northern states.[73] We have also shown that the delayed introduction of egg, one of breastfed infants' richest sources of vitamin D, increases the risk of developing egg allergy by age 12 months by at least 5-fold.[17] Finally, increasing vitamin D insufficiency in Melbourne over the last 20 years,[74] paralleling the rise in food allergy, is supported by our own data showing that 20% of pregnant women are vitamin D insufficient.[69,75]

Using the Healthnuts population based study we found that infants of Australian-born parents, but not of parents born overseas, with vitamin D insufficiency (<50 nM/L) were more likely to be peanut (aOR 11.51, 95% CI 2.01, 65.79, $P = .006$) and/or egg (aOR 3.79, 95% CI 1.19, 12.08, $P = .025$) allergic than those with adequate vitamin D levels independent of eczema status.[76] Among those with Australian-born parents, infants with vitamin D insufficiency were more likely to have multiple (≥2) than single food allergies (aOR 10.48, 95% CI 1.60, 68.61 vs aOR 1.82, 95% CI 0.38, 8.77 respectively).These results provide the first direct evidence that vitamin D sufficiency may be an important protective factor for food allergy in the first year of life.

Vitamin D could influence the onset and resolution of food allergy via several plausible mechanisms. The vitamin D receptor is widely expressed in the immune system including T cells, in particular promoting the expression of IL-10 secreting T regulatory cells crucial to maintaining immune tolerance[77] and, potentially, playing a key role in the induction of tolerance in food allergic individuals.[78] Vitamin D metabolites also contribute to innate epithelial defenses by stimulating production of antimicrobial proteins such as cathelicidins[79,80] and defensins.[81] Randomized controlled trials assessing the potential role of vitamin D in the prevention of food allergy are urgently needed.

Modulation of the Maternal and Infant Microbiome

Changes in the microbiota, induced by a range of modern environmental factors and dietary patterns, are implicated in the rising predisposition to a range of inflammatory and metabolic disorders.[82] This underscores the likely importance of strategies that improve gut homeostasis and the microbiome as part of disease prevention strategies.[2,83] A low-fiber, high-fat 'western' diet is associated with adverse changes in gut microbiome, altered gut barrier function,[84] increased systemic endotoxin and low-grade Toll-like receptor (TLR)-mediated systemic inflammation with increased C-reactive protein (CRP), IL-1β, tumor necrosis factor (TNF) and IL-6. Animal models provide clear evidence that the gut microbiota modulate immune programming, and that manipulation of the microbiome can prevent not only allergic disease[85] and autoimmune

https://CafePezeshki.IR

phenomena, but also the risk of obesity, cardiovascular and metabolic disease through well-described metabolic effects (reviewed in references 2 and 82).

Early microbial diversity, beginning in utero, is a major driving factor[86,87] in the normal maturation of both Th1[7,88] and T_{REG} function[89,90] and suppressing the propensity for Th2 allergic responses in early childhood.[8] Epidemiologic studies also indicate that a 'high microbial environment' during pregnancy affords greater protection from allergy than postnatal exposure alone.[91] Thus, while continued postnatal microbial exposure is critical for immune maturation and allergy protection, the role of the antenatal period must not be overlooked or underestimated.

Contrary to long-standing assumptions, the womb is not 'sterile' after all. In normal healthy pregnancies, microbes can be detected in amniotic fluid, placental and fetal membranes, cord blood and meconium, providing a 'pioneer' microbiome.[92] In murine studies, labeled bacteria are transferred from mother to fetus during pregnancy.[93] It is increasingly clear that the maternal microbial environment during pregnancy is also important in early immune programming, providing an initial antenatal source of immunostimulation.[82,94]

So far, most allergy prevention studies aimed at improving early colonization have focused on improving postnatal colonization in the infant, rather than on influencing immune development during fetal life. The first attempts to increase gut microbial diversity for allergy prevention were with probiotic supplements.[95] Although some of these studies used probiotics in pregnancy, most only used probiotics the last 2 to 4 weeks of gestation with the dominant goal of influencing infant colonization in the postnatal period.[83] The only RCT ($N = 241$) to use probiotics earlier than this for allergy prevention (but still for only 8 weeks in late pregnancy) significantly reduced infant eczema.[96]

Collectively there have now been more than 20 studies to examine the effects of probiotics in allergy prevention. Although the findings have been variable, the most consistent finding has been protection from early allergic outcomes such as eczema (reviewed in references 83 and 97). Several meta-analyses have now been performed, each generally concluding that probiotics reduce the risk of eczema but have no consistent effects on food allergy or other allergic outcomes.[97–101] The most recent meta-analysis[97] included 13 prevention studies and found that probiotic treatment reduced the incidence of eczema by 21% (RR 0.79, 95% CI 0.71–0.88). This effect was still evident when the analysis was restricted to patients with IgE-associated eczema (RR 0.80, 95% CI 0.66–0.96).

We speculate that, given the likely role of the maternal microbiome in pregnancy for both immune and metabolic homeostasis,[102] it is logical to investigate the effects of the combination of pre- and probiotics (synbiotics) much earlier in pregnancy, at a time when fetal responses are first initiated.[94] Providing some support for this, a recent large-scale observational study of 40,614 Norwegian mother-child pairs found that probiotic milk consumption in pregnancy (assessed at 22 weeks' gestation) was associated with a reduced incidence of atopic eczema and allergic rhinoconjunctivitis at 3 years of age.[103] To our knowledge the only RCT ($N = 256$) to use probiotics from the first trimester did not assess immune effects or allergic outcomes but reported a number of metabolic benefits for both the mother and the fetus.[104] Even in the final weeks of pregnancy, probiotics have been shown to significantly alter expression of innate TLR-related genes in the placenta and in the fetal gut.[93] We have also shown changes in cord blood serum cytokines.[105]

There is now growing interest in using 'prebiotic' fiber to promote favorable colonization and reduce inflammation. In humans, prebiotic fiber selectively stimulates growth of beneficial gut microbiota, particularly bifidobacteria but also lactobacilli,[106] in a dose dependent manner. Prebiotic fermentation products, short-chain fatty acids (SCFA), have direct antiinflammatory effects.[107] This promotes intestinal integrity and reduces systemic endotoxin and antigenic load in experimental models. Acetate, butyrate and propionate are among the most abundant SCFA and play a critical role in local and systemic metabolic function and stimulating regulatory immune responses.[84] Accordingly, human randomized controlled trials using prebiotics have shown some beneficial effects on the microbiome and immune function with reduced systemic inflammation, and metabolic dysregulation.[108]

There are now several studies in the postnatal period showing beneficial effects on early colonization and a reduction of eczema with prebiotic supplementation[106,109] although effects on the prevention of food allergy have been disappointing, which is somewhat surprising since eczema and food allergy so frequently co-associate in the first year of life. The first major study to investigate the effect of prebiotics on allergy prevention used a mixture of galactooligosaccharide/fructoologosaccharide prebiotics during the first 6 months of life in formula-fed infants at high risk of atopy.[106] At 6 months of age the rate of eczema was significantly lower in the treatment group (9.8%; 95% CI 5.4–17.1%) compared with the placebo group (23.1%; 95% CI 16.0–32.1%). By 2 years of age, the cumulative incidence of eczema, recurrent wheeze and allergic urticaria were all significantly lower in the treatment group compared with the control group, although the follow-up was limited to approximately half of the original population.[110] In a similar study of formula-fed infants at low risk of allergy, there was also a significant reduction in eczema in those randomized to a formula containing prebiotics (neutral oligosaccharides and pectin-derived acidic oligosaccharides) compared with regular formula.[109] The results of other studies are awaited before recommendations can be considered.

Studies of prebiotic oligosaccharides in pregnancy are also still limited. In animal models, prebiotics in pregnancy alter colonization and metabolic homeostasis[111] and reduce eczema-like inflammation in offspring.[112] Observational studies in human pregnancy show that high-fiber diets are associated with a reduced risk of pre-eclampsia and dyslipidemia. To our knowledge, the only RCT to use prebiotics in pregnancy was too small ($N = 48$) to reliably assess immune effects on the fetus or clinical effects, but did achieve favorable changes in maternal gut microbiota.[113] This highlights the need for human studies of prebiotics in pregnancy.

While the use of a prebiotic alone may be effective,[106] the combination with bifidobacteria and lactobacilli probiotics is a logical strategy to assist in favorable diversity, already showing some benefit in the postnatal period.[114] Prebiotics promote microbial diversity by stimulating the growth of commensals. Prebiotics also provide the substrate for antiinflammatory short-chain fatty acid production by bacteria. This is likely to have more global effects on gut homeostasis than only adding

https://CafePezeshki.IR

one or two probiotic strains into the vast and complex ecosystem of the gut.

In summary, at present there is no clear evidence that prebiotics, probiotics or synbiotics prevent food allergy.

Targeting and Individualizing Prevention Strategies – Considering Phenotypic, Environmental and Genotypic Risk

The effectiveness of any 'preventive' intervention is likely to vary with both genetic and environmental factors, including maternal allergic status, which may also have direct effects on the immunologic milieu during pregnancy and lactation. Just as concepts of individualized 'precision medicine' are being explored for disease treatment, prevention strategies may also ultimately need to be tailored according to the context, conditions and other factors determining risk. This requires a better understanding of both the genetic and environmental determinants of allergic risk, which are likely to be extremely variable and complex, and raises a series of issues that will become increasingly relevant as technologies evolve, including how to target interventions, how to identify specific groups at risk and how to refine strategies according to the level of risk.

At present there are no good early markers of genetic risk apart from 'family history', which remains the only predictor of allergic disease in use. This is crude and imperfect with variable specificity (48–67%) and sensitivity (22–72%) and a positive predictive value generally less than 40%.[115–117] Because there are many and diverse genetic determinants of allergy, predicting risk through genotyping is not yet possible. In the meantime there have been attempts to identify early predictive biologic markers. Currently none of these has any established predictive value.[118]

A better understanding of the genetic predispositions existing to food allergy will lead to the determination of whether a rise in food allergy is occurring asymmetrically between high-risk and low-risk groups. There is evidence that Asian populations may be more susceptible to allergic disease when living in 'westernized' environments.[119,120] Earlier studies of respiratory disease observed that both allergic symptoms and sensitization were more common in Asian Australians than in non-Asian Australians.[119] Rates were also higher in Australian-born Asians than in Asian immigrants, in whom the prevalence increased with length of stay in Australia.[119] Recently, the Healthnuts study (2011) found a higher rate of food-sensitized eczema among children of Asian descent.[121] Interestingly, on examination of risk factors for eczema development (a closely associated infantile allergic disease) the study found that Asian children were not only more likely to have eczema than their non-Asian counterparts but that their parents were less likely to have allergic disease than non-Asian parents. This was particularly so for Asian parents who had migrated to Australia less than five years previously, suggesting a strong gene-environment interaction even over and above that of a migrational generational effect.[122] More recent studies have similarly noted that non-white races are more susceptible to food allergy. In the USA, the 2007 National Health Interview Survey found that non-Hispanic children had higher rates of reported food allergy compared with Hispanic children.[123] Asian populations in particular are also highly susceptible to food allergy,[120] suggesting a strong genetic propensity that is amplified by a western environment. This is consistent with earlier work indicating evolutionary differences in genetic polymorphisms affecting candidate genes.

Finally, eczema does appear to be an important risk factor for the development of food allergic disease: up to 50% of infants with moderately severe early-onset eczema (within the first 3 months) develop challenge-proven food allergy by age 1 year.[124] This population-based observation has been noted in clinical populations and suggests that eczema genes (such as filaggrin, *FLG*) may be important determinants of food allergic disease. A multisite study of peanut allergy found that *FLG* null mutations were associated with a significantly increased risk of peanut allergy;[125] however, history of eczema and sensitization status was not available for all infants, therefore the impact of *FLG* on these outcomes could not be assessed independently of food allergy. In the Healthnuts study we found that *FLG* null mutations were associated with food sensitization (but not food allergy over and above that risk) independent of eczema status. This suggests that there could be a different pathogenesis for food sensitization and food allergy. That is, the epidermal barrier dysfunction due to filaggrin deficiency might cause food sensitization regardless of clinical eczema status, but filaggrin-induced skin barrier dysfunction might not play a further role in the progression to food allergy from sensitization. These results provide support for the dual allergen hypothesis proposed by Gideon Lack.[126] Expanding on this hypothesis, filaggrin deficiency might provide a mechanism for the development of sensitization, but a second factor (or factors), either environmental or genetic (or both), may be important for converting food sensitized infants to food allergic status.

Natural History of Food Allergy

Food allergy is most commonly acquired during the first year of life, with peak incidence of 5% to 10% occurring at 1 year of age. The prevalence falls until late childhood, where it plateaus at about 3.5% through adulthood. The prevalence of perceived, but unconfirmed, food allergy or food intolerance is as high as 25%.[127]

It appears that prevalence of food allergies has been increasing over recent years. In 2003, Sicherer and colleagues[128] reported that the rate of allergy to peanut or tree nut, or both, in children, rose from 0.6% to 1.2% between 1997 and 2003, primarily as a result of an increase in the reported allergy to peanuts from 0.4% to 0.8% over this period. In 2004, the overall prevalence of food allergy in the USA was reported as 6% in young children and 3.7% in adults.[129] The prevalence of milk allergy in children vs adults was 2.5% vs 0.3%, egg 1.3% vs 0.2%, peanut 0.8% vs 0.6%, tree nut 0.2% vs 0.5%, fish 0.1% vs 0.4 % and shellfish 0.1% vs 2.0%. Prevalence of sensitization to foods peaked at 10% at 1 year, declining to 3% at 6 years of age. Egg and milk IgE were the most common positives, followed by wheat and soy; no clinical confirmation of food allergy was reported.

In a Danish study by Host and Halken,[130] 1,749 children were followed prospectively from birth to the age of 3 years. Milk allergy was suspected in 117 children (6.7%) and confirmed by milk elimination and oral challenge in 39 (2.2%), with more than half having documented IgE-mediated disease. In a study from the Isle of Wight,[131] all children born over a 1-year period

https://CafePezeshki.IR

($N = 1,456$) were followed for the development of peanut and tree nut allergy until 4 years of age. Fifteen (1.2%) of the 981 skin-tested children were found to be sensitized to peanuts or tree nuts. In a large German study,[132] radioallergosorbent tests (RASTs) were performed yearly to the age of 6 years on a birth cohort of 4,082 children.

It has long been established that, whereas milk and egg allergies are most frequently outgrown in childhood, peanut allergy most commonly remains a lifelong issue. Tree nut, fish and shellfish allergy are also much more likely to continue into adulthood than are egg and cow's milk allergy. Recent studies suggest that milk[133] and egg allergy[134] are more persistent than they were 15 years ago. In addition, the eventual tolerance or persistence of allergy may be predictable by degree of positivity of allergy tests or concomitant allergic conditions. Cow's milk and egg allergy in particular are more likely to resolve early although the first data to look longitudinally[134] found that up to 60% of children presenting to a tertiary center with food allergy had developed tolerance by 16 years of age. However this study was limited because it followed the self-fulfilling clinical prophesy that those with a sustained elevated skin prick test were unlikely to have developed oral tolerance and therefore were not offered oral food challenges – the most objective way to formally diagnose tolerance. Recently Peters et al followed a population-based longitudinal cohort and found that 47% of infants with challenge-proven food allergy at 12 months had resolution by age 2 years.[135] This study was unique in that oral food challenges were systematically undertaken in all infants with a positive skin prick test (SPT), irrespective of how large the wheal size, minimizing underdiagnosis of tolerance. Furthermore, egg allergy was subphenotyped by undertaking baked egg challenges in addition to raw egg allergy challenges. The study found that those with baked egg tolerance (80% of egg allergic infants at age 12 months) were three times more likely to develop tolerance by age 2 years than those who were baked egg allergic. This study was supported by a similarly designed study from the CoFAR collaboration although the latter assessed the rate of egg allergy resolution in a clinic cohort of older children.[136]

In addition to baked egg allergy status described by Peters et al,[135] predictors of egg allergy remission in the CoFAR study[136] included initial reaction characteristics (isolated urticaria/angioedema vs other presentations), baseline egg-specific IgE level, egg SPT wheal size, eczema severity and IgG4 and IL-4 responses. Further studies assessing prognostic implications for food allergy should therefore carefully subphenotype at baseline using clear and valid criteria (including baked egg challenges for egg allergy) as well as ensuring that analysis of tolerance is made using the gold standard outcome, oral food challenge.

In addition to a lower general prevalence, peanut and tree nut allergies appear to have a lower rate of resolution than either egg or cow's milk allergies. Again very few longitudinal data exist and only peanut data from clinic recruited cohorts are available.[137] Ho and colleagues[137] demonstrated that peanut SPT wheal of 6 mm or greater (hazard ratio 2.74, 95% CI 1.13–3.79) and specific IgE >3 kU_A/L (hazard ratio 2.74, 95% CI 1.13–6.61) were predictive of persistent peanut allergy. As per the Savage report,[134] challenges in this cohort were only initiated if SPT wheal sizes fell below a threshold consistent with the 95% PPV for allergy diagnosis.[137] Information about peanut allergy resolution using systematic challenges is urgently needed as are any longitudinal data regarding tree nut allergy resolution.

Although it had generally been thought that once food allergies have resolved they are unlikely to recur, the unsettling recurrence of peanut[138] and fish[139] allergy has been reported in patients with previously negative food challenges following a history of earlier allergy. Further to this point, in 2003, Fleischer and colleagues[140] reported that in a group of 84 patients with peanut allergy, 55% of those with peanut IgE levels <5 kU_A/L were able to pass peanut challenges, while 63% of those with levels <2 kU_A/L were able to tolerate peanuts. Recurrence of the peanut allergy was reported in 2 patients, both of whom did not ingest peanuts regularly after they had passed their challenges. Two years later,[141] this group also reported that 9% of patients with tree nut allergy could ultimately pass a double-blind, placebo-controlled food challenge to tree nut.

It seems that there are likely different phenotypes of food allergy, whose natural history depends not only on the amount of IgE measured or concomitant allergic conditions but also the specific epitope against which the IgE is directed. Vila and colleagues[142] demonstrated that the specific cow's milk IgE from patients with persistent cow's milk allergy is more likely to bind to the linear (sequential) epitopes of α1- and β-casein as compared to higher levels of IgE to the conformational (native) epitopes in children who had lost their clinical sensitivity to cow's milk as documented by oral food challenge.

Lately, the phenomenon that some children with egg allergy can tolerate heated egg (egg in baked goods) but not whole egg has been studied. Lemon-Mulé and colleagues[143] recently reported that a majority of egg allergic children could tolerate heated egg, particularly those with smaller SPT and egg-specific IgE levels. Furthermore, continued ingestion of heated egg led to decreased skin test wheal diameter, ovalbumin-specific IgE and ovalbumin- and ovomucoid-specific IgG4. The authors noted that these immunologic changes parallel those that one would expect to see in clinical tolerance. The same group earlier reported similar immunologic findings in milk allergic children who could tolerate heated milk products.[144] Seventy five percent of the milk allergic children were able to tolerate heated milk. The authors postulated that this tolerance could be due to the loss of conformational epitopes that comes from heating. There is now an evolving practice of offering baked cow's milk or baked egg oral food challenges to infants and children with cow's milk and egg allergy respectively with the aim of providing a more liberated diet and the potential to induce tolerance to the uncooked food allergen.[145,146]

Conclusions and Future Directions

The modern environment, with its compound risk factors for development of allergy, presents many challenges. Strategies to effectively overcome these risk factors present even greater challenges, particularly as many risk factors are driven by wider social, cultural and economic factors and cannot necessarily be addressed by individual efforts. If the hygiene hypothesis is found to be central to the rise of both atopy in general and food allergy more specifically, this effect might be expressed through a delayed generational effect and the impact of maternal epigenetic modification on fetal priming of the immune system.

Countries with a westernized lifestyle appear to have the highest rates of allergic disease, and allergies are less common in developing countries. To date there has been little information on these differences or why they might be occurring. Emerging evidence suggests that changes in the environment

https://CafePezeshki.IR

related to a western lifestyle and to economic development are the most important factors causing the rise in allergic disease.[1] In particular, improved hygiene, less exposure to microbial organisms, changes in diet (eating less fish and vegetables), less exposure to sunlight (reduced UV and therefore reduced vitamin D), and possibly increased use of antibiotics are thought to be the main factors contributing specifically to the rise in food allergy.

44 Enterocolitis, Proctocolitis and Enteropathies

SCOTT H. SICHERER | ANNA NOWAK-WĘGRZYN

KEY POINTS

- A number of gastrointestinal food allergic disorders are not typically associated with food-specific IgE antibodies.
- These dietary protein-induced cell-mediated disorders usually present in infancy.
- There is a broad differential diagnosis to consider when evaluating infants with possible gastrointestinal food allergy.
- Diagnosis may require medically supervised oral food challenges, and treatment requires dietary elimination.
- Except for celiac disease, these non-IgE-mediated gastrointestinal allergies typically resolve during childhood.

This chapter focusses upon four non-IgE-mediated food hypersensitivity disorders that affect the gastrointestinal tract: food protein-induced proctocolitis, enterocolitis, enteropathy and celiac disease.[1] These disorders have overlapping symptoms, but are distinguishable clinically and have distinct patterns of symptoms and clinical course.[2]

Epidemiology/Etiology

DIETARY PROTEIN PROCTOCOLITIS

Eosinophilic proctocolitis is characterized by the presence of mucusy, bloody stools in an otherwise healthy infant. The disorder is attributed to an immune response directed, most commonly, against cow's milk protein. The mean age at diagnosis is approximately 60 days, with a range of 1 day to 6 months.[3–6] The bleeding is often mistakenly attributed to perirectal fissures, although bleeding associated with fissures tends to present with streaks of blood on hard, formed stool rather than mixed in frothy, mucusy stool, which is typical of proctocolitis. Failure to thrive is absent. About 60% of cases occur in breastfed infants where the immune response results from maternal ingestion of the food allergen, usually cow's milk, which is passed in immunologically recognizable form into the breast milk. In formula-fed infants, the reaction is associated with cow's milk or, less commonly, soy.[4,7] Proctocolitis has rarely been described in infants fed hypoallergenic, extensively hydrolyzed formulas.[8] Associated peripheral blood eosinophilia, hypoalbuminemia and/or anemia are uncommon.[4,9,10] Markers of atopy such as atopic dermatitis or a positive family history of atopy are not significantly increased compared with the general population.

Endoscopic examination is usually not needed for diagnostic purposes but, when performed, shows patchy erythema, friability and a loss of vascularity generally limited to the rectum.[11] High numbers of eosinophils (5 to 20 per high-power field) or eosinophilic abscesses are seen in the lamina propria, crypt epithelium and muscularis mucosa.[9,12] The eosinophils are frequently associated with lymphoid nodules (lymphonodular hyperplasia)[9,13] and rarely with granuloma formation.[14] However, lymphonodular hyperplasia is not unique to this condition.[9,12] The pathophysiology is unknown. Because inflammation is confined to the lower colon and is common in breastfed infants, it has been hypothesized that dietary antigens complexed to breast milk IgA may play a part in the activation of eosinophils and the distribution of the inflammatory process.[3]

The frequency of food allergy causing rectal bleeding in infants has not been extensively studied. Xanthakos and colleagues[5] performed colonoscopy and biopsy on 22 infants presenting with rectal bleeding, and proved eosinophilic colitis in 14 (64%). The remainder had normal biopsies (23%) or nonspecific colitis (14%). This group recommended dietary elimination for those with eosinophilic colitis and the majority had resolution within 1 to 3 weeks. However, the relationship of cow's milk protein to symptoms was not proven by rechallenge. Arvola and colleagues[15] examined 40 infants presenting with rectal bleeding. Infants were randomized to either avoid cow's milk protein or maintain their current diet. The duration or severity of bleeding was no different between the two groups. During follow-up, cow's milk allergy was diagnosed in 18% of the infants (based upon various criteria including flares of atopic dermatitis and urticaria upon food challenge as well as rectal bleeding) and for these infants, there was a reduced length of bleeding when they had been randomized to an elimination diet at study outset. Atopic dermatitis and inflammation of the colonic mucosa were associated with persistence of cow's milk allergy to the age of 1 year. These studies indicate that food allergy may not be a common cause of rectal bleeding in infants unless there are additional signs of allergy, and that milk protein-induced proctocolits has to be differentiated from benign idiopathic neonatal transient eosinophilic colitis.[6,16]

FOOD PROTEIN-INDUCED ENTEROCOLITIS SYNDROME (DIETARY PROTEIN ENTEROCOLITIS) (Box 44-1)

Food protein-induced enterocolitis syndrome [FPIES]) describes a symptom constellation of profuse vomiting, lethargy and diarrhea, usually diagnosed in the first months of life and most commonly attributable to an immune response to cow's milk or soy.[17]

https://CafePezeshki.IR

BOX 44-1 CLINICAL PEARLS: FOOD PROTEIN-INDUCED ENTEROCOLITIS SYNDROME (FPIES)

- May mimic sepsis with presentations that include vomiting, lethargy, diarrhea, acidemia, leukocytosis, thrombocytosis, hypotension and methemoglobinemia.
- Common triggers include milk, soy, rice and oats.
- For infants with milk or soy FPIES, use an extensively hydrolyzed casein-based formula rather than a soy or milk formula due to common (up to 50%) concomitant FPIES to these foods.
- For infants with milk/soy FPIES, avoid oats/rice as first solids.
- Onset of FPIES after the age of 1 year is uncommon and FPIES typically resolves in the first 1 to 5 years.
- Children with detectable milk-specific IgE antibodies have a more protracted course than those without IgE antibodies; some may convert to immediate IgE-mediated milk allergy.

Inflammation involves both the small and large bowels. Unlike allergic proctocolitis, the majority of affected infants are asymptomatic while exclusively breastfed on an unrestricted maternal diet. When the causal protein remains in the diet (e.g. in young infants fed with cow's milk or soy-based formulas), chronic symptoms can include watery or bloody diarrhea, poor growth, anemia, hypoalbuminemia and fecal leukocytes; the illness may progress to dehydration and hypotension over the course of days to weeks.[18–20] Removal of the causal protein leads to resolution of symptoms but re-exposure results in a characteristic delayed (by about 1 to 3 hours) onset of repetitive, often projectile vomiting, lethargy, elevation of the peripheral blood polymorphonuclear leukocyte count and possibly reduced temperature, thrombocytosis, hypotension, diarrhea, dehydration, acidemia and methemoglobinemia.[21] These reactions mimic sepsis.

Powell[22] initially characterized the syndrome. She described nine infants with severe, protracted diarrhea and vomiting. The symptoms developed at 4 to 27 days after birth (mean, 11 days) in infants on a cow's milk-based formula. Switching to a soy-based formula resulted in transient improvement, but symptoms generally recurred in 7 days. Seven of the nine infants were below birth weight, and eight of nine presented with dehydration. Eight of the infants appeared acutely ill and underwent sepsis evaluations that were negative. All infants were noted to have low serum albumin, elevated peripheral blood polymorphonuclear leukocyte counts, and stools that were positive for hemoglobin and reducing substances. The hospital course usually involved improvement while on intravenous fluids, followed by recurrence of dramatic symptoms with reintroduction of soy- or cow's milk-based formula, including the development of shock in several infants. Follow-up with oral challenges was carried out with cow's milk and soybean formulas at a mean age of 5.5 months, and 14 of the 18 challenges were positive. Ten of 14 challenges resulted in vomiting (onset 1 to 2.5 hours after ingestion; mean 2.1 hours) and all experienced diarrhea (onset 2 to 10 hours; mean 5 hours) with blood, polymorphonuclear leukocytes and eosinophils, and increased carbohydrate in the stool. There was a rise in peripheral blood polymorphonuclear cell counts in all positive challenges, peaking at 6 hours after ingestion, with a mean rise of 9900 cells/mm^3 (range 5,500 to 16,800 cells/mm^3). Only isolated gastrointestinal symptoms were reported.

The results of these studies led Powell[22,23] to propose criteria for a positive oral challenge to diagnose food protein-induced enterocolitis of infancy.[24] Confirmation of the allergy included a negative search for other causes, improvement when not ingesting the causal protein and a positive oral challenge resulting in vomiting/diarrhea, evidence of gastrointestinal inflammation through stool examination, and a rise in the peripheral polymorphonuclear leukocyte count to over 3,500 cells/mL.

Numerous foods, other than milk and soy, have subsequently been documented as triggers for FPIES, including rice, oat, meats, fish, fruits, vegetables and egg.[25–29] The dramatic nature of the presentation often results in evaluations for sepsis or surgical diagnoses,[30] and a delay in final diagnosis until more than one episode has occurred.[25]

Since infantile FPIES is a diagnosis that can be made clinically, there are no large series in which biopsies have been performed solely in patients fulfilling Powell's criteria. Regarding immunopathology, studies have focussed upon the role of T cells and the importance of tumor necrosis factor (TNF)-α.[31–35] In a large cohort of Japanese infants with non-IgE-mediated food allergy, TNF-α, interleukin (IL)-6, and Th2 cytokines (IL-3, IL-5 and IL-13), but not interferon (IFN)-γ or IL-17 were increased in the supernatant from milk protein-stimulated peripheral blood mononuclear cell cultures of patients compared to nonallergic controls.[36] Chung and colleagues[37] examined the presence of TNF-α in duodenal biopsy specimens using immunostains in infants with FPIES. Semiquantitative analyses revealed higher staining for TNF-α in affected infants with villus atrophy compared to those without atrophy and in normal controls. Taken together, these studies support the notion that TNF-α plays a role in the acute and chronic symptoms of FPIES. It is also known that the regulatory cytokine transforming growth factor (TGF)-β1 is involved in the protection of the epithelial barrier of the gut from the penetration of foreign antigens.[37–39] Chung and colleagues[37] demonstrated that the type 1, but not type 2, receptor for TGF-β1 were decreased in duodenal biopsy specimens in patients with FPIES compared to controls. Analysis of humoral features in milk-induced enterocolitis showed milk-protein specific IgA, but very low levels of specific IgG1 and IgG4; this has been theorized to be pathogenic because IgG4 might otherwise block complement fixing antibodies.[40] Specific IgE is sometimes noted as well, and may be a marker of persistence.[21,41,42]

DIETARY PROTEIN ENTEROPATHY

This disorder is characterized by protracted diarrhea, vomiting, malabsorption and failure to thrive. Additional features may include abdominal distention, early satiety, edema, hypoproteinemia and protein-losing enteropathy.[43] Symptoms usually begin in the first several months of life, depending on the time of exposure to the causal proteins. The disorder was described primarily from the 1960s to the 1990s[44–47] and was commonly attributed to cow's milk protein. A decrease in prevalence was documented in Finland[48] and Spain[49] and attributed to a rise in breastfeeding and/or the use of adapted infant formula. There have been no clear reports of this diagnosis in the past several years, although presentations of eosinophilic gastroenteritis with protein-losing enteropathy share many features with previous descriptions of this disorder.[50–52]

Unlike gluten-sensitive enteropathy (celiac disease), this enteropathy generally resolves in 1 to 2 years, and there is no increased threat of future malignancy.[53]

https://CafePezeshki.IR

CELIAC DISEASE

Celiac disease, also termed *celiac sprue* or *gluten-sensitive enteropathy* and estimated to affect 1% of the population, is caused by an immune response triggered by wheat gluten or related rye and barley proteins that results in inflammatory injury to the small intestinal mucosa.[54–57] The classic presentation occurs in infants after weaning, at the time when cereals are introduced into the diet. Early (<4 months of age) or delayed (>7 months) introduction of wheat may be a risk factor,[58,59] and breastfeeding may be a related protective factor.[60] Symptoms partly reflect malabsorption, with patients exhibiting failure to thrive, anemia and muscle wasting. Additional symptoms are varied and include diarrhea, abdominal pain, vomiting, osteoporosis, bone pain and aphthous stomatitis. Subclinical or minimal disease is possible, delaying diagnosis into adulthood.[57] Chronic ingestion of gluten-containing grains in patients with celiac disease is associated with increased risk of enteropathy-associated T cell lymphoma. Celiac disease is associated with autoimmune disorders and IgA deficiency. Another associated disorder is *dermatitis herpetiformis*,[61] a gluten-responsive dermatitis characterized by pruritic, erythematous papules, and/or vesicles distributed symmetrically on the extensor surfaces of the elbows and knees, and also on the face, buttocks, neck and trunk.

Endoscopy of the small bowel in active celiac disease typically reveals total villous atrophy and extensive cellular infiltrate. The disorder is caused by gliadin-specific T cell responses against deamidated gliadin produced by tissue transglutaminase.[62] Gliadin stimulation of monocytes and macrophages may also contribute to the inflammatory response.[63,64] Antigen presentation appears to be a central issue in the immunopathology because about 95% of patients are HLA-DQ2, with the remainder being HLA-DQ8.[54,65] Gliadin is one of the few substrates for tissue transglutaminase, which deamidates specific glutamines within gliadin, creating epitopes that bind efficiently to DQ2 gut-derived T cells.[66] The activation of DQ2- or DQ8-restricted T cells initiates the inflammatory response.[56] Elimination of gliadin from the diet results in a down-regulation of the T cell-induced inflammatory process and normalization of the mucosal histology.

Differential Diagnosis

Because the gastrointestinal tract has a limited number of responses to inflammatory damage, there is an overlap in the symptoms observed with these disorders. Differentiating them requires consideration of key, distinct clinical features and directed laboratory examinations. Moreover, numerous medical disorders must be considered in the evaluation of patients presenting with gastrointestinal complaints. Some of these disorders include other food hypersensitivities, but food intolerance (nonimmune disorders such as lactase deficiency) and toxic reactions (e.g. bacterial poisoning) are potential considerations.

The differential diagnosis can encompass virtually any cause of abdominal complaint, including the following categories: infection (viral, bacterial, parasitic), anatomic (pyloric stenosis, anal fissures, motility disorders, lymphangiectasia, Hirschsprung's disease, reflux, intussusception), inflammatory disorders (inflammatory bowel disease), metabolic disorders (disaccharidase deficiencies), malignancy, immunodeficiency and others. The differential diagnosis of severe FPIES includes anaphylaxis. Depending on the constellation of findings, various diagnostic strategies are used, description of which is beyond the scope of this chapter. However, the presence of a number of clinical elements may underscore the possibility of a food allergic disorder. The general approach to the diagnosis of food-allergic disorders affecting the gut is outlined in Figure 44-1. Various features may suggest a differentiation of the disorders described in this chapter from those related to IgE antibody-mediated gastrointestinal allergies (oral allergy, gastrointestinal anaphylaxis) and those that are sometimes associated with IgE antibodies (eosinophilic gastroenteropathies and reflux). The timing of symptoms following ingestion of the causal food (acute in IgE antibody-mediated disease), symptoms (isolated vomiting in gastroesophageal reflux disease) and selected test results (biopsy revealing an eosinophilic infiltrate in allergic eosinophilic gastroenteropathy) differentiate these food allergic disorders. The food-related disorders must also be distinguished from a host of disorders that have similar clinical findings but alternative etiologies. Table 44-1 delineates the disorders whose features may most closely overlap the cell-mediated food allergic disorders.

The distinguishing clinical features of dietary protein-induced proctocolitis, enteropathy, enterocolitis and celiac disease are listed in Table 44-2. Although they may represent a spectrum of disorders with similar etiologies, the treatment and natural course of these diseases vary, making a specific diagnosis imperative. The causal foods, symptoms and family history usually indicate the likely disorder. In some cases, the diagnosis requires initial confirmation of reactivity/association determined by resolution of symptoms with an elimination diet and recurrence of symptoms after oral challenge.[1,2] In some cases, specific tests are needed (e.g. serologic tests for IgA endomysial or tissue transglutaminase antibody and small bowel biopsy). The disorders are not IgE antibody-mediated, but if there has been immediate onset of symptoms following ingestion or an association of gastrointestinal allergy with other features of IgE antibody-mediated food allergy (e.g. atopic dermatitis, asthma), screening tests for food-specific IgE antibody (prick skin tests, serum food-specific IgE antibodies) may be helpful in defining the process causing the reactions. A number of tests are of unproved value for the diagnosis of food allergy and should not be used. These include measurement of IgG4 antibody, provocation-neutralization (drops placed under the tongue or injected to diagnose and treat various symptoms) and applied kinesiology (muscle strength testing).[67]

Evaluation and Management

DIETARY PROTEIN PROCTOCOLITIS

The diagnosis of dietary protein proctocolitis should be entertained in an infant who is otherwise well and presents with mucusy bloody stools, an absence of symptoms indicating a systemic disease, coagulation defect or another source of bleeding. The definitive diagnosis requires withdrawal of the presumed allergen with monitoring for resolution of symptoms; however, additional testing and refeeding of the eliminated protein is advisable after resolution because transient rectal bleeding in infancy is more frequently not related to allergy.[15] A survey of 56 pediatric gastroenterologists showed that 84% prescribe empiric dietary trials.[5] In the absence of biopsy confirmation and especially in the absence of other signs of atopy,

https://CafePezeshki.IR

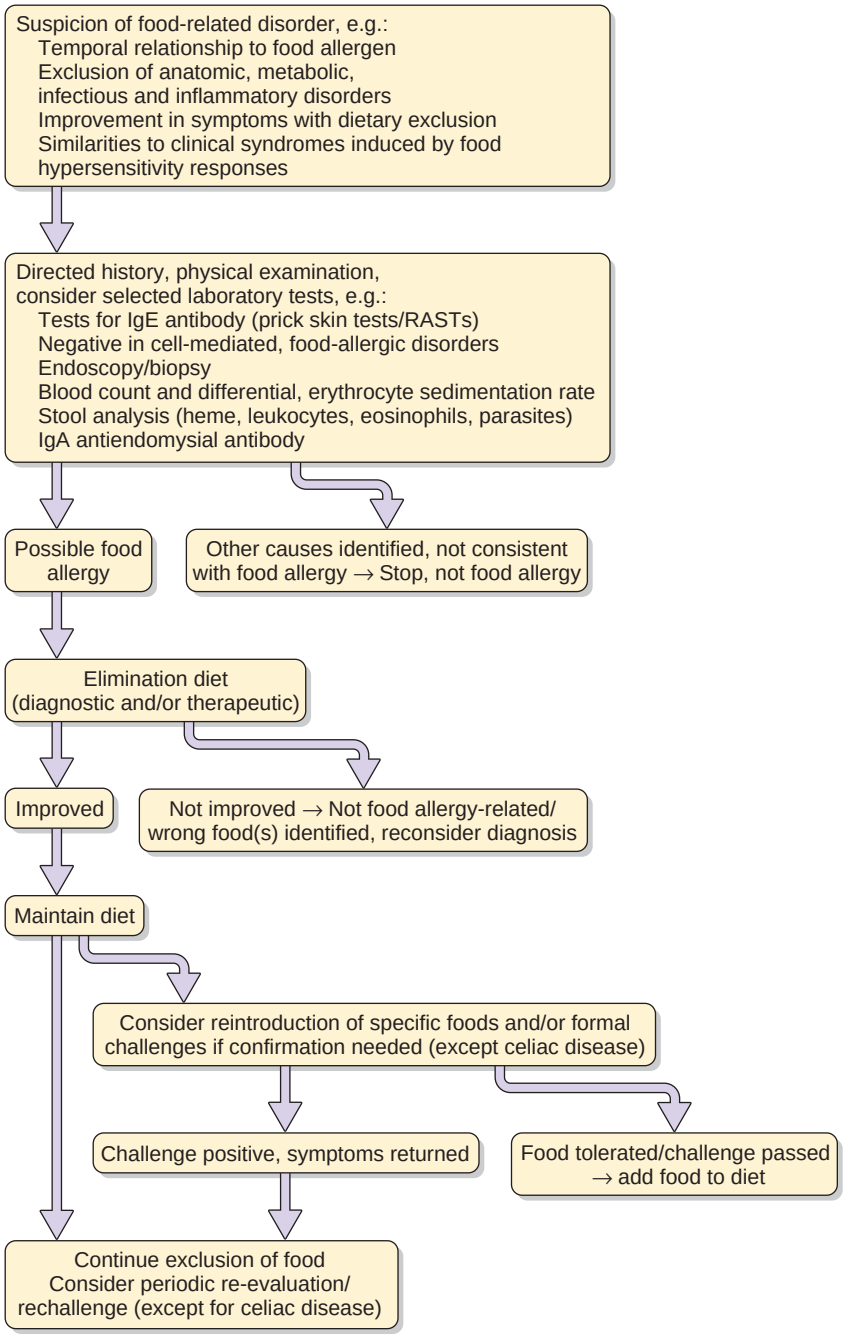

Figure 44-1 Evaluation of food allergy requires a simultaneous consideration of alternative diagnoses (infection, anatomic, metabolic, etc.) and disorders caused by food allergy, including those described in this chapter and others (i.e. oral allergy syndrome, anaphylaxis, eosinophilic gastroenteropathies, food-related reflux disease) and nonimmune adverse reactions to foods (lactose intolerance). Laboratory tests and decisions for elimination and challenge are based on specific elements of the history and an appreciation for the clinical manifestations and course of the various disorders (see text). *RAST* – Radioallergosorbent test.

refeeding should be considered soon after resolution of symptoms, given the high rate of spontaneous resolution.[6,16] In cow's milk or soy formula-fed infants, substitution with a protein hydrolysate formula can be undertaken. The majority of infants who develop this condition while ingesting protein hydrolysate formulas will experience resolution of bleeding with the substitution of an amino acid-based formula, although follow-up challenges to prove that the formula substitution was required have not been systematically undertaken.[5,8,68] Management in breastfed infants requires maternal restriction of cow's milk or possibly soy, egg or other foods.[4] In up to 12% of breastfed infants, bleeding may persist despite extensive food elimination from the maternal diet and requires switching the infant to a hypoallergenic formula. If breastfeeding is continued, chronic bleeding may lead to mild anemia despite iron supplementation and to hypoalbuminemia. In spite of the persistent symptoms, most children become tolerant to cow's milk by the age of 12 months and have no long-term sequelae.[3] Progressive bleeding, despite dietary restriction, should prompt re-evaluation with consideration for proctocolonoscopy and biopsy.[69] Since there is generally no risk of a severe reaction, the foods can be gradually reintroduced into the diet either as a trial to prove a causal relationship or months afterward to monitor for resolution of the allergy. However, if there is a suspicion of mild enterocolitis (e.g. vomiting in addition to hematochezia) or a history to suggest IgE-mediated reactions, dietary advancement may

https://CafePezeshki.IR

require caution with repeated testing (e.g. skin or serum tests for specific IgE to the causal food) and medically supervised oral food challenges (OFCs).

FOOD PROTEIN-INDUCED ENTEROCOLITIS SYNDROME

As noted earlier, the diagnosis of FPIES rests on clinical and challenge criteria. Most patients do not undergo a formal challenge during infancy because the diagnosis becomes self-evident after elimination of the causal protein, and frequently patients experience inadvertent re-exposure, proving their sensitivity before a diagnostic test feeding.[67] It must be appreciated that chronic ingestion, or re-exposure to the causal food, can result in a clinical picture that is severe, may mimic sepsis, and may include acidemia and methemoglobinemia.,[21,25,27,41,42,70–72] Approximately half of infants with cow's milk reactions also react to soy, and among children reacting to milk/soy, about 25% react to additional proteins such as rice or oat.[41,42,71] Since there is a high percentage of patients with sensitivity to both cow's milk and soy, switching directly to a casein hydrolysate is recommended. For the rare patients reactive to hydrolysate, an amino acid-based formula is appropriate.[42,73] Caution and delay are also advised regarding the introduction of common triggers such as rice and oat when milk/soy reactions have already occurred.[17,74]

Follow-up challenges should be performed at intervals to determine tolerance (approximately every 12 to 24 months, depending on the clinical severity). These challenges should be performed under physician supervision with intravenous fluids and emergency medications immediately available because dramatic reactions, including shock, can occur. Re-evaluation for the development of antigen-specific IgE antibody before challenge is helpful because 4–30% of cases develop IgE antibodies to the FPIES food, and among those with food-specific IgE, one in four converts to IgE-mediated reactions over time.[21,41,42] Patch testing does not provide diagnostic information.[75,76] In the experience of the authors,[21,42] about half of positive challenges require treatment (usually intravenous fluids). In view of the presumed T cell involvement in FPIES pathophysiology, corticosteroids have been administered for severe reactions. A small case series suggested effectiveness of intravenous ondansetron for stopping emesis induced during FPIES OFCs.[77] Five children older than 3 years who developed emesis during an FPIES OFC were treated with a 0.2 mg/kg dose of ondansetron, together with an intravenous physiologic saline bolus. Three of the four children treated with intravenous ondansetron experienced resolution of emesis and lethargy within 10 to 15 minutes, while one required an additional dose of ondansetron. Another child who was treated with oral ondansetron required an additional dose of intravenous ondansetron to improve severe abdominal pain. Intramuscular ondansetron has been used in five young children (four were under the age of 3 years) with rapid resolution of symptoms during the OFC.[78] Ondansetron is usually well tolerated, although special caution may be warranted in children with underlying heart disease due to the potential to prolong the QT interval. More studies are needed to define the role of ondansetron in FPIES management.

While intravenous fluids constitute first-line management in the treatment of FPIES, the role of epinephrine in treatment is not known, but it should be available in case of severe cardiovascular reactions. Given the risk for hypotension, the challenge is best performed under physician supervision with consideration for obtaining intravenous access. Food challenges for this non-IgE-mediated syndrome are typically performed with 0.06 to 0.6 g/kg of the causal protein, with lower doses for those patients with a history of severe reactions. The challenge protocol and definition of a positive response are shown in Table 44-3.

TABLE 44-1 Examples of Clinical Disease That May Overlap Symptoms of Cell-Mediated, Dietary Protein-Induced Disease

Clinical Disease	Symptoms
Proctocolitis	Anal fissure Infection Perianal dermatitis Transient idiopathic neonatal eosinophilic colitis Necrotizing enterocolitis Volvulus Hirschsprung's disease Intussusception Coagulation disorders
FPIES	Sepsis/infection Necrotizing enterocolitis Intussusception Lymphangiectasia Volvulus Ileus Metabolic disorder
Enteropathy	Infection Eosinophilic gastroenteropathy with protein loss Bowel ischemia Inflammatory bowel disease Lymphangiectasia Autoimmune enteropathy Immune deficiency Tropical sprue Malignancy

TABLE 44-2 Clinical Features Helpful in Distinguishing Dietary Protein-Induced Proctocolitis, Enteropathy, Enterocolitis and Celiac Disease

	Vomiting	Diarrhea	Growth	Foods	Other	Onset
Proctocolitis	Absent	Minimal, bloody	Normal	Breast/milk/soy		Days to 6 months
FPIES	Prominent	Prominent	Poor	Milk/soy/rice/oat	Re-exposure: severe, subacute symptoms	Days to 1 year; adult onset to shellfish
Enteropathy	Variable	Moderate	Poor	Milk/soy	Edema due to intestinal protein loss	2–24 months
Celiac	Variable	Variable	Poor	Gluten	HLA-DQ2–associated	>4 months

https://CafePezeshki.IR

TABLE 44-3 Oral Food Challenges for Food Protein-Induced Enterocolitis Syndrome

Diagnostic Step	Procedures and Assessment
Preparation for challenge	Verify normal weight gain, no gastrointestinal symptoms while off causal protein Obtain baseline stool sample and peripheral blood polymorphonuclear leukocyte count Consider intravenous access Medications ready to treat reaction
Administration of challenge	Administer challenge (typically 0.15–0.6 g of food protein/kg body weight) Observe for symptoms (usual onset of vomiting 1–3 hours) Repeat peripheral blood polymorphonuclear leukocyte count 6 hours after ingestion Collect subsequent stools for 24 hours
Evaluation of positive challenge	Symptoms (vomiting, lethargy, diarrhea) Rise in peripheral polymorphonuclear leukocyte count (>3,500 cells/mm^3) Fecal blood (gross or occult) Fecal leukocytes Fecal eosinophils Positive challenge: three of five criteria positive Equivocal: two of five criteria positive

From Powell[24] and Sicherer et al.[21]

The natural history is variable, depending on the population studied. A large population-based cohort study from Israel reported resolution of milk FPIES in 90% by age 2 years.[79] A retrospective study of 35 children from Australia evaluated over a span of 16 years showed rice (14 children), soy[12] and milk[7] to be the most common triggers, and sensitivity was lost by the age of 3 years to rice and soy in about 80%.[25] In a cohort of 23 Korean infants with milk/soy FPIES, resolution rates were 64% for milk and 92% for soy by 10 months of age and all were tolerant by 20 months.[80] In a retrospective US study, overall significantly lower rates of resolution of FPIES were found, 35% by age 2 years, 70% by age 3 years and 85% by age 5 years.[41] In a mixed design US study, overall median age at resolution of milk FPIES was 13 years, while the median age for patients with undetectable milk IgE antibodies was 5 years, indicating that IgE positivity is associated with a more persistent form of FPIES.[42] These differences may reflect differences in study designs and/or selection bias toward a more severe and persistent phenotype among children evaluated at referral centers. About 50% of children outgrow rice or oat FPIES by age 4 to 5 years.[41,42,81] However, some patients maintain their allergy well beyond the age of 6 years, even into adulthood.[41,42,81]

DIETARY PROTEIN ENTEROPATHY AND CELIAC DISEASE

There are no specific diagnostic tests for dietary protein-induced enteropathy; therefore, the diagnosis depends on exclusion of alternative diagnoses, biopsy evidence of enteropathy, and proof of sensitivity through dietary elimination and rechallenge. Since the symptoms are not as dramatic as enterocolitis syndrome, observation during dietary ingestion and exclusion of the causal protein must be undertaken to verify the diagnosis. Unlike dietary protein enteropathy, celiac disease can be evaluated in part through specific in vitro tests. Tests for IgA antiendomysial antibody (using tissue transglutaminase) are sensitive (85–98%) and specific (94–100%) with excellent positive (91–100%) and negative (80–98%) predictive values.[56,82,83] If celiac disease is suspected based on a suspicious cadre of findings (family history, steatorrhea, anemia, failure to thrive), serologic tests for IgA endomysial antibody and a small bowel biopsy should be undertaken.[55,56,84,85] If there is enteropathy, but negative serology, alternative diagnoses (see Tables 44-1 and 44-2) should be reconsidered. If the diagnosis is not strongly suspected, the in vitro tests can be undertaken, and if negative, the diagnosis is generally excluded, but a positive test would warrant confirmation with a biopsy. A gluten-free diet is necessary to treat celiac disease and must be maintained indefinitely. However, enteropathy induced by milk generally resolves in 1 to 2 years, at which time rechallenge is warranted.

Treatment

There are no curative therapies for dietary protein-induced proctocolitis, enteropathy, enterocolitis or celiac disease; treatment is based on dietary elimination. Only patients with dietary protein-induced enterocolitis or some individuals with celiac disease and 'celiac crisis' experience severe reactions, so these patients must also be instructed on how to proceed in the event of an accidental ingestion. Such patients should report to an emergency department in the event that fluid resuscitation is needed.

Education concerning dietary management is reviewed elsewhere (Chapter 48). It must be emphasized that education about the details of avoidance is crucial so that dietary elimination trials and therapeutic interventions are accurately undertaken. Often, recurrence of symptoms is caused by poor adherence or insufficient education. Issues of cross-contamination, label reading, restaurant dining and even the use of medications that may contain causal food proteins make avoidance of major dietary proteins very difficult. With celiac disease, oat does not contain gluten,[56,86] but contamination of oat flour with wheat gluten remains a problem. Support groups and the advice of a knowledgeable dietician are crucial adjuncts for patients undertaking these nutritionally and socially limiting diets.

Even without performing adjunctive laboratory tests or challenges to confirm a specific disorder, switching between milk, soy and casein-hydrolysate formulas is commonly undertaken by pediatricians and families as a test of intolerance or allergy. There are no specific guidelines concerning these formula changes. It is helpful to know that only a small proportion of infants with IgE-mediated cow's milk allergy (14%) will react to soy.[87] In contrast, those with FPIES are more likely (40–50%) to react to soy protein. For these infants, a switch to extensively hydrolyzed cow's milk-based formula should be considered. For the few infants with symptoms that persist while taking a casein hydrolysate, amino acid-based formula may be required.[42,88] Breastfeeding is preferred over commercial formulas as the source for infant nutrition, but maternally ingested protein can elicit allergic symptoms in the breastfed infant.[19,89,90] Therefore, maternal dietary manipulation (e.g. avoidance of milk protein) can be undertaken for treatment of breastfed infants, but with infants who have multiple food allergies this may be difficult, so substitution with infant formulas may be needed in some cases.

Except for celiac disease, resolution of the allergy is expected, so a review of the diet and any accidental exposures, and tests

https://CafePezeshki.IR

as indicated are undertaken on a yearly basis with the expectation that proctocolitis will resolve in 1 year and protein-induced enteropathy and enterocolitis in general in 1 to 3 years. It has been hypothesized that some adults with isolated gastrointestinal responses to foods (usually seafood) may have a stable form of mild enterocolitis.[91]

Conclusions

Dietary protein-induced proctocolitis, enterocolitis (FPIES) and enteropathy (including celiac disease) represent well-characterized immunologic responses to dietary proteins (Box 44-2). Although distinct in their clinical presentation, they represent cell-mediated hypersensitivity disorders that are not based on IgE antibody-mediated mechanisms. The symptoms of these disorders generally present in infancy or early childhood and must be differentiated from disorders with similar symptoms, and from each other. A careful clinical history, limited laboratory studies, and directed elimination and challenge can readily disclose the type of disorder and causal foods. Knowledge of the course of these disorders assists in making a plan for long-term therapy: either reintroduction of the food to determine if tolerance has occurred or prolonged dietary elimination. The immunologic mechanisms of these disorders are being elucidated, and these advances are likely to permit improved diagnostic and therapeutic strategies in the future.

BOX 44-2 KEY CONCEPTS: EVALUATION AND MANAGEMENT OF DIETARY PROTEIN-INDUCED, CELL-MEDIATED DISORDERS

- The differential diagnosis of cell-mediated (non-IgE-mediated) gastrointestinal food allergic disorders includes other types of food hypersensitivity (IgE-mediated, eosinophilic gastroenteropathy), nonimmune reactions to foods, and disorders with similar manifestations (infection, anatomic disorders, metabolic disease).
- Diagnosis requires a history, physical examination, exclusion of alternative diagnoses and selected diagnostic procedures, including dietary elimination and oral challenge, biopsy and selected laboratory evaluations.
- Proctocolitis occurs in infants and consists of mucusy, bloody stools attributed primarily to cow's milk proteins passed in maternal breast milk. However, rectal bleeding in infants is not commonly caused by food allergy.
- Enteropathy occurs in infancy and has symptoms related to protein malabsorption. It is most commonly caused by cow's milk protein and generally resolves by age 1 to 3 years.
- FPIES occurs in infancy and has symptoms that include prominent vomiting, lethargy, diarrhea and growth failure with possible progression to a sepsis-like clinical picture. It is usually attributed to cow's milk and/or soy protein and usually resolves by the age of 1 to 5 years.
- Celiac disease often presents at weaning due to an immunologic response to gluten. The disease may present at any age. Classic symptoms include vomiting, anemia, poor growth, and steatorrhea. The diagnosis is assisted through serology for IgA antiendomysial antibodies and is a lifelong disorder requiring elimination of gluten.

45 Allergic and Eosinophilic Gastrointestinal Disease

AMANDA B. MUIR | JONATHAN E. MARKOWITZ | CHRIS A. LIACOURAS

KEY POINTS

- IgE-mediated anaphylactic reactions to foods occur immediately after ingestion, are acute life-threatening events, and can cause gastrointestinal, pulmonary and cardiovascular symptoms.
- Eosinophilic esophagitis (EoE), involving chronic eosinophilic inflammation limited to the esophagus, causes weight loss, feeding difficulties, emesis, dysphagia and food impaction.
- Eosinophilic gastroenteritis (EoG) involves eosinophilic infiltration into any area of the gastrointestinal tract, most commonly the stomach and small intestine.
- Eosinophilic proctocolitis (EoP) usually presents in early infancy as a result of milk protein intolerance.

Overview

Gastrointestinal disorders involving an accumulation of eosinophils include a variety of conditions including classic IgE-mediated food allergy, inflammatory bowel disease, gastroesophageal reflux and the primary eosinophilic gastrointestinal disorders (eosinophilic esophagitis, eosinophilic gastroenteritis and eosinophilic colitis). The goal of this chapter is to provide an overview of those conditions that are characterized by an eosinophilic infiltration in the gastrointestinal tract and are largely driven by food-specific antigens. Food hypersensitivity will be briefly reviewed; the majority of the discussion will focus on the primary eosinophilic gastrointestinal disorders.

Food Allergy or Hypersensitivity

IgE-MEDIATED ALLERGY AND ANAPHYLAXIS

Type I (IgE-mediated) immediate hypersensitivity reactions to foods are most common in young children, with 50% of these reactions developing in the first year of life. The majority are reactions to cow's milk or to soy protein from infant formulas.[1] Other food allergies begin to predominate in older children, including egg, fish, peanut and wheat. Together with milk and soy, these account for more than 90% of food allergy in children.[2]

Blinded food challenges have shown that symptoms referable to the gastrointestinal tract in IgE-mediated allergy typically begin within minutes of the ingestion, although occasionally they may be delayed for up to 2 hours. They tend to be short-lived, lasting 1 to 2 hours.[3,4] Symptoms include nausea, vomiting, abdominal pain and diarrhea; there may also be oral symptoms, skin manifestations, wheezing or airway edema.

Eosinophilic Gastroenteropathies

The eosinophilic gastroenteropathies are an interesting, yet somewhat poorly defined set of disorders that must include the infiltration of at least one layer of the gastrointestinal tract with eosinophils, in the absence of other known causes for eosinophilia (e.g. parasitic infections or drug reactions).[5,6] Peripheral eosinophilia is not required for diagnosis, although it is a frequent finding. First reported over 50 years ago, the clinical spectrum of these disorders was defined solely by various case reports. As these reports became more frequent, various aspects of the disease became better described and stratified. Additional insight into the role of the eosinophil in health and disease has allowed further description of these disorders with respect to the underlying defect that drives the inflammatory response in those afflicted. Perhaps most important to the definition of these disorders has been the understanding of the heterogeneity of the sites affected within the gastrointestinal tract (Box 45-1).

Eosinophilic gastroenteropathies are thought to arise from the interaction of genetic and environmental factors. Of note, approximately 10% of individuals with one of these disorders has a family history in an immediate family member.[7] In addition there is evidence for the role of allergy in the etiology of these conditions, including the observations that up to 75% of patients are atopic[8,9] and that an allergen-free diet can sometimes reverse disease activity.[8–10] Interestingly, only a minority of individuals with eosinophilic gastroenteropathies have food-induced anaphylaxis[11] and therefore these disorders exhibit properties that are intermediate between pure IgE-mediated allergy and cellular mediated hypersensitivity disorders.

EOSINOPHILIC ESOPHAGITIS

Eosinophilic esophagitis (EoE) represents a chronic, immune/antigen-mediated esophageal disease characterized clinically by symptoms related to esophageal dysfunction and histologically by eosinophil-predominant inflammation.[12] This disorder has been given several names including eosinophilic esophagitis, allergic esophagitis, primary eosinophilic esophagitis and idiopathic eosinophilic esophagitis.

Etiology

EoE is caused by an abnormal immunologic response to specific antigens. In the vast majority of cases the antigens responsible are food antigens, although there appears to be a contribution from other environmental antigens in certain individuals.[13] While several studies have documented resolution of EoE with

strict avoidance of food antigens, in 1995 Kelly et al published the seminal paper on EoE.[14] Because the suspected etiology was an abnormal immunologic response to specific unidentifiable food antigens, each patient was treated with a strict elimination diet which included an amino acid based formula. Patients were also allowed clear liquids, corn and apples. Seventeen patients were initially offered a dietary elimination trial; 10 patients adhered to the protocol. The initial trial was determined by a history of anaphylaxis to specific foods and abnormal skin testing. These patients were subsequently placed on a strict diet consisting of an amino acid based formula for a median of 17 weeks. Symptomatic improvement was seen within an average of 3 weeks after the introduction of the elemental diet (resolution in 8 patients, improvement in 2). In addition, all 10 patients demonstrated a significant improvement in esophageal eosinophilia. All patients reverted to previous symptoms upon reintroduction of foods.

While an exact explanation for this type of response was not determined, Kelly et al suggested an immunologic basis, secondary to a delayed hypersensitivity or a cell-mediated hypersensitivity response, as the cause for EoE. Spergel et al demonstrated that foods that cause EoE do not do so through immediate hypersensitivity reactions.[9] By using a combination of traditional skin prick testing and a lesser used technique of atopy patch testing, they established that a delayed cellular mediated allergic response may be responsible for many cases of EoE. Further supporting a delayed type response, $CD8^+$ lymphocytes have been identified as the predominant T cell within the squamous epithelium of patients diagnosed with EoE.[15]

A link between EoE and atopy has been established.[10,16] It is these links between atopy and EoE that originally suggested that food allergies play a role in the pathogenesis of this disease. The role of food allergy was confirmed when patients improved on elemental diets. Elimination of the responsible food usually does not lead to rapid resolution of the symptoms. Rather, improvement of symptoms occurs approximately 1 to 2 weeks after the removal of the causative antigen. Also, in patients with EoE, symptoms do not always occur immediately after reintroduction to the foods. It may take several days for symptoms to develop, suggesting either a mixed IgE and T cell mediated allergic response or strictly a T cell delayed mechanism in the pathogenesis of this disease. While both IgE and T cell mediated reactions have been identified as possible causative factors, T cell mediated reactions seem to be the predominant mechanism of disease.[17]

Several authors have suggested that aeroallergens may contribute to the development of EoE. Mishra et al used a mouse model to show that the inhalation of Aspergillus caused EoE.[18] They found that the allergen-challenged mice developed elevated levels of esophageal eosinophils and features of epithelial cell hyperplasia that mimic EoE. In addition, Fogg et al reported a case of a 21-year-old female with asthma and allergic rhinoconjunctivitis who also had EoE.[19] The patient's EoE became symptomatic with exacerbations during pollen seasons, followed by resolution during winter months.

Familial clustering of cases of EoE has led to the assumption that there may be a genetic predisposition to the disease. In recent years, several candidate genes have been identified as risk variants for the development of EoE. Among these are the genes that code for eotaxin-3,[20] thymic stromal lymphoprotein (TSLP)[21] and filaggrin.[22] A genome-wide association approach to identify EoE risk variants was undertaken in two independent EoE and control populations, revealing a single susceptibility locus in both cohorts that corresponded to locus 5q22.1,[21] in which 11 single nucleotide polymorphisms (SNPs) resided within a single haplotype block spanning the *TSLP* gene. *TSLP* has been implicated in the development of atopic disease previously,[23,24] and more recently Noti et al showed that in a mouse model of eosinophilic esophagitis, neutralization with anti-TSLP antibody alleviated tissue eosinophilia associated with disease.[25]

Clinical Manifestations

Eosinophilic esophagitis can occur in all age groups but traditionally presents in younger patients with a male to female ratio of about 3:1. However, with increased awareness of the disorder among internist-gastroenterologists, there has also been increased recognition of the disorder in adults. Estimates of prevalence are approximately 50 patients per 100,000 population, but EoE appears to be more prevalent in certain populations.

Patients typically present with one or more of the following symptoms: vomiting, regurgitation, nausea, epigastric or chest pain, water brash, globus and/or decreased appetite.[10,26] Less common symptoms include growth failure and hematemesis. Esophageal dysmotility and dysphagia are less common in younger children but become increasingly prevalent in adolescents and adults. Symptoms can be frequent and severe in some patients but extremely intermittent and mild in others. The majority of patients may experience daily dysphagia or chronic nausea or regurgitation while others may have infrequent or rare episodes of dysphagia. Some patients develop coping mechanisms to adapt to their chronic dysphagia including overchewing food, drinking excessively during meals to propel food downward, dipping foods in 'lubricants' such as ketchup or gravy and avoiding meats. It is important for the physician to perform a detailed history of these compensatory mechanisms. Up to 50% of patients manifest additional allergy-related symptoms such as asthma, eczema or rhinitis. Furthermore, more than 50% of patients have one or more parents with history of allergy (Box 45-2).

Children with EoE have been studied in comparison to those with gastroesophageal reflux (GER).[8,9] While the symptoms of vomiting and abdominal pain occurred similarly in both groups, dysphagia, diarrhea and growth failure were predominant in those with EoE (Table 45-1).

Evaluation and Diagnosis

Patients with chronic refractory symptoms of gastroesophageal reflux disease (GERD) or dysphagia should undergo evaluation for EoE. While laboratory and radiologic assessment may be appropriate, the majority of these patients should undergo an

https://CafePezeshki.IR

upper endoscopy with biopsy. Historically, the diagnosis of EoE was often given when an isolated severe histologic esophagitis unresponsive to aggressive acid blockade, associated with symptoms similar to those seen in gastroesophageal reflux disease, was seen.[27] The diagnosis is further supported if the patient responds both clinically and histologically to the elimination of a specific food. In the past, a 24-hour pH probe was required to demonstrate that the esophageal disease was not acid induced; however, more recent guidelines allow for diagnosis in the setting of appropriate clinical and histologic findings. According to the most recent consensus guidelines, the threshold of esophageal eosinophilia should be 15 or more eosinophils per HPF on esophageal biopsies.[12]

However, very high levels of esophageal eosinophilia have been demonstrated with GER alone,[28] emphasizing that failure of appropriate medical therapy is an important feature of the diagnosis. A more recently recognized condition, known as PPI-responsive esophageal eosinophilia (PPI-Ree), has also complicated the diagnostic picture. PPI-Ree was first discovered among cohorts of patients with symptoms and endoscopic and histologic findings characteristic of EoE, in whom all findings normalized after treatment with proton pump inhibitors.[29] For these reasons, where possible, it is preferable to defer endoscopy until after a course of aggressive acid suppression with proton pump inhibitors. At that point, findings of esophageal eosinophilia are more likely to represent true EoE in the appropriate clinical setting. Currently, upper endoscopy with biopsy is the only diagnostic test that can accurately determine if the esophageal inflammation of EoE is present.

Once EoE is suspected, patients should be encouraged to seek an allergy consultation. Skin prick testing and serum allergen-specific IgE measurements may provide some clues to possible food allergens. Unfortunately, these tests are most useful in determining IgE-based allergic disorders. Since EoE is considered to be either a T cell mediated disease or a mixed IgE and T cell mediated disorder, the sensitivity and specificity of skin prick tests alone are low. Atopy patch testing (the placement of an antigen on the skin for several days followed by assessment for localized skin reaction) may be more useful in determining the antigens responsible for causing esophageal eosinophilia,[9] although this remains to be established. If no specific antigen(s) are found through allergy testing, a trial of an elimination diet, consisting of removal of the antigens that most commonly cause EoE, can be attempted.[30] The most common foods identified as causing EoE are milk, soy, egg and wheat. If all of these measures fail, an elemental diet utilizing an amino acid based formula should be considered. The assessment of success should be based on both the improvement of clinical symptoms and histologic improvement.

Once EoE has resolved, foods should be reintroduced in a systematic manner. Because of the possibility of delayed reactions, it is advisable to wait several days to one week between each new food introduction. This time period is usually sufficient to see a recurrence of symptoms; if symptoms develop, the food should be discontinued. However, in some cases symptoms do not occur despite recurrence of eosinophilic infiltration. A repeat endoscopy with biopsy is required in order to evaluate for the presence of esophageal mucosal injury. Since clinical symptoms often occur sporadically, biopsy remains the most important way to accurately determine the presence or resolution of EoE.

While upper endoscopy with biopsy can precisely determine the diagnosis, noninvasive diagnostic tests have proven to be less useful. These include the evaluation of serum IgE levels and quantitative peripheral eosinophils, radiographic upper gastrointestinal series (UGI), pH probe and manometry, allergen-specific IgE measurements and skin prick and patch testing. A promising new modality is the esophageal string test, where a string is swallowed but then anchored at the mouth so it can be removed and analyzed for the presence of eosinophil-derived proteins. Initial reports show that results from this test correlate strongly with histologic findings of eosinophilia.[31]

EoE should be considered only when the eosinophilia is isolated strictly to the esophagus. To make an accurate diagnosis, the remainder of the gastrointestinal tract must be normal. When EoE is suspected, the sensitivity for detecting the disease is increased when more biopsies are obtained from the

esophagus. Sensitivity seems to be highest when at least five biopsies are obtained.[32]

EoE has been associated with visual findings on endoscopy: concentric ring formation called 'trachealization' or a 'feline esophagus', longitudinal linear furrows and patches of small, white papules on the esophageal surface.[33] Most investigators believe that the esophageal rings and furrows are a response to full thickness esophageal tissue inflammation. The white papules appear to represent the formation of eosinophilic microabscesses (Figures 45-1 and 45-2).

In 2000, Fox et al utilized high-resolution probe endosonography in patients with EoE in order to determine the extent of tissue involvement.[34] They compared eight patients identified with EoE to four control patients without esophagitis and discovered that the layers of the esophageal wall were thicker in EoE patients than in the control group (2.8 to 2.2 mm). Additionally, the mucosa to submucosa ratio (1.6 to 1.1 mm) and the muscularis propria thickness (1.3 to 1.0 mm) were greater in EoE patients. These findings suggested that EoE patients had more than just surface involvement of eosinophils.

Complications of Disease

While stomach pain, vomiting and failure to thrive are hallmarks of pediatric EoE, food impaction and dysphagia are often found in teenagers diagnosed with EoE.[35] Food impaction prevalence is increasing in parallel with the incidence of EoE.[36] This may be due to the fact that the esophagus in EoE is both more rigid and dysmotile than a normal esophagus. Up to 37% of patients with EoE have been shown to have abnormal esophageal peristalsis,[37] either weak or absent. In addition, the distensibility of the esophagus in EoE patients with a history of food impaction and stricture is decreased.[38]

In addition to food bolus impaction, esophageal stricture is another significant complication of EoE. Esophageal stricture not only causes esophageal dysfunction and dysphagia, but often requires esophageal dilation. There is enhanced collagen deposition in the lamina propria of patients with EoE when compared to patients with GERD.[39] Excessive collagen deposition eventually leads to lumen narrowing and stricture. Stricture formation is part of the natural history of untreated EoE. Adults with longstanding untreated disease are more likely to develop esophageal stricture when compared to those with a relatively short duration of disease.[40] Based on this finding, it is postulated that years of unremitting inflammation eventually lead to excessive esophageal collagen deposition and stricture.

While the pathogenesis of fibrosis in EoE is poorly understood, this complication can lead to decreased quality of life and lifelong dysphagia. Despite successful therapy, patients with EoE continue to have increased lamina propria collagen when compared to control patients. This suggests some degree of permanence in esophageal remodeling,[41] underscoring the importance of prompt diagnosis.

Management

The identification and removal of allergic dietary antigens is the mainstay of treatment for EoE. While removal of the offending food(s) reverses the disease process in patients with EoE, in many cases the identification of these foods is difficult. Often, patients with EoE cannot correlate their gastrointestinal symptoms with the ingestion of specific foods. Several reports have demonstrated that several days may be required for symptoms to recur upon ingestion of antigens that cause EoE.[14,26] Even when a particular food causing EoE has been eliminated, it may take days or weeks for the symptoms to resolve. In addition,

Rings - 16%

https://CafePezeshki.IR

although one food may be identified, there may be several other foods (not identified) that could also be contributing.

While attempts should be made to identify and eliminate potential food allergens through a careful history and the use of allergy testing, it may be difficult to determine the responsible allergenic foods; the administration of a strict diet, utilizing an amino acid based formula, is often necessary. The use of an elemental diet rapidly improves both clinical symptoms and histology in patients with EoE.[10,14,42] Because of poor palatability, the elemental formula is commonly administered by continuous nasogastric feeding, although some more palatable options have emerged in the last few years. The diet may be supplemented with water, and some have also approved the use of a protein-free single antigen juice such as white grape or apple.

Reversal of symptoms typically occurs within 10 days with histologic improvement within 4 weeks. Although the strict use of an amino acid based formula may initially be difficult for patients (and parents) to accept, its benefits may outweigh the risks of other treatments and the rapid improvement in symptoms proves very reinforcing to families. While the use of other medications, such as corticosteroids, may temporarily improve the disease and its symptoms, the disease recurs upon their discontinuation. In contrast, when foods that cause EoE are identified through a combination of allergy testing, endoscopy, elimination and selective reintroduction, then lifelong remission without medication can be attained.

Treatment of true EoE with aggressive acid blockade, including medical and surgical therapy, has not been proven effective. Several published reports have demonstrated the failure of H_2 blocker and proton pump therapy in patients with EoE.[43,44] While acid blockade may improve clinical symptoms by improving acid reflux that occurs secondary to the underlying inflamed esophageal mucosa, it does not reverse the esophageal histologic abnormality. Although some case reports suggested that fundoplication was beneficial for patients with EoE, in 1997 Liacouras reported on two cases of failed Nissen fundoplication in patients who were diagnosed with severe eosinophilic esophagitis.[45] Both patients underwent fundoplication for presumed acid reflux esophagitis unresponsive to medical therapy. However, post-surgical evaluation of both patients revealed ongoing clinical symptoms. Repeat esophagogastroduodenoscopy demonstrated persistent esophageal eosinophilia. Subsequently, both patients responded to oral corticosteroids with resolution of symptoms and histologic improvement.

Prior to 1997, reports suggested that systemic corticosteroids improved the symptoms of EoE in adults identified with a severe eosinophilic esophagitis.[46,47] In 1997, Liacouras et al were the first to publish the use of oral corticosteroids in 20 children diagnosed with EoE.[44] These patients were treated with oral methylprednisolone (average dose 1.5 mg/kg/day; maximum dose 48 mg/day) for 1 month. Symptoms were significantly improved in 19 of 20 patients by an average of 8 days. A repeat endoscopy with biopsy, 4 weeks after the initiation of therapy, demonstrated a significant reduction of esophageal eosinophils, from 34 to 1.5 eosinophils per HPF. However, upon discontinuation of corticosteroids, 90% had recurrence of symptoms.

In 1999, Faubion et al reported that swallowing a metered dose of aerosolized corticosteroids was also effective in treating the symptoms of EoE in children.[48] Four patients diagnosed with EoE manifested by epigastric pain, dysphagia and a severe esophageal eosinophilia unresponsive to aggressive acid blockade were given fluticasone, 4 puffs twice a day. Patients were instructed to use an inhaler but to immediately swallow after inhalation in order to deliver the medication to the esophagus. Histologic improvement was not determined. Within 2 months, all 4 patients responded with an improvement in symptoms. Two patients required repeat use of inhalation therapy. Success with this therapy has been confirmed.

Later, Konikoff et al performed a randomized double-blind placebo-controlled trial utilizing swallowed fluticasone in patients with EoE.[49] The study revealed symptom improvement and decreased esophageal eosinophils in those who received the study drug compared to those who received placebo. Aceves et al reported an effective alternative by using liquid budesonide mixed with a sucralose suspension.[50]

Side-effects can include esophageal candidiasis and growth failure.[51,52] As with all therapies that do not involve removal of antigens, symptoms often recur in patients upon discontinuation of the therapy.

Other forms of medical therapy that have been evaluated previously include the mast cell stabilizing agent cromolyn sodium and the leukotriene antagonist montelukast.[53–57] While each of these medications represents an appealing option from a pathophysiologic standpoint, the available data do not support their use, based either upon lack of clinical improvement or minimal to no histologic resolution.

The latest innovation in therapy is the use of biologic agents directed at the cytokine interleukin 5 (IL-5). IL-5 plays in important role in eosinophil recruitment, activation and proliferation. In the past, two small studies demonstrated the effectiveness of anti IL-5 in improving both symptoms and esophageal histology.[58,59] The first large-scale pediatric trial utilizing an anti-IL-5 monoclonal antibody, reslizumab, had mixed results. Patients receiving active drug showed improvement in biopsy findings compared to placebo. However, subjects receiving both active drug and placebo showed symptomatic improvement, which resulted in failure to meet one of the study endpoints required to receive FDA approval.[60] The drug is still in testing for the indication of eosinophilic asthma.

EOSINOPHILIC GASTROENTERITIS

Eosinophilic gastroenteritis (EoG) is a general term that describes a constellation of symptoms attributable to the gastrointestinal tract, in combination with pathologic infiltration by eosinophils. This group includes eosinophilic gastritis, gastroenteritis and enterocolitis. There are no strict diagnostic criteria for this disorder and it has been largely shaped by multiple case reports and series. A combination of gastrointestinal complaints with supportive histologic findings is sufficient to make the diagnosis. These conditions are grouped together under the term EoG for the discussion here, though it is likely that they are distinct entities in most patients (Box 45-3).

EoG was originally described by Kaijser in 1937.[61] It is a disorder characterized by tissue eosinophilia that can affect different layers of the bowel wall, anywhere from mouth to anus. The gastric antrum and small bowel are most frequently affected. In 1970, Klein et al classified EoG into three categories: a mucosal, muscular and serosal form.[62]

Etiology

EoG affects patients of all ages, with a slight male predominance. Most commonly, eosinophils infiltrate only the mucosa,

https://CafePezeshki.IR

BOX 45-3 CHARACTERISTICS OF EOSINOPHILIC GASTROENTERITIS

- Clinical characteristics:
  - nausea, vomiting, regurgitation
  - severe abdominal pain
  - diarrhea, protein losing enteropathy
  - gastrointestinal bleeding
  - ascites
  - intestinal obstruction
- >95% gastric antrum involved
- Peripheral eosinophilia (>50%)
- Associated allergies, eczema, asthma, rhinitis, atopy

leading to symptoms associated with malabsorption such as growth failure, weight loss, diarrhea and hypoalbuminemia. Mucosal EoG may affect any portion of the gastrointestinal tract. A review of the biopsy findings in 38 children with EoG revealed that all patients examined had mucosal eosinophilia of the gastric antrum.[63] Seventy-nine percent of the patients also demonstrated eosinophilia of the proximal small intestine, with 60% having esophageal involvement and 52% having involvement of the gastric corpus. Those with colonic involvement tended to be less than 6 months of age and were ultimately classified as having allergic colitis.

Details of the etiology of EoG remain unknown, although it is now recognized to be a result of both IgE and non-IgE mediated sensitivity.[9] The association between IgE mediated inflammatory response (typical allergy) and EoG is supported by the increased likelihood of other allergic disorders such as atopic disease, food allergies and seasonal allergies.[64,65] Specific foods have been implicated in the cause of EoG in some patients.[66,67] In contrast, the role of non-IgE mediated immune dysfunction, in particular the interplay between lymphocyte-produced cytokines and eosinophils, has received attention. IL-5 is a chemoattractant responsible for tissue eosinophilia.[68] Desreumaux et al found that among patients with EoG, the levels of IL-3, IL-5 and granulocyte-macrophage colony stimulating factor (GM-CSF) were significantly increased as compared to control patients.[69] Once recruited to the tissue, eosinophils may further recruit similar cells through their own production of IL-3 and IL-5, as well as production of leukotrienes.[70] This mixed type of immune dysregulation in EoG has implications for the way this disorder is diagnosed, as well as the way it is treated.

Clinical Manifestations

The most common symptoms of EoG include colicky abdominal pain, bloating, diarrhea, weight loss, dysphagia and vomiting.[54,71] In addition, up to 50% of patients have a past or family history of atopy.[63] Features of severe disease include gastrointestinal bleeding, iron deficiency anemia, protein losing enteropathy (hypoalbuminemia) and growth failure.[71] Approximately 75% of affected patients have an elevated blood eosinophilia.[70] Males are more commonly affected than females. Rarely, ascites can occur.[72,73]

In an infant, EoG may present in a manner similar to hypertrophic pyloric stenosis, with progressive vomiting, dehydration, electrolyte abnormalities and thickening of the gastric outlet.[74,75] When an infant presents with this constellation of symptoms, in addition to atopic symptoms such as eczema and reactive airway disease, an elevated eosinophil count, or a strong family history of atopic disease, then EoG should be considered in the diagnosis before surgical intervention.

Uncommon presentations of EoG include acute abdomen (even mimicking acute appendicitis)[76] or colonic obstruction.[77] There have also been reports of serosal infiltration with eosinophils, with associated complaints of abdominal distention, eosinophilic ascites and bowel perforation.[73,78–82]

Evaluation and Diagnosis

EoG should be considered in any patient with a history of chronic symptoms including vomiting, abdominal pain, diarrhea, anemia, hypoalbuminemia or poor weight gain in combination with the presence of eosinophils in the gastrointestinal tract. Other causes of eosinophilic infiltration of the gastrointestinal tract include the other disorders of the eosinophilic gastroenteropathy spectrum, as well as parasitic infection, inflammatory bowel disease, neoplasm, chronic granulomatous disease, collagen vascular disease and the hypereosinophilic syndrome.[83–87]

A number of tests may aid in the diagnosis of EoG, however no single test is pathognomonic and there are no standards for diagnosis. Eosinophils in the gastrointestinal tract must be documented before EoG can be truly entertained as a diagnosis. This is most readily done with biopsies of either the upper gastrointestinal tract through esophagogastroduodenoscopy or the lower tract through flexible sigmoidoscopy or colonoscopy. A history of atopy supports the diagnosis but is not a necessary feature. Peripheral eosinophilia or an elevated IgE level occurs in approximately 70% of affected individuals.[88] Measures of absorptive activity such as the D-xylose absorption test and lactose hydrogen breath testing may reveal evidence of malabsorption, reflecting small intestinal damage. Radiographic contrast studies may demonstrate mucosal irregularities or edema, wall thickening, ulceration or luminal narrowing. A lacy mucosal pattern of the gastric antrum known as *areae gastricae* is a unique finding that may be present in patients with EoG.[89]

Evaluation of other causes of eosinophilia should be undertaken, including stool analysis for ova and parasites and serologic tests for specific parasites in endemic areas. Signs of intestinal obstruction warrant abdominal imaging. Allergen-specific IgE testing, as well as skin testing for environmental antigens, is rarely useful. Skin testing using both traditional prick tests and patch tests may increase the sensitivity for identifying foods responsible for EoG by evaluating both IgE mediated and T cell mediated sensitivities.[9]

Management

There is as much ambiguity in the treatment of EoG as there is in its diagnosis. This is in large part because the entity of EoG was defined mainly by case series, each of which employed its own mode of treatment. Since EoG is such a difficult disease to diagnose and relatively rare in prevalence, randomized trials for its treatment are uncommon, leading to considerable debate as to the optimal treatment.

Food allergy is considered one of the potential underlying causes of EoG. The elimination of pathogenic foods, as identified by any form of allergy testing or by random removal of the most likely antigens, should be a first-line consideration. Unfortunately, this approach results in improvement in a limited number of patients. In severe cases, or when other treatment options have failed, the administration of a strict diet, utilizing

https://CafePezeshki.IR

an elemental formula, has been shown to be successful.[65,90] In these cases, elemental formula provided as the sole source of nutrition has been reported to be effective in the resolution of clinical symptoms and tissue eosinophilia.

When the use of a restricted or elemental diet fails, corticosteroids are often employed due to their high likelihood of success in attaining remission.[54] However, when weaned, the duration of remission is variable and can be short-lived, leading to the need for repeated courses or continuous low doses of steroids. In addition, the chronic use of corticosteroids carries an increased likelihood of undesirable side-effects, including cosmetic problems (cushingoid facies, hirsutism, acne), decreased bone density, impaired growth and personality changes. A response to these side-effects has been to look for substitutes that may act as steroid-sparing agents, while still allowing for control of symptoms. Anecdotally, immunomodulators more commonly used as steroid-sparing agents in inflammatory bowel disease, such as mercaptopurine or azathioprine, have been used with some success.

Orally administered cromolyn sodium also has been effective in some patients,[54,91–93] and recent reports have detailed the efficacy of other oral antiinflammatory medications. Montelukast, a selective leukotriene receptor antagonist used to treat asthma, has been reported to successfully treat two patients with EoG.[56,94] Treatment of EoG with inhibition of leukotriene D4, a potent chemotactic factor for eosinophils, relies on the theory that the inflammatory response in EoG is perpetuated by the presence of the eosinophils already present in the mucosa. This therapy causes an interruption in the chemotactic cascade and breaks the inflammatory cycle. Suplatast tosilate, another suppressor of cytokine production, has also been reported as a treatment for EoG.[95]

Given the possibilities for treatment of EoG, the combination of therapies incorporating the best chance of success with the smallest likelihood of side-effects should be employed. When particular food antigens that may be causing disease can be identified, elimination of those antigens should be first-line therapy. When testing fails to identify potentially pathogenic foods, systematic elimination of the most commonly involved foods[96] can be employed. If this approach fails, a total elimination diet with an amino acid based formula should be considered. Trials of nonsteroidal antiinflammatory medications such as cromolyn, montelukast and suplatast are a reasonable option, although some might prefer to wait for more detailed studies. Monoclonal antibodies against IL-5 may also hold some promise in the future, although current studies are limited to patients with EoE; further research will be necessary in the EoG population.

When other treatments fail, corticosteroids remain a reliable treatment for EoG, with attempts at limiting the total dose or the number of treatment courses where possible. Due to the diffuse and inconsistent nature of symptoms in this disease, serial endoscopy with biopsy is a useful and important modality for monitoring disease progression.

EOSINOPHILIC PROCTOCOLITIS

Eosinophilic proctocolitis (EoP), also known as allergic proctocolitis or milk protein proctocolitis, has been recognized as one of the most common etiologies of rectal bleeding in infants.[63,97] This disorder is characterized by the onset of rectal bleeding, generally in children less than 2 months of age.

Etiology

The gastrointestinal tract plays a major role in the development of oral tolerance to foods. Through the process of endocytosis by the enterocyte, food antigens are generally degraded into nonantigenic proteins.[98,99] Although the gastrointestinal tract serves as an efficient barrier to ingested food antigens, this barrier may not be mature for the first few months of life.[100] As a result, ingested antigens may have an increased propensity for being presented intact to the immune system. These intact antigens have the potential to stimulate the immune system and drive an inappropriate response directed at the gastrointestinal tract. Because the major component of the young infant's diet is milk or formula, it stands to reason that the inciting antigens in EoP are derived from the proteins found in them. Cow's milk and soy proteins are the foods most frequently implicated in EoP.

Commercially available infant formulas most commonly utilize cow's milk as the protein source. There are at least 25 known immunogenic proteins within cow's milk, beta-lactoglobulin and the caseins being the most antigenic.[101] It is thought that up to 7.5% of the population in developed countries exhibit cow's milk allergy, although there is wide variation in the reported data.[102–104] Soy protein allergy is considered to be less common than cow's milk allergy, with a reported prevalence of approximately 0.5%.[101] However, soy protein intolerance becomes more prominent in individuals who have developed milk protein allergy, with prevalence from 15% to 50% or more in milk protein sensitized individuals.[105] For this reason, substitution of a soy protein based formula for a milk protein based formula in patients with suspected milk protein proctocolitis is often unsuccessful.

Maternal breast milk represents a different challenge to the immune system. Up to 50% of cases of EoP occur in breastfed infants; however it is thought that, rather than developing an allergy to human milk protein, the infants are manifesting allergy to antigens ingested by the mother and transferred via the breast milk. The transfer of maternal dietary protein via breast milk was first demonstrated in 1921.[106] More recently, the presence of cow's milk antigens in breast milk has been established.[107–109]

When a problem with antigen handling occurs, whether secondary to increased absorption through an immature gastrointestinal tract or through a damaged epithelium secondary to gastroenteritis, sensitization of the immune system results. Once sensitized, the inflammatory response is perpetuated with continued exposure to the inciting antigen. This may explain the reported relationship between early exposure to cow's milk protein or viral gastroenteritis and the development of allergy.[110–112]

Clinical Manifestations

Diarrhea, rectal bleeding and increased mucus production are the typical symptoms seen in patients who present with EoP.[63,113] There is a bimodal age distribution with the majority of patients presenting in infancy (mean age at diagnosis of 60 days[114]) and the other group presenting in adolescence and early adulthood.

The typical infant with EoP is well appearing with no constitutional symptoms. Rectal bleeding begins gradually, initially appearing as small flecks of blood. Usually, increased stool frequency occurs accompanied by water loss or mucus streaks. The

https://CafePezeshki.IR

TABLE 45-2 Characteristics of Eosinophilic Proctocolitis vs Food Protein Induced Enterocolitis Syndrome (FPIES)

	Eosinophilic Proctocolitis	FPIES
Appearance	Well	Ill, dehydrated, shocky
Blood streaked stools	Common	Rare
Diarrhea	Mild	Severe
Abdominal pain	Mild to none	Severe
Vomiting	No	Aggressive
Age of onset	<3 months	3–6 months
Failure to thrive	No	Yes
Common foods	Milk, soy	Milk, soy, rice, among others
Laboratory findings	Normal	Anemia, hypoalbuminemia

development of irritability or straining with stools is also common and can falsely lead to the initial assumption of anal fissuring. Atopic symptoms such as eczema and reactive airway disease may be associated. Continued exposure to the inciting antigen causes increased bleeding and may, on rare occasions, cause anemia and poor weight gain. Despite the progression of symptoms, the infants are generally well appearing and rarely appear ill. Other manifestations of gastrointestinal tract inflammation such as vomiting, abdominal distention or weight loss almost never occur and would be suggestive of another problem such as food protein induced enterocolitis syndrome (FPIES) (Table 45-2).

Evaluation and Diagnosis

EoP is primarily a clinical diagnosis, although several laboratory parameters and diagnostic procedures may be useful. Initial assessment should be directed at the overall health of the child. A toxic appearing infant is not consistent with the diagnosis of EoP and should prompt evaluation for other causes of gastrointestinal bleeding. A complete blood count is useful because the majority of infants with EoP have a normal or borderline low hemoglobin. An elevated serum eosinophil count may be present. Stool studies for bacterial pathogens such as *Salmonella* and *Shigella* should be considered in the setting of rectal bleeding. A stool specimen may be analyzed for the presence of white blood cells, and specifically for eosinophils. The sensitivity of these tests is not well documented, and the absence of a positive finding on these tests does not exclude the diagnosis.[115] Eosinophils can also accumulate in the colon in other conditions such as pinworm and hookworm infections, drug reactions, vasculitis and inflammatory bowel disease, and it is important to exclude these, especially in older children.

Although not always necessary, flexible sigmoidoscopy may be useful to demonstrate the presence of colitis. Visually, one may find erythema, friability or frank ulceration of the colonic mucosa. Alternatively, the mucosa may appear normal, or show evidence of lymphoid hyperplasia.[116,117] Histologic findings typically include increased eosinophils in focal aggregates within the lamina propria, with generally preserved crypt architecture. Findings may be patchy, so care should be taken to examine many levels of each specimen if necessary.[118,119]

Management

In a well appearing patient with a history consistent with EoP, it is acceptable to make an empiric change in the protein source of the formula. Because of the frequent development of soy protein EoP in milk-sensitized individuals, a protein hydrolysate formula is often the best choice.[111] Resolution of symptoms begins almost immediately after the elimination of the problematic food. Although symptoms may linger for several days to weeks, continued improvement is the rule. If symptoms do not quickly improve, or persist beyond 4 to 6 weeks, other antigens should be considered, as well as other potential causes of rectal bleeding. In breastfed infants, dietary restriction of milk and soy containing products from the mother's diet may result in improvement; however, care should be taken to ensure that the mother maintains adequate protein and calcium intake from other sources.

EoP in infancy is generally benign and withdrawing the milk protein trigger resolves the condition. Though gross blood in the stool usually disappears within 72 hours, occult blood loss may persist for longer.[114] The prognosis is excellent and the majority of patients are able to tolerate the culprit milk protein by 1 to 3 years of age. In older individuals it is more difficult to identify the food triggers and therefore patients usually require medical management. Though there is a paucity of clinical data regarding therapy for this condition, it appears that glucocorticoids and aminosalicylates are efficacious.[6] The prognosis for older onset EoP is less favorable than the infant presentation and is typically chronic and relapsing.

OTHER MANIFESTATIONS OF GASTROINTESTINAL ALLERGY

Although we have described several specific manifestations of allergic bowel disease in the sections above, there remain numerous nonspecific complaints that may occur in the infant that have also been linked to food allergy. These nonspecific complaints create an especially difficult situation for the practitioner, as only a proportion of infants with these complaints will have them as a result of allergy. Further, there are no specific findings that, independently, can confirm or exclude the diagnosis. Among these potential nonspecific manifestations are gastroesophageal reflux, colic, constipation and diarrhea.

Gastroesophageal Reflux

Gastroesophageal reflux (GER) is a common complaint among infants, children and adults. Up to two thirds of 4-month-old infants experience regurgitation on a daily basis,[120] with other complaints such as forceful vomiting, arching, irritability and feeding refusal occurring to varying degrees. Furthermore, many infants and children may experience GER without the presence of any overt signs or symptoms. Most cases of GER are not attributable to a specific underlying cause; however, one of the leading identifiable causes of GER in this population is food allergy.[121,122]

The association between GER and cow's milk allergy (CMA) was prospectively investigated.[122] In a 3-year prospective study, infants with symptoms compatible with GER underwent pH monitoring and endoscopy to confirm the presence of GER. Patients with a reflux index (percentage of time with acid reflux) of greater than 5% and the presence of esophagitis were considered to have GER. The presence of CMA in these patients

https://CafePezeshki.IR

was assessed using skin prick tests, by the presence of eosinophils in fecal mucus, nasal mucus or peripheral blood, and by circulating levels of anti-beta-lactoglobulin IgG. Patients who had positive assays for CMA and GER were placed on a cow's milk restricted diet with a protein hydrolysate formula. After 3 months, a double-blind cow's milk challenge was performed to confirm the diagnosis of CMA. This stringent method of diagnosing both GER and CMA revealed a surprisingly high prevalence (42%) of patients with GER who also had CMA. Further, this author group went on to show that 14 of 47 patients (30%) had GER that was attributable to the CMA itself, based on resolution of symptoms on a restricted diet followed by return of symptoms when re-challenged. Whether cow's milk or other food allergies are responsible for such a high proportion of GER in all populations remains to be seen; however these results imply that refractory cases of GER warrant consideration of food allergy as a contributing factor.

Infantile Colic

Infantile colic is a term that is generally used to describe acute self-limited episodes of irritability (presumably due to abdominal pain) that occur in otherwise healthy infants in the first several months of life.[123] Although the labeling of an infant as having 'colic' implies there is no organic disease responsible, a subset of infants diagnosed with colic will have an underlying organic cause. Food allergies, and specifically CMA, have been highly implicated in the organic etiologies of infantile colic.

Traditionally, changing the infant's formula is a common way of dealing with colic; often several formula changes are made (e.g. from cow's milk based to soy based to hydrolyzed protein). It is often unclear, however, whether the formula change is responsible for the eventual resolution of symptoms, as colic by definition begins to resolve by 4 to 5 months of age.

Diarrhea

The presence of diarrhea in the context of food allergies can be multifactorial. As discussed in previous sections, eosinophilic gastroenteritis (EoG) and eosinophilic proctitis (EoP) may both lead to intestinal mucosal damage and subsequent diarrhea. However, food allergy may also result in diarrhea in the absence of mucosal damage or eosinophilic infiltration.

Gastrointestinal symptoms, in particular diarrhea, are commonly seen among children with atopic eczema;[124,125] avoidance of particular foods in these patients will alleviate the symptoms.[125] In patients with gastrointestinal symptoms related to milk ingestion (confirmed by double-blind challenge), the instillation of milk into the intestinal lumen resulted in increased production of histamine and eosinophil cationic protein within 20 minutes.[126] Albumin concentration in the intestine also increased, suggesting increased gut permeability and leakage; none of these findings were seen in normal controls.

Constipation

Constipation is a common problem among infants and children, and although often short-lived or self-limited, a substantial proportion may have symptoms that persist for 6 months or more.[127] It has long been suggested that cow's milk plays a role in the development of chronic constipation,[128] and there is evidence that CMA is a causative factor. One of the most compelling studies involved a blinded cross-over study of cow's milk restriction in children with chronic constipation.[129] In this trial, 65 children with chronic constipation (all of whom received cow's milk in their regular diet) were randomized to receive either cow's milk or soy milk for 15 days, followed by a washout period and reversal of the previous diet. Sixty-eight percent of the children had improvement in their constipation while taking soy milk, while none had improvement on cow's milk. Re-challenging the responders with cow's milk resulted in return of constipation. Evidence of CMA was based upon higher frequencies of co-existing rhinitis, dermatitis and bronchospasm in responders, as well as increased likelihood of elevated IgE to cow's milk antigens and inflammatory cells on rectal biopsy. A subsequent study revealed further evidence of the causative nature of CMA in constipation.[130]

Approach to the Potentially Allergic Infant with Nonspecific Gastrointestinal Symptoms

Because gastrointestinal complaints such as those listed in the section 'Other Manifestations of Gastrointestinal Allergy' are quite common in the infant population, the practitioner who cares for infants will commonly be faced with the issue of when to implicate food allergy. Further complicating the issue is that general allergic complaints such as atopic eczema and rhinitis are also quite common in this population. Optimally, the allergic contribution to any gastrointestinal complaint would be investigated through double-blind food challenges. However, this is not practical for most practitioners.

Any infant with gastrointestinal symptoms refractory to standard treatment may be manifesting signs of food allergy. Because CMA is implicated most commonly in this population, removal of this antigen from the diet is a reasonable approach. However, this change should be made in concert with appropriate investigations for other etiologic factors (e.g. anatomic studies such as upper gastrointestinal series in chronic reflux, stool cultures in chronic diarrhea). Soy formula may be substituted for cow's milk formula, although hypersensitivity to both milk and soy protein is not uncommon. Protein hydrolysate formulas represent a good option, more likely to result in improvement in a truly allergic infant. Breastfeeding mothers may need to restrict their intake of milk and soy for several weeks before the antigens no longer appear in breast milk. The use of amino acid based elemental formulas should be reserved for those who have failed hydrolyzed protein formulas and, preferably, those who have some other objective positive findings of allergy. It should be remembered that the natural history of allergy in the infant is often self-limited, and thus improvement with dietary elimination does not independently confirm food allergy. Formally re-challenging the infant with the suspected food antigen is a better way to confirm that allergy existed and was responsible for the symptoms in question. Formal consultation with an allergist in this context is highly advisable.

Conclusion

Eosinophilic disorders of the gastrointestinal tract are becoming increasingly recognized as distinct clinical entities with specific management strategies. While EoG is rare and difficult to diagnose, EoP and EoE are much more common and easily diagnosed by endoscopic biopsy. While EoP is a well accepted entity, the diagnosis of EoE has recently been receiving a great

https://CafePezeshki.IR

deal of attention. Recent literature suggests a mini-epidemic of EoE in the pediatric population, though controversy still exists regarding the etiology and treatment.

Future research should focus on clarifying the prevalence and natural history (e.g. the potential development of strictures) and optimizing the diagnostic approach and treatment options of all gastrointestinal eosinophilic disorders. The particular management challenges posed by these conditions warrant close liaison between gastroenterologists, allergists and dietitians. In addition, patients and families require particular support, especially when trying to adopt restricted diets. Patient-founded, support advocacy groups have been established for this purpose (e.g. American Partnership for Eosinophilic Disorders, www.APFED.org).

Awareness of food-induced allergic and eosinophilic disease of the gastrointestinal tract has increased, but many unanswered questions remain. The variation in geographic distribution of EoG and EoE has yet to be explained. The pathogenesis of these conditions has to be fully elucidated, in particular the role of environmental and infectious agents. Advances need to be made in diagnosing these conditions, especially with the use of less invasive techniques than endoscopy with biopsy, and also in better identifying offending food antigens and allergens. In addition, biochemical studies need to be pursued so that we can determine a cause of these disorders. Is the eosinophil dysregulation due to an immunologic defect or an allergy? These and other research questions reinforce the limitations of our current understanding of gastrointestinal eosinophilic disease.

46 Oral Allergy Syndrome

JULIE WANG

KEY POINTS

- OAS is an IgE-mediated allergy that is due to cross-reactivity between pollens and homologous food proteins.
- There is significant regional variation in OAS prevalence.
- Several pollen-food associations have been described.
- Although symptoms are generally mild and limited to the oropharyngeal area, systemic reactions can occur.
- Management entails avoiding the foods that trigger symptoms; heated food forms are often well-tolerated when the relevant allergens are heat-labile proteins.

Oral allergy syndrome (OAS) is an IgE-mediated allergy that is due to cross-reacting, homologous proteins between pollens and food proteins.[1] First reported over 70 years ago,[2] OAS involves primarily localized oropharyngeal symptoms in pollen allergic individuals ingesting fresh fruits and vegetables. The increased prevalence of allergic rhinitis and OAS in recent years,[3] along with advances in identification of relevant allergenic proteins, have led to a better understanding of the diverse associations characterizing OAS.

Epidemiology

Few studies have examined the prevalence of OAS in children; a recent Italian study reported that approximately 25% of children with pollen-induced allergic rhinitis have OAS.[4] Since OAS develops after sensitization to pollens is established, symptoms can develop to food(s) that were previously tolerated. Thus, it is not surprising that the prevalence of OAS in adults is higher, ranging from 30% to 70% among individuals with allergic rhinitis.[5–8] Those who are sensitized to multiple pollens have a higher likelihood of developing clinical allergy to plant-derived foods.[5,9] In addition, data suggest that OAS is more likely in those who have had a longer duration of allergic rhinitis.[4]

Significant regional variations in OAS prevalence have been reported. Differences in pollen exposures as well as differences in relevant proteins contribute to the variations in clinical features. For example, OAS to apple is primarily due to birch pollen sensitization in northern and central Europe, whereas grass pollen sensitization is the main driver of symptoms for OAS to apple in Spain.[10] Regionally distinct allergen sensitization patterns are also reported for kiwi.[11] These geographic differences may be due to regional pollen exposures as well as differing dietary patterns. In addition, changes in environmental exposures can lead to new sensitizations. For example, two patients who previously tolerated jackfruit while living in the Philippines (a birch-free region) were reported to later develop OAS to jackfruit while in Switzerland, a birch-endemic area.[12]

Molecular Basis/Pathogenesis

Different phenotypes of IgE-mediated food allergies exist depending on whether the allergy is due to primary or secondary sensitization to food allergens. OAS develops as a result of secondary sensitization, since pollen allergens are the primary sensitizers, and the symptoms elicited by homologous proteins in plant-derived foods are a secondary phenomenon.[13] Conformational epitopes of relevant pollen allergens involved in OAS are generally heat-labile and highly susceptible to gastric digestion, resulting primarily in limited symptoms in the oropharyngeal areas. However, in some cases, systemic reactions or reactions to cooked forms of the foods can occur.

A number of plant proteins that are widely distributed throughout the plant kingdom are mediators of OAS. Pathogenesis-related (PR) proteins are commonly involved. IgE antibodies to the major birch tree pollen (Bet v 1) cross-react with homologous plant food allergens belonging to the PR-10 protein family, often resulting in symptoms to fruits of the order Rosaceae (i.e. apple, pear, cherry and apricot). Other plant-derived foods that contain homologous proteins include peanut, hazelnut and soy, foods that also trigger classic IgE-mediated food allergies.

Profilin is a second category of proteins involved in mediating OAS.[14] The birch tree pollen Bet v 2 is a profilin protein. Although Bet v 2 is reported to be responsible for a broader spectrum of cross-reactivity than Bet v 1,[15] this broad sensitization is not always correlated with clinical reactivity.[16]

Cross-reactive carbohydrate determinants (CCDs) are a group of high molecular weight allergens (45–60 kDa) contained in various pollens and foods[17] that are highly cross-reactive IgE-binding structures.[18] In vitro studies show that 30% to 40% of pollen-allergic individuals have specific IgE against CCDs,[19] but their role in OAS remains less clear.

As more is learned about plant proteins involved in triggering IgE-mediated reactions to foods, a broader term, pollen food allergy syndrome (PFAS), has been coined. Plant-related proteins not only trigger localized symptoms seen in OAS, but also systemic symptoms. Thus, PFAS is used to describe the wide spectrum of symptoms, ranging from localized oropharyngeal to systemic symptoms, that can result from plant-derived foods.

Lipid transfer proteins (LTPs), belonging to the PR-14 family,[20] are major allergens involved in systemic reactions to

https://CafePezeshki.IR

plant-related foods that occur in individuals without pollen allergies. Unlike the PR-10 proteins and profilin, LTPs are not susceptible to heat[21] and gastric digestion.[22] LTPs have been identified in a wide variety of foods, including Rosacea fruits as well as other unrelated plant-derived foods (i.e. peanut, corn, asparagus, grape, lettuce, sunflower seeds).[12,23,24]

Pollen-Food Associations/Syndromes

Several associations and syndromes have been described (Table 46-1).

BIRCH-FRUIT-VEGETABLE SYNDROME

Many individuals with birch pollen allergy report symptoms when ingesting foods belonging to the order Rosaceae (e.g. apple, pear, peach). The major birch tree pollen allergen, Bet v 1, accounts for most of this cross-reactivity.[25] There is high variability in prevalence of birch-fruit-vegetable syndrome depending on geographic location, with higher rates in birch endemic areas. Birch trees are more common in northern and central Europe and higher rates of OAS to apple are reported in Denmark (34% of birch pollen allergic patients) as compared to Italy (9% of birch pollen allergic patients).[26,27] Although birch trees are not as common outside the northeastern states in the USA, there is a high degree of homology among trees of the Fagales order (e.g. birch, oak, walnut, beech, alder, hazel). Thus, a very high rate of OAS is seen in the USA, with one study reporting that 75.9% of birch pollen allergic patients had clinical symptoms from exposure to apple.[28]

Bet v 1-related proteins have also been identified in peanut,[29] hazelnut[30] and soy.[31] Individuals sensitized to the Bet v 1-homologs in these foods often have no symptoms or localized, transient symptoms with ingestion, despite having detectable IgE levels to these foods. In recent years, there is improved understanding and new technology that allows identification of the relevant allergenic proteins for individuals in order to distinguish between those who have IgE to the major allergens of peanut (Ara h 1, 2, 3) and who are more likely to have systemic reactions, versus those who have elevated IgE to the birch pollen homologous protein (Ara h 8) who have a high chance of tolerance.[32] Similar work has been done for hazelnut[33] and soy.[31,34]

TABLE 46-1 Pollen-Food Associations

Associations	Examples of Foods That may Trigger Symptoms
Birch-fruit-vegetable syndrome	Apple, pear, peach, almond, hazelnut, peanut, soy
Celeriac-mugwort-spice syndrome	Carrot, caraway, parsley, fennel, coriander, fenugreek, cumin, dill, aniseed
Ragweed-melon-banana association	Banana, cantaloupe, honeydew, watermelon, cucumber, zucchini
Lipid transfer protein (LTP) syndrome	Peach, apple, hazelnut, peanut
Latex-fruit syndrome	Avocado, banana, chestnut, potato, tomato

CELERIAC-MUGWORT-SPICE SYNDROME

Celeriac (also known as turnip-rooted or knob celery) contains Bet v 1 homologs that can trigger OAS in birch endemic areas. However, celeriac allergy has also been reported in birch-free areas; in these cases, mugwort pollen allergens are the primary sensitizers.[14,35] Unlike individuals with celeriac-birch allergy who generally have undetectable IgE levels to celery, those affected by celeriac-mugwort syndrome often have elevated IgE levels to cooked and uncooked celeriac, supporting the finding that different allergens are involved in these two groups.[36] In these individuals who react to cooked celeriac the relevant allergens have been identified to be profilins and cross-reactive carbohydrate determinants.[37,38] Other foods in the Apiaceae family that may trigger similar symptoms include carrot, caraway, parsley, fennel, coriander, fenugreek, cumin, dill and aniseed.[14,39,40]

RAGWEED-MELON-BANANA ASSOCIATION

Many ragweed allergic patients have detectable IgE to at least one member of the gourd family Cucurbitaceae (e.g. watermelon, cantaloupe, honeydew, zucchini, cucumber).[41] The relevant allergen in these cases is profilin;[14] thus, symptoms are usually limited to the oropharyngeal areas. Banana also has homologous proteins and can trigger similar symptoms in ragweed allergic individuals.[42] Although these symptoms are often mild, reports of systemic reactions to melon range from 11% to 20%,[43,44] suggesting that more stable allergens such as LTPs may be involved at least for some. Moreover, individuals with ragweed-melon-banana association have higher rates of asthma than pollen-allergic individuals without melon allergy, further lending support for a more severe phenotype in these individuals.[43]

LIPID TRANSFER PROTEIN SYNDROME

Allergies to plant-derived foods can occur in individuals without associated pollen allergies.[45] LTPs act as the primary sensitizer for individuals with allergies to fruits and/or vegetables but no reported symptoms of allergic rhinitis and negative skin tests to pollens,[46,47] particularly in Mediterranean areas.[48–50] Affected individuals have significantly higher rates of systemic reactions (82% vs 45%), including anaphylaxis (73% vs 18%), less frequent oral symptoms (64% vs 91%) and later onset of symptoms to plant-derived foods (19 years of age vs ~12 years) when compared to those who have concurrent pollen allergy. Furthermore, those without pollen allergy have symptoms primarily to the fruits of the order Rosaceae, whereas those with pollen allergy tend to have more diverse sensitizations to different families of fruits, resulting in symptoms to a greater number of foods in general. While the nonpollen allergic group have a higher rate of systemic reactions, the risk of asthma is reported to be higher in those who have concurrent pollen allergy.[14]

The stability of LTPs in the acidic and proteolytic conditions of the gastrointestinal tract as well as their resistance to heating[51] are important factors contributing to the higher rates of systemic reactions reported for this syndrome as compared to the birch-fruit-vegetable syndrome. Data also suggest that LTPs may sensitize via the gastrointestinal route[52] in addition to the respiratory route;[53] thus, LTP may be considered to be a true food allergen.

https://CafePezeshki.IR

LATEX-FRUIT SYNDROME

Significant cross-reactivity between latex and various fruits has been demonstrated, with reports of up to 88% of latex allergic adults having evidence of specific IgE to plant-derived foods.[54,55] While a high degree of immunologic cross-reactivity exists between latex and plant food allergens, the clinical significance appears to be much lower. In a German study of 136 adults with latex allergy, 42.5% reported symptoms with fruit ingestion, but only 32.1% of those reporting symptoms had detectable fruit-specific IgE.[56] In another study that included 57 fruit-allergic individuals, 86% were sensitized to latex, but only 10.5% (6 of 57) had clinically relevant latex allergy.[57]

Primary sensitization to latex occurs via inhalation. Latex-fruit syndrome can manifest with only localized oral symptoms or trigger systemic reactions.[58] The diversity of symptoms is due to the variety of latex allergens that have been identified, including profilins (Hev b 8) as well as more stable allergens such as hevein.[13] A major allergen that belongs to the PR-3 protein family, Hev b 11, retains its IgE-binding epitopes even after the allergen is extensively degraded in simulated gastric fluid.[59]

Diagnosis

The most important aspect of food allergy diagnosis is the history. Since allergic reactions to plant-derived foods may be due to either primary sensitization from a major food allergen or to a secondary phenomenon with pollens being the primary sensitizer, documentation of the onset and type of symptoms can be very informative for characterizing and managing the allergy. OAS symptoms are generally mild, with localized oropharyngeal symptoms such as lip/mouth itching and swelling that develop acutely with exposure; however, systemic reactions, including anaphylaxis, can occur as well (Table 46-2).[60] Severity of symptoms can have seasonal variations with worsening during the pollen season. In one study of 159 individuals with birch pollen allergy and food-related symptoms, 44% reported worsening of their symptoms during the birch pollen season.[8] This is believed to be a result of up-regulation of birch pollen (Bet v 1 and 2)-specific IgE due to the seasonal pollen exposure.[61]

The utility of skin prick tests (SPTs) and serum specific IgE levels (sIgEs) for the diagnosis of OAS is variable depending on the food allergen in question. In general, SPTs and sIgEs are poor predictors for clinical reactivity to foods. In particular for OAS, commercial extracts used for SPTs may not contain all the relevant allergens and/or may have low potency for the heat labile allergens as a result of extract processing. Proteases contained in fruits can significantly affect potency as well. For pineapple, bromelain destroys profilin in extracts prepared without protease inhibitors.[62]

Although not technically standardized, using fresh fruits and vegetables for SPTs generally has improved diagnostic utility compared to commercial extracts. In one study of 36 grass and/or birch pollen allergic individuals, SPTs with fresh hazelnut, apple and melon had high sensitivity (89–97%) and specificity (>70%). The negative predictive value was >90%, but the positive predictive value was more variable, ranging from 50% to 85%.[63] Since it is not always possible to have fresh fruits and vegetables available for SPTs, use of frozen fruits is an acceptable alternative as freezing does not alter the antigenic properties of fresh fruits.[64]

Several other factors can significantly affect the sensitivity of fresh food SPTs. Allergenicity increases with ripening in several foods, including banana[65] and peach.[66] Time of storage and storage conditions can further influence allergenicity. The apple allergen, Mal d 1, has been shown to increase significantly with storage.[67] Differing levels of allergen are also noted among different cultivars. For example, high variations in Mal d 1 and LTP content are found across different apple cultivars.[68,69]

Measurement of sIgE may also be used to support the diagnosis of OAS. In a study of patients with a clinical history of OAS to melons, the positive predictive value was comparable for sIgE (ImmunoCAP®; Thermo Fisher Scientific, Waltham, MA, USA) and fresh food SPT (44% for sIgE vs 42% for SPT), and a slightly higher negative predictive value was observed for fresh food SPT (77% SPT vs 70% sIgE).[44] Similar to SPTs, the utility of sIgE measurement varies for different food allergens.

With advances in the identification and characterization of relevant allergens, recombinant proteins for the detection of sIgE are increasingly being used for food allergy diagnostic purposes. While component resolved diagnosis (CRD) has been shown to be useful to distinguish between phenotypes of allergy for some foods such as peanut and hazelnut,[32,33] the utility of CRD for other plant-derived food allergies is variable. In one study of individuals with birch pollen allergies, CRD was not shown to have added diagnostic utility in predicting clinical reactivity to raw fruits and vegetables.[70] Another group reported improved sensitivity of CRD with individual celeriac allergens compared with extract-based ImmunoCAP diagnosis (88% for CRD vs 67% for extract).[71] However, sIgE levels to individual allergens or extract did not predict severity of reactions to celeriac. Similarly, while some studies note the value of measuring sIgE to individual peach proteins for characterization of peach reactions,[72,73] these levels were not predictive of systemic symptoms.[74] Further studies are needed to determine the role of CRD in the diagnosis of OAS.

Since SPT and sIgE results do not always correlate with clinical reactivity, double-blind, placebo-controlled food challenge remains the gold standard for food allergy diagnosis. While standardized protocols are established for challenges to food allergens that are the primary sensitizer, there are currently no standardized protocols for diagnosing OAS. Adequate blinding of fresh foods is also a challenge. In many cases, a convincing history is sufficient to diagnose OAS; Anhoej et al reported high sensitivity and specificity of case histories in predicting challenge outcome for apple and melon.[63]

TABLE 46-2 Clinical Manifestations of Oral Allergy Syndrome (OAS)/Pollen Food Allergy Syndrome (PFAS)

Localized, oropharyngeal symptoms:
Lip/mouth swelling
Lip/mouth/throat itching
Laryngeal edema
Systemic symptoms:
Cutaneous – urticaria, angioedema
Ocular – conjunctivitis
Upper respiratory tract – rhinorrhea, congestion
Lower respiratory tract – wheezing
Gastrointestinal – abdominal pain, cramps, nausea, vomiting, diarrhea
Anaphylaxis

Management

Since consensus guidelines for the management of OAS do not exist, management of OAS is highly variable among practicing physicians.[75] In a survey of US allergists, responses ranged from advising avoidance of only the offending fruits or vegetables to recommending elimination of entire botanical families of foods. It is important to note that clinical reactivity to one member of a botanical family does not guarantee that symptoms will occur to all foods in a botanical family. In one study of 23 individuals with OAS to peach, 63% reported symptoms to more than one Prunoideae fruit,[76] and another study of 26 individuals with fruit allergy reported that 46% had reactions to more than one Rosaceae fruit.[77] Thus, elimination of entire botanical families is not necessary and will be overly restrictive for many affected individuals.

As previously stated, allergenicity can vary between different cultivars of fruits.[68,69] Therefore, choosing lower allergenic cultivars may reduce symptoms for some. In addition, the distribution of allergen is not uniform throughout the fruit. Much higher concentrations of LTP are found in the skin of apples and peaches compared to the pulp.[78] In one small study, over 40% of individuals with allergies to apple and pear were able to tolerate the flesh, but had symptoms upon ingestion of the whole fruit.[79]

When heat-labile proteins are the main elicitor of symptoms, heating or cooking the fruits and vegetables denatures the relevant proteins, which allows affected individuals to ingest the foods without incurring symptoms. For foods that are more typically eaten in the uncooked form (e.g. apples), brief heating in the microwave can sufficiently denature the Bet v 1-homolog while maintaining the integrity of the fruit. A recent study showed that continuous consumption may be of benefit for OAS triggered by apple; frequent consumption was associated with reductions in OAS symptoms.[80] This has not been explored in controlled trials or reported for other foods.

Since plant-derived foods can also trigger systemic reactions, prescription of self-injectable epinephrine and education on the management of severe reactions is advisable. A study of Spanish children with peach allergy found that 28% reported having severe reactions that required treatment with epinephrine.[81] Factors identified to increase an individual's risk for systemic reactions include prior history of a systemic reaction to the food, reaction to cooked forms of the food,[20,37] positive SPT to the commercial food extract,[82] lack of pollen sensitization[45] and sensitization to LTP.[83] Additionally, concurrent atopic conditions and medications are important details to consider. For example, individuals taking daily antihistamines for allergic rhinitis may not notice early, mild OAS symptoms, leading to increased consumption of the triggering foods and thus increasing the risk of systemic symptoms.[84]

IMMUNOTHERAPY

Immunotherapy has been explored for the treatment of OAS as it has proven to be an effective treatment for allergic rhinitis. Several small studies have demonstrated reductions in oral symptoms in over half of subjects receiving immunotherapy to pollens for the treatment of OAS; however, these studies were limited by the lack of objective outcome measures and/or placebo controls.[85–88] Other studies have shown no significant benefit of immunotherapy (subcutaneous, oral or sublingual) for OAS.[88–90] Immunotherapy using specific food allergens has also been explored, but relapse of symptoms occurs quickly after discontinuation immunotherapy.[80] Moreover, a case report of OAS developing after a patient started on birch pollen sublingual therapy has been published.[91] Therefore, immunotherapy remains an unproven approach for treating OAS.

Conclusions

Oral allergy syndrome (pollen food allergy syndrome) is a common food allergy that occurs as a result of cross-reactivities between plant pollens and proteins in plant-derived foods. As more understanding of relevant allergens is gained, advances in diagnosis and management may be possible.

KEY CONCEPTS FOR OAS

CHARACTERISTICS

- Patients sensitized to multiple pollens or who have had a longer duration of allergic rhinitis are at higher risk for OAS.
- OAS symptoms are generally mild, with localized oropharyngeal symptoms such as lip/mouth itching and swelling.
- Systemic reactions can occur as well; anaphylaxis can occur in 2% of cases.
- Seasonal variations for OAS have been observed, with some reporting worsening of symptoms during the pollen season.

DIAGNOSIS

- History is the most important aspect of OAS diagnosis.
- While SPT and measurement of sIgE levels can identify the pollens that are triggering allergic rhinitis, SPT and sIgE are less reliable for identifying the triggering foods for OAS.
- SPT with fresh fruits and vegetables correlate better with clinical symptoms when compared to commercial extracts; however, this is not standardized.
- Double-blind, placebo-controlled food challenge remains the gold standard for food allergy diagnosis.

MANAGEMENT

- Symptoms elicited by one food do not necessarily predict symptoms elicited by all members within a botanical family; thus, patients are advised to avoid only the fruits and/or vegetables that trigger symptoms.
- When heat-labile proteins are the main elicitor of symptoms, heating the food allergens denatures the relevant protein(s), allowing symptom-free consumption.
- Since OAS can lead to systemic reactions and anaphylaxis in some cases, it is important for patients to be knowledgeable about the identification and treatment of systemic reactions, including indications for self-injectable epinephrine.

Atopic Dermatitis and Food Hypersensitivity

JULIE WANG | HUGH A. SAMPSON

KEY POINTS

- About one third of children with moderate to severe atopic dermatitis (AD) are affected by food hypersensitivity.
- A food allergy evaluation should be considered in children with moderate to severe AD.
- Egg allergy is the most common food hypersensitivity in children with AD; milk, eggs and peanuts generally cause more than 75% of the IgE-mediated reactions.
- Appropriate diagnosis of food allergy and elimination of the responsible food allergen lead to significant clearing of eczematous lesions in the majority of children with AD and food hypersensitivity.
- Infants with AD and egg allergy are at high risk for developing respiratory allergy and asthma.

Introduction

Atopic dermatitis (AD) is a complex, chronic disorder that has been referred to as 'the itch that rashes'. The origin of AD is multifactorial, including many commonly encountered triggers. In 1892 Besnier[1] used the term 'neurodermatitis' to describe a chronic, pruritic skin condition seen in patients with a nervous disorder. In the early 1900s, Coca and Cooke[2] noted the occurrence of a similar disorder with asthma and hay fever, and used the term 'atopy' to refer to the constellation of these allergic diseases. The term 'atopic dermatitis' was then coined by Wise and Sulzberger[3] in 1933 to comprehensively describe this inheritable skin disorder. Since its earliest description, AD has had one primary feature: intense pruritus triggered by a variety of stimuli. In this chapter, we review how the ingestion of specific foods can trigger the condition of AD.

A strong correlation exists between AD and other atopic conditions, and AD is often the first manifestation of the 'atopic march'. Approximately 50% of patients with AD develop it in the first year of life, and as many as 50% to 80% of children with AD will develop allergic respiratory disease later in life.[4] Because of these early historical observations, investigators have explored the role of various allergens as triggers for the pathogenesis of AD (Box 47-1).

Food allergy has been strongly correlated with the development and persistence of AD, especially during infancy and early childhood. The skin is the site that is most often involved in food hypersensitivity reactions. For most skin manifestations of food hypersensitivity, pruritus is a hallmark of the disease. As depicted in Figure 47-1, the earlier the onset and the more severe the AD, the more likely it is that the child will develop food allergies.[5]

Pathophysiology

In the early 20th century, Schloss,[6] Talbot[7] and Blackfan[8] published case reports of patients who had improvement in their AD after removing specific foods from their diets. Subsequent conflicting reports spurred controversy related to the role of specific food allergens in the pathogenesis of AD.[9] This controversy has continued into the 21st century, although there is now significant laboratory and clinical evidence that would suggest the debate is no longer valid. Factors important in the pathophysiology of AD include barrier function, innate and adaptive immune responses and genetics, all of which have some relationship to allergen exposure.[10,11] Studies have demonstrated that allergen-induced, IgE-mediated mast cell activation has, as its end product, hypersensitivity reactions characterized by tissue (i.e. skin) infiltration of eosinophils, monocytes and lymphocytes.[10–12] The pattern of cytokine and chemokine expression found in lymphocytes infiltrating acute AD lesions is predominantly that of the T helper cell type 2 (Th2) (interleukin [IL]-4, IL-5, and IL-13).[13,14] In addition, these cytokines promote influx of activated eosinophils and release of eosinophil products.[13–16] Epidermal, myeloid-derived dendritic cells express high-affinity IgE receptors (FcεRI) that bind IgE and are noted in biopsy tissue from inflamed AD skin. These cells take up and present allergens to Th1, Th2 and T regulatory cells, all of which are important in AD.[10] In addition, IgE-bearing Langerhans cells that are up-regulated by cytokines are highly efficient at presenting allergens to T cells, activating a combined Th1/Th2 profile in chronic lesions. Thus, it appears that IgE antibody and the Th2 cytokine/chemokine milieu combine to play a major role in AD.

Several articles have speculated on the role of food-specific T cells in the pathophysiology of AD and have used the atopic patch test (APT) to provide further information.[17–21] In some patients who may have a delayed response to foods, authors hypothesize that the reactions may occur via high-affinity IgE receptors expressed on Langerhans and dendritic cells leading to allergen-specific T cell responses capable of promoting IgE production and delayed-type hypersensitivity reactions.

Genetic mutations resulting in clinical disease have provided additional insight into the potential relationship of AD and food allergy. Two disorders provide particularly compelling information. IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) is a fatal disorder characterized by autoimmune enteropathy, endocrinopathy, severe dermatitis, elevated serum IgE and multiple food allergies.[22] IPEX syndrome results from a mutation in FOXP3, a protein that plays

https://CafePezeshki.IR

a central role in the generation of regulatory T cells that are important for balance between oral tolerance and food allergy development. Similarly, mutations in the *SPINK5* gene have been associated with Netherton syndrome, an autosomal recessive disorder characterized by an AD-like rash and associated Th2 skewing and increased IgE levels. Japanese investigators have also found an association of *SPINK5* mutations in children with AD and food allergy.[23] More recently, a significant association has been found between loss-of-function mutations of filaggrin, a key epidermal protein for maintaining the barrier function of the skin, and food allergy.[24,25]

BOX 47-1 ALLERGIC TRIGGERS OF ATOPIC DERMATITIS

FOOD ALLERGENS (MOST COMMON)

- Milk
- Eggs
- Peanuts
- Soy
- Wheat
- Shellfish
- Fish

AEROALLERGENS

- Pollen
- Mold
- Dust mite
- Animal dander
- Cockroach

MICROORGANISMS

- Bacteria
  - *Staphylococcus aureus*
  - *Streptococcus* species
- Fungi/yeasts
  - *Pityrosporum ovale/orbiculare*
  - *Trichophytan* species
  - Other yeast species (e.g. *Candida*, *Malassezia*)

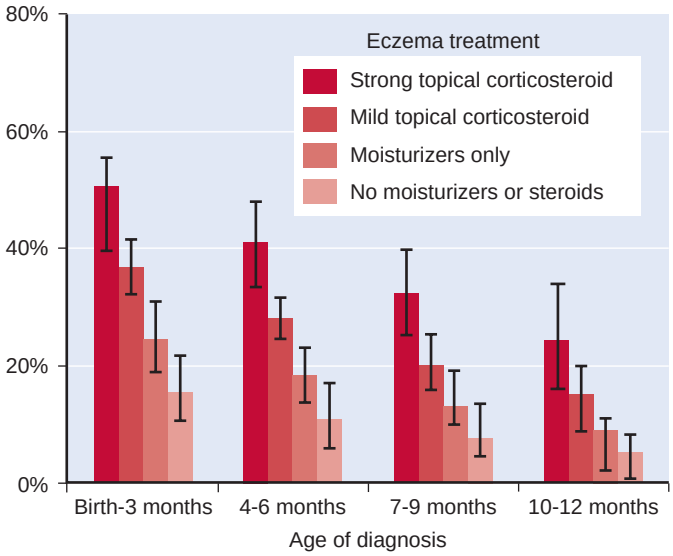

Figure 47-1 The prevalence of infants allergic to foods (peanut, egg, sesame) is correlated with the age of diagnosis of eczema and treatment required for eczema. Infants diagnosed at a younger age and with increased severity of eczema had higher prevalence of food allergy. *(From Martin PE & The* HealthNuts *Study Investigators. Clin Exp Allergy 2015;45(1):255–64.*

Laboratory Investigation

Several studies support a role for food-specific IgE antibodies in the pathogenesis of AD. Many patients have elevated concentrations of total IgE and food-specific IgE antibodies.[26,27] More than 50 years ago, Wilson and Walzer[28,29] demonstrated that the ingestion of foods would allow antigens to penetrate the gastrointestinal barrier and then be transported in the circulation to IgE-bearing mast cells in the skin. Additional investigations have shown that in children with food-specific IgE antibodies undergoing oral food challenges, positive challenges are accompanied by increases in plasma histamine concentration,[30] elaboration of eosinophil products[31] and activation of plasma eosinophils[32] (Box 47-2).

Children with AD who were chronically ingesting foods to which they were allergic were found to have increased 'spontaneous' basophil histamine release (SBHR) from peripheral blood basophils in vitro compared with children without food allergy or normal subjects.[33] After placement on the appropriate elimination diet, food-allergic children experienced significant clearing of their skin and a significant fall in their SBHR.[33] Other studies have shown that peripheral blood mononuclear cells from food-allergic patients with high SBHR elaborate specific cytokines termed histamine-releasing factors (HRFs) that activate basophils from food-sensitive, but not food-insensitive, patients. Furthermore, passive sensitization experiments in vitro with basophils from nonatopic donors and IgE from patients allergic to specific foods showed that basophils could be rendered sensitive to HRFs.[33]

Food allergen-specific T cells have been cloned from normal skin and active skin lesions in patients with AD.[34,35] There has been some disagreement in the literature about the validity of in vitro lymphocyte proliferation responses to specific foods in this disorder. There appears to be an increase in antigen-specific lymphocyte proliferation, but there is considerable overlap in individual responses with that seen in normal individuals. Cutaneous lymphocyte associated antigen (CLA) is a homing molecule that interacts with E-selectin and directs T cells to the skin. A study compared patients with milk-induced AD to control subjects with milk-induced gastrointestinal reactions without AD and with nonatopic control subjects.[34] Casein-reactive T cells from children with milk-induced AD had a significantly higher expression of CLA than *Candida albicans* reactive T cells from the same patients and either casein or *C. albicans* reactive T cells from the control groups.[34]

BOX 47-2 LABORATORY INVESTIGATION OF ATOPIC DERMATITIS AND FOOD HYPERSENSITIVITY

Positive food challenges produce increases in:
- Plasma histamine concentrations
- Activation of plasma eosinophils and eosinophil products

Patients ingesting foods to which they are allergic have:
- Increased spontaneous basophil histamine release
- Histamine-releasing factors that activate basophils from food-sensitive patients

Patients with milk allergy have:
- Higher expression of milk-specific activated cutaneous lymphocyte antigen

Patients with milk and peanut allergy (or food allergy?) have:
- Differential patterns of expression of IgE binding epitopes that add insight into prognosis

https://CafePezeshki.IR

An alternative and emerging paradigm has been championed by several investigators: that sensitization to food allergens occurs due to cutaneous exposure to antigen, e.g. peanut protein in house dust, due to poor barrier function in the skin of AD patients.[10,36] Lack and colleagues found an association between peanut allergy in preschool children with AD and increased exposure to peanut-based skin oils.[37] Subsequent studies from the same group noted a dose-response effect between environmental peanut exposure and the development of peanut allergy.[38] These observations have led to the hypothesis that environmental exposure to allergens through skin of infants with AD is responsible for allergen sensitivity and allergic disease.[36] Results using a murine model of filaggrin (FLG) deficiency support the theory that skin barrier dysfunction and inflammation can lead to epicutaneous sensitization to food proteins, e.g. ovalbumin[39] and peanut.[40] Further research should elucidate the role of filaggrin in AD and food allergies as well as identify additional factors involved in skin barrier function since more than 50% of patients with moderate to severe AD do not have *FLG* mutations and 60% of all carriers of *FLG*-null alleles do not have AD.[41]

Clinical Studies

Multiple clinical studies have addressed the role of food allergy in AD. Investigators have shown that elimination of the relevant food allergen can lead to improvement in skin symptoms and that repeat challenges can lead to recurrence of symptoms.

A number of studies have addressed the therapeutic effect of dietary elimination in the treatment of AD. Atherton and colleagues[42] reported that two thirds of children with AD between the ages of 2 and 8 years showed marked improvement during a double-blind, cross-over trial of milk and egg exclusion. However, there were problems in this study, including high dropout and exclusion rates, as well as confounding variables such as environmental factors and other triggers of AD. Another trial by Neild and colleagues[43] was able to demonstrate improvement in some patients during the milk and egg exclusion phase, but no significant difference was seen in 40 patients completing the cross-over trial. Juto and colleagues[44] reported that approximately one third of AD patients had resolution of their rash and that one half improved on a highly restricted diet. The cumulative results of these studies support the role for food allergy in the exacerbation of AD. Notably, most of the trials failed to control for confounding factors such as other trigger factors, as well as the placebo effect or observer bias.

In one of the original prospective follow-up studies, Sampson and Scanlon[45] studied 34 patients with AD, of whom 17 had food allergy diagnosed by double-blind, placebo-controlled food challenges (DBPCFCs). These patients were placed on appropriate allergen elimination and experienced significant improvement in their clinical symptoms. At 1- to 2-year and 3- to 4-year follow-ups, the subjects were compared with control subjects who did not have food allergy and to children with food allergy who were not compliant with their diet. Food-allergic patients with appropriate dietary restriction demonstrated highly significant improvement in their AD compared with the control groups.

Lever and colleagues[46] performed a randomized controlled trial of egg elimination in young children with AD and a positive radioallergosorbent test (RAST) to eggs who presented to their dermatology clinic. At the end of this study, egg allergy was confirmed by oral challenge, and 55 children who were allergic to egg were ultimately identified. There was a significant decrease in the skin area affected in the children avoiding eggs compared with the control subjects (percent involvement, 19.6% to 10.9% vs 21.9% to 18.9%). There was also a significant improvement in symptom score ($P = .04$) for the children avoiding eggs.

Oral food challenges have been used to demonstrate that food allergens can induce symptoms of rash and pruritus in children with food allergy-related AD. Sampson and colleagues[45,47,48] and Eigenmann and colleagues[49] published a number of articles using DBPCFCs to identify causal food proteins that are involved as trigger factors of AD. In studies during the past 25 years, Sampson and colleagues have conducted more than 4,000 oral food challenges with greater than 40% of the challenges resulting in reaction (personal communication). These studies showed that cutaneous reactions occurred in 75% of the positive challenges, generally consisting of pruritic, morbilliform or macular eruptions in the predilection sites for AD. Isolated skin symptoms were seen in only 30% of the reactions; gastrointestinal (50%) and respiratory (45%) reactions also occurred. Almost all reactions occurred within the first hour of beginning the oral challenges. Clinical reactions to egg, milk, wheat and soy accounted for almost 75% of the reactions. Some patients had repeated reactions during a series of daily challenges and had increasingly severe AD, further showing that ingestion of the causal food protein can trigger pruritus and scratching with recrudescence of typical lesions of AD.

Subsequent studies confirmed that a limited number of foods cause clinical symptoms in younger patients with AD.[50,51] Milk, eggs and peanuts generally cause more than 75% of the IgE-mediated reactions. If soy, wheat, fish and tree nuts were added to this list of foods, more than 98% of the foods that cause clinical symptoms would be identified.

Prevention

Longitudinal studies have been conducted in general population birth cohorts and cohorts of high-risk infants to determine the role of breastfeeding, maternal diet restriction during pregnancy and lactation, the use of hydrolyzed formulas and delayed food introduction on development of AD and other atopic diseases. These studies led to new recommendations for early nutritional interventions by the American Academy of Pediatrics in 2008.[52] A meta-analysis determined that exclusive breastfeeding during the first 3 months of life is associated with lower incidence rates of AD during childhood in children with a family history of atopy.[53] The authors concluded that breastfeeding should be strongly recommended to mothers of infants with a family history of atopy as a possible means of preventing AD.

In two series, infants from atopic families whose mothers excluded eggs, milk and fish from their diets during lactation (prophylaxis group) had significantly less AD and food allergy compared at 18 months with those infants whose mothers' diets were unrestricted.[54,55] Follow-up at 4 years showed that the prophylaxis group had less AD, but there was no difference in food allergy or respiratory allergy.[55] In a 2006 Cochrane review,[56] the authors concluded that dietary avoidance of allergenic foods by lactating mothers of infants with AD may reduce the severity of the eczema, however larger trials are needed to confirm this.

In the German Infant Nutritional Intervention Study (GINI),[57] 2,252 healthy term infants were randomized to receive

https://CafePezeshki.IR

one of four blinded formulas during the first 4 months of life when breastfeeding was insufficient: partially (PHW) or extensively hydrolyzed whey (EHW), extensively hydrolyzed casein (EHC) or cow's milk (CM). These infants were followed for 6 years for allergic manifestations. The study showed a long-term preventive effect of hydrolyzed infant formulas for AD until age 6 years with the relative risk of a physician diagnosis of AD compared with CM of 0.79 (95% CI, 0.64–0.97) for PHW and 0.71 (95% CI, 0.58–0.88) for EHC. No preventive effect was seen for EHW. Similar findings were noted in a high-risk birth cohort of 120 infants from the Isle of Wight followed for 8 years.[58] In the prophylactic group, infants were either breastfed with the mother maintaining a low allergen diet or given extensively hydrolyzed formula and placed on an allergen elimination diet (egg, milk, soy, wheat, nuts, fish) and dust mite avoidance through age 12 months, and compared to control infants in routine care. Those in the intervention group were noted to have reduced asthma (OR 0.24), AD (OR 0.23), allergic rhinitis (OR 0.42) and atopy (OR 0.13) compared to the controls ($P < .001$).

Timing of solid food introduction and its influence on AD has been examined as well. A study by Saarinen and Kajosaari[59] found that while exclusive breastfeeding for the first 6 months of life led to decreased AD at 1 year of age compared to early introduction of solids (at 3 months), no difference in the prevalence of AD was observed during follow-up at 5 years. Fergusson and Horwood[60] also noted an increased risk for AD with early introduction of a diverse number of solid foods in the first 4 months of life using a birth cohort of 1,265 children followed to the age of 10 years. In contrast, delayed introduction of solid foods has not been shown to have a protective effect against AD.[61] Thus, current recommendations encourage exclusive breastfeeding until 4–6 months of age as well as introduction of solid foods at 4–6 months of age.[62]

Vitamin D is another factor recently implicated in atopy, therefore several studies have explored its potential role in AD. In a study examining cord blood vitamin D levels in 231 high-risk infants from an Australian prospective birth cohort, reduced maternal vitamin D levels during pregnancy were noted to be significantly associated with eczema in the first year of life.[63] In addition, Peroni et al reported an association between vitamin D deficiency and increased severity of AD in children.[64] Vitamin D deficiency has also been noted to correlate with IgE-mediated food sensitization[65] as well as food allergy.[66] Recently, Baek et al[67] have suggested that severity of AD is independently associated with vitamin D status and allergic sensitization to foods.

Gut microbiota is hypothesized to have an immune regulatory role in protecting from allergic disorders. Thus, there has been interest in exploring the possibility of probiotic supplementation for the primary prevention of allergies in children at high risk for allergy (defined as those with a biological parent or sibling with current or history of allergic rhinitis, asthma, eczema or food allergy).[62] In a double-blind placebo-controlled trial of 241 mother-infant pairs, a significant reduction of risk for developing eczema during the first 24 months of life was seen in infants whose mothers received probiotics 2 months before delivery and during the first 2 months of breastfeeding.[68] Recent systematic reviews concluded that probiotic supplementation in pregnancy and early life moderately reduces the incidence and severity of atopic dermatitis.[69,70] Thus, World Allergy Organization (WAO) guidelines suggest that probiotics be used in pregnant women at high risk for allergy in their children, in women who are breastfeeding infants at high risk for allergy, and in infants at high risk for allergy because studies have shown a benefit for the prevention of eczema.[71]

Epidemiology of Food Allergy in Atopic Dermatitis

The prevalence of food allergy in patients with AD varies with the age of the patient and severity of AD. In a study of 2,184 Australian infants, investigators found that the earlier the age of onset of AD and the greater the severity of disease, the greater the frequency of associated high levels of food-specific IgE.[72] Lowe and colleagues[73] also noted that, in some infants, sensitization precedes and predicts the development of AD, while in others AD precedes and predicts the development of sensitization. In a study of children with AD, Burks and colleagues[50,51] diagnosed food allergy in approximately 35% of 165 patients with AD referred to both university allergy and university dermatology clinics. Many of the patients were referred to an allergist, which might lead to an ascertainment bias favoring food-allergic subjects, so Eigenmann and colleagues[49] addressed this potential bias by studying 63 unselected children with moderate to severe AD who were referred to a university dermatologist. After an evaluation including oral food challenges, 37% of these patients were diagnosed with food allergy. In another study[74] that evaluated more than 250 children with AD, investigators noted that increased severity of AD in the younger patients was directly correlated with the presence of food allergy. Additional studies in adults with severe AD are relatively limited and have not shown a significant role for food allergy[75] or success in reducing symptoms during trials of elimination diets.[76]

Diagnosis

GENERAL APPROACH

The diagnosis of food allergy in AD is complicated by several factors related to the disease: (1) the immediate response to ingestion of causal foods is down-regulated with repetitive ingestion, making obvious 'cause and effect' relations by history difficult to establish; (2) other environmental trigger factors (other allergens, irritants, infection) may play a role in the waxing and waning of the disease, obscuring the effect of dietary changes; and (3) patients have the ability to generate IgE to multiple allergens, many not associated with clinical symptoms, making diagnosis based solely on laboratory testing impossible (Box 47-3).

The National Institute of Allergy and Infectious Diseases (NIAID) guidelines for the diagnosis and management of food allergy suggest that a food allergy evaluation should be considered in children with moderate to severe AD.[62] As outlined in Chapter 41, a careful medical history is essential in the diagnostic work-up (Figure 47-2). For breastfed infants, a maternal dietary history is also helpful because of the passage of food proteins in breast milk. Selected foods are then evaluated by tests for specific IgE (e.g. prick skin test [PST], food-specific IgE tests), as reviewed in Chapter 41. A small number of foods account for more than 90% of reactions[47,51,77] (Table 47-1). Food additives have been documented to cause flaring of AD, but with a much lower prevalence.[78–80] Patients with AD will often have positive skin tests and/or food-specific IgE tests for several

https://CafePezeshki.IR

BOX 47-3 FACTORS RELATED TO ATOPIC DERMATITIS THAT COMPLICATE THE DIAGNOSIS OF FOOD ALLERGY

Immediate response to ingestion of causal foods is apparently down-regulated with repetitive ingestion, making obvious 'cause and effect' relations by history difficult to establish.
Other environmental trigger factors (other allergens, irritants, infection) may play a role in the waxing and waning of the disease, obscuring the effect of dietary changes.
Patients have the ability to generate IgE to multiple allergens, making diagnosis based solely on laboratory testing impossible.

TABLE 47-1 Foods Responsible for the Majority of Food-Allergic Reactions

Infants	Children	Older Children/ Adults
Cow's milk	Cow's milk	Peanuts
Eggs	Eggs	Tree nuts
Peanuts	Peanuts	Fish
Soy	Soy Wheat Tree nuts (walnut, cashew, etc.) Fish Shellfish	Shellfish

members of a botanical family (e.g. wheat and grass) or animal species (e.g. egg and chicken), more likely indicating immunologic cross-reactivity but not symptomatic intra-botanical or intra-species cross-reactivity. Therefore, the practice of avoiding all foods within a botanical family when one member is suspected of provoking allergic symptoms generally appears to be unwarranted.

After the laboratory studies are performed, the best initial treatment would be elimination of the suspected food from the diet, followed by a food challenge if indicated (Table 47-2). No further testing or food challenges may be necessary in cases of severe, acute reactions or if dramatic improvement in skin disease occurs. Because symptoms are chronic in AD and often a large number of foods are implicated, it is generally necessary to perform diagnostic oral food challenges.

Oral Food Challenges

As outlined in Chapter 41, oral food challenges are invaluable in the appropriate diagnosis and management of patients with AD and possible food allergy. Oral challenges are also necessary to evaluate the resolution (or development of tolerance) of the specific food allergy and can be performed safely.[81,82] However, oral challenges are contraindicated when there is a clear, recent history of food-induced airway reactivity or anaphylaxis. Additionally, patients should not be instructed to perform home food challenges because of the potential risk of severe allergic reactions.[83]

Management

The elimination of food proteins can often be a difficult task, and incomplete elimination of the offending food can lead to confusion and inconclusive results during an open trial of dietary elimination. For example, in a milk-free diet, patients must be instructed not only to avoid all milk products but also to read all food labels in order to identify 'hidden' sources of cow's milk protein, as reviewed in Chapter 48.

Natural History

Most children outgrow their allergies to milk, eggs, wheat and soy[84] (Box 47-4), although studies have shown that the rate of resolution of some food allergens (e.g. egg and milk) may be slower than previously described. In one study of the natural history of egg allergy in children followed in a pediatric allergy

- Fish
- Shellfish

practice, investigators found the age distribution of resolution of allergy to be 4% by age 4 years, 12% by age 6 years, 37% by age 10 years, and 68% by age 16 years.[85] The egg-specific IgE level was predictive of allergy outcome and it can be used in combination with skin testing results to counsel patients on prognosis.[86] Perry et al also showed that food-specific IgE levels are helpful in determining the likelihood that a child has outgrown their food allergy.[87] Patients allergic to peanuts, tree nuts, fish and shellfish are much less likely to lose their clinical reactivity.[88,89] It does appear, however, that approximately 20% of patients who have a reaction to peanuts early in life may outgrow their sensitivity.[89] Only approximately 9% of patients with tree nut allergy will outgrow their allergy.[90] Clinical reactivity is lost over time more quickly than the loss of food-specific IgE measured by PST or serum food-specific IgE testing.[87] Certainly, children with food allergy need to be followed at regular intervals with food-specific IgE testing and PST, followed by oral food challenge when indicated, to determine when clinical tolerance is achieved.

Conclusions

The number of triggers associated with disease pathogenesis and clinical symptoms for patients with AD is vast. The role of allergens as a trigger factor, particularly food allergens, early in life is clearly very important. A careful history and appropriate diagnostic testing coupled with a comprehensive treatment program can be disease modifying and life altering for patients with AD.

48 Management of Food Allergy

MARION GROETCH | HUGH A. SAMPSON

KEY POINTS

- The management of food allergy entails dietary avoidance of the identified allergen to prevent chronic and acute food allergic reactions.
- Allergen elimination diets should not be prescribed lightly as they present great challenges to families and come with potential social, psychological, financial and nutritional burdens.
- Patients with food allergies and their caregivers must learn how to read and interpret product labels to successfully identify and eliminate food allergens.
- Children with food allergies may have inadequate nutrient intake and poor growth if the elimination diet is not well designed to substitute for nutrients lost to the elimination diet.
- The use of nutritionally appropriate substitute formulas and foods may be required.

Overview

The therapeutic management of food allergy entails dietary avoidance of the identified allergen to prevent chronic and acute food allergic reactions. Many alternative immunomodulatory approaches are being explored as a means to prevent immunoglobulin E (IgE)-mediated food allergic reactions, although most have not yet moved into clinical practice. Therefore, at this time, with the exception of extensively heated (baked) milk or egg proteins for a subset of patients with milk and egg allergy, strict dietary avoidance is the only consistently viable management option.[1–4]

Allergen elimination diets present great challenges to families and come with potential social, psychological, financial and nutritional burdens.[5–10] Food is an integral part of social gatherings and without adequate planning the child and family may feel unable to participate fully in daily activities. Going to parties, eating in friends' homes, even going to school or camp requires planning so that these opportunities can be safely enjoyed. Eating competence is also vitally important to the socialization of the child, and children with food allergies may have food aversions and self-limited diets beyond the elimination diet (see Chapter 42). Anxiety issues may even arise about eating and food in general, which will further impact the child's ability to participate fully in activities. Shopping and meal preparation requires significantly more time when avoiding allergens, and specialty allergen-free foods can be more expensive. Lastly, elimination diets may impact nutrient intake; great care must be taken to plan for a diet that continues to provide appropriate nutrition for growth and development. Rickets, vitamin and mineral deficiencies, suboptimal growth and failure to thrive have all been associated with food elimination diets.[11]

In addition to comprehensive education on how to recognize and treat food allergic reactions (see Chapter 58), food allergy management entails teaching the family how to avoid the allergen, manage the allergy in all areas of daily living, and provide a nutritionally balanced diet within the context of the allergen avoidance diet. The goal of providing extensive education is to reduce the risk of accidental allergen exposure, as well as to empower the family, and eventually the child, to participate in all daily activities while avoiding the food to which they are allergic. (See Box 48-1 for a sample elimination diet with substitutions.) Living with food allergies is a daily challenge but, with planning, activities can be safe and manageable, and the allergen avoidance diet nutritionally complete and enjoyable.

Avoidance Diets – General

Elimination diet education begins with knowing how to identify the allergen in the food supply. The elimination of a single allergen from the diet may seem an easy task. If the allergen plays a minor role in our food supply, such as cashew nut, the task may be simple enough. On the other hand, if the allergen is pervasive in our food supply, such as milk or wheat, avoidance issues become much more complex. Avoidance of a single allergen such as cow's milk necessitates avoidance of many common foods including not only milk, butter, cheese, yogurt and ice cream, but also numerous manufactured products such as crackers, breads, cookies, cereals, cakes, and processed meats and cold cuts that may also contain milk protein as an ingredient. Allergen avoidance sheets are available (www.foodallergy.org or www.cofargroup.org – click on Food Allergy Education Program) and are helpful when used as a starting point for allergen avoidance education. Allergen avoidance sheets identify foods and ingredients that typically contain the allergen, in addition to identifying situations that may require special caution. It should be noted that avoidance sheets do not provide the extensive education needed for strict dietary elimination.

LABEL READING

Those shopping for a family member with food allergies must understand how to read and interpret product labels to successfully identify and eliminate food allergens.[12]

Food labeling legislation is dependent on the country or region in which the product is sold. Ingredients considered

https://CafePezeshki.IR

BOX 48-1 SAMPLE ELIMINATION DIET

BREAKFAST

Gluten-free oat pancakes[a] or oatmeal with blueberries (or cooked blueberry compote)
100% pure maple syrup
Calcium fortified orange juice – 4 ounces

SNACK

Fresh watermelon or applesauce
Buckwheat or crispy rice crackers with white bean spread (white beans pureed with olive oil)

LUNCH

Homemade chicken fingers[b]
Baked sweet potato fries or mashed potatoes made with rice milk and milk-free, soy-free margarine
Carrot and red pepper strips with vinaigrette for dipping (or cooked carrots with milk-free, soy-free margarine)
Enriched alternative milk beverage or commercial hypoallergenic formula

SNACK

Enriched alternative milk beverage or commercial hypoallergenic formula
Homemade Birthday Brownie

DINNER

Turkey meatballs in tomato sauce (use a fruit puree to bind the meat and a gluten-free breadcrumb or a dry infant oat or rice cereal as a breadcrumb substitute)
Brown rice or quinoa pasta with olive oil
Steamed broccoli florets
Enriched grain 'milk' or commercial hypoallergenic formula
Fresh peach (or canned peaches packed in own juice)
This sample menu eliminates milk, egg, wheat, soy, peanut, tree nut, fish and shellfish. For a strict diagnostic elimination diet, you may choose to substitute the cooked fruits and vegetables for the raw versions. Serving size and texture modifications should be individualized and based on the child's nutritional needs and feeding skills.

major allergens based on the labeling laws of a specific country or region are listed in Table 48-1.

In the United States of America (USA), The Food Allergen Labeling and Consumer Protection Act (FALCPA) mandates clear, plain language labeling of all ingredients derived from the foods considered major allergens. Those foods considered major allergens in the USA are listed in Table 48-1.[13] The plain language stipulation requires the presence of a major food allergen to be listed, using its common name (e.g. milk) rather than a scientific term (e.g. casein, whey) on the product label in one of the following ways:

- In parentheses, following the food protein derivative, for example: casein (milk)
- In the ingredient list, for example: milk, wheat, peanut
- Immediately below the ingredient list in a 'contains' statement, for example: CONTAINS EGG.[14]

Additionally, a major food allergen may not be omitted from the product label even if it is only an incidental ingredient such as in a spice, flavoring, coloring, additive, or used merely as a processing aid. These regulations only apply to ingredients derived from the eight foods that are considered the major allergens. An individual with allergy to an ingredient not covered under FALCPA, such as garlic or sesame, would still need to call the manufacturer to ascertain if garlic, sesame or sesame oil was included in a vague ingredient term such as 'spice' or 'natural flavoring' of a product.

Manufactured food products, including those imported for sale in the USA, dietary supplements, medical foods and infant formulas are all required to comply with FALCPA.[13] Currently, highly refined vegetable oils derived from major food allergens (including highly refined soy and peanut oils) are not considered allergens by FALCPA because highly refined oils have almost complete removal of allergenic protein and have not been shown to pose a risk to human health.[15] In the USA, soy oil is almost always a highly refined oil, meaning it would not be considered an allergenic ingredient. Peanut oil, on the other hand, may or may not be highly refined. Peanut oil can also be present as expeller-pressed, cold-pressed, expelled or extruded, which may contain enough peanut protein to cause an allergic reaction. As the ingredient list of a finished food will not tell a consumer the nature of the oil ingredient or how the oil was

TABLE 48-1 Major Allergens by Country or Region

Country or Countries	USA, Mexico, Hong Kong, China	Australia and New Zealand	Canada	European Union
Allergens requiring full disclosure on package labels based on allergy labeling regulation in specified country	Milk Egg Wheat Soy Peanut Tree nuts Fish Crustacean shellfish	Milk Egg Wheat Soy Peanut Tree nuts Fish Crustacean shellfish Sesame	Milk Egg Wheat Soy Peanut Tree nuts Fish Crustacean shellfish Mollusks Sesame	Milk Egg Wheat Soy Peanut Tree nuts Fish Crustacean shellfish Mollusks Mustard Celery Lupine Sesame All gluten-containing grains

The specific tree nut, fish or shellfish species must be identified.

https://CafePezeshki.IR

processed, it will not be possible to tell from a product label if the peanut oil listed is highly refined or otherwise processed. Calling the manufacturer may provide more specific information. However, since peanut oil is infrequently used in manufactured products and the labeling of the oil is not sufficient to determine if the ingredient is safe, avoidance of peanut oil is frequently recommended. Tree nut oils and sesame oil are typically not highly refined and will pose a risk to allergic consumers and therefore should be avoided.[14,15]

The presence of ingredients in manufactured foods due to cross-contact is not required to be listed on product labels. Cross-contact occurs when an 'allergen-safe' food unintentionally comes in contact with an allergen during the use of shared storage, transportation or production equipment or routine methods of growing and harvesting crops. Cross-contact may lead to significant levels of hidden allergens in a product without identification on the product label. Many manufacturers are addressing the issue of cross-contact with precautionary labeling such as: 'May contain [allergen]', 'Manufactured in a facility that also manufactures [allergen]' or 'Manufactured on shared equipment with [allergen]'. Those with food allergies should be aware that these statements are currently voluntary and unregulated. A variety of statements are being employed, some of which provide food allergic consumers with little meaningful information on the potential presence of allergens in prepackaged foods. For instance, in a 2010 study, product labels stating, 'Good Manufacturing Practices were used to segregate ingredients in a facility that also processes peanut, tree nuts, milk, shellfish, fish, and soy ingredients,' were interpreted to mean that the product was safe for these otherwise undisclosed ingredients; however, milk was detected in two, and egg in one of the three products with this statement.[16] A 2007 study by Hefle and colleagues[17] evaluated 179 products with peanut advisory labeling. Two different lot numbers of each of these 179 products were analyzed for detectable peanut allergen. The results revealed that 7% (13/179) of the products tested contained detectable levels of peanut in one or both lots and the type of advisory statement used did not reflect the degree of risk. Precautionary statements carry a small but real risk to the consumer with food allergies and no one statement represents a greater or lesser degree of risk than another. The FDA is currently working on developing a long-term strategy to assist manufacturers in using allergen precautionary labeling that is truthful and not misleading, conveys a clear and uniform message and adequately informs US consumers of risk. In the USA, the National Institutes of Allergy and Infectious Diseases (NIAID) expert panel guidelines for the diagnosis and management of food allergy suggest advising patients to avoid precautionary-labeled products. However, individual guidance based on clinical assessment may be appropriate.

Although similar legislation exists in many countries, the foods identified as allergens (see Table 48-1) and slight variations of regulations exist. For instance, precautionary statements in Canada must use the wording, 'May Contain –,' to prevent confusion and misinterpretation. Unique to the European Union (EU) food businesses are required to provide allergy information on food sold unpackaged or pre-packed for direct sale (such as in bakeries, delicatessens and caterers).[18] In Australia, a voluntary incident trace allergen labeling (VITAL) system may be used by food producers to provide standardized, consistent precautionary advice to consumers with food allergy.

Although label ambiguities continue to exist, the package label provides information to the consumer about the contents of a product and should be read each and every time a product is purchased. Healthcare professionals must be prepared to offer extensive education to patients with food allergies so that safe food selections can be made.

DAILY LIVING WITH FOOD ALLERGIES

Once a food item is purchased and brought into the home, that item must continue to be carefully handled to prevent cross-contact with the identified allergen. Storage of ingredients in the home should be planned to prevent cross-contact. A separate shelf in the refrigerator or cupboard may be reserved for the allergen-free foods. Meal preparation to prevent cross-contact in the home is also essential. All food preparation areas, cooking utensils and cooking equipment should be cleansed with warm soapy water and rinsed. Allergen-free foods and meal items can be prepared first, covered, and removed from the area prior to the preparation of other foods for the home. Families will also benefit from guidance on how to prepare meals without their allergenic ingredients.

Families living with food allergies report that avoiding eating in restaurants is the number one cause of decreased quality of life due to the food allergy.[19] Those with food allergies may be especially at risk while dining out since restaurants are not required to list ingredients and the wait staff is generally ignorant about the ingredients in a dish.

Planning ahead and communication with restaurant staff is the first key step in obtaining a safe restaurant meal. Calling ahead to ask how a food allergy is accommodated as well as avoiding the restaurant's busiest hours is often helpful. Families should be taught to inform the staff that their child has a food allergy, not simply to ask if a menu item contains their allergen. 'Chef Cards' provide a written list of ingredients to avoid for specific allergens and are available from organizations such as Food Allergy Research and Education (FARE; www.foodallergy.org). In addition to ingredient inquiries, families must learn to inform restaurant staff about cross-contact risk. Cross-contact in a restaurant environment is not uncommon. For example, the same grill might be used to make a cheeseburger that is used for a plain hamburger, or the French fries might have been cooked in the same deep fat fryer as fried shrimp or milk-containing onion rings. The same tongs or mixing bowls may be used to assemble a salad with nuts as are used to assemble a plain green salad. Families should be taught to speak directly to the chef or food service manager to inquire about ingredients and cross-contact risk. It is important to inform the chef that a clean cooking area, cooking equipment and utensils must be used. Ordering single ingredient foods, prepared simply, will decrease the risk of hidden ingredients. When the food arrives at the table, families should confirm with the chef that the meal was prepared correctly and not have their child eat the food if there is any doubt as to the safety of the meal. Lastly, as always, emergency medications should be available when eating at home or away from home.

Certain types of eating establishments will present a greater risk of allergen exposure. For example, cafeterias, buffets and salad bars have inherently greater risk of cross-contact due to spillage and shared serving utensils. Asian and other ethnic restaurants may use more allergenic ingredients (soy, peanuts, tree nuts, fish and shellfish) in a wide variety of dishes and the

https://CafePezeshki.IR

cooking equipment is generally not washed between each meal prepared. Ice cream parlors use the same scooper for all flavors of ice cream. Asking for a clean scooper may not eliminate the risk as previous servings with a contaminated scooper into the otherwise safe flavor may have already caused cross-contact. For seafood allergies, seafood restaurants may be problematic even if a non-seafood item is ordered because of the greater risk of cross-contact in the kitchen.[20]

Children with food allergies will attend schools just like their nonallergic peers and some planning ahead will help to make the environment safer. Management issues in schools involve methods to prevent relevant exposure to allergens and plans to recognize and treat allergic reactions and anaphylaxis.[21] Physicians should provide written, easy-to-follow instructions in the form of an emergency care plan (ECP), which includes direction on recognizing and treating an allergic reaction including the medication to be given and the appropriate dosing. Parents will need to provide a copy of the ECP to the school staff and inform teachers, nurses, administrators and food service staff about the food allergy. Families should plan to meet with school personnel prior to the start of the school year. Communication with the school about topics such as classroom parties, transportation, supervision in the lunch room if needed, substitute teacher notification, field trips and after-school programs will help to plan food allergy management in all areas of the school environment. FARE has developed a variety of resources and products including a downloadable ECP for physicians to complete and management tips for classrooms and school cafeterias. The Centers for Disease Control and Prevention has published a document entitled Voluntary Guidelines for Managing Food Allergies in Schools and Early Care and Education Programs, a PDF that can be downloaded directly from their website (www.cdc.gov/HealthyYouth/foodallergies/pdf/13_243135_A_Food_Allergy_Web_508.pdf) or accessed via the FARE website at www.foodallergy.org. Parents, physicians, school administrators, teachers, school nurses, food service staff, and childcare and camp staff will find these resources valuable in the planning required to keep children with food allergies safe. Additionally, the Consortium of Food Allergy Research (CoFAR) has developed and validated an extensive food allergy education program that has free and downloadable patient education handouts on specific allergen avoidance diets, fact sheets on specific food allergic disorders, label reading, cross-contact, restaurant meals, cooking without allergens, nutrition and management issues in schools and camps (www.cofargroup.org).[22]

Nutrition

OVERVIEW

Fundamental to the care of any infant or child, including those with food allergies, is the assessment of nutritional status. Children with food allergies may have inadequate nutrient intake if the elimination diet is not well designed to substitute for nutrients lost to the elimination diet. Additionally, feeding problems such as food aversion and a limited acceptance of a variety of foods are common in children with food allergies and may significantly contribute to poor energy and overall nutrient intake. Certain food allergic disorders such as eosinophilic gastrointestinal disorders are commonly accompanied by poor appetite and early satiety, which may have an impact on overall nutrient intake.[23–25] Numerous studies have demonstrated that children with food allergies are at risk of inadequate nutritional intake and poor growth.[7,26–30]

A comprehensive baseline nutrition assessment includes gathering, verifying and interpreting data from anthropometric measurements, dietary history, medical history, physical examination and laboratory indices. Additionally, when assessing pediatric nutritional status, eating abilities and competencies must also be determined. Key indicators of potential nutritional risk in children with food allergies are a greater number of eliminated foods or greater nutritional value of eliminated foods, picky or self-selective eating, feeding delays/difficulties, poor variety or volume of foods provided/accepted or an unwillingness of the child to ingest supplemental formula or other substitute foods.[31]

GROWTH

Several studies have evaluated growth in the pediatric population with food allergy. Christie and colleagues compared height, weight, body mass index and estimates of energy and nutrient intakes in a group of 98 children with food allergy and 99 children without food allergy and found that children with two or more food allergies were shorter, based on height-for-age percentiles than those with no food allergy or only one food allergy.[26] Similarly, Isolauri and colleagues found length and weight-for-length indices in a group of 100 infants with food allergy decreased compared with healthy, age-matched controls.[28] Jensen and colleagues found height for age was significantly reduced in a group of patients living with cow's milk allergy for more than 4 years when compared with height of parents and siblings as well as normal controls.[32] Additionally, it is possible that children with food allergies may have decreased growth despite adequate nutritional intake. Flammarion and colleagues[30] conducted a cross-sectional study comparing children with food allergies ($N = 96$) who had been counseled by a dietitian to paired controls without food allergies ($N = 95$). Children with food allergies had weights and heights within the normal range; however, they were smaller for their age than the nonallergic controls, even when they received similar nutrition. Suboptimal nutrition in this population may exacerbate the risk and decreased growth can more easily become poor growth. So while there may be other contributing factors associated with decreased growth in children with food allergy, in general the primary cause of poor growth likely stems from inadequate substitution in the elimination diet.

The NIAID Food Allergy Guidelines recommend close growth monitoring for all children with food allergies.[12] Review of current and historical growth should be completed according to current standards of care that are based on Centers for Disease Control and Prevention (CDC) and World Health Organization (WHO) or other national standards. Measurements, including weight, length or height, and head circumference as age appropriate, should be obtained and plotted on appropriate growth charts (WHO charts for infants and children from birth to 24 months and CDC charts for children age 2 to 20 years). Growth typically follows predictable increases in length, weight and head circumference and significant changes in growth velocity are not expected. Plotting growth measurements on the appropriate standardized growth chart will allow assessment of growth velocity for that particular child as well as provide a comparison of growth with the reference population.

https://CafePezeshki.IR

Weight for length (under 2 years) and body mass index (BMI; 2 years and older), defined as weight in kilograms divided by the square of height in meters, may be helpful as they take into consideration weight for height. The WHO considers less than the 3rd percentile and greater than the 97th percentile to reflect abnormal growth. The CDC defines underweight in children as a BMI of less than the 5th percentile. Children are considered to be overweight when their BMI is greater than the 85th percentile and obese when their BMI is greater than the 95th percentile.

DIETARY INTAKE ASSESSMENT

Dietary intakes can be obtained by 24-hour recall or multiple-day food diary or food frequency questionnaire. A 24-hour recall is generally useful when assessing intake in an infant who is predominantly breastfed or bottle-fed but may provide limited information for older children, as accuracy of a mixed diet may not be reflected with recall. For older infants and children, a food diary will provide a more accurate estimate of intake. A food diary of at least three days (including one weekend and two weekdays) should include the amount and types of foods ingested and the timing of meals and snacks. Questions about typical dietary patterns or food frequency questionnaires may also be used and are especially useful in assessing specific nutrient intakes. For example, assessment of calcium and vitamin D intake may be determined by asking about frequency and amounts of dairy or enriched dairy substitutes consumed.

A registered dietitian will be able to compare dietary patterns to recommendations from the Dietary Reference Intakes (DRI; http://fnic.nal.usda.gov/dietary-guidance/dietary-reference-intakes) or food group guides specified by the US Department of Agriculture (www.choosemyplate.gov) or provided by governmental agencies in other countries. The DRI and other guidelines may be used as a tool to assess nutrient intake, plan interventions and/or monitor the patient's ongoing nutrient intakes.[33] Even clinicians who are not trained to assess nutrient intake may glean valuable information from a food diary or food frequency questionnaires. For instance, unusual meal or snack patterns such as feeding on demand beyond infancy, or unusual food intakes such as excessive fruit juice consumption may become apparent and give clues to potential causes of poor growth or nutritional status in a child.

EATING COMPETENCE

Eating competence describes a child's ability to eat and enjoy a wide variety of foods of varying flavors and textures that will support adequate nutrition for growth and development. Eating competence and pediatric nutrition are often discussed side by side because feeding problems are common in childhood, with an estimated 25% to 35% of otherwise healthy children affected.[34] Eating is a complex, learned process involving the acquisition of physical skills, behaviors, acquired tastes, and attitudes and feelings about eating in general as well as about particular food items.[35,36] Even mild, self-selective or 'picky' eating can impact nutrient intake and, in combination with an allergen elimination diet, can have serious nutritional implications. Assessment of eating competencies will provide the information needed to provide an effective nutrition care plan. See Chapter 42 for more information on management of feeding problems.

ESTIMATING NUTRITIONAL NEEDS

Energy

The estimated energy requirement (EER) is the average dietary energy intake that is predicted to maintain energy balance. For children, the EER includes the needs associated with the deposition of tissues at rates consistent with good health. There is no established recommended dietary allowance (RDA) for energy because energy intakes exceeding the EER would be expected to result in excessive weight gain. EER can be calculated using the equations provided in the DRI reports (www.nap.edu) or by using the interactive DRI calculator for healthcare professionals available on the USDA website (http://fnic.nal.usda.gov/fnic/interactiveDRI/). Energy is provided in the pediatric diet through three major classes of macronutrients: proteins, carbohydrates and fats.

Protein. Adequate protein in the diet is crucial in all age groups. Many excellent sources of protein are also common allergens including milk, egg, soy, fish, shellfish, peanut and tree nuts. Diets must be carefully planned to meet protein needs when high quality protein sources are eliminated from the diet. Inadequate dietary protein intake may be a contributing factor in the decreased stature reportedly seen in the population of children with food allergies.

Protein needs may be estimated using the DRI for protein found in Table 48-2.[37] An estimated 65% to 70% of protein needs should come from sources of high biologic value, meaning animal products for the most part, which contain a full complement of indispensable amino acids. Animal products (milk, eggs, meat, fish and poultry) are not necessary to provide optimal protein, but most alternative sources from plants, legumes, grains, nuts, seeds and vegetables do not contain a full complement of indispensable amino acids and therefore greater dietary planning will be required. Additionally, dietary protein recommendations are based on the assumption that energy intake is adequate. If energy intake is insufficient, free amino acids will be oxidized for energy, allowing for less available amino acids for anabolic and synthetic pathways.[37]

Fat. Adequate dietary fat is crucial as fats are an important source of concentrated energy, support the transport of fat-soluble vitamins and provide the two fatty acids – omega 3, alpha-linolenic acid (ALA) and omega 6, linoleic acid (LA) – which are essential in the human diet. Dietary fat needs may be estimated using the DRI for fats in Table 48-2.[37] Adequate dietary fat is an especially important source of energy and nutrients for rapidly growing infants and toddlers. Dietary fat intakes below 22% of total caloric intake increase risk of energy, vitamin E and essential fatty acid deficiency. Dietary fat is present in a wide variety of foods, such as dairy products, eggs, meat, fish and poultry, vegetable oils and margarines and many manufactured and processed snack foods, convenience meals and desserts. Children on allergen-restricted diets, who must eliminate not only the allergen but also many processed and manufactured foods, may find it especially difficult to meet dietary fat needs without adding supplemental fats (in the form of vegetable oils) to the diet.

Carbohydrates. Carbohydrates make up the remaining energy sources and provide an important supply of numerous vitamins, minerals and trace elements. Carbohydrates should

Adapted from the DRI report: Dietary Reference Intakes for Energy, Carbohydrate, Fiber, Fat, Fatty Acids, Cholesterol, Protein, Amino Acids (2002/2006). Available at: www.nap.edu.

AI – adequate intake is the recommended average daily intake level based on observed or experimentally determined approximations or estimates of nutrient intake by a group (or groups) of apparently healthy people that are assumed to be adequate. The AI is used when an RDA cannot be determined.

AMDR – acceptable macronutrient distribution range is the range of intake for an energy source that is associated with reduced risk of chronic disease while providing adequate intakes of essential nutrients.

ND – not determinable.

**RDA* – recommended dietary allowances are set to meet the needs of almost all individuals in a group.

comprise between 45% and 65% of total caloric intake. Grains, dairy products, legumes, fruits and vegetables provide dietary carbohydrates. Simple sugars and foods with added sugars also contribute carbohydrates and additional energy, but are of little further nutritional benefit and should be limited to no more than 25% of total energy intake. Dietary carbohydrates are an important source of iron, thiamin, niacin, riboflavin and folic acid. Children on wheat avoidance diets should substitute alternative grains to meet the recommended dietary allowance (RDA) for carbohydrate of 130 g/day for adults and children 1 year of age or older.

Macronutrient intake should be considered in the nutritional assessment and modifications made to ensure an appropriate nutritional balance. Meeting the recommended dietary intakes of macronutrients can often be challenging when food groups are eliminated due to food allergies. Acceptable macronutrient distribution ranges (AMDR) have also been established for protein, carbohydrates and fats and indicate the range of intake for a particular energy source, expressed as a percentage of total caloric intake that is associated with reduced risk of chronic disease, while providing adequate intakes of essential nutrients.[37] The AMDR may be found in Table 48-2 and can be used to guide the appropriate intake and distribution of carbohydrates, fats and proteins.

Micronutrients

Variety in the diet contributes to adequacy of nutrients provided. When a food group is eliminated, the nutrients provided by that food group must be provided by other dietary sources. In 2002, Christie and colleagues[26] found that children with multiple food allergies or cow's milk allergy consumed less dietary calcium than age-specific recommendations compared with children without cow's milk allergy and/or one food allergy. Henricksen and colleagues[27] surveyed a sample of families with young children with milk allergy and/or egg allergy and assessed dietary intake using a complete 4-day, weighed recording. Children on milk-free diets had significantly lower intake of energy, fat, protein, calcium, riboflavin and niacin.

While it is important to ensure adequate intake of all essential nutrients, certain nutrients will be at greater risk of insufficiency depending on the food allergen and must be adequately replaced by other foods in the diet. When foods are chosen carefully, and appropriate substitutions are made, the diet for a child with food allergies can be nutritionally adequate. When dietary modifications are inadequate to meet vitamin, mineral and trace element needs, appropriate supplementation may be considered. Dietary supplements, however, may pose a risk of contamination with food allergens and they should be chosen carefully, with consideration for safe ingredients as well as risk assessment of potential cross-contact during manufacturing.

Common Allergen Elimination Diets of Early Childhood

The prevalence of food allergy in infants and young children is approaching 8%[38] with the major allergens of early childhood being milk, egg, soy, peanut and wheat.

COW'S MILK ALLERGY

Cow's milk allergy (CMA) affects predominantly the pediatric population, as approximately 80% of children with CMA eventually develop clinical tolerance. Recent epidemiologic studies indicate that milk allergy may be more persistent with fewer children becoming tolerant to milk in the first few years of life. One large retrospective study from a specialty clinic reported resolution rates in 807 children with CMA and found the rates of resolution were 19% at the age of 4 years, 42% by 8 years, 64% by 12 years, and 79% by 16 years.[39] In a recent observational cohort of 244 infants with CMA, 52.5% of patients had resolution of milk allergy at a median age of 62 months and a median age of last follow-up at 66 months.[40] These studies indicate that children with CMA may be required to eliminate

https://CafePezeshki.IR

milk, a nutrient-dense food source, for longer durations throughout childhood.

The nutritional effect of cow's milk elimination in the pediatric population is great because milk is not only a good source of fat, protein, calcium and vitamin D but is also the primary source for most young children. Milk also provides vitamin B_{12}, vitamin A, pantothenic acid, riboflavin and phosphorus. Finding a nutritionally dense substitute for cow's milk in the pediatric diet is essential and parents of children with CMA require detailed advice about nutritionally sound food choices.

In 2010, the World Allergy Organization (WAO) Diagnosis and Rationale for Action against Cow's Milk Allergy (DRACMA) guidelines provided recommendations for the treatment of cow's milk allergy (CMA).[41] Specific guidance was provided on how long an infant should maintain a substitute milk and what kind of substitute milk is appropriate based on the symptom or food allergic disorder. DRACMA recommends a cow's milk substitute of adequate nutritional value for infants and young toddlers until 2 years of age. Adequate substitutes are identified as either breast milk (with maternal milk avoidance and calcium supplementation) or a substitute formula, which can be either extensively hydrolyzed or amino acid based in early infancy. Soy formula is not recommended for pre-term infants and has no benefit over hypoallergenic formula in CMA.[41,42] The type of formula recommended may vary based on the age and nutritional needs of the patient, the type of food allergic disorder and the degree of severity of the presenting symptoms. See Table 48-3 for substitute pediatric formula recommendations based on DRACMA guidelines.

Transitioning an infant from a complete formula to a milk product is typically considered around 1 year of age or, ideally, when at least two thirds of the total daily caloric intake comes from a varied solid food diet since a wide variety of foods is more likely to contribute to micronutrient adequacy. However, other criteria for the infant with CMA must be considered as the milk elimination diet may not be nutritionally equivalent to the diet that is not restricted. Additionally, the enriched alternative beverage (soy, tree nut, seed or grain-based 'milks') may not provide comparable nutrition. Alternative mammalian milks, such as goat's or sheep's milk, are also not suitable due to homologous proteins and the strong risk of cross-reactivity.[43]

For children with concomitant milk and soy allergy, enriched rice, coconut and almond milks may provide a good source of calcium and vitamin D, but they provide essentially no protein and are low in fat. Therefore, protein requirements will need to be met entirely through the solid food diet before switching to these enriched 'milk' beverages. Fat intake will also need to be assessed and additional fat in the form of vegetable oils may be required. Christie and colleagues showed that the risk of consuming inadequate intakes of calcium and vitamin D among children with CMA was decreased if a safe enriched soymilk or commercially prepared infant/toddler formula was provided, suggesting that children with milk allergy should continue to include an adequate, nutrient-dense milk substitute in the diet.[26] It is often the case that a 1-year-old child is not capable of meeting protein and fat needs exclusively through the solid food diet, therefore maintaining the child on a hypoallergenic commercial formula, as recommended in DRACMA guidelines, certainly may be warranted.[41]

The nutritional impact of milk allergy is great because milk is an excellent source of protein, calcium, vitamin D, phosphorus, vitamin A, vitamin B_{12} and riboflavin. Possible alternative dietary sources for these nutrients can be found in Table 48-4.

EGG ALLERGY

Eggs contribute protein, vitamin B_{12}, riboflavin, pantothenic acid, biotin and selenium in the diet. Many foods supply the nutrients found in eggs. Egg in the diet does not usually account for a large proportion of daily dietary intake and therefore the nutrients lost through egg avoidance are not significant if the allergy stands alone and the diet is otherwise varied.

Egg is a common ingredient in many recipes such as baked goods, casseroles and meat-based dishes such as meatballs, meatloaf and breaded meats. Learning to replace egg in the diet will help families to continue to enjoy traditional foods. Many commercial egg substitutes actually contain egg protein and therefore are not suitable for those with egg allergy, although egg-free replacers for baking are available. A free downloadable cooking handout from the CoFAR food allergy education program (www.cofargroup.org) will help families learn how to substitute for egg in their favorite recipes.

BAKED MILK AND EGG TOLERANCE

We now know that as many as 70% of patients with milk and egg allergy tolerate extensively heated (baked) milk and egg

TABLE 48-3 Pediatric Formula Recommendations Based on DRACMA Guidelines

Food Allergy Symptom or Disorder	First Formula Recommendation	Second Formula Recommendation	Third Formula Recommendation
IgE-mediated allergy Low risk anaphylaxis	Extensively hydrolyzed formula	Amino acid based formula	Soy formula
IgE-mediated allergy High risk anaphylaxis	Amino acid based formula	Extensively hydrolyzed formula	Soy formula
Food protein-induced enterocolitis (FPIES) or proctitis/proctocolitis	Extensively hydrolyzed formula	Amino acid based formula	–
Eosinophilic esophagitis	Amino acid based formula	–	–
Heiner syndrome	Amino acid based formula	Extensively hydrolyzed formula	Soy formula

*Diagnosis and Rationale for Action Against Cow's Milk Allergy.[41]

https://CafePezeshki.IR

TABLE 48-4 Nutrients Provided by Milk and Milk Products and Alternative Dietary Sources

Nutrients in Cow's Milk	Alternative Sources
MACRONUTRIENTS	
Dietary protein	Commercial formula, meat, fish, poultry, egg, soybean or enriched soy beverage, peanut, other legumes, tree nuts
Dietary fat	Commercial formula, vegetable oils, milk-free margarine, avocado, meats, fish, poultry, peanut, tree nuts, seeds
MICRONUTRIENTS	
Calcium	Commercial formula, enriched alternative 'milk' beverage (soy, rice, almond, coconut, oat, potato), calcium fortified tofu, calcium fortified juice
Vitamin D	Commercial formula, enriched alternative 'milk' beverage, fortified milk-free margarine, fortified eggs, liver, fish liver oils, fatty fish
Vitamin A	Retinol: Liver, egg yolk, fortified milk-free margarine Carotene: Dark green leafy vegetables, deep orange fruits and vegetables (broccoli, spinach, carrots, sweet potatoes, pumpkin, apricot, peach, cantaloupe), enriched alternative 'milk' beverage
Pantothenic acid	Meats, vegetables (broccoli, sweet potato, potato, tomato products), egg yolk, whole grains, legumes
Riboflavin	Dark green leafy vegetables, enriched and whole grain products
Vitamin B_{12}	Meat, fish, poultry, egg, enriched alternative 'milk' beverage, fortified cereals, nutritional yeast

ingredients.[44,45] Heating milk and egg ingredients generally decreases protein allergenicity by destroying conformational epitopes. The introduction of extensively heated milk and egg to the diet of those who tolerate baked milk and egg ingredients can improve the nutritional quality of the diet and decrease the strain and burden of strict avoidance, and importantly, appears to represent an alternative approach to oral immunomodulation. Nowak-Wegrzyn et al[44] introduced baked milk into the diets of children who were baked milk tolerant yet reactive to unheated milk. Children who incorporated baked milk into the diet were 16 times more likely to become tolerant to unheated milk compared to a comparison group of children ($P < .001$) who continued strict avoidance of milk ingredients.[45] Children who incorporated baked egg into the diet were 14.6 times more likely than children in the comparison group ($P < .0001$) to develop regular egg tolerance, and they developed tolerance earlier (median 50.0 vs 78.7 months; $P < .0001$).[46]

Although the patients who tolerate baked egg and milk ingredients can have a more liberalized diet, there are additional complexities in avoidance. For instance, a cake may have baked milk or egg ingredients in the cake and unbaked ingredients in the frosting or filling. Flavorings on crackers or chips may be topically applied after the item is baked. Other products such as quiche may have too much milk or egg protein to be tolerated. A general guideline is to allow only the amount of baked ingredient to which the patient has been shown to be tolerant (based on physician-supervised oral food challenge) and to avoid commercial products with baked egg or milk listed as the first or second ingredient. Generally, commercial products such as plain cookies or breads that carry a precautionary statement do not need to be avoided but a soy yogurt or vegan cheese for instance may carry the risk of cross-contact with a fresh milk ingredient, so caution is still warranted.

WHEAT ALLERGY

The child with wheat allergy must avoid all wheat-containing foods, resulting in the elimination of many processed and manufactured products, including bread, cereal, pasta, crackers, cookies and cakes. Wheat is also commonly used as a minor ingredient in other commercial food products such as condiments and marinades, cold cuts, soups, soy sauce, some low or non-fat products, hard candies, licorice and jelly beans. Wheat contributes carbohydrates as well as many micronutrients such as thiamin, niacin, riboflavin, iron and folic acid. Whole grain wheat products also contribute fiber to the diet. Alternative dietary sources of these nutrients should be provided. Four servings of wheat-based products, such as whole grain and enriched cereals or breads, generally provide greater than 50% of the RDA/AI for carbohydrate, iron, thiamin, riboflavin and niacin for children 1 year of age and older, as well as a significant source of vitamin B_6 and magnesium. Elimination of wheat products from the diet has great nutritional impact when nutrient-dense alternatives are not provided. Alternative sources for the nutrients found in wheat can be found in Table 48-5.

Many alternative flours are available to patients with wheat allergy, including rice, corn, oat, arrowroot, potato, sorghum, soy, barley, buckwheat, rye, amaranth, millet, teff and quinoa. It has been reported that 20% of individuals with one grain allergy may be clinically reactive to another grain, therefore use of alternative grains should be individualized and based on tolerance as determined by the patient's allergist.[47] Alternative flours (grain, vegetable, legume, seed or nut) may improve the nutritional quality, variety and convenience of the wheat-restricted diet. Many of these flours are commercially available for home use and there is also a broad array of gluten-free products available that may be suitable for the patient with wheat allergy. Choosing those made from enriched or whole grains will improve the nutritional quality of the diet.

SOYBEAN ALLERGY

Soybean/soy protein is an ingredient in a surprising variety of manufactured products. Eliminating many manufactured foods with soy as an ingredient will have an impact on the variety of manufactured products available to those with soy allergy. Highly refined soybean oil is a soy ingredient that is not considered an allergen and does not require labeling as such.[48] Studies show that the vast majority of soy-allergic individuals can also tolerate soy lecithin although soy lecithin must be labeled as an allergen.[15] Products containing soy lecithin, with a 'Contains soy' statement, may in fact be safe for consumption by most patients with soy allergy. Families should never assume

https://CafePezeshki.IR

TABLE 48-5 Nutrients Provided by Wheat and Alternative Dietary Sources

Nutrients Provided by Wheat	Alternative Dietary Sources
MACRONUTRIENTS	
Carbohydrates	Products made with alternative grains: amaranth, buckwheat, corn, millet, oat, rice, sorghum, teff, quinoa; fruits, vegetables, legumes
Fiber	Fruits, vegetables, alternative whole grain products, legumes
MICRONUTRIENTS	
Thiamin	Enriched and whole alternative grain products, nuts, legumes, liver, pork, sunflower seeds
Riboflavin	Enriched and whole alternative grain products, milk, dark green leafy vegetables
Niacin	Enriched and whole alternative grain products, meat, fish, poultry, liver, peanuts, sunflower seed, legumes
Folic acid	Enriched and whole alternative grain products, beef liver, dark green leafy vegetables, legumes, seeds
Iron	Heme iron: Meat, liver, fish, shellfish, poultry Non-heme iron: Enriched and whole alternative grain products, legumes and dried fruits

that a product is safe without first calling the manufacturer to determine if any soy ingredient other than soy lecithin is contained in the product.

While soy itself is a nutritionally dense food, it generally is not a major component of the diet, and therefore the nutrients lost due to soy elimination may easily be replaced. If there are other food allergies or dietary patterns such as a vegetarian diet, then the child with soy allergy may be at nutritional risk.

PEANUT ALLERGY

Peanut allergy affects approximately 1.8% of children in the USA.[38] Avoidance of peanuts in the diet does not necessarily pose any specific nutritional risk when there are no other nutritional risk factors.

Approximately 20% of young children with peanut allergy may eventually develop clinical tolerance. Children with peanut allergy are at greater risk for tree nut allergies. In fact, about 35% of those allergic to peanut will react to at least one tree nut although these two foods are botanically different, peanut being a legume rather than a nut.[47] Cross-reactivity between peanuts and legumes is rare with only about 5% of those with a peanut allergy reacting to another legume.[47] However the legume lupine (lupin) appears to carry a greater risk of cross-reactivity with peanut. In recognition of the risk of cross-reactivity with peanut as well as the risk of having a primary allergy to lupine, the EU has included lupine as a major allergen, with products containing lupine or its derivatives requiring full disclosure on EU product labels.[49] Lupine is not, however, considered a major allergen in the USA, Canada or Australia.[48]

Oral Food Challenges

A child with food allergies may undergo an oral food challenge to identify or confirm immediate and occasionally delayed food allergic reactions or to determine if clinical tolerance to a particular food has been acquired. The individual patient history and the results of prick skin tests and food-specific serum IgE values will determine if an oral food challenge is appropriate. The type of challenge is determined by the history, the age of the patient and the likelihood of encountering subjective reactions. The food challenge requires evaluation of the patient prior to the procedure and preparation of the office for the organized conduct of the challenge, for a careful assessment of the symptoms and signs and the treatment of reactions.

During the physician-supervised oral food challenge, the challenge food is administered gradually in incremental doses.[50] The patient is observed for symptoms during the procedure and for a period of time after the full test dose is administered. Challenges can be open, single-blind or double-blind. While the utility of the double-blind, placebo-controlled food challenge (DBPCFC) as the 'gold standard' for food allergy testing is acknowledged, the NIAID Food Allergy Guidelines noted that open or single-blind challenges could also be acceptable for food allergy evaluation when the challenge outcome is negative or when objective symptoms are elicited that recapitulate the reaction history.[12] Regardless of the type of food challenge, emergency medications should be available and an emergency treatment protocol should be in place.

There are a number of primary documents available to the practicing allergist/immunologist to guide the administration of the physician-supervised oral food challenge.[50,51] In 2012, the American Academy of Allergy, Asthma and Immunology (AAAAI) and the European Academy of Allergy and Clinical Immunology (EAACI) jointly published a consensus report on standardizing the DBPCFC, which is part of the PRACTALL initiative.[50] The Adverse Reactions to Foods Committee of the AAAAI published a work group report on oral food challenge testing, which is a comprehensive guide on conducting physician-supervised oral food challenges.[51] These documents offer in-depth, practical guidance and should be utilized by practicing allergists/immunologists to ensure that safe and scientifically sound challenge procedures are conducted.

Conclusions

Current management of food allergy entails dietary avoidance of the identified allergen, requiring extensive education (Box 48-2). Allergen elimination diets should not be prescribed lightly and the global impact of these diets should be considered. In theory, elimination of dietary allergens may seem an easy enough task, but avoidance issues are complex and accidental ingestions are not uncommon. Hence, food allergy management must also include comprehensive education on how to recognize and treat a food-allergic reaction. This topic is discussed fully in Chapter 58.

BOX 48-2 KEY FOOD ALLERGY MANAGEMENT POINTS

- Avoidance of the identified allergen is key in the management of food allergies. Provide comprehensive education on the scope of allergen elimination issues such as label reading, avoiding hidden sources of the allergen and cross-contact risk. Allergen avoidance sheets are an excellent resource to begin educating families about allergen elimination.
- Provide education to help families manage daily living activities such as going to school or camp, eating in restaurants or friends' homes, shopping and cooking. The goal of education is to reduce the risk of accidental allergen exposure while empowering the family, and eventually the child, to participate in all daily living activities while avoiding the food to which they are allergic. Visit www.cofargroup.org for free patient handouts on many issues of food allergy management.
- Ensure that a nutrient-dense alternative food source is recommended to substitute for the nutrients lost to the elimination diet. Follow-up to ensure that the alternative food has been accepted and incorporated into the diet is essential.
- Encourage the family to offer a variety of developmentally appropriate allergen-free foods of varying tastes and textures to help the child develop eating competence and allow even a food elimination diet, with appropriate substitutions, to provide adequate nutrition.
- Use of a milk substitute such as breast milk or a commercially available, hypoallergenic formula may be warranted until 2 years of age in children with milk allergy.
- All children with food allergies should receive nutrition counseling and close growth monitoring as they are at risk of inadequate nutrient intake and poor growth.
- Educate the family on how to recognize and treat a food-allergic reaction.
- Recommend that children with food allergy wear medical alert jewelry.
- Instruct families to have their child's epinephrine autoinjector device immediately available at all times.
- Instruct families to seek medical help immediately by calling 9-1-1 or getting transportation to an emergency room if their child experiences a food-allergic reaction, even if epinephrine has already been given.

Immunotherapeutic Approaches to the Treatment of Food Allergy

STACIE M. JONES | A. WESLEY BURKS

KEY POINTS

- Restoration or induction of immune tolerance is the primary goal for immunotherapy (IT) for food allergy, requiring significant immunomodulation to be effective.
- Emerging immunotherapeutic approaches to food allergy have largely induced desensitization but have met with some clinical successes, i.e. sustained unresponsiveness, in subsets of patients with food allergy.
- Immunomodulation has been noted with a variety of immunotherapy approaches to food allergy, with oral immunotherapy offering the most robust impact to date.
- Factors such as biomarkers or patient characteristics that can predict successful immunotherapy for food allergy are currently lacking.
- Further study in larger, more diverse populations of food-allergic patients is needed before immunotherapy for food allergy can be broadly applied to the clinical setting.

Introduction

Food allergy is an immune-mediated disorder that can often be life-threatening but is always life-altering.[1] In food allergy significant immune deviation is evident, preventing oral tolerance of foods and resulting in allergic sensitization that leads to clinical allergy.[2] Immune deviation in food allergy includes reductions in regulatory T cell and tolerogenic dendritic cell activity, with Th2 skewing of the immune response and Th2-predominant cytokine production, increased IgE and elevated mast cell and basophil activation.[2,3] Restoration or induction of immune tolerance is the over-arching goal of any approach employing allergen immunotherapy for food allergy, requiring significant immunomodulation to be effective (Table 49-1). In fact, true immunologic tolerance to foods may not be achievable without some level of ongoing treatment or allergen exposure. Allergen immunotherapy has been documented for decades as a safe, effective treatment for many allergic disorders.[4] Despite its success for other allergic diseases, subcutaneous immunotherapy (SCIT) has not been implemented for the treatment of food allergy due to its unacceptable safety profile in early studies.[5,6] Due to the lack of active treatment options for food allergy, a vast amount of clinical and translational research has focussed on the development of novel immunotherapeutic strategies. Several approaches have emerged as promising future therapeutic options (Figure 49-1).

Common terms have been employed to describe the clinical state of allergic disease in response to immunotherapy. *Desensitization* refers to a change in the threshold dose of allergen required to induce allergic symptoms after allergen ingestion. This is a reversible state in which effector cells are rendered less reactive by administration of allergen, thus consistent allergen dosing is required to maintain protection from allergic reactions. *Tolerance* refers to the long-lasting beneficial effects of treatment, presumably due to the impact of therapy on adaptive immune cells that persists after the treatment is stopped. The immunomodulatory effects of desensitization can be seen early (days to weeks to months) in the course of immunotherapy; however, a state of relative tolerance is only achieved after a longer duration of therapy (months to years). *Sustained unresponsiveness* reflects a state of relative tolerance or longer-term desensitization requiring only intermittent allergen exposure to maintain suppression of allergic reactions; however, this state may be reversible when all treatment is discontinued. This chapter will highlight the allergen-specific and allergen-nonspecific immunomodulatory treatments that are currently under investigation for IgE-mediated food allergy, in addition to those in preclinical development (Table 49-2). None of these therapies has achieved US Food and Drug Administration (FDA) designation for safe use in patients, but several hold promise for the future.

Allergen-Directed Immunotherapy

During the past decade, clinical trials in food allergy have focussed primarily on allergen-specific immunotherapy encompassing three major forms: oral (OIT), sublingual (SLIT) and epicutaneous (EPIT) immunotherapy. Each of these forms of immunotherapy is in different stages of investigation with similar immunologic targets but with clear differences in the route of administration, antigen dose and clinical research outcomes, and these therapies are the primary focus of this chapter (Table 49-3). Novel immunotherapeutic approaches are in early stages of development.

ORAL IMMUNOTHERAPY (OIT)

Oral immunotherapy is the therapeutic approach most explored in clinical trials for food allergy to date. Unlike other therapies that have been adapted from preclinical studies or treatment models shown to be effective in other diseases, OIT trials began in earnest over 10 years ago in small, uncontrolled trials using commercially available food products. Early open-label trials have shown a beneficial response to OIT to a variety of allergens, such as milk, egg and fish, with evidence of clinical desensitization in up to 80% of subjects treated.[7,8] More recent trials have expanded to multicenter, randomized controlled OIT

https://CafePezeshki.IR

trials that have taken advantage of the foods as 'therapeutic tools'. OIT products are viewed by the FDA as new therapeutics and are bound by FDA regulation for labeling and widespread, safe usage in the clinical setting. Most clinical trials to date are FDA registered and accessible through the NIH clinical trials registry (www.clinicaltrials.gov).

Typically, OIT protocols encompass three phases of allergen delivery using a standard protocol in a well-controlled setting: (1) initial escalation dosing of 6 to 8 doses of allergen given rapidly during a single day under medical supervision; (2) build-up dosing under observation weekly or biweekly until a target dose is reached after 6 to 12 months; and (3) daily maintenance dosing at home (typically for years). OIT is associated with beneficial short-term and longer-term treatment responses for most individuals through immunomodulation that involves tissue and circulating effector cells.[2] Despite the benefits seen, safety concerns further highlight the need for larger trials and FDA registration before widespread use is acceptable.[9–11]

Recent randomized, controlled, multicenter clinical trials have provided valuable efficacy and safety data for evaluation of OIT as an active treatment.[12–19] In a trial of peanut OIT, 28 children (ages 1–16 years) were randomized to receive peanut OIT (maintenance dose = 4,000 mg) versus placebo OIT.[19] Peanut OIT treatment was associated with clinical desensitization when compared to placebo OIT treatment after 12 months (5,000 mg [~20 peanuts] vs 280 mg [~1 peanut], $P < .001$). In a recent randomized trial, 62% of children (ages 7–16 years) on active OIT could be desensitized to a dose of 1,400 mg (~5 peanuts) of peanut after 6 months of OIT at a dose up to 800 mg compared to none of placebo OIT subjects ($P < .001$).[12] Similar findings were noted during a 6-month milk OIT trial in 20 milk-allergic children (ages 6–21 years) randomized to milk OIT (maintenance dose = 500 mg) compared to placebo OIT when assessing change in reaction threshold at baseline oral food challenge (OFC) compared to 6-month OFC (5,100 mg [~160 mL] vs 0 mg, $P = .002$).[18] Other milk OIT

TABLE 49-1 Immunologic Changes IgE-mediated Food Allergy vs Effective Immunotherapy

Immune Parameters	Food Allergy	Effective Immunotherapy
Allergen-specific IgE	Increased	Decreased
Allergen-specific IgG4	Negligible	Increased
Allergen-specific IgA	Negligible	Increased
IgE epitope binding	Variable	Targeted binding
Mast cell and basophil activation	Increased	Decreased
Th2 cytokines	Increased	Decreased
Regulatory T cell activity	Negligible	Increased

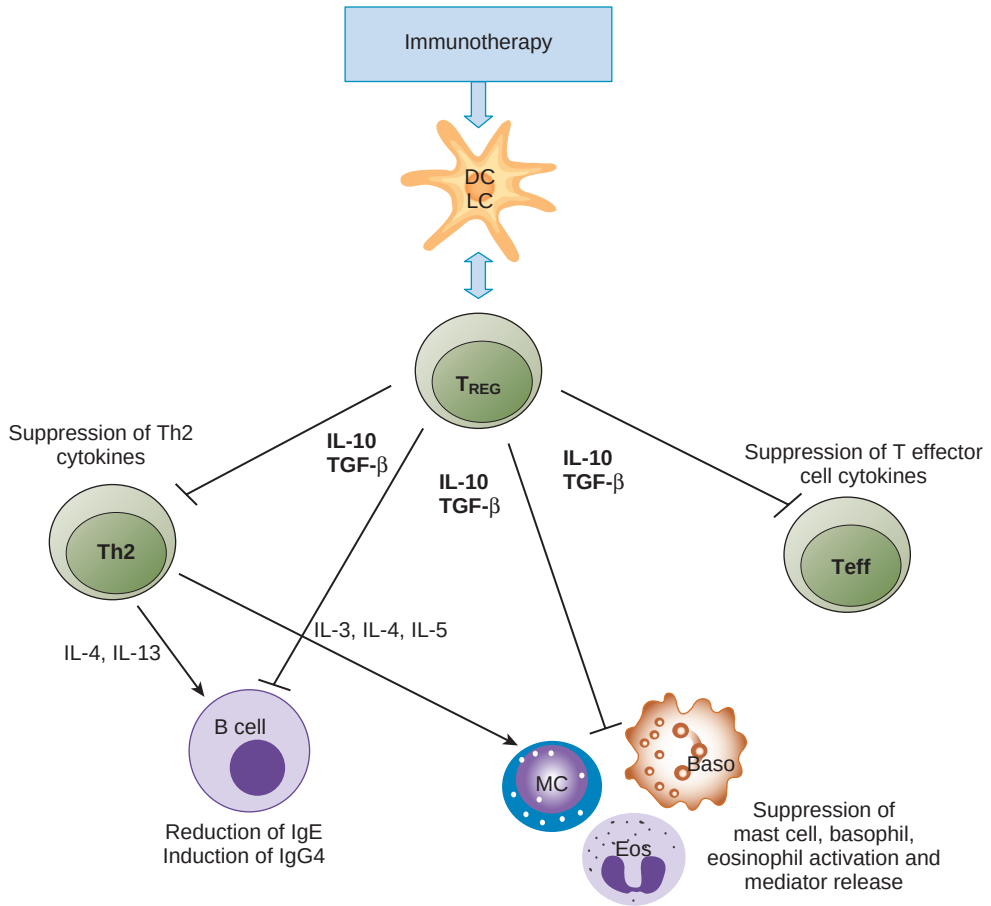

Figure 49-1 Immunotherapeutic approaches for the treatment of food allergy requires modulation of the allergic response to foods through activation of dendritic cells (DC), Langerhans cells (LC) and regulatory T cells (T_{REG}) with subsequent suppression of a variety of effector cell types (*Th2* – type 2 T helper cells; B cells, *MC* – mast cells; *Baso* – basophils; *Eos* – eosinophils).

TABLE 49-2 Immunotherapeutic Approaches for Treatment of Food Allergy

Immunotherapy	Stage of Study	Food Allergen
ALLERGEN-SPECIFIC THERAPY		
Subcutaneous IT	Human Phase I	Peanut
Oral IT	Human Phase I–III	Peanut, milk, egg, fish, fruits
Heated antigen	Human Phase I–II	Egg, milk
Sublingual IT	Human Phase I–II	Peanut, milk, hazelnut, kiwi, peach
Epicutaneous IT	Human Phase I–II	Peanut, milk
Recombinant protein IT with adjuvants	Human Phase I	Peanut
Recombinant protein IT	Preclinical	Peanut
Peptide IT	Preclinical	Peanut, egg
Plasmid DNA IT	Preclinical	Peanut
ISS-ODN IT	Preclinical	Peanut
Human Fc-FC fusion proteins	Preclinical	Peanut
Engineered allergen	Preclinical	Egg, peanut, milk, fish, fruits
Mannoside-conjugated BSA	Preclinical	Bovine serum albumin (BSA)
Antigen-fixed leukocytes	Preclinical	Peanut
ALLERGEN-NONSPECIFIC THERAPY		
Anti-IgE therapy	Human Phase I–II	Peanut, milk
Traditional Chinese medicine	Human Phase I–II	Peanut, tree nut, fish, shellfish, sesame
Probiotics/Prebiotics	Longitudinal study	Nonspecific
Lactococcus lactis for peptide/cytokine delivery	Preclinical	Milk
Toll-like receptor 9	Preclinical	Peanut
Trichuris suis egg therapy	Preclinical	Peanut
FUTURE THERAPY		
Adjuvant treatment	Preclinical	
Nanoparticle use	Preclinical	
IgE receptor molecules	Preclinical	

trials in children have shown similar clinical findings.[14–17] In a study from the Consortium of Food Allergy Research (CoFAR), 55 egg-allergic children (ages 5–18 years) were randomized to egg versus placebo OIT.[13] After 10 months of OIT (maintenance dose = 2,000 mg), 55% of egg OIT subjects were desensitized to 5 g of egg (~ ¾ whole egg) compared to 0% of placebo OIT subjects (5,000 mg vs 50 mg; $P < .001$), and 75% of egg OIT subjects passed a 10 g (~1.5 whole egg) OFC at 22 months. These studies highlight the efficacy of OIT induction of desensitization and treatment-specific immunomodulation (as described below).[9–11]

In a recent study, investigators delivered combination OIT to participants (ages 4–25 years) sensitized to up to five foods ($N = 25$ subjects) compared to those that were mono-allergic ($N = 15$)[20] and reported that multi-allergen OIT could be delivered with similar safety and efficacy to single-allergen OIT. Alternatively, in a multisensitized mouse model of tree nut allergy, OIT with a single tree nut induced desensitization to multiple nuts with associated immune changes.[21] Further clinical studies are ongoing to evaluate the efficacy and safety of multi-allergen OIT and cross-reactive allergen OIT.

Several studies have evaluated longer-term outcomes of OIT, including sustained unresponsiveness.[13,22–24] All of these studies have been either uncontrolled, open-label studies or open-label extension phases of randomized, controlled trials that include years of OIT dosing. In an open-label study of 6 egg-allergic children (ages 3–13 years), all passed an OFC after 33 months of OIT and introduced egg into their diet.[23] After 5 years of peanut OIT (maintenance dose = 4,000 mg), 50% of subjects demonstrated sustained unresponsiveness to 5 g of peanut protein and were considered treatment successes with incorporation of a median of 555 mg/day (range, 0–4,000 mg/day) of peanut in their diets ~3 days/week.[24] During a 60-week trial of milk OIT compared to milk SLIT, OFCs were performed after 1 and 6 weeks off therapy in subjects demonstrating desensitization at week 60;[22] 10% failed at week 1 and 20% failed at 6 weeks. In the CoFAR egg OIT trial, sustained unresponsiveness treatment successes improved as therapy was extended, with 27.5% noted at 24 months, 47.5% at 36 months and 55% at 48 months.[13,25] Among peanut OIT subjects surveyed about duration of treatment effects, none of the treatment successes reported symptoms with peanut consumption after 3 to 4 years.[24] Follow-up of successful milk OIT yielded 22% of subjects reporting limitations with milk consumption due to symptoms, although for various reasons only 20% were ingesting milk on an unlimited basis.[26] Another study found that twice-weekly ingestion (150–200 mL) was effective to maintain

TABLE 49-3 Comparison of Allergen-Targeted Immunotherapies in Clinical Trials

	OIT	SLIT	EPIT
Daily maintenance dose	300–4,000 mg	2–7 mg	50–500 µg
Primary side-effects	Oral, gastrointestinal (systemic symptoms associated with infection, exercise, menses)	Oropharyngeal	Skin
Desensitization	Significant, sustained effect	Moderate, sustained effect	Ongoing investigation
Sustained unresponsiveness	Effective in subset of patients	Ongoing investigation	Ongoing investigation
Long-term tolerance	Ongoing investigation	Unknown	Unknown
Immune modulation	Significant	Present	Ongoing investigation

EPIT – Epicutaneous immunotherapy; OIT – oral immunotherapy; SLIT – sublingual immunotherapy.

https://CafePezeshki.IR

desensitization.[27] Following 2 to 3 years after completion of egg OIT, 67% of egg OIT subjects compared to 18.2% of placebo OIT subjects could consume both baked and concentrated egg.[25] Overall, sustained unresponsiveness is possible in a subset of subjects, but the long-term impact of OIT remains unclear. To address this issue further, the Immune Tolerance Network IMPACT trial is evaluating long-term tolerance among peanut-allergic children (ages 1–4 years) in a randomized, controlled 3-year peanut OIT trial.

Immunologic changes associated with clinical findings following successful OIT have been compelling. Single-allergen OIT has been associated with beneficial immunomodulatory effects including reduced basophil and mast cell activation, down-regulation of Th2 effector cells and cytokine production, as well as initial increased T regulatory cell activity and reduced IgE antibodies with increased IgG4 antibodies.[13,18,19,22,24,28–30] Some of these changes following peanut OIT, in particular those related to basophil activation, are antigen specific but some are also associated with nonspecific stimuli including evidence of basophil suppression after anti-IgE stimulation or after nonspecific antigen (egg) stimulation.[30] Peanut OIT has also been shown to induce transient tolerance with associated increase in antigen-induced T_{REG} function and intracellular IL-10 levels and decreases in methylation of Foxp3, a known indicator of T_{REG} cell suppressive function.[29] Following long-term peanut OIT, treatment successes were associated with reduced peanut-specific IgE and Ara h 1 and 2, and skin prick tests (SPT) when compared to treatment failures, parameters that were predictive of outcomes.[24] Low baseline specific IgE levels were predictive of treatment success for desensitization in both milk[31] and egg[32] OIT studies, but not predictive of success in the multicenter CoFAR egg OIT study.[13] Analysis of IgE and IgG4 binding epitopes before and after milk[33] and peanut[34] OIT is particularly interesting. Reductions in IgE binding and increases in IgG4 binding with overlap of key binding epitopes are associated with response to therapy; however, in some individuals significant discordance indicates that antigen-nonspecific changes may play a role.[34] Overall, the immunodulation following OIT is often robust and strongly linked to clinical outcomes.

OIT trials have been conducted through study protocols under close monitoring by experienced research staff in clinical research centers with necessary rescue equipment and procedures in place. Although OIT has demonstrated clinical efficacy, meta-analyses highlight the fact that insufficient data exist for full efficacy assessments and safety concerns persist.[9,10,35–38] Generally, side-effects associated with OIT treatment trials are mild to moderate, predominantly oropharyngeal and easily treated;[13,18,19,39,40] however, more severe reactions have been reported. Currently, the highest rate of adverse events related to OIT occurs during the first year of therapy with up to ~10–15% of subjects withdrawing, often due to gastrointestinal side-effects.[13,24] During blinded peanut OIT,[19] symptoms were noted in most active treatment subjects when compared to placebo treated subjects. During OIT, ~45% of active subjects compared to ~10% of placebo subjects experienced dose-associated symptoms, primarily mild and oropharyngeal, but with ~1% requiring epinephrine.[18,19] During the first year of blinded egg OIT, 75% of 11,860 OIT doses were symptom free versus 96% of 4,018 placebo doses.[13] During years 3 and 4, 95% of OIT doses were symptom free.[25]

Acute illness with viral infections, menses and exercise have been associated with lowering the reaction threshold for subjects on stable OIT dosing[41] and often require dose adjustments in the face of acute illness.[39] Additionally, eosinophilic esophagitis has been reported in association with OIT, adding potential risks for a subset of children.[42,43] The implementation of rush OIT protocols has been associated with increased adverse symptoms and has been generally abandoned as a viable treatment option.[14,39,44,45] Pre-treatment with omalizumab has shown promise for reducing side-effects and shortening time to maintenance therapy.[46–48] Overall, additional studies in larger study cohorts are needed before OIT can be sanctioned and encouraged for widespread use.[9,10,35–38] Larger scale Phase II and Phase III studies are underway currently for peanut OIT and are planned for other allergens.

Treatment with extensively heated (baked) milk and/or egg allergen may prove to be an important treatment option that mirrors allergen immunotherapy. Clinical trials performed in milk[49] and egg[50] allergic children have demonstrated that ~70–80% of milk or egg allergic children can safely ingest baked milk or egg products.[49,50] Daily consumption of 1 to 3 servings of baked allergen products was safe and associated with accelerated tolerance development and immunomodulation when compared to age-matched controls.[50–53] Questions remain regarding the best way to identify those patients tolerant of baked milk/egg, the effective dose required, the degree of heating needed, the role of the food matrices and the ability of heated proteins to induce lasting tolerance.

SUBLINGUAL IMMUNOTHERAPY (SLIT)

Sublingual immunotherapy (SLIT) has been employed in asthma and allergic rhinitis in the form of allergen extracts and sublingual allergen tablets with favorable safety and efficacy profiles.[54–56] SLIT presumably works by allergen interaction with pro-tolerogenic Langerhans cells in the oral mucosa, leading to down-regulation of the allergic response. Several clinical trials have been conducted using SLIT for food allergy. As with OIT, SLIT protocols include escalation and maintenance dosing, although SLIT doses are smaller, generally less than 10 mg daily. Participants administer SLIT by placing a gradually increasing dose of allergen extract under the tongue, holding it there for several minutes and then spitting out or swallowing.

The first published reports of SLIT for food allergy appeared more than a decade ago, when SLIT for kiwi allergy was described in a case report in which a 29-year-old woman with a history of multiple anaphylactic reactions to kiwi was desensitized.[57] That patient subsequently underwent approximately 5 years of maintenance therapy with a solution made from fresh kiwi pulp and became tolerant of the fruit.[58] In a study of hazelnut SLIT, 22 adults received 8 to 12 weeks of treatment with hazelnut SLIT or placebo SLIT.[59] In the subsequent food challenge, almost half of patients in the hazelnut SLIT group consumed 20 g of hazelnut compared to only 9% of the placebo SLIT group. Systemic symptoms were noted in only 0.2%. Oropharyngeal symptoms were observed in 7.4% of subjects, many with oral allergy syndrome reported at baseline. In a study of peach SLIT, 49 adults received peach SLIT ($N = 33$) or placebo SLIT ($N = 16$) during 6 months of treatment.[60] During the post-therapy food challenge, the peach SLIT group consumed peach at levels that were 3-fold higher than those in the placebo SLIT group before experiencing symptoms.

https://CafePezeshki.IR

SLIT studies have expanded to include both pediatric and adult patients with milk or peanut allergy in the last few years. In a 6-month, open-label study of 8 children (age >6 years) with cow's milk allergy, milk SLIT led to an increase in the mean volume of milk that elicited allergy symptoms from 39 mL to 143 mL.[61] In a study of 30 milk-allergic children (ages 6–17 years), milk SLIT was compared to milk OIT in a two-center study.[22] Participants were randomly assigned to receive SLIT alone (7 mg) or SLIT followed by OIT at two different doses (1 or 2 g) during 60 weeks of immunotherapy. At the end of the study, 1 of 10 SLIT-only participants achieved desensitization to 8 g of milk protein, while 6 of 10 participants in the lower-dose SLIT+OIT group and 8 of 10 patients in the higher-dose SLIT+OIT group achieved desensitization. Overall, SLIT in combination with OIT was associated with more robust clinical benefits than SLIT alone; however, systemic side-effects occurred only in the SLIT+OIT groups with higher levels of antihistamine and epinephrine usage. Symptoms reported with milk SLIT were limited to the oropharynx.[22]

The first randomized, controlled trial of peanut SLIT was performed in a single-center study of 18 children (ages 1–11 years) receiving 12 months of SLIT (maintenance dose = 2 mg daily) with peanut or placebo.[62] At the conclusion of 1 year of treatment, those receiving peanut SLIT were able to safely consume 1,710 mg (~8 peanuts) of peanut protein, compared to only 85 mg (<0.5 peanut) in those receiving peanut SLIT ($P = .011$), representing a 20-fold increase in peanut consumption. During dosing, side-effects were minimal and localized to the oropharynx, noted in 11.5% of peanut SLIT subjects compared to 8.6% of placebo SLIT subjects. Symptoms were typically untreated, and no participant required epinephrine during treatment. Immunologic changes were noted in peanut SLIT subjects when compared from baseline to OFC at 12 months including decreased peanut-specific IgE ($P = .003$), SPT size ($P = .02$), basophil activation ($P = .009$), and IL-5 levels ($P = .015$) with increase in peanut-specific IgG4 ($P = .014$). Clinical benefits in addition to evidence of immunomodulation suggested modification of the allergic response by peanut SLIT in these young children. A subsequent multicenter study from CoFAR of 40 peanut-allergic patients (ages 12–40 years) evaluated the efficacy of peanut SLIT vs placebo SLIT.[63] Treatment success was defined during OFC when 5 g of peanut protein was consumed or when a 10-fold or higher increase in peanut protein consumption was achieved when comparing baseline to follow-up OFC. After 44 weeks of therapy (target maintenance dose = 1,386 μg), 14 (70%) of 20 subjects who received peanut SLIT compared to only 3 (15%) of 20 subjects who received placebo SLIT demonstrated treatment success: primarily greater than a 10-fold increase in eliciting dose over baseline challenge. The median dose of peanut consumed at the 44-week OFC compared to baseline OFC was significantly higher for peanut SLIT subjects (371 mg [about 1 peanut] vs 21 mg, $P = .01$) when compared to placebo SLIT subjects (146 mg vs 71 mg, $P = .14$). When evaluation took place at week 68 the mean consumed dose rose to 996 mg, which was significantly higher than at week 44 ($P = .05$). For the 12 of 17 placebo subjects that crossed over to higher dose SLIT (target maintenance dose = 3,696 μg) and completed a 5 g OFC, the median consumed dose was higher than at baseline OFC (603 mg vs 71 mg, $P = .02$). Although the results were encouraging, none of the subjects treated with low-dose or high-dose SLIT was able to consume the full 5 g OFC during the desensitization phase. Peanut SLIT was well tolerated with 95% of doses being symptom free when local oropharyngeal symptoms were excluded. Clinical outcomes were associated with only modest immunologic changes including reductions in basophil activation and modest changes in titrated skin tests. No significant changes were noted in peanut-specific IgE or IgG4 levels. Differences in the two peanut SLIT studies may be explained by the difference in ages of the study cohorts, subject selection and differences in target maintenance doses, indicating that further study is warranted.

A retrospective comparison study of peanut-allergic children treated with either peanut OIT or SLIT indicated that after 12 months of therapy patients who received SLIT reacted at lower eliciting dose thresholds and were less likely to pass food challenges evaluating desensitization.[64] Thus, available evidence for milk and peanut allergy suggests that SLIT therapy is less effective than OIT for desensitization but has a better safety profile.[22,64] Studies of SLIT have also largely excluded patients with a history of severe allergic reactions. Among patients who have undergone treatment, response has been variable and potentially age dependent and allergen dependent. Therefore, the applicability of SLIT in the general food-allergic population remains unclear. There are ongoing SLIT studies in younger age groups and using different SLIT delivery systems that should help us better understand the possible role of this type of immunotherapy for food allergy for the future.

EPICUTANEOUS IMMUNOTHERAPY (EPIT)

Epicutaneous immunotherapy is a newer form of immunotherapy that utilizes a novel delivery of allergen to the skin surface through application of an allergen-containing patch. EPIT has been utilized for grass pollen-induced allergic rhinitis with demonstrated efficacy and safety.[65] In preclinical studies of EPIT for food allergy, effective antigen delivery and treatment outcomes have been noted and have led to clinical trials in milk and peanut allergy. EPIT acts by delivering a small dose of allergenic protein directly to the epidermal layer of the skin where it is taken up, activating Langerhans cells that subsequently traffic to regional lymph nodes and lead to down-regulation of effector cell responses.[66–69] In mouse studies, fluorescently labeled allergen (Alexa488-ovalbumin) applied via an allergen patch remained in the epidermal layer without evidence of systemic absorption but with induction of downstream immunologic effects.[67] In mouse studies, investigators sensitized mice to ovalbumin, peanut or aeroallergen and then treated with EPIT, SCIT or sham therapy for 8 weeks.[70] Mice treated with EPIT showed reduced airway hyperreactivity to inhaled allergen, decreased allergen-specific IgE levels and increased allergen-specific IgG2a when compared to controls ($P < .05$), changes that were similar to treatment-induced effects noted with SCIT.[70] Reduced inflammation was also noted on bronchoalveolar lavage with evidence for decreased eosinophils, eotaxin and cytokines with both EPIT and SCIT when compared to controls ($P < .001$). Further preclinical studies have demonstrated allergen-specific induction in tolerogenic regulatory T cells with repeated allergen patch application, a treatment effect that was eliminated when EPIT was applied to tape-stripped skin.[71] In a mouse model of peanut-induced eosinophilic gastrointestinal disorders, peanut EPIT treatment resulted in expansion of a CD25+ T regulatory cell population that was long-lasting and that could be adoptively transferred to peanut-sensitized, untreated animals to provide

https://CafePezeshki.IR

protection.[72,73] These findings from preclinical studies have highlighted the novel mechanistic action of EPIT and beneficial treatment effects that have paved the way for the first human studies in milk- and peanut-allergic individuals.

To date, all EPIT studies conducted for food allergy have employed the technology developed by DBV Technologies, Inc. (Paris, France). This technology consists of a small, adhesive patch, known as the Viaskin™ device, that has been electrostatically coated with allergen and is applied to the upper arm or interscapular space. The first study conducted was a 3-month double-blind, placebo-controlled pilot study in milk-allergic infants and children (3 months to15 years).[74] Nineteen subjects were randomized to treatment with milk or placebo EPIT applied at 48-hour intervals during 3 months of treatment (using the Diallertest™ device, a precursor to Viaskin™). The cumulated dose of cow's milk consumed during OFC (baseline vs 3 months) trended higher in the milk EPIT group (1.77 ± 2.98 mL vs 23.61 ± 28.61 mL) compared to the placebo group (4.36 ± 5.87 mL vs 5.44 ± 5.88 mL) ($P = .13$). Adverse events were higher among milk EPIT treated subjects when compared to placebo treatment and were limited to mild skin reactions at the patch site and increased risk of local eczema (OR 8.20; 2.72–24.5; $P < .001$). This limited duration pilot study of EPIT in food-allergic children provided early evidence that EPIT could be used safely with potential for beneficial clinical outcomes.

Since completion of the EPIT pilot study in children, the focus of clinical trials for EPIT has been on peanut allergy, with both Phase I and Phase II studies conducted using the Viaskin™ patch device. A Phase I safety trial was conducted among 100 peanut-allergic participants (ages 6–25 years), categorized as severe and nonsevere based on reaction history, using a randomized, double-blind, placebo-controlled trial design comparing placebo Viaskin™ to four different doses of peanut Viaskin™ patches administered over 2 weeks of therapy. The peanut Viaskin™ proved safe and convenient up to a dose of 250 μg for children and up to 500 μg in adolescents and adults.[75] Overall, 2 of 80 active EPIT and 1 of 20 placebo EPIT subjects dropped out due to adverse events; 90% experienced mild or moderate local symptoms, and systemic symptoms were mostly mild and transient, with no severe reactions and no epinephrine use.

The first peanut efficacy trial (ARACHILD), a randomized, controlled study, included 54 peanut-allergic children (ages 5–17 years), all treated with the peanut patch (100 μg pp) and challenged after 6 months of blinded therapy. OFCs were conducted at 6-month intervals over an 18-month period to assess reaction threshold. Safety data after 12 to 18 months were satisfactory and consistent with Phase I results. Treatment was associated with some level of desensitization with up to 67% responders (defined as ≥10-fold increase in cumulative reactive dose from baseline) at 18 months with 4 subjects reaching 1–2.5 g of peanut protein (~3.5–8 peanuts).[76]

A large randomized, controlled Phase IIb trial (VIPES) has enrolled 221 highly peanut-allergic individuals (ages 6–55 years) in 22 centers in the USA and Europe, for a 1-year treatment comparison of peanut EPIT vs placebo EPIT. Results are expected for 2015 with a planned extension phase up to 36 months. Additionally, the CoFAR study group has initiated a randomized, controlled study of peanut EPIT planned for 30 months of treatment in 75 children and young adults (ages 4–25 years). Additional EPIT studies with other allergens are in planning and implementation stages.

NOVEL IMMUNOTHERAPY APPROACHES IN EARLY DEVELOPMENT

Novel immunotherapeutic applications in food allergy are under investigation in murine models.[77] *Modified or recombinant allergen immunotherapy* has taken advantage of recombinant technology to alter the host response to allergen through modification of the antigenic features of the protein and has been used in preclinical trials and a single Phase I study. Based on positive findings from a peanut mouse model using heat-killed *Escherichia coli* (HKE) in combination with modified Ara h1, 2, and 3 proteins (HKE-EMP123),[78,79] a Phase I clinical trial using HKE-EMP123 delivered rectally was conducted in nonallergic adults and peanut-allergic adults.[80] In peanut-allergic subjects, 50% had significant allergic reactions preventing further dosing (30% required epinephrine), while healthy controls tolerated the treatment. Other immune-specific approaches in preclinical studies include peptide vaccine immunotherapy, plasmid DNA immunotherapy, cytokine-modulated immunotherapy, immunostimulatory sequence-conjugated protein-modulated immunotherapy, human immunoglobulin fusion proteins, sugar-conjugated BSA and antigen-fixed leukocytes.[77,81] These approaches may provide an important first step in organ-targeted immunotherapy with molecules that induce immunomodulation with improved safety profiles.

Allergen Nonspecific Immunotherapy

Several immunomodulatory therapies that globally impact the allergic immune response are under investigation as single-agent treatments or as adjunctive treatments to synergize with allergen-targeted immunotherapy. These treatment approaches do not target specific allergens, thus they may be applicable for individuals allergic to multiple allergens or those with severe allergic reactions that could benefit from additional safety considerations.

HUMANIZED MONOCLONAL ANTI-IgE

Humanized monoclonal anti-IgE has proven to be a valuable biologic therapy for a variety of allergic disorders. Omalizumab, a recombinant, humanized, monoclonal anti-IgE antibody, is FDA approved for the treatment of allergic asthma and chronic urticaria and has demonstrated efficacy when used in concert with rush immunotherapy for allergic rhinitis,[82] as an adjunctive therapy to minimize systemic immunotherapy reactions in allergic asthmatics[83] and as an effective treatment for chronic urticaria.[84] The mechanism of action involves binding of antibody to the Fc portion of free IgE molecules with added benefit of reducing high-affinity receptors on effector cells, thereby reducing the potential for anaphylaxis in a global, nonallergen targeted manner.[84] These molecules are associated with an extended half-life of IgE and treatment response that are typically reversible with drug cessation. The first clinical trial of anti-IgE for peanut allergy used a novel antibody, Hu-901, to demonstrate efficacy in increasing the reaction threshold to peanut during oral food challenge (OFC) from 178 mg to 2,805 mg.[85] However, ~25% of subjects were non-responders. A second multicenter, randomized, controlled trial using omalizumab to treat peanut allergy was initiated in 26 subjects, but was stopped prematurely due to safety issues during baseline OFCs.[86] Fourteen subjects randomized to receive omalizumab

https://CafePezeshki.IR

or placebo during 20 to 22 weeks of treatment completed OFC assessment prior to study discontinuation. The dose threshold of peanut flour at ≥1,000 mg was noted in 44% of omalizumab-treated subjects compared to 20% of placebo-treated subjects, but over half of the subjects did not reach the 1,000 mg threshold, leaving unanswered questions about efficacy.

Omalizumab treatment before and during OIT has shown benefits in reducing side-effects and shortening build-up dosing time to maintenance therapy during a trial of 11 subjects treated with milk OIT[47] and during a trial of 13 children treated with peanut OIT.[48] Both studies report lower overall side-effect profiles during build-up and maintenance dosing. Additionally, omalizumab pre-treatment in both studies reduced the time interval of OIT build-up phase to maintenance therapy by several months when compared to other studies employing OIT alone. In a Phase I study of 25 children and adults with multi-food allergy, 16-week pre-treatment with omalizumab was used to advance multi-allergen OIT over weeks rather than months with 94% of dosing reactions reported as mild and only one subject reported to have a severe allergic reaction.[46] Adverse reactions were still noted in all of the pilot studies, some requiring epinephrine administration, thus the risk of OIT is not fully mitigated by omalizumab pre-treatment based on current studies. New studies are currently assessing the role of omalizumab combined with OIT in randomized, controlled multicenter trials. Additionally, other molecules in preclinical development are focussed on improving or altering binding affinity of anti-IgE molecules[87] while others focus on displacement of IgE from its receptor.[88]

TRADITIONAL CHINESE MEDICINE

Traditional Chinese medicine has been used for centuries to treat a variety of disorders, with anecdotal reports of medicinal benefits for allergic disorders. FAHF-2 was developed as a formulation of nine Chinese herbs and studied extensively in preclinical studies. FAHF-2 was shown to block peanut-induced anaphylaxis and induce immunologic changes when comparing peanut-sensitized to sham-sensitized mice, with effects sustained for up to 6 months (25% of the lifespan of a mouse).[89] During a Phase I study,[90] subjects received FAHF-2 tablets or placebo over 1 week. Treatment was well tolerated, with only minor gastrointestinal symptoms in ~10% of participants and with associated reductions in serum IL-5 levels. A Phase II, multicenter clinical trial has recently been completed in multifood-allergic adolescents and adults (ages 12–50 years). A treatment response was not identified but may have been influenced by poor compliance by participants requiring dosing of 10 tablets three times daily over 6 months of treatment.[91] A newer form of treatment, designed to reduce dosing barriers, is in development.

OTHER THERAPIES

Based on an ever-increasing body of evidence about the role of host microbiome in allergic and inflammatory disease,[92–95] therapeutic intervention with agents that alter the microbiome and impact the immune response may be of value. Probiotics, such as *Lactobacillus* and *Bifidobacterium* species, and oligosaccharide prebiotics promote beneficial bacterial colonization of the gastrointestinal tract and may have immunomodulatory effects.[95,96] To date, studies using probiotics or prebiotics have not been utilized effectively in clinical trials for food allergy. Other therapies, such as *Lactococcus lactis* supplementation and expression systems and Toll-like receptor-9 (TLR9) agonists, have shown some benefit in allergic animal models.[81] *Trichuris suis* egg therapy has shown benefit for autoimmune disorders and in a murine model of food allergy, but side-effects have limited the overall benefit to date.[81]

Future Approaches to Immunotherapy

Novel therapies have been utilized in vaccine development for infectious diseases, cancer and neurologic inflammatory disorders, using targeted treatment to enhance immune responses and/or target treatments to specific organ systems. Immune adjuvants are such agents that work by amplification of the adaptive immune response to incite immune deviation. Lipopolysaccharide-derived lipid A ligands of the Toll-like receptor-4 (TLR4) pathway have been used effectively in human vaccines for infectious disease and cancer and in combination with SCIT and SLIT to enhance treatment responses for allergic disease.[97–99] These TLR4 adjuvants have not been studied in food allergy trials to date.

Nanotechnology may provide another treatment approach in food allergy. Nanoparticles are in research and development phases to deliver medications for numerous diseases.[100] Because of their small size (<100 nm) and potential for tissue targeting, nanoparticles can be delivered through a variety of routes to a variety of specific tissues to impact local immune environments and have been evaluated with some success in several preclinical studies for food allergy.[101,102]

Conclusions

In conclusion, immunotherapeutic approaches for the treatment of food allergy hold promise for the future. These therapies are not fully vetted in large populations and require further study before widespread clinical use can be recommended. Several of these approaches are in Phase II clinical trials with Phase III studies planned targeting future FDA registration. The future is bright for patients with food allergy and for clinicians and families who are seeking treatment options that will make a difference.

Role of Barrier Dysfunction and Immune Response in Atopic Dermatitis

NATALIJA NOVAK | DONALD Y.M. LEUNG

KEY POINTS

- Pruritus and chronic or relapsing eczematous dermatitis with typical distribution are essential for diagnosis of atopic dermatitis (AD).
- Interactions between susceptibility genes, the host's environment, pharmacologic abnormalities and immunologic factors contribute to the pathogenesis of AD.
- Recent genome-wide association studies have confirmed the association of single-nucleotide polymorphisms (SNPs) of loci of the epidermal differentiation complex (EDC) with AD.
- Bacterial and viral antigens as well as allergens and autoantigens play a role in the pathogenesis of AD.

Atopic dermatitis is a highly pruritic chronic inflammatory skin disease that commonly presents during early childhood.[1] It is frequently associated with a personal or family history of respiratory allergy, i.e. allergic asthma and/or rhinitis, and can have profound effects on patients' lives, career choices and social interactions. Recent interest in AD has been sparked by reports of its increasing prevalence.[2] Management approaches in AD have evolved from our rapidly increased understanding of the mechanisms underlying this skin disease and novel therapeutic avenues.

Epidemiology

Atopic dermatitis is a common skin disease with a lifetime prevalence in children of 10% to 20% in the USA, Northern and Western Europe, Japan, and other westernized countries. Environmental factors are critical in determining disease expression. Some of the potential risk factors that have received attention as being associated with the rise in atopic disease include small family size, increased income and education both in whites and blacks, migration from rural to urban environments, and increased use of antibiotics, that is, the so-called 'western lifestyle'. These observations are supported by observations that allergic responses are driven by T helper cell type 2 (Th2) immune responses, whereas infections are induced by Th1 responses. Since Th1 responses antagonize the development of Th2 cells, a decreased number of infections or the lack of Th1 signals during early childhood could predispose to Th2 allergic responses (see Chapters 1 and 2).

Diagnosis and Differential Diagnosis

Clinical features of AD are listed in Box 50-1. Of the major features, pruritus and chronic or relapsing eczematous dermatitis with typical distribution are essential for diagnosis.[3] Intense pruritus and cutaneous reactivity are cardinal features of AD. Pruritus may be intermittent throughout the day but is usually worse at night. Its consequences are scratching, prurigo papules, lichenification and eczematous skin lesions. Patients with AD have a reduced threshold for pruritus. As a result, allergens, reduced humidity, excessive sweating and low concentrations of irritants (e.g. wool, acrylic, soaps and detergents) can exacerbate itching and scratching.

During infancy AD is generally more acute with excoriation, vesicles over erythematous skin and serous exudate. The rash primarily involves the face, scalp and extensor surfaces of the extremities (Figure 50-1). In the patient with chronic AD, skin lesions become lichenified (Figure 50-2) and the rash localizes to the flexural folds of the extremities. Approximately half of children with AD continue to have persistent skin disease as adults. At all stages of AD, patients usually have dry, lackluster skin. Chronic hand eczema, the most common form of occupational skin disease, may be the primary manifestation in many adults with AD. Other features, including exogenous allergy or elevated IgE, are variable although commonly seen in AD.

Box 51-1 lists a number of inflammatory skin diseases, immunodeficiencies, skin malignancies, metabolic disorders, and infectious diseases that share features of AD. The differential diagnosis of AD should be considered particularly in patients with refractory AD. Infants presenting in the first year of life with failure to thrive, diarrhea, a generalized scaling erythematous rash and recurrent cutaneous and/or systemic infections should be evaluated for severe combined immunodeficiency syndrome (see Chapter 9). Wiskott-Aldrich syndrome is an X-linked recessive disorder characterized by thrombocytopenia, defects in humoral and cellular immunity and recurrent bacterial infections. The hyperimmunoglobulin E (hyper-IgE) syndrome is characterized by elevated serum IgE levels, defective T and B cell function, recurrent deep-seated bacterial infections including cutaneous abscesses caused by *Staphylococcus aureus* and/or pruritic skin disease caused by *S. aureus*, such as pustulosis, or recalcitrant dermatophytosis, reported with human immunodeficiency virus as well as with a variety of infestations such as scabies. Dock8 deficiency should be considered in patients with severe recurrent eczema herpeticum. Other conditions that can be confused with AD include psoriasis, ichthyosis, and seborrheic dermatitis.

Figure 50-1 Infant with acute atopic dermatitis. Note the oozing and crusting skin lesions. *(Reproduced with permission from Weston WL, Morelli JG, Lane A, editors. Color textbook of pediatric dermatology. 3rd ed. St Louis: Mosby; 2002.)*

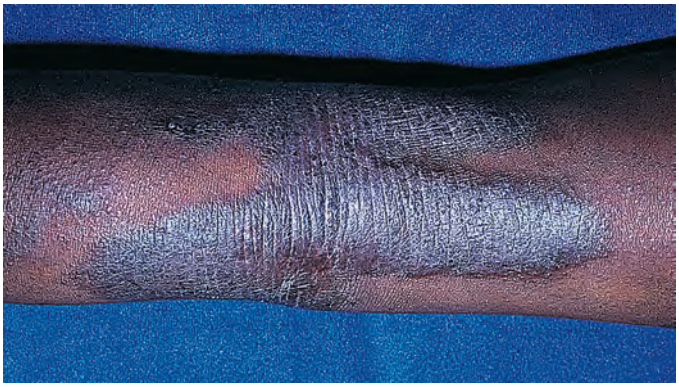

Figure 50-2 Adolescent with lichenification of the popliteal fossa from chronic atopic dermatitis. *(Reproduced with permission from Weston WL, Morelli JG, Lane A, editors. Color textbook of pediatric dermatology. 3rd ed. St Louis: Mosby; 2002.)*

BOX 50-1 CLINICAL FEATURES OF ATOPIC DERMATITIS*

ESSENTIAL FEATURES

- Pruritus
- Facial and extensor eczema in infants and children
- Flexural eczema in adults
- Chronic or relapsing dermatitis

FREQUENTLY ASSOCIATED FEATURES

- Personal or family history of atopic disease
- Xerosis
- Cutaneous infections
- Nonspecific dermatitis of the hands or feet
- Elevated serum IgE levels
- Positive immediate-type allergy skin tests
- Early age of onset

OTHER FEATURES

- Ichthyosis, palmar hyperlinearity, keratosis pilaris
- Pityriasis alba
- Nipple eczema
- White dermatographism and delayed blanch response
- Anterior subcapsular cataracts, keratoconus
- Dennie-Morgan infraorbital folds, orbital darkening
- Facial erythema or pallor
- Perifollicular accentuation

*Other skin conditions that may mimic atopic dermatitis should be excluded (see Box 51-1).

Adolescents or adults who present with an eczematous dermatitis with no history of childhood eczema, respiratory allergy or atopic family history may have allergic contact dermatitis (see Chapter 53). Of note, topical glucocorticoid contact allergy has been reported increasingly in patients with chronic dermatitis on topical corticosteroid therapy.

Pathogenesis

Interactions between susceptibility genes, the host's environment, pharmacologic abnormalities and immunologic factors contribute to the pathogenesis of AD. There are two disease models: first, that AD is a skin disease that primarily derives from an intrinsic defect of epithelial cells and skin barrier, thereby facilitating as a second step numerous modifications of innate and adaptive immunity (the outside-inside hypothesis); second, that AD is primarily an immunologic disease with mechanisms related to the overactivation of the immune system and Th2 dominated immune responses that impact secondarily on skin barrier function (the inside-outside hypothesis).[4] However, it is most likely that a combination of both hypotheses and a continuous interplay contributes to the complexity of AD.

Genetics

The fact that AD and atopic disorders frequently affect more than one family member accounts for the strong genetic background of this disease. Several genetic factors contribute to the complex pathophysiology of AD, indicating that it is not a monogenic but a genetically complex disorder.[5,6] It seems most likely that not only AD itself but, in particular, different subtypes of AD such as AD with early onset, childhood AD versus adulthood AD or AD with IgE mediated allergic reactions might be based on distinct genetic constellations.[7–9] Therefore, one approach to achieve clarity could be systematic distinction of genetic modifications associated with (1) skin barrier dysfunction, (2) deficient innate immune responses and (3) modified adaptive immune reactions in AD.[10,11]

GENETICS AND SKIN BARRIER DYSFUNCTION

Dry skin, mirrored by increased transepidermal water loss, reduced skin hydration and decreased amounts of natural moisturizing factor indicate skin barrier impairment in AD.[12,13] A candidate gene region for AD, localized on chromosome 1q21,[5] contains a selection of genes encoding structural proteins of epidermal cornification, such as S100A proteins, profilaggrin, small proline-rich region proteins (SPRRs) and late envelope proteins (LEP), which form the so-called 'epidermal differentiation complex' (EDC). Filaggrin is an essential protein in maintenance of the formation of the stratum corneum barrier.[14] In recent years, loss-of function mutations in the filaggrin gene have been shown to be strongly associated with AD.[15] This finding was replicated and confirmed by an impressive series of independent studies.[16,17] Moreover, a closer look at the filaggrin loss-of-function carriers within the group of AD

https://CafePezeshki.IR

patients revealed that specific clinical features and subtypes of AD are highly associated, including AD with early onset and a high number of allergen sensitizations. Moreover, specific interactions between genetic predisposition and environmental factors such as cat exposure at the time of birth seem to increase the risk for manifestations of eczema during the first year of life, in particular in children with filaggrin mutations.[18] In addition, in the context of a genetically determined disturbed skin barrier in AD, there are reports of associations of polymorphisms in the *SPINK5* gene, which encodes the lymphoepithelial kazal-type related inhibitor (LEKTI), an inhibitor of serine proteases. Other studies have reported on the association with AD of genetic modifications in the gene region encoding the stratum corneum chymotryptic enzyme (SCCE), leading to impaired stratum corneum integrity and function.[19] Studies have also reported on gene associations with other epidermal components, such as collagen 29 (COL29),[20] or a genetic variant on chromosome. In addition to these genetically predetermined factors, highly active endogenous proteases such as mast cell chymase (MCC), as well as exogenous proteases derived from house dust mite allergens or *S. aureus*, cleave corneodesmosomes and accelerate desquamation of corneocytes.[21] They may also delay epithelial regeneration by binding proteinase-activated receptors (PAR)-2 and thereby contribute to skin barrier impairment in AD.[22] Recent genome-wide association studies have confirmed the association of SNPs of loci of the EDC with AD.[23,24] As well as from these genetic changes, epigenetic modifications have been demonstrated in lesional skin of AD patients and are another putative factor impacting on epidermal skin barrier function.[25]

GENETICS AND INNATE IMMUNITY

First-line host defense mechanisms of the innate immune system are maintained by pattern-recognition receptors (PRR) that sense the environment for invading pathogens. Toll-like receptors (TLR), intracellular nucleotide-binding oligomerization domain (NOD) proteins and the LPS receptor CD14[26,27] belong to the PRRs and discriminate between diverse pathogen associated molecular patterns. Deficient maturation of the immune system and decreased efficiency in responding to PRR stimulation are suspected to account not only for higher prevalence of atopy but also the greatly increased propensity of AD patients to microbial infections. Several studies have focussed on a putative association between variations within gene regions encoding components of the innate immune system and AD. A polymorphism within the *TLR2* gene has been shown to be associated with severe forms of AD with recurrent bacterial infections[28] and has been linked to functional modifications of TLR2.[29] However, no association of polymorphisms in the *TLR2*, *TLR4* and *TLR6* genes with AD could be shown in other studies.[30,31] A polymorphism in the *TLR9* gene of putative functional relevance on TLR9 promoter activity was associated with pure AD.[32]

SNPs within five known loci (1q21.3 [*LCE3A*], 5q31.1 [*IL13*, *KIF3A*, *SLC22A4*], 11q13.5 [*C11orf30*] and 20q13.33 [*TNFRSF6B*]) as well as four new loci (4q27 [*IL2*, *IL21*], 11p13 [*PRR5L*], 16p3 [*CLEC16A*] and 17q21.32 [*TNFRSF6B*]) were detected in genome-wide study thresholds for association with AD in a recent study.[23] Moreover, 36 SNPs within three chromosomal regions, i.e. 2q12, 6p21 and 11p15.4, were significantly associated with AD in another study.[24]

GENETICS AND ADAPTIVE IMMUNITY

Induction of different receptors on effector cells, dendritic cells or other cells after passage of allergens and microbial pathogens into the skin contributes to numerous other mechanisms involving the adaptive immune system. To date, a wide repertoire of genetic modifications of gene regions encoding components of adaptive immunity has been associated with AD.[6,33,34] Soluble factors such as cytokines and chemokines, which play a crucial role as soluble mediators of the adaptive immune system, show profound variations in AD, and it is more than likely that some of these deviations are already genetically encoded.[35] These comprise genetic variations on chromosome 5q31-33 that cover genes of the Th2 cytokine cluster such as interleukin (IL)-3, IL-4, IL-5, IL-13 and granulocyte-macrophage colony stimulating factor (GM-CSF),[6,7] functional mutations of the promoter region of *RANTES/CCL5* (17q11) and gain-of-function polymorphisms in the *IL4RA* gene (16q12).[6,7,36] Interestingly, polymorphisms in the *IL4RA* gene region were associated with AD with low IgE serum levels and no allergen sensitization. Beyond this, polymorphisms in the *IL18* gene associated with AD might contribute to modified IL-18 production of peripheral blood mononuclear cells (PBMC) of patients with AD after stimulation with microbial components.[37]

SYSTEMIC IMMUNE RESPONSE

Most patients with AD have peripheral blood eosinophilia and increased serum IgE levels. Nearly 80% of children with AD develop allergic rhinitis or asthma. Serum IgE level is strongly associated with the prevalence of asthma, which suggests that allergen sensitization through the skin predisposes the patient to respiratory disease because of its effects on the systemic allergic response. Indeed, epicutaneous sensitization of mice with protein antigen induces allergic dermatitis, elevated serum IgE, airway eosinophilia and hyperresponsiveness to methacholine. This suggests that epicutaneous exposure to allergen in AD enhances the development of allergic asthma.

An increased frequency of skin-homing T cells producing IL-4, IL-5 and IL-13 but little interferon (IFN)-γ has been found in the peripheral blood of patients with AD. There is evidence that this predominance of Th2 cells results partially from selective apoptosis of circulating memory/effector Th1 cells. These immunologic alterations are important because IL-4 and IL-13 are the only cytokines that induce germline transcription at the C_ε exon, thereby promoting isotype switching to IgE. IL-4 and IL-13 also induce the expression of vascular adhesion molecules, such as vascular cell adhesion molecule-1 involved in eosinophil infiltration, and down-regulate Th1-type cytokine activity. IL-5 plays a key role in the development, activation and cell survival of eosinophils. In contrast, IFN-γ inhibits IgE synthesis as well as the proliferation of Th2 cells and expression of the IL-4 receptor on T cells. The decreased IFN-γ produced by T cells from AD patients may be the result of reduced production of IL-18. Furthermore, an inverse relationship between skin colonization with *S. aureus* and spontaneous IFN-γ production of $CD4^+$ T cells as well as induced IFN-γ production of $CD8^+$ T cells has been observed.[38]

A number of determinants support Th2 cell development in AD. These include the cytokine milieu in which T cell development is taking place, pharmacologic factors, the costimulatory signals used during T cell activation, and the antigen-presenting

https://CafePezeshki.IR

cells (APCs). In this regard, IL-4 promotes Th2 cell development, whereas IL-12, produced by macrophages, dendritic cells or eosinophils, induces Th1 cells. Mononuclear cells from patients with AD have increased cyclic adenosine monophosphate (cAMP)-phosphodiesterase (PDE) enzyme activity. This cellular abnormality contributes to the increased IgE synthesis by B cells and IL-4 production by T cells in AD as IgE and IL-4 production is decreased in vitro by PDE inhibitors.

SKIN IMMUNOPATHOLOGY

Pathology

Clinically unaffected skin of AD patients exhibits mild epidermal hyperplasia and a sparse perivascular T cell infiltrate. Furthermore, increased transepidermal water loss and reduced skin hydration is detectable even in nonlesional AD skin.[39] AD has a biphasic nature, characterized by an acute phase, which is predominated by Th2 cytokines, followed by a chronic phase, featuring Th1 cytokines.[40] Acute eczematous skin lesions are characterized by marked intercellular edema (spongiosis) of the epidermis. Dendritic APCs such as Langerhans cells (LCs) and macrophages in lesional and, to a lesser extent, in nonlesional skin of AD patients have surface-bound IgE molecules. Within 24 to 48 hours after allergen application rapid influx of IgE-receptor bearing inflammatory dendritic epidermal cells (IDEC) and up-regulation of FcεRI expression are detectable in the epidermis of atopy patch test lesions.[41] In the dermis of the acute lesion there is a marked perivenular T cell infiltrate with occasional monocyte-macrophages. The critical role of T cells in AD is suggested by the obligate role of T cells in mouse models of AD. The lymphocytic infiltrate consists predominantly of activated memory T cells bearing CD3, CD4 and CD45RO. Eosinophils, basophils and neutrophils are rarely present in acute AD; mast cells are found in normal numbers but in various stages of degranulation. There is an increase in *S100A7*, *S100A8* and *S100A9* gene expression together with activation of Th2 and Th22 cytokines during the acute phase of AD.[42]

Chronic lichenified lesions are characterized by a hyperplastic epidermis with elongation of the rete ridges and prominent hyperkeratosis. There is an increased number of IgE-bearing DCs in the epidermis, and macrophages dominate the dermal mononuclear cell infiltrate. Mast cells are increased in number. Increased numbers of eosinophils are observed in chronic AD skin lesions. Eosinophils secrete cytokines and mediators that augment allergic inflammation and induce tissue injury in AD through the production of reactive oxygen intermediates and release of toxic granule proteins.

After topical treatment with calcineurin inhibitors, there is a decreased number of infiltrating T cells, B cells and eosinophils as well as expression of Th2 cytokines in addition to frequency of $CD8^+$ T cells expressing the Th1 cytokine IFN-γ has been observed.[43,44] Later on, surface expression of FcεRI epidermal DCs and number of epidermal inflammatory DC subtypes decreased, while frequency of LCs increased.

Cytokine Expression

Th2- and Th1-type cytokines contribute to the pathogenesis of skin inflammation in AD. As compared with the skin of normal controls, unaffected skin of AD patients has an increased number of cells expressing IL-4 and IL-13, but not IL-5, IL-12, or IFN-γ, mRNA. Acute and chronic skin lesions, when compared to normal skin or uninvolved skin of AD patients, have significantly greater numbers of cells that are positive for IL-4, IL-5 and IL-13 mRNA. However, acute AD is not characterized by significant expression of IFN-γ or IL-12.

Chronic AD skin lesions have significantly fewer IL-4 and IL-13 mRNA-expressing cells, but greater numbers of IL-5, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-12 and IFN-γ mRNA-expressing cells than acute AD. IL-5 and GM-CSF probably contribute to the increased numbers of eosinophils and macrophages. The increased expression of IL-12 in chronic AD skin lesions is of interest in that cytokine plays a key role in IFN-γ induction. Its expression in eosinophils and/or macrophages may initiate the switch to Th1 or Th0 cell development in chronic AD.

Aside from Th2 cytokines, elevated expression of Th22 cytokines has been observed in AD skin[42,45] and small numbers of $IL\text{-}17^+$ cells have been demonstrated to infiltrate the dermis of AD skin lesions.[46,47] Higher mRNA expression of Th17 and Th22 cytokines has been observed in intrinsic AD as compared to extrinsic AD. Severity score of AD positively correlated with mRNA expression of Th2 cytokines in the skin and negatively correlated with expression of barrier proteins.

Activated T cells infiltrating the skin of AD patients have also been found to induce keratinocyte apoptosis, which contributes to the spongiotic process found in AD skin lesions. This process is mediated by IFN-γ, which up-regulates *Fas* on keratinocytes. The lethal hit is delivered to keratinocytes by *Fas*-ligand expressed on the surface of T cells that invade the epidermis and soluble *Fas*-ligand released from T cells. Additionally, there is some evidence that caspase-3 cleavage in the spinous epidermal layer also contributes to spongiosis.[48] Mechanisms of IFN-γ induced keratinocyte apoptosis in AD have been analyzed in more detail and three apoptosis-related genes (*NOD2*, *DUSP1* and *ADM*) and eight genes overexpressed in AD skin lesions (*CCDC109B*, *CCL5*, *CCL8*, *IFI35*, *LYN*, *RAB31*, *IFITM1* and *IFITM2*) have been identified as playing a key role in this process.[49]

Another factor inducing keratinocyte cell death is alpha toxin released by *S. aureus*. The amount of the enzyme acid sphingomyelinase, which is capable of preventing Th2 mediated increase of alpha toxin induced cell death, is reduced in AD skin.[50] Additionally, it has been demonstrated that filaggrin is able to inhibit *S. aureus* alpha toxin mediated keratinocyte cell death.[51] Together these data provide evidence for increased keratinocyte cell death in AD due to lower filaggrin expression and the increased Th2 micromilieu in the skin.

The role of regulatory T cell subtypes in AD is still unclear. There is some evidence for functional deficiency of resident T_{REG} cells in the skin,[52] while other studies report increased local numbers of $CD4^+CD25^+Foxp3^+$ T_{REG} cells in patients with AD. In addition, it has been demonstrated that activated CD25-expressing T cells with a phenotype of regulatory T cells, lacking CCR6 expression, promote Th2 immune responses in patients with AD.[53] However, additional studies are required to elucidate the role of T_{REG} cells in AD.

Antigen-Presenting Cells

Atopic dermatitis skin contains an increased number of IgE-bearing LCs, which appear to play an important role in cutaneous allergen presentation to Th2 cells.[54] Binding of IgE to LCs occurs primarily via high-affinity IgE receptors. The clinical importance of these IgE receptors on LCs is supported by the observation that the presence of FcεRI-expressing LCs bearing

https://CafePezeshki.IR

IgE molecules is required to provoke eczematous skin lesions by application of aeroallergens on uninvolved skin of AD patients. In contrast to mast cells and basophils where the FcεRI is a tetrameric structure constitutively expressed at high levels, this receptor on APCs consists of the α-chain, which binds IgE and γ-chain dimers containing an immunoreceptor tyrosine-based activation motif (ITAM) for downstream signaling, but lacks the classic β-chain.[55] It is assumed that allergens which invade the skin are taken up by IgE molecules bound to FcεRI-expressing DCs. In the epidermis, FcεRI expression on DCs is related to the atopic state of the individual, with higher expression in AD lesions as compared to nonlesional skin of AD patients or epidermal skin of nonatopic individuals. Different FcεRI-bearing DC subtypes have been identified in lesional AD skin. $CD207^+/CD1a^+$, i.e. LCs, as well as $CD207^-/CD1a^+/FcεRI^+$ DCs are located in the epidermis. $CD1c^+/FcεRI^+$ DCs represent the major DC subpopulation of the dermal compartment, while low numbers of $CD207^+/FcεRI^+/CD1a^+$ DCs are also detectable in the dermis.[56]

Furthermore it has been demonstrated that the ability of cutaneous DC subsets to prime Th1, Th2, Th17 and Th22 immune responses in vitro is the same for DC derived from skin lesions of patients with AD or patients with other inflammatory skin diseases such as psoriasis. This indicates that chemokine expression and release together with other soluble and cellular factors of the skin micromilieu might be crucial for the outcome of T cell responses and disease-specific T cell responses in the skin.[57]

Besides myeloid DCs, macrophage-like cells with high histamine receptor 1 expression are detectable in the dermis of lesional AD skin and might amplify inflammation after stimulation with histamine released by mast cells and other cells.[58]

MYELOID DENDRITIC CELLS (MDC) CONTRIBUTE TO ALLERGIC SENSITIZATION AND MAINTENANCE OF INFLAMMATION WITH TH2-TH1 SWITCH

Langerhans cells bearing FcεRI are the main myeloid DC population present in nonlesional AD skin; upon allergen challenge and inflammation, FcεRI bearing myeloid DCs, so-called 'inflammatory dendritic epidermal cells (IDECs)' are detectable in the epidermis. After IgE binding and internalization of the allergen, LCs migrate to peripheral lymph nodes and present the processed allergen efficiently to naïve T cells, thus initiating a Th2 immune response with sensitization to the antigen. Beyond, the activated LCs can present the allergen-derived peptides locally to transiting antigen-specific T cells and induce a T cell mediated secondary immune response. Concomitantly, aggregation of FcεRI on the surface of LCs in vitro promotes the release of chemotactic factors, which in vivo supposedly contribute to the recruitment of IDECs into the epidermis. IDECs mainly present at inflammatory sites, produce high amounts of proinflammatory cytokines after FcεRI cross-linking, display a high stimulatory capacity toward T cells and serve as amplifiers of the allergic inflammatory immune response.[59] Moreover, stimulation of FcεRI on the surface of IDECs induces the release of IL-12 and IL-18 and enhances the priming of naïve T cells into IFN-γ producing Th1 or Th0 cells. These mechanisms may contribute to the switch from the initial Th2 immune response in the acute phase to the Th1 immune responses in the chronic phase.[59]

Precursor cells of myeloid DCs display lower responsiveness to TGF-β, which might contribute to a lower number of LCs in favor of higher numbers of DCs with inflammatory properties differentiating from precursor cells.[60] Additionally, DCs and precursor cells of DCs of patients with AD show an attenuated response to IFN-γ stimulation, which in part results from a lower expression of IFN-γRI and IFN-γRII, leading to lower phosphorylation of STAT-1 and lower expression of IFN-γ inducible genes. Together this reduced IFN-γ response might contribute to the overbalance of the Th2 immune response in the acute phase of AD.[61]

PLASMACYTOID DENDRITIC CELLS

Human plasmacytoid DCs (PDCs) are the only professional interferon (IFN) producing cells and express the IL-3 receptor α-chain (CD123) and the blood dendritic cell antigen (BDCA)-2.[62] Stimulation of PDCs with viral antigens induces the production of IFN-α/β, which is of crucial importance for the defense against viral infections. Human PDCs bear the PRRs TLR7 and TLR9 on their cell surface. Furthermore, they express the high-affinity receptor for IgE (FcεRI).[63,64] Based on a close interaction of FcεRI with TLR9, the amount of IFN-α and IFN-β released in response to TLR9 stimulation is profoundly down-regulated in PDCs after FcεRI aggregation and allergen challenge in vitro.[63,65,66] In view of frequent FcεRI aggregation induced by allergen challenge of PDCs of AD patients, this counterregulation might account for a profoundly reduced release of IFNs after viral antigen stimulation.

Furthermore, as compared to psoriasis, contact dermatitis or lupus erythematosus, the frequency of PDCs in the lesional epidermal skin of AD is low, although PDCs are recruited to the dermis during atopy patch test (APT).[40] This might result from Th2 cytokines or IL-10 in the skin micromilieu, leading to apoptosis of PDCs and, together with the counterregulation of FcεRI with TLRs, promote enhanced susceptibility of AD patients to viral skin infections.

Inflammatory Cell Infiltration

Several chemokines have been linked to recruitment of inflammatory cell subtypes such as DCs, T cells eosinophils, etc. to the skin in AD, including CCL2, CCL3, CCL4, CCL5, CCL11, CCL13, CCL18, CCL20, CCL22, CCL26 and CCL27.[67] Moreover, serum levels of some of these chemokines correlate directly with disease activity[67] and decrease in response to successful topical treatment, as shown for CCL5 and CCL11 after tacrolimus treatment.[68] A role of CCL18 in the amplification of allergic inflammation by increased homing of memory T cells has been demonstrated.[69,70] Another chemokine shown to be selectively up-regulated in AD was CCL1, the ligand to C-C chemokine receptor (CCR)8, which in vitro promoted the recruitment of T cells and Langerhans cell-like DCs.[71] IL-16, a chemoattractant for $CD4^+$ T cells, is increased in acute AD skin lesions. The C-C chemokines, RANTES/CCL5, monocyte chemotactic protein-4 (MCP-4/CCL13) and eotaxin/CCL11 have also been found to be increased in AD skin lesions and likely contribute to the chemotaxis of eosinophils and Th2 lymphocytes into the skin.

IL-31 is a novel cytokine, preferentially expressed by Th2 cells, which signals through a heterodimeric receptor composed of IL-31 receptor A and oncostatin M receptor.[72] Interestingly, up-regulated IL-31 expression has been observed in pruritic AD

https://CafePezeshki.IR

skin lesions[73] and was inducible by both stimulation of cutaneous lymphocyte antigen bearing (CLA^+) T cells of AD patients with staphylococcal enterotoxin B (SEB) in vitro and application of SEB to the skin of AD patients in vivo.[72–74] Furthermore, IL-31 induced the expression of the inflammatory chemokines CCL1, CCL17 and CCL22 in keratinocytes.[75] Since IL-31 induces severe pruritus and dermatitis in transgenic mice[75] and IL-31 receptor showed most abundant expression in dorsal root ganglia,[72] these findings provide a new link between staphylococcal colonization, subsequent T cell recruitment and activation and pruritus induction in patients with AD.[72]

In terms of T cells infiltrating the inflamed skin, it has been suggested that the so-called 'Th17 cells' may be of relevance not only in psoriasis but also in AD. Reports from animal models combined with studies using atopy patch tests or microarrays imply that Th17 may be induced in the skin by the topical application of allergens and may therefore assist skin infection in AD. However, as compared to psoriasis, Th17 most likely plays a rather minor role in AD skin.[76]

INTRINSIC DEFECT OF KERATINOCYTES IN ATOPIC DERMATITIS

Keratinocytes play an important role in the production of antimicrobial protein and cytokines in response to stimulation by invading pathogens, mediating both innate and adaptive inflammatory immune reactions. In addition, AD keratinocytes express high levels of the IL-7 like cytokine thymic stromal lymphopoietin (TSLP), which activates myeloid dendritic cells (DCs) to increase expression of IL-5, IL-13, CCL17 and CCL22. Skin-specific overexpression of TSLP in a transgenic mouse resulted in an AD-like phenotype, with the development of eczematous lesions containing inflammatory dermal cellular infiltrates, an increase in Th2 $CD4^+$ T cells expressing cutaneous homing receptors and elevated serum levels of IgE,[77] pointing to an important role of TSLP in AD.[78] DCs primed by TSLP may convert to strong inducers of T cell responses of the Th2 type in vitro,[79] so that enhanced TSLP release triggered by frequent allergen challenge, microbial infections and inflammation might initiate and perpetuate Th2 immune responses in AD.

Chronic Skin Inflammation

Chronic AD is linked to the prolonged survival of inflammatory cells in atopic skin. IL-5 expression during chronic AD plays a role in prolonging survival of eosinophils and enhancement of their function. In chronic AD, increased GM-CSF expression maintains the survival and function of monocytes, LCs and eosinophils. Epidermal keratinocytes from AD patients have significantly higher levels of RANTES expression following stimulation with tumor necrosis factor (TNF)-α and IFN-γ than keratinocytes from psoriasis patients. This may serve as one mechanism by which cytokines such as TNF-α enhances the chronicity and severity of eczema. Mechanical trauma can also induce the release of TNF-α and many other proinflammatory cytokines from epidermal keratinocytes. Thus, chronic scratching plays a role in the perpetuation and elicitation of skin inflammation in AD.

Antimicrobial Peptides

The innate immune system provides a rapid response to invasion of microbes. Research results from recent years strongly imply that impaired innate immune mechanisms with deficiency of the antimicrobial peptides (AMPs), which are represented by human intracellular proteins, i.e. human cathelicidin LL-37, human β-defensin (HBD)2 and HBD3 as well as dermcidin-derived antimicrobial proteins in sweat, might contribute to the susceptibility of AD patients to skin infections.[80] Defensins are broad-spectrum antibiotics that kill a wide variety of bacterial and fungal pathogens. Antimicrobial activity against viral pathogens is maintained by LL-37.[81] Efficient killing of *S. aureus* is achieved by LL-37 together with HBD2. Since inflammatory mediators up-regulate AMP expression, chronic inflammatory skin diseases such as psoriasis and contact dermatitis are characterized by increased amounts of AMP. Conversely, only weak up-regulation of HMD2, 3 and LL-37 is detectable in both lesional and nonlesional skin of patients with AD.[82] The Th2 cytokines IL-4, IL-13 and IL-10 down-regulate AMP expression in vitro and might account for low AMP in AD skin.[80,83] Moreover, reduced mobilization of human HBD3 accounts for defective killing of *S. aureus* in AD.[84] In addition to the propensity to bacterial infections due to low HBD2, 3 and LL-37 expression, cathelicidin deficiency in AD might also predispose to severe viral infections such as eczema vaccinatum caused by orthopox virus[81,85] and eczema herpeticum (EH).[86] In support of this concept, lower levels of cathelicidin are detectable in skin lesions of AD patients with one or more episodes of EH in their history as compared to AD patients without EH.[85] Dermcidin (DCD) is another recently discovered AMP with antibacterial and antimycotic properties and is constitutively expressed in human eccrine sweat glands. The amount of several DCD derived peptides in sweat was found to be significantly reduced in AD patients with a history of bacterial and viral infections[87] and is another cause of higher susceptibility of AD patients to microbial infections. Interestingly, both incubation of keratinocytes with vitamin D_3 in vitro, as well as treatment of AD patients with oral vitamin D_3, increases cathelicidin production of keratinocytes in AD patients, pointing to a novel opportunity to improve innate immune responses in AD patients therapeutically in the near future.[88–91]

Immunologic Triggers

FOODS

Well-controlled studies have demonstrated that food allergens induce skin rashes in children with AD. Based on double-blind, placebo-controlled food challenges, approximately 40% of infants and young children with moderate to severe AD have food allergy.[92,93] Food allergies in AD patients exacerbate eczema and contribute to severity of skin disease in some patients whereas urticaria reactions or other noncutaneous symptoms are triggered in other patients. Removal of food allergens from the patient's diet can lead to significant clinical improvement but requires a great deal of education because most of the common allergens (e.g. egg, milk, wheat, soy and peanut) contaminate many foods and are therefore difficult to avoid.

Infants and young children with food allergy generally have positive immediate skin tests or serum IgE directed to various foods. Positive food challenges are accompanied by significant increases in plasma histamine levels and eosinophil activation. Importantly, food allergen-specific T cells have been cloned from the skin lesions of patients with AD, providing direct

https://CafePezeshki.IR

evidence that foods can contribute to skin inflammation. In mouse models of AD, oral sensitization with foods results in the elicitation of eczematous skin lesions on repeat oral food challenges. In patients, however, immediate skin tests for specific allergens do not always indicate clinical sensitivity. Therefore clinically relevant food allergy must be verified by controlled food challenges or carefully investigating the effects of a food elimination diet, which is being done in the absence of other exacerbating factors.

AEROALLERGENS

A number of well-controlled studies have demonstrated that pruritus and eczematoid skin lesions develop after intranasal or bronchial inhalation challenge with aeroallergens, but not placebo, in AD patients sensitized to inhalant allergens. Epicutaneous application of aeroallergens by patch test techniques on uninvolved atopic skin elicits eczematoid reactions in 30% to 50% of patients with AD. Positive reactions have been observed to dust mite, weeds, animal dander and molds. In contrast, patients with respiratory allergy and healthy volunteers rarely have positive allergen patch tests.

Several studies have examined whether avoidance of aeroallergens results in clinical improvement of AD. Most of these reports have involved uncontrolled trials in which patients were placed in mite-free environments, for example hospital rooms in which acaricides or impermeable mattress covers were used. Such methods have invariably led to improvement in AD. One double-blind, placebo-controlled study using a combination of effective mite-reduction measures, as compared to no treatment, in the home has reported that a reduction in house dust mites is associated with significantly greater improvement in AD.

STAPHYLOCOCCUS AUREUS

Patients with AD have an increased tendency to develop bacterial (Figure 50-3), viral (Figure 50-4) and fungal skin infections. *S. aureus* is found in over 90% of AD skin lesions. The density of *S. aureus* on inflamed AD lesions without clinical superinfection can reach up to 10^7 colony-forming units per cm^2 on lesional skin. Pulsed-field gel electrophoresis of *S. aureus* isolated from families of AD children showed that similar strains are detectable in parents and their children.[94] This finding argues for a high recolonization rate of atopic children.[94] The importance of *S. aureus* is supported by the observation that even AD patients without overt infection show a greater reduction in severity of skin disease when treated with a combination of antistaphylococcal antibiotics and topical corticosteroids as compared to topical corticosteroids alone.

One strategy by which *S. aureus* exacerbates or maintains skin inflammation in AD is by secreting a group of toxins known to act as superantigens, which stimulate marked activation of T cells and macrophages. The skin lesions of over half of AD patients have *S. aureus* that secrete superantigens such as enterotoxins A and B and toxic shock syndrome toxin-1. An analysis of the peripheral blood skin-homing CLA^+ T cells from these patients as well as T cells in their skin lesions reveals that they have undergone expansion of the beta region of the T cell receptor variable chain consistent with superantigenic stimulation. Most AD patients make specific IgE antibodies directed against the staphylococcal superantigens found on their skin. Basophils from patients with IgE antibodies directed to superantigens release histamine on exposure to the relevant superantigen, but not in response to superantigens to which they have no specific IgE. This raises the interesting possibility that superantigens induce specific IgE in AD patients and mast cell degranulation in vivo when the superantigens penetrate their disrupted epidermal barrier. This promotes the itch-scratch cycle critical to the evolution of skin rashes in AD.

A correlation has also been found between the presence of IgE anti-superantigens and severity of AD. Utilizing a humanized murine model of skin inflammation, the combination of

https://CafePezeshki.IR

S. aureus superantigen plus allergen has been shown to have an additive effect in inducing skin inflammation. Superantigens can also augment allergen-specific IgE synthesis, suggesting that several mechanisms exist by which superantigens could aggravate the severity of AD.

Increased binding of *S. aureus* to AD skin is likely related to underlying atopic skin inflammation. This concept is supported by several lines of investigation. First, it has been found that treatment with topical corticosteroids or tacrolimus will reduce *S. aureus* counts on atopic skin, although they have no antibiotic actions. Second, acute inflammatory lesions have more *S. aureus* than chronic AD skin lesions or normal-looking atopic skin. Scratching likely enhances *S. aureus* binding by disturbing the skin barrier and exposing extracellular matrix molecules known to act as adhesins for *S. aureus*, for example fibronectin and collagens. Finally, in studies of *S. aureus* binding to skin lesions of mice undergoing Th1 versus Th2 inflammatory responses, bacterial binding was significantly greater at skin sites with Th2-mediated inflammation. Importantly, this increased bacterial binding did not occur in IL-4 gene knockout mice, indicating that IL-4 plays a crucial role in the enhancement of *S. aureus* binding to skin. IL-4 appears to enhance *S. aureus* binding to the skin by inducing the synthesis of fibronectin, an important *S. aureus* adhesin. Interestingly, studies of human AD have found a role for fibrinogen in the binding of *S. aureus* to atopic skin. Because acute exudative lesions likely have increased plasma-derived fibrinogen, this may provide a mechanism for further binding of *S. aureus* to acute AD lesions.

The highly increased binding of *S. aureus* to AD skin is not enough to account for the highly increased numbers of *S. aureus* found on AD as compared to normal skin. Once bound to AD skin, *S. aureus* must therefore rapidly proliferate as the result of impaired local immune responses. Interestingly, superantigens induce corticosteroid resistance of human T cells by up-regulation of the glucocorticoid-induced TNF receptor-related protein ligand (GITR-L) on monocytes[95] and signaling via the Raf-MEK-ERK1/ERK2 pathway of T cell receptor signaling.[96] These mechanisms might be of relevance in a subgroup of AD patients recalcitrant to treatment with corticosteroids.

VIRAL INFECTIONS

AD in childhood as well as in adulthood can be complicated by localized or widespread cutaneous viral infections, which are specific for the disease. Virus infections observable in AD patients are most often caused by herpes simplex virus (HSV), human papilloma virus or molluscipox virus.[97] EH is a disseminated HSV 1 or 2 infection with severe systemic illness that occurs in 10% to 20% of patients with AD.[98] Risk factors for EH are an early onset of AD, severe and untreated AD, head and neck dermatitis, previous HSV infections and EH, and an elevated serum IgE combined with higher level of specific sensitizations, especially against *Malassezia sympodialis*.[99,100] Moreover, genetic variants in *IFNG* and *IFNGR1* as well as *IRF2* and *STAT6* were associated with EH and linked to lower IFN-γ response in EH patients in vivo and in vitro.[101–103] Reduced gene expression in Claudin-1, a tight junction protein, has been identified as another putative risk factor for a higher propensity to viral infections induced by HSV of a subgroup of patients with AD.[104] Co-factors such as *S. aureus* and *S. aureus*-released alpha toxins might also be responsible for higher susceptibility of a subgroup of AD patients to EH since it has been demonstrated that alpha toxins promote viral entry of HSV into human keratinocytes via ADAM10, a disintegrin and metalloprotease.[105] Furthermore, filaggrin and its breakdown products are reported to be capable of preventing HSV replication in vitro. Consequently, lower filaggrin expression due to loss-of function mutations in the *FLG* gene or secondary factors such as increased levels of IL-25, IL-4/IL-13 or other factors down-regulating filaggrin expression might increase the risk for disseminated HSV infections of the skin.[106]

AUTOALLERGENS

In the 1920s several investigators reported that human skin dander could trigger immediate hypersensitivity reactions in the skin of patients with severe AD.[107] The potential molecular basis for these observations was demonstrated by Valenta et al, who reported that the majority of sera from patients with severe AD contain IgE antibodies directed against human proteins. One of these IgE-reactive autoantigens, a 55 kDa cytoplasmic protein in skin keratinocytes, has been cloned from a human epithelial cDNA expression library and designated Hom s 1. Such antibodies were not detected in patients with other skin diseases such as chronic urticaria, systemic lupus erythematosus or in healthy controls. Although the autoallergens characterized to date have mainly been intracellular proteins, they have been detected in IgE immune complexes of AD sera, suggesting that release of these autoallergens from damaged tissues could trigger responses mediated by IgE or T cells. This concept is supported by the recent observation that IgE autoallergen titers decreased with resolution of AD. These data suggest that, whereas IgE immune responses are initiated by environmental allergens, allergic inflammation can be maintained by human endogenous antigens, particularly in severe AD.

The reason for the development of IgE autoreactivity is currently unclear but it has been supposed that it might be based on chronic tissue damage due to repeated exposure to allergens in sensitized persons. Several atopy related autoantigens (ARA), including Hom s 1–5 and DSF 70, have been characterized so far. Strong IgE autoreactivity is detectable in particular in AD patients with high total serum IgE levels, a large number of sensitizations to food- and aeroallergens, early onset of AD and severe course.[108] Thus, IgE autoreactivity has been supposed to start in early infancy[109] and to contribute to very severe, therapy-resistant and chronic courses of disease. Specific IgE against the stress-inducible enzyme manganese superoxide dismutase (MnSOD), which cross-reacts to the skin-colonizing yeast *Malassezia sympodialis*, correlates with disease activity and has been found to induce T cell reactivity in vitro and eczematous reactions in APT in MnSOD-sensitized patients with AD.[110] Hom s 4 induced Th1 responses accompanied by the release of IFN-γ, a cytokine involved in epithelial damage and chronic stages of skin inflammation.[108,111] These observations imply that autoreactivity might contribute to impairment of the allergic inflammatory reaction as well as to chronification of the disease.

Conclusions

Atopic dermatitis is a common genetically transmitted inflammatory skin disease frequently found in association with respiratory allergy (Box 50-2). The diagnosis is mainly based on clinical parameters (Figure 50-5). The keys to management are: skin hydration; use of effective topical antiinflammatory agents such as corticosteroids, tacrolimus or pimecrolimus; and

BOX 50-2 KEY CONCEPTS

ATOPIC DERMATITIS

- Atopic dermatitis (AD) affects 10% to 20% of children.
- AD is a genetically transmitted chronic inflammatory allergic skin disease.
- Skin-homing T cells express T helper cell type 2 (Th2) cytokines that induce IgE and eosinophilia.
- Antigen-presenting cells in the skin (e.g. Langerhans cells) express surface-bound IgE molecules.
- Transition from acute to chronic AD is associated with a switch from predominantly Th2 cytokines to a combination of Th1 and Th2 cytokine gene expression.
- Immunologic triggers include foods, aeroallergens, microbial agents and autoallergens.

BOX 50-3 THERAPEUTIC PRINCIPLES

ATOPIC DERMATITIS

- Skin hydration and emollients are needed to repair skin barrier function.
- Topical antiinflammatory agents (corticosteroids, pimecrolimus, tacrolimus) are the cornerstones of therapy for acute flares and prevention of relapses.
- Avoidance of food and inhalant allergens may prevent flares.
- Antimicrobial therapy is often useful in poorly controlled patients.
- Sedating antihistamines may promote sleeping at night.
- Nonsedating antihistamines may be useful for patients with concomitant urticaria or coexisting respiratory allergy.
- Considerations for refractory patients include phototherapy, systemic glucocorticoids, cyclosporine, interferon-γ, mycophenolate and methotrexate.

avoidance of allergenic triggers and skin irritants (Box 50-3). With a better understanding of the immunoregulatory abnormalities underlying AD, new paradigms are emerging to treat acute flares of AD more effectively and to prevent relapses of this skin condition.

51 Management of Atopic Dermatitis

MARK BOGUNIEWICZ | DONALD Y.M. LEUNG

KEY POINTS

- Proper skin hydration and skin barrier protection are key to management of atopic dermatitis (AD).
- Topical antiinflammatory therapy includes use of topical steroids and calcineurin inhibitors.
- Identification and elimination of relevant triggers is an essential component of managing AD.
- Patient and caregiver education is a critical part of caring for patients with AD.
- The risks vs benefits of systemic therapy need to be considered for patients failing conventional therapy.

Atopic dermatitis (AD) is a common, frequently relapsing inflammatory disease that affects up to 20% of children (see the 'Epidemiology' section of Chapter 50) and has a significant impact on the quality of life of patients and families. Management approaches in AD have evolved with our increasing understanding of the mechanisms underlying this skin disease. While AD is the most common chronic skin disease of children, it is important to bear in mind the differential diagnosis of a pruritic rash when starting therapy, especially if there are atypical features or the response to treatment is suboptimal. Note that, while rare, cutaneous T cell lymphoma/mycosis fungoides can occur in adolescents and even children (see Box 51-1). Given the complex nature of AD and its chronic, relapsing course, it will often require a multipronged approach directed at healing or protecting the skin barrier and addressing the immune dysregulation to improve the likelihood of successful outcomes. This includes proper skin hydration and identification and elimination of flare factors such as irritants, allergens, infectious agents and emotional stressors, as well as pharmacologic therapy (Figure 51-1).[1]

Hydration and Skin Barrier Protective Measures

As discussed in Chapter 50, patients with AD have genetic or immune-mediated abnormalities in skin barrier function.[2] Of note, filaggrin contributes not only to barrier integrity, but also to hydration through generation of hygroscopic amino acids that are a key component of natural moisturizing factor (NMF). NMF is also involved in the maintenance of skin pH and regulation of key biochemical events, including protease activity, barrier permeability and cutaneous antimicrobial defense. Filaggrin may also contribute to the acid mantle through acid degradation products. Children with AD have dry skin (xerosis) with microfissures and epidermal defects that serve as portals of entry for irritants, allergens and skin pathogens. Transepidermal water loss occurs even through normal appearing skin.

Hydration of the skin can be accomplished through warm (note that lukewarm and tepid are not comfortable temperatures for bathing!) soaking baths for approximately 10 minutes, followed by immediate application of a moisturizer or medication to prevent evaporation and promote healing. Bathing also removes irritants, allergens and skin pathogens and provides symptomatic relief. Bathing should also be an enjoyable activity. This can be accomplished by providing appropriate bath toys for younger children that are reserved for tub time, or a caregiver may choose to read to them. Older children can read or play hand-held games that are safe for a tub. It is important that areas involved by eczema are immersed, not just wet. Wet towels can be used to hydrate the head and neck regions, with masks created to make the experience both therapeutic and enjoyable. Young children need to be supervised. Baths can be taken several times per day during eczema flares, while showers may be substituted in milder disease or to accommodate busy schedules, especially in the mornings. Cleansers with minimal defatting activity and a neutral pH can be used as necessary. Preparations formulated for sensitive skin that are dye and fragrance free are generally well tolerated. Antibacterial cleansers may be helpful for patients with folliculitis or recurrent skin infections. Patients should be instructed not to scrub with a washcloth while using cleansers. Addition of bleach (sodium hypochlorite) to bath water, especially for patients with methicillin-resistant *Staphylococcus aureus* (MRSA), has been advocated. However, the amount of bleach per volume of water (e.g. an eighth to a half cup per tub of water) and the frequency of such treatments (e.g. 1 to 3 times weekly) have not been well studied and bleach baths can cause significant skin irritation. In a single-center controlled study, children with AD were treated with dilute sodium hypochlorite baths (a half cup of 6% bleach added to 40 gallons of water) twice weekly for 5 to 10 minutes, combined with nasal mupirocin twice daily for 5 days each month, over a 3-month period.[3] Patients tolerated the dilute bleach baths although the number of patients colonized with MRSA was low and, despite clinical improvement, patients remained colonized by *S. aureus* even after 3 months of intervention.

Use of an effective moisturizer combined with hydration therapy will help to restore and preserve the stratum corneum barrier.[4] Moisturizers can also improve skin barrier function, reduce susceptibility to irritants, improve clinical parameters of AD and decrease the need for topical corticosteroids.[5–7] Ingredients that contribute to effective moisturizers include humectants to attract and hold water in the skin such as glycerol, occlusives such as petrolatum to retard evaporation, and emollients such as lanolin to lubricate the stratum corneum.[8]

BOX 51-1 DIFFERENTIAL DIAGNOSIS OF ATOPIC DERMATITIS

CONGENITAL DISORDERS
- Netherton's syndrome
- Familial keratosis pilaris

CHRONIC DERMATOSES
- Seborrheic dermatitis
- Contact dermatitis (allergic or irritant)
- Nummular eczema
- Psoriasis
- Ichthyoses

INFECTIONS AND INFESTATIONS
- Scabies
- Human immunodeficiency virus-associated dermatitis
- Dermatophytosis

MALIGNANCIES
- Cutaneous T cell lymphoma (mycosis fungoides/Sézary syndrome)
- Letterer-Siwe disease

AUTOIMMUNE DISORDERS
- Dermatitis herpetiformis
- Pemphigus foliaceus
- Graft-versus-host disease
- Dermatomyositis

IMMUNODEFICIENCIES
- Wiskott-Aldrich syndrome
- Severe combined immunodeficiency syndrome
- Hyper-IgE syndrome
- Dedicator of cytokinesis 8 (DOCK8) associated immunodeficiency
- Immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX) syndrome

METABOLIC DISORDERS
- Zinc deficiency
- Pyridoxine (vitamin B_6) and niacin
- Multiple carboxylase deficiency
- Phenylketonuria

Moisturizers are available as ointments, creams, lotions and oils. While ointments have the fewest additives and are the most occlusive, in a hot, humid environment they may trap sweat with associated irritation of the skin. Lotions and creams may be irritating due to added preservatives, solubilizers and fragrances. Lotions contain more water than creams and may be drying due to an evaporative effect. Oils are also less effective moisturizers. Moisturizers should be obtained in the largest size available (one pound jars) since they may need to be applied several times each day on a chronic basis. Vegetable shortening (Crisco®) can be used as an inexpensive moisturizer. Of note, patients and caregivers should understand that petroleum jelly (Vaseline®) is an occlusive, not a moisturizer, and thus needs to be applied on damp, not dry skin. Even young children can be taught to apply their moisturizer, allowing them to participate in their skin care. Patients and caregivers need to be instructed to apply moisturizers routinely but not over or immediately prior to topical medications to avoid dilution or interference with medication on skin.

A number of studies suggest that AD is associated with decreased levels of ceramides, contributing not only to a damaged permeability barrier but also making the stratum corneum susceptible to colonization by *S. aureus*.[9] A ceramide-dominant emollient added to standard therapy in place of moisturizer in children with 'stubborn-to-recalcitrant' AD was shown to result in clinical improvement.[10] Several ceramide-containing creams are available, including Epiceram® which is registered as a medical device and thus available only by prescription. Preliminary data suggest clinical benefit comparable to a topical mid-potency corticosteroid.[11] Other nonsteroidal creams registered as medical devices with unique ingredients include MAS063DP (Atopiclair®)[12] and S236 (Mimyx®).[13] These creams are not regulated by the US Food and Drug Administration (FDA) and have no restrictions on age or length of use. They may be especially attractive to parents who have concerns about using topical corticosteroids and calcineurin inhibitors. However, they are costly and their place in the treatment algorithm for AD has not been definitively established.

Topical Antiinflammatory Therapy

TOPICAL GLUCOCORTICOIDS

Glucocorticoids have been the cornerstone of antiinflammatory treatment for over 50 years. Because of potential side-effects, topical glucocorticoids are used primarily to control acute exacerbations of AD.[1]

Patients should be carefully instructed in the use of topical glucocorticoids to avoid potential side-effects. The potent fluorinated glucocorticoids should be avoided on the face, the genitalia and the intertriginous areas. Patients should be instructed to apply topical glucocorticoids to their skin lesions and to use emollients over uninvolved skin. Failure of a patient to respond to topical glucocorticoids is often due to the inadequate amount applied. It is important to remember that it takes approximately 30 g of cream or ointment to cover the entire skin surface of an adult-sized patient for one application. The fingertip unit (FTU) has been proposed as a measure for applying topical corticosteroids and has been studied in children with AD.[14,15] This is the amount of topical medication that extends from the tip to the first joint on the palmar aspect of the index finger. It takes approximately one FTU to cover the hand or groin, 2 FTUs for the face or foot, 3 FTUs for an arm, 6 FTUs for a leg, and 14 FTUs for the trunk. Of note, adequate application of topical corticosteroids has been shown to correlate with clinical improvement.[16] Obtaining medications in larger quantities can result in significant savings for patients.

There are seven classes of topical glucocorticoids, ranked according to their potency based on vasoconstrictor assays from super-potent (class I) to low potent (class VII). Because of their potential side-effects, the super-potent and high-potent glucocorticoids should be used only for short periods of time and in areas that are lichenified, but not on the face or intertriginous areas. The goal is to use moisturizers to enhance skin hydration and lower-potency glucocorticoids or nonsteroidal agents for long-term therapy if needed. Side-effects from topical glucocorticoids are related to the potency ranking of the compound and the length of use as well as the area of the body to which the drug is applied, so it is incumbent on the clinician to balance the need for a more potent steroid with the potential for side-effects. In general, ointments have a greater potential to occlude the epidermis, resulting in enhanced systemic absorption compared to creams. Side-effects from topical glucocorticoids can be divided into local and systemic. Local side-effects include the

https://CafePezeshki.IR

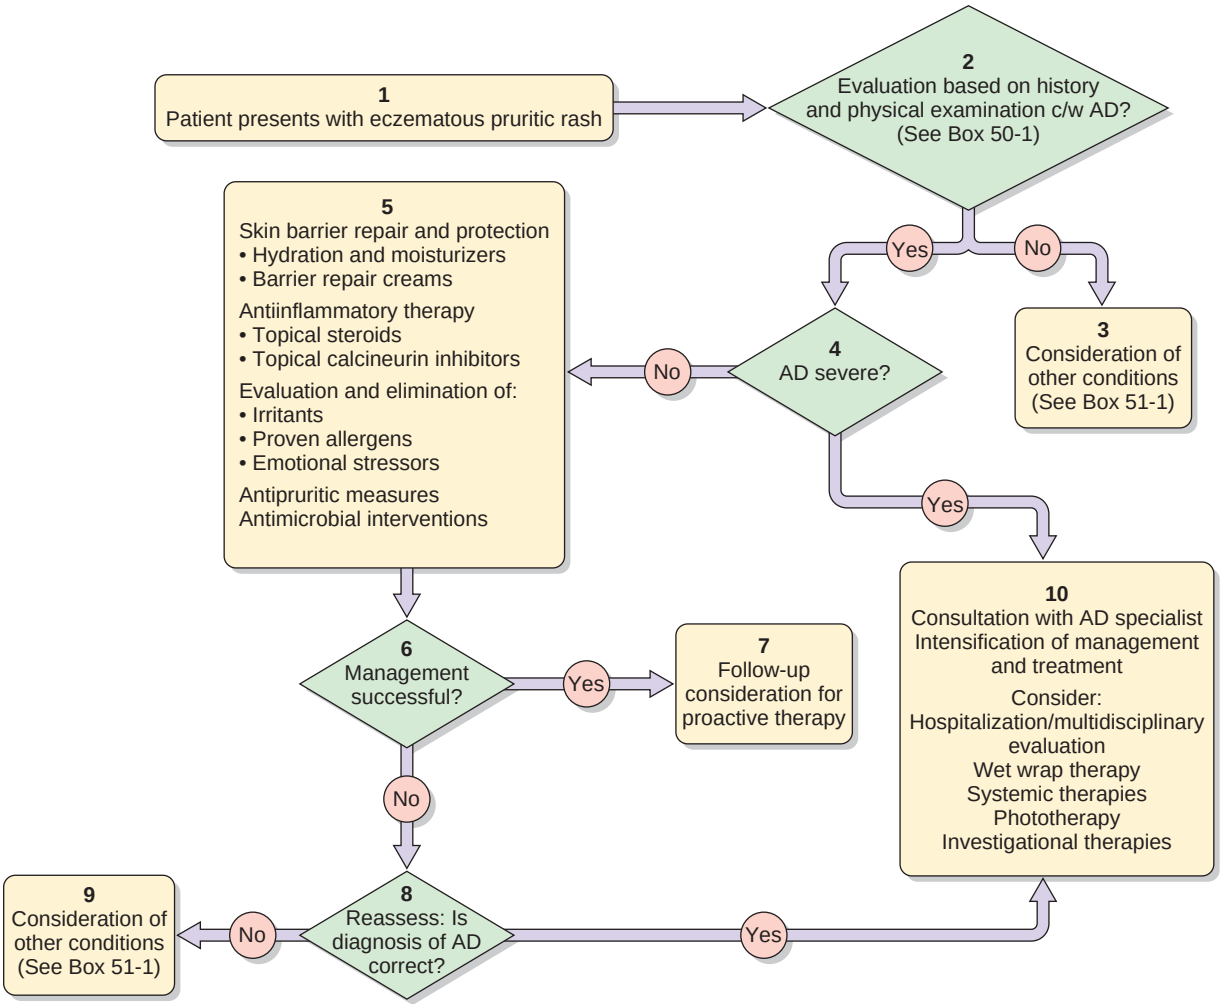

Figure 51-1 Clinical algorithm for diagnosis and management of atopic dermatitis.

development of striae and skin atrophy.[17] Systemic side-effects in AD are uncommon unless high-potency steroids are used under occlusion, but adrenal suppression and cataracts have been reported.[18–20] However, disease activity, rather than the use of topical corticosteroids, was shown to be responsible for low basal cortisol values in patients with severe AD.[21] Of note, patients and caregivers continue to use topical corticosteroids suboptimally, primarily due to concerns about their use.[22] This may include delaying application of the medication for a number of days after the start of a flare, which contributes to suboptimal outcomes. An expert consensus from the Dermatology Working Group pointed out that 'in an ideal world, dermatologists, dermatology nurses, … practitioners, … pharmacists would work together to advise and reinforce information about the correct way to apply topical corticosteroids, and to address concerns about the safety of these highly effective agents. But in the real world, expert advice, even when given, is soon forgotten …'.[15] Patients and caregivers need to have a basic understanding of topical corticosteroids, including their risks and benefits. Patients may erroneously assume that the potency of a topical corticosteroid is defined by the percent stated after the compound name (as discussed under 'Education of Patients and Caregivers' later in this chapter). At times, patients may be prescribed a high-potency corticosteroid with instructions to discontinue it within 7 to 14 days without a plan to step down, resulting in rebound flaring of their AD. Of note, only a few topical corticosteroids have been approved for use in very young children. These include desonide and fluticasone cream down to 3 months of age, alclometasone down to 1 year of age and mometasone down to 2 years of age. Indications are typically for up to 3 to 4 weeks.

Patients with AD are often labeled as topical corticosteroid treatment failures. Reasons for this may include inadequate potency of the preparation or insufficient amount dispensed or applied, *S. aureus* superinfection, steroid allergy and possibly corticosteroid insensitivity. A much more common reason for therapeutic failure is nonadherence to the treatment regimen. As with any chronic disease, patients or caregivers often expect quick and lasting benefits and become frustrated with the relapsing nature of AD.[23] These factors need to be considered when faced with a patient not responding to therapy before considering alternative therapy, especially systemic treatment.

TOPICAL CALCINEURIN INHIBITORS

Since their approval by the FDA in 2000 and 2001, respectively, the topical calcineurin inhibitors (TCIs) – tacrolimus ointment (Protopic 0.03% and 0.1%) and pimecrolimus cream (Elidel

https://CafePezeshki.IR

1%) – have become well-established, effective and safe nonsteroidal treatments for pediatric AD.[24] They are currently indicated as second-line treatment for intermittent, noncontinuous use in children aged 2 years and older with moderate-severe AD (tacrolimus ointment 0.03%) and mild-moderate AD (pimecrolimus cream 1%). Tacrolimus ointment 0.1% is indicated for patients 16 years and older. Nevertheless, patients and caregivers frequently misunderstand their place in the treatment algorithm and have concerns about the boxed warning for these drugs. Of note, a Joint Task Force of the American College of Allergy, Asthma and Immunology and the American Academy of Allergy, Asthma and Immunology reviewed the available data and concluded that the risk/benefit ratios of tacrolimus ointment and pimecrolimus cream are similar to those of most conventional therapies for the treatment of chronic relapsing eczema.[25] In addition, a case-control study of a large database that identified a cohort of 293,253 patients with AD found no increased risk of lymphoma with the use of TCIs.[26] Children may be prescribed TCIs to replace topical corticosteroids when they are not doing well or during a flare of AD, with unrealistic expectations for this class of drugs. Patients and caregivers may not be instructed about potential side-effects, a common reason for TCIs being discontinued, and patients labeled as treatment failures. While several studies have explored the use of TCIs in children under 2 years of age[27] and as early intervention to reduce the incidence of flare and need for topical steroid rescue,[28] they would currently be considered to be off-label therapy.

PROACTIVE THERAPY

As discussed in Chapter 50, normal appearing skin in AD is not normal; there are immune and skin barrier abnormalities, as well as *S. aureus* colonization. In patients whose eczema tends to relapse in the same location, an approach that has gained increased attention is that of proactive therapy. After a period of stabilization, topical antiinflammatory therapy is instituted in areas of previously involved but normal-appearing skin, rather than waiting for a flare of eczema in a traditional reactive approach. Studies with topical corticosteroids[29–32] and TCIs,[33,34] including in pediatric patients,[35,36] have shown clinical benefit with this approach. Of note, it is important to recognize that eczema first needs to be brought under control before a 2 to 3 times weekly, long-term regimen can be instituted. This approach would currently be considered off-label in the USA, but it has been approved in EU countries for children 2 years and older for up to 12 months with tacrolimus ointment and shown to be a cost-effective approach by the National Health Service of the UK.[37]

Identification and Elimination of Triggering Factors

Patients with AD have hyperreactive skin and a number of different triggers including irritants, allergens, infectious agents and emotional stressors can contribute to cutaneous inflammation and flare of eczema.

IRRITANTS

Patients with AD are more susceptible to irritants than are normal individuals. Thus it is important to identify and eliminate or minimize exposure to irritants such as soaps or detergents, chemicals, smoke, abrasive clothing and extremes of temperature and humidity. Alcohol and astringents found in toiletries can be drying. Cleansers, ideally formulated for sensitive skin, should be used in place of soaps, especially fragranced ones. Using a liquid rather than powder detergent and adding a second rinse cycle will facilitate removal of the detergent. Recommendations regarding environmental conditions should include temperature and humidity control to avoid problems related to heat, humidity and perspiration. Every attempt should be made to allow children to be as normally active as possible. Certain sports such as swimming may be better tolerated than others that involve intense perspiration, physical contact or heavy clothing and equipment, but chlorine should be rinsed off after swimming with the aid of a cleanser and the skin lubricated. Although ultraviolet light may be beneficial to some patients with AD, sunscreens should be used to avoid sunburn. Sunscreens formulated for the face are often better tolerated.

SPECIFIC ALLERGENS

Potential allergens can be identified by taking a careful history and carrying out selective allergy tests. Negative skin tests or serum tests for allergen-specific immunoglobulin E (IgE) have a high predictive value for ruling out suspected allergens. Positive skin or in vitro tests, particularly to foods, often do not correlate with clinical symptoms and should be confirmed with controlled food challenges and, if indicated, trials of specific elimination diets.[38] Avoidance of foods implicated in controlled challenges has been shown to result in clinical improvement. Infants who do not improve on formulas containing hydrolyzed proteins can be tried on amino acid formulas. However, these can add a significant financial burden for the family. Extensive elimination diets which, in some cases, can be nutritionally deficient, are rarely if ever required, because even with multiple positive allergy tests, the majority of children will react to three or fewer foods on controlled challenge. Unfortunately, patients with multiple positive allergy tests are often labeled as multiple food-allergic with no attempts to prove clinical relevance. Food challenges after getting the eczema under control and establishing a baseline for immediate, and less frequently delayed, reactions can be of immense value in managing the patient and helping the family with this stressful issue. It is noteworthy that in one retrospective study, 325 (89%) of 364 supervised oral food challenges were reported as negative.[39] In addition, consultation with a dietitian familiar with food allergies can be extremely helpful to ensure a nutritionally sound diet for the child and suggest practical advice to caregivers.[40] The Food Allergy Research & Education website (www.foodallergy.org) is a useful resource for patients and families with food allergy (see also Chapter 45 on food allergy).

In patients allergic to dust mites, prolonged avoidance of dust mites has been found to result in improvement of AD.[41–44] Avoidance measures include: using dust mite-proof casings on pillows, mattresses and box springs; washing bedding in hot water weekly; removing bedroom carpeting; and decreasing indoor humidity levels with air conditioning. Because there are many triggers that can contribute to the flare of AD, attention should be focussed on identifying and controlling the flare factors that are important to the individual patient. In addition, allergic contact dermatitis may be overlooked in children and

https://CafePezeshki.IR

patch testing should be considered in children with AD (see Chapter 53).[45] In a study to determine the frequency of positive and relevant patch tests in children referred for patch testing in North America, of the children with a relevant positive reaction, 34.0% had a diagnosis of AD.[46]

EMOTIONAL STRESSORS

AD patients often respond to frustration, embarrassment and other stressful events with increased pruritus and scratching. In some instances, scratching is simply habitual; less commonly it is associated with secondary gain. Psychologic evaluation or counseling should be considered in patients who have difficulty with emotional triggers or psychologic problems contributing to difficulty in managing their disease. Relaxation, behavioral modification or biofeedback may be helpful in patients who habitually scratch.[47]

INFECTIOUS AGENTS

Children with AD often are colonized or infected with various microbial organisms including bacteria, especially *Staphylococcus aureus* (Figure 51-2), viruses including herpes simplex virus, and occasionally yeast or fungi. Methicillin-resistant *S. aureus* (MRSA) is becoming an increasingly important pathogen in patients with AD. Antistaphylococcal antibiotics are helpful in the treatment of patients who are heavily colonized or infected with *S. aureus*.[48] Cephalosporins or penicillinase-resistant penicillins are usually beneficial for patients who are not colonized with resistant *S. aureus* strains. Erythromycin and other macrolide antibiotics are usually of limited utility due to increasing frequency of erythromycin-resistant *S. aureus*. Topical mupirocin is useful for the treatment of localized impetiginized lesions; however, in patients with extensive skin infection, a course of systemic antibiotics is more practical. Retapamulin ointment 1%, used twice daily for 5 days, was shown to be as effective as oral cephalexin twice daily for 10 days in the treatment of patients with secondarily infected dermatitis and was well tolerated.[49] Use of topical neomycin, on the other hand, can result in development of allergic contact dermatitis because neomycin is among the more common allergens causing contact dermatitis.[50] Treatment for nasal carriage with an intranasal antibiotic may lead to clinical improvement of AD.[51] MRSA may require culture and sensitivity testing to assist in appropriate antibiotic selection. However, patients and caregivers need to be instructed that the best defense against microbes is an intact skin barrier, and basic skin care principles as discussed above should be emphasized. Of note, antiinflammatory therapy alone, with either a topical corticosteroid or topical calcineurin inhibitor, has been shown to improve AD and reduce *S. aureus* colonization of the skin.[52]

Although antibacterial cleansers have been shown to be effective in reducing bacterial skin flora,[53] they may be too irritating to use on inflamed skin in AD. Baths with dilute sodium hypochlorite (bleach) may also be of benefit to AD patients, especially those with recurrent MRSA as discussed above under 'Hydration and Skin Barrier Protective Measures', although they can be irritating. Of note, a single-center controlled study, while showing clinical benefit, did not demonstrate decreased skin colonization by *S. aureus* even with combined nasal treatment with mupirocin and after 3 months of treatment.[3] A 2014 review discusses an approach to recurrent MRSA infections in patients with AD.[54] Some studies have shown that silver-impregnated clothing reduced staphylococcal colonization, improved clinical parameters and reduced topical corticosteroid use in AD.[55]

AD can be complicated by disseminated herpes simplex virus infection, resulting in Kaposi's varicelliform eruption or eczema herpeticum (Figure 51-3). Vesicular lesions are umbilicated, tend to crop, and often become hemorrhagic and crusted. These lesions may coalesce to large, denuded and bleeding areas that can extend over the entire body. Herpes simplex can provoke recurrent dermatitis and may be misdiagnosed as impetigo, although herpetic lesions can become superinfected by *S. aureus*.[56] The presence of punched-out erosions, vesicles and/or infected skin lesions that fail to respond to oral antibiotics should initiate a search for herpes simplex. This can be diagnosed by a Giemsa-stained Tzanck smear of cells scraped from the vesicle base or by viral culture or polymerase chain reaction (PCR). Test results may be falsely negative if the samples are inadequate. Ideally, vesicle fluid should be obtained

Figure 51-2 Patient with atopic dermatitis who is secondarily infected with *Staphylococcus aureus*. Note multiple pustules and areas of crusting. *(From Weston WL, Morelli JG, Lane A, editors. Color textbook of pediatric dermatology. 3rd edn. St Louis: Mosby; 2002.)*

https://CafePezeshki.IR

by unroofing one or more intact vesicles. Lumbar puncture should be considered if meningitis is suspected, but the presence of infected lesions over the lumbar areas should preclude this procedure. Ophthalmology consultation should be obtained for patients with periocular or suspected eye involvement. Treatment may be with oral acyclovir for less severe infections or intravenous acyclovir for widely disseminated disease or toxic-appearing patients at 30 mg/kg/day divided every 8 hours (for patients <1 year old) or 1,500 mg/m^2/day divided every 8 hours (for patients >1 year old) for 7 to 21 days, depending on the clinical course.[57] Valacyclovir is indicated in pediatric patients 12 years or older for treatment of herpes labialis (2 g every 12 hours for 1 day) and patients 2 to <18 years of age for treatment of chickenpox (20 mg/kg 3 times daily for 5 days) up to a maximum dose of 1 g 3 times daily. Detailed instructions on preparing a liquid suspension (including shelf life) are available under 'Extemporaneous Preparation of Oral Suspension' in the manufacturer's package insert. Of note, the suspension needs to be used within 4 weeks of being prepared. Acyclovir prophylaxis may be necessary for patients with recurrent eczema herpeticum.

In patients with AD, smallpox vaccination, or even exposure to vaccinated individuals, may cause a severe widespread skin rash called eczema vaccinatum that is similar in appearance to eczema herpeticum.[58] An increased risk of fatalities resulting from eczema vaccinatum has been reported in AD. Even if not fatal, eczema vaccinatum is often associated with severe scarring and lifelong complications following recovery from this illness.

Fungi may play a role in chronic inflammation of AD. There has been particular interest in the role of Malassezia (Pityrosporum) in AD. *Malassezia sympodialis* is a lipophilic yeast commonly present in the seborrheic areas of the skin. IgE antibodies against *M. sympodialis* are found in AD patients, most frequently in patients with a head and neck distribution of dermatitis. The potential importance of *M. sympodialis* as well as other dermatophyte infections is further supported by the reduction of AD skin severity in patients treated with antifungal agents.[59] However, even patients with IgE antibodies to *M. sympodialis* often respond better to topical steroids than to topical antifungal therapy, and systemic antifungal therapy may benefit AD patients through antiinflammatory properties.[60]

CONTROL OF PRURITUS AND SLEEP DISTURBANCE

The treatment of pruritus in AD should be directed primarily at the underlying causes. Reduction of skin inflammation and dryness with topical glucocorticoids and skin hydration, respectively, will often symptomatically reduce pruritus. Inhaled and ingested allergens should be eliminated if documented to contribute to eczema. Systemic antihistamines act primarily by blocking the H_1 receptors in the dermis and thereby ameliorating histamine-induced pruritus. However, histamine is only one of many mediators that can induce pruritus of the skin, minimizing benefit from antihistamine therapy. Some antihistamines have anxiolytic agents and may offer symptomatic relief through their tranquilizing and sedative effects. Studies of newer nonsedating antihistamines have shown variable results in the effectiveness of controlling pruritus in AD patients although they may be useful in the subset of AD patients with concomitant urticaria. Because pruritus is usually worse at night, sedating antihistamines such as hydroxyzine or diphenhydramine may offer an advantage with their soporific side-effects when used at bedtime. Doxepin hydrochloride has both tricyclic antidepressant and H_1- and H_2-histamine receptor blocking effects. Thus, it may be useful in treating children and adolescents who do not respond to H_1 sedating antihistamines. If nocturnal pruritus remains severe, short-term use of a sedative to allow adequate rest may be appropriate. Treatment of AD with topical antihistamines or topical anesthetics is not recommended because of potential cutaneous sensitization. Other treatment options for sleep disturbance used by the behavioral health clinicians in the AD program at National Jewish Health include clonidine and melatonin.

Other Treatments

TAR PREPARATIONS

Coal tar preparations may have antipruritic and antiinflammatory effects on the skin.[61] They may also have a beneficial effect on the skin barrier, as a recent study showed that coal tar can increase filaggrin protein in the skin.[62] Tar shampoos can be beneficial for scalp dermatitis. Tar preparations should not be used on acutely inflamed skin because this can result in skin irritation. Side-effects associated with tars include folliculitis and photosensitivity.

PHOTOTHERAPY

Natural sunlight in moderation may be beneficial to patients with AD; however, if the sunlight occurs in the setting of high heat or humidity, triggering sweating and pruritus, it may be deleterious. Broad-band ultraviolet B, broad-band ultraviolet A, narrow-band ultraviolet B (NB-UVB) (311 nm), UVA-1 (340–400 nm) and combined UVAB phototherapy can be useful adjuncts in the treatment of AD. Of note, UVB therapy was shown to increase skin barrier proteins including filaggrin in AD.[63] Studies in children are limited and, in general, UV therapy should be restricted to adolescents, except in exceptional cases.[1] Short-term adverse effects with phototherapy may include erythema, pain, pruritus and pigmentation; long-term adverse effects include premature skin aging and cutaneous malignancies.

SYSTEMIC THERAPY

Children who are considered candidates for systemic therapy should be evaluated by specialists in AD.[1] Patients with refractory AD often will respond to conventional therapy with appropriate education regarding the relapsing nature of AD and proper skin care.[64] In addition, other diseases with eczematous rash may need to be considered (see Box 51-1).

Systemic Glucocorticoids

The use of systemic glucocorticoids, such as oral prednisone, is rarely indicated in the treatment of chronic AD.[1] The dramatic clinical improvement that may occur with systemic glucocorticoids is frequently associated with a severe rebound flare of AD following the discontinuation of systemic glucocorticoids. Short courses of oral glucocorticoids may be appropriate for an acute exacerbation of AD while other treatment measures are being instituted. If a short course of oral glucocorticoids is given, it is important to taper the dosage and begin intensified

https://CafePezeshki.IR

skin care, particularly with topical glucocorticoids and frequent bathing followed by application of emollients, in order to prevent rebound flaring of AD. Patients with oral steroid-dependent AD, or who are treated with frequent courses of systemic steroids, need to be evaluated for corticosteroid side-effects, including adrenal suppression, osteoporosis, cataracts and muscle weakness, and switched to other therapy.

Cyclosporin A

Cyclosporin A (CsA) is a potent immunosuppressive drug that acts primarily on T cells by suppressing cytokine transcription. Studies, including in children, have demonstrated that patients with severe AD, refractory to conventional treatment, can benefit from short-term CsA treatment with reduced skin disease and improved quality of life.[65] A 1-year study of CsA (5 mg/kg/day) in a pediatric population using either intermittent or continuous treatment showed no significant differences between these two approaches with respect to efficacy or safety parameters, and a subset of patients remained in remission after treatment was stopped.[66] In addition, children as young as 22 months of age were shown to respond to low-dose (2.5 mg/kg/day) CsA.[67] Nevertheless, risks must be weighed against benefits and lab parameters, especially serum creatinine and blood pressure, monitored.[1]

Azathioprine

Azathioprine is a purine analog with antiinflammatory and antiproliferative effects. It has been used for severe AD, including in children, although no controlled trials have been reported.[68] Myelosuppression is a significant adverse effect, although thiopurine methyl transferase levels may predict individuals at risk.[1]

Mycophenolate Mofetil

Mycophenolate mofetil (MMF), a purine biosynthesis inhibitor used as an immunosuppressant in organ transplantation, has been used for treatment of refractory inflammatory skin disorders.[1] The drug has generally been well tolerated although herpes retinitis and dose-related bone marrow suppression have been reported. A retrospective analysis of children treated with MMF as systemic monotherapy for severe, recalcitrant AD found that of 14 patients, 4 achieved complete clearance, 4 had >90% improvement, 5 had 60–90% improvement and 1 failed to respond.[69] Initial responses occurred within 8 weeks (mean 4 weeks), and maximal effects were attained after 8 to 12 weeks at MMF doses of 40–50 mg/kg/day in younger children and 30–40 mg kg/day in adolescents. MMF was well tolerated in all patients, with no infectious complications or significant lab abnormalities.

Education of Patients and Caregivers

Education is a critical component of AD management, especially when the disease is severe or relapsing. Important components include teaching about the chronic or relapsing nature of AD, exacerbating factors and therapeutic options with risks versus benefits and prognosis. Strategies include one-on-one communication, direct demonstration with reinforcement, group discussions, classroom teaching and written materials including an AD Home Care or Action Plan. Observing the patient's or caregiver's method of treatment will often reveal fundamental errors which may explain why a patient is not experiencing the expected therapeutic response. Patients or caregivers are often observed applying inadequate amounts of topical medications, layering therapy, thus diluting or blocking specific drugs and misunderstanding the potency of topical corticosteroids based on the misperception that corticosteroid potency is based on the percent value (e.g. 2.5% vs 0.05%), rather than on the specific corticosteroid preparation (e.g. mometasone vs hydrocortisone). AD Home Care or Action Plans are integral to the management of children with AD; without them, patients or caregivers may forget or confuse skin care recommendations.[47] These plans should fit the child's and family's needs and should be reviewed and modified at all follow-up visits.

Providing patients and caregivers with appropriate educational resources is an important component of management. Educational brochures and videos can be obtained from the National Eczema Association (800-818-7546 or www.nationaleczema.org). Information, instruction sheets and brochures including the comprehensive booklet, *Understanding Atopic Dermatitis,* are available from National Jewish Health Lung Line (800 222-LUNG or www.nationaljewish.org) as well as from national organizations such as the American Academy of Allergy, Asthma & Immunology (www.aaaai.org) or the American Academy of Dermatology (www.aad.org).

Wet Wrap Therapy

Wet wrap therapy has been used successfully as part of a step-up therapy regimen for treating severe or recalcitrant AD for over two decades.[70] This therapeutic intervention can improve penetration of topical medications, reduce pruritus and inflammation and act as a barrier against trauma from scratching.[47] A study of wet wraps demonstrated recovery of the epidermal barrier with clinical improvement associated with release of lamellar body and restoration of intercellular lipid lamellar structure.[71] Of note, 1 week after discontinuation of wet wraps, increased water content and decreased transepidermal water loss (TEWL) was still maintained. Wet wrap therapy has been shown to benefit patients during acute flares of AD.[72] This study points to the usefulness of this intervention in acute AD flares and suggests that the time for topical corticosteroid application may be shortened. A technique used successfully at National Jewish Health in Denver employs clothing, such as long underwear and cotton socks, selectively wetted based on distribution of the patient's eczema, applied over an undiluted layer of topical corticosteroids with a dry layer of clothing on top.[47] Treating facial eczema requires nursing skills with wet, followed by dry, gauze expertly applied with spaces for eyes and mouth carefully cut out and secured with a dressing such as surgical Spandage® (Figure 51-4). A DVD demonstrating wrap therapy can be purchased through the Professional Education Department at National Jewish Health (www.nationaljewish.org). Wraps may be removed when they dry out (after approximately 2 hours), however it is often practical to apply them at bedtime and most children are able to sleep with them on. Overuse of wet wraps may result in chilling or maceration of the skin and may be complicated by secondary infection. However, a controlled study of wet wrap therapy with topical corticosteroids found that *S. aureus* colonization was decreased with this intervention.[73] While use of wet wrap therapy over topical calcineurin inhibitors is not indicated on current package labeling, this approach is used 'off-label' by clinicians. Wet wrap therapy

https://CafePezeshki.IR

Figure 51-4 Facial eczema treated with wet, followed by dry, gauze, and secured with a dressing such as surgical Spandage®. *(Reprinted from Boguniewicz M, Nicol N, Kelsay K, et al. A multidisciplinary approach to evaluation and treatment of atopic dermatitis. Semin Cutan Med Surg 2008;27:115–27, with permission from Elsevier.)*

should be thought of as an acute crisis intervention, not as part of maintenance therapy, although occasionally it can be used on a more chronic basis to select areas of resistant dermatitis with appropriate monitoring. An evidence-based critical review of wet wrap therapy in children concluded, with a grade C recommendation, that: (1) wet wrap therapy using cream or ointment and a double layer of cotton bandages, with a moist first layer and a dry second layer, is an efficacious short-term intervention treatment in children with severe and/or refractory AD; (2) the use of wet wrap dressings with diluted topical corticosteroids is a more efficacious short-term intervention treatment in children with severe and/or refractory AD than wet wrap dressings with emollients only; (3) the use of wet wrap dressings with diluted topical corticosteroids for up to 14 days is a safe intervention treatment in children with severe and/or refractory AD, with temporary systemic bioactivity of the corticosteroids as the only reported serious side-effect; (4) lowering the absolute amount of applied topical corticosteroid to once daily application and further dilution of the product can reduce the risk of systemic bioactivity.[74] Recently, the largest controlled study of wet wrap therapy in children using a validated scoring tool and patient questionnaire showed that in patients with moderate to severe AD, SCORAD improved significantly and, importantly, the benefit of this intervention could be demonstrated one month after discharge from the program, even though the treatment itself was discontinued before discharge (used for an average of 4 days).[75] Importantly, none of these patients required treatment with a systemic immunosuppressive agent.

Multidisciplinary Approach to Atopic Dermatitis

Given the complex nature of AD, its relapsing course and incompletely understood pathogenesis, a significant number of patients have suboptimal outcomes with their prescribed treatment regimens. In addition, there is a significant impact on the quality of life of patients and families that leads to frustration and often a search for alternative therapies, which may not be in the best interest of the child. While children with AD of all severities could benefit from a multidisciplinary approach, those who especially should be considered candidates include those failing conventional therapy, those with recurrent skin infections, those diagnosed with multiple food allergies, those whose disease is having a significant impact on their or their family's quality of life, those with concerns about medication side-effects and those with need for in-depth education. The significant and sustained clinical improvement often seen in patients treated with a multidisciplinary approach may be due, in large part, to in-depth, hands-on education, along with changes in environmental exposures, reduction in stressors and assurance of adherence with therapy. Of note, a high percentage of these patients experience significant improvement, even when treated with medications that previously were believed to be ineffective, when the treatment is integrated into a comprehensive and individualized management program.

The Atopic Dermatitis Program (ADP) at National Jewish Health in Denver, Colorado, consists of a team of pediatric allergist-immunologists with extensive experience in basic and clinical research in AD, a nurse practitioner/dermatology clinical specialist, pediatric psychiatrist, child psychologists, allergy-immunology fellows-in-training, physician assistants, nurse educators, child life specialists, creative art therapist, social workers, dietitians and rehabilitation therapists.[47] Dermatologists are available for consultation if the diagnosis of AD is in question or phototherapy is being considered. Patients undergo comprehensive evaluation and treatment that is tailored to their needs and the goals of the family. Our ADP provides single-day consultations, multi-day outpatient clinic visits, rarely inpatient hospitalization or a day program for more extensive evaluation, education and treatment typically over 5 to 14 days. In the controlled environment of the day program, patients and caregivers interact with members of the multidisciplinary team and, importantly, with other patients and families in group meetings and informal settings. In addition, sleep disturbance and response to interventions can be evaluated with overnight observation.[76]

ALLERGEN IMMUNOTHERAPY

Allergen-specific immunotherapy (AIT) has been added as a therapeutic consideration in the most recent AD Practice Parameter Update for selected AD patients with environmental allergies, based on studies with house dust mite immunotherapy.[1] Most of the studies have been done in adult patients and, anecdotally, patients on AIT may have flares of their eczema with allergen injections. Well-controlled studies in children with AD are still required to determine the role for AIT in this disease. In addition, preliminary studies with sublingual immunotherapy suggest a role for a subset of children with AD sensitized to dust mite allergen,[77] but again these data need to be reproduced in a larger pediatric population, especially in light of the natural history of AD for different subsets of patients.

Investigational or Unproven Therapy

INTRAVENOUS IMMUNOGLOBULIN

High-dose intravenous immunoglobulin (IVIG) could have immunomodulatory effects in AD. In addition, IVIG could

https://CafePezeshki.IR

interact directly with microbes or toxins involved in the pathogenesis of AD. IVIG has been shown to contain high concentrations of staphylococcal toxin-specific antibodies that inhibit the in vitro activation of T cells by staphylococcal toxins.[78]

Treatment of severe refractory AD with IVIG has yielded conflicting results. Studies have not been controlled and have involved small numbers of patients.[79,80] Children appear to have a better response than adults, including to IVIG as monotherapy, and the duration of response was also shown to be more prolonged in children. However, additional controlled studies are needed to establish efficacy in a more definitive manner.

INTERFERON-γ

IFN-γ is known to suppress IgE responses and down-regulate Th2 cell proliferation and function. Several studies of patients with AD, including a multicenter, double-blinded, placebo-controlled trial, have demonstrated that treatment with recombinant IFN-γ results in clinical improvement.[81] Reduction in clinical severity of AD was correlated with the ability of IFN-γ to decrease total circulating eosinophil counts. Influenza-like symptoms are commonly observed side-effects seen early in the treatment course.

PROBIOTICS

Data from one meta-analysis suggest a modest role for probiotics in children with moderately severe disease in reducing the Scoring of Atopic Dermatitis Severity Index score (mean change from baseline, −3.01; 95% confidence interval, −5.36 to −0.66; $P = .01$).[82] Duration of probiotic administration, age and type of probiotic used did not affect outcome. Another meta-analysis found that current evidence is more convincing for probiotic efficacy in prevention rather than treatment of pediatric AD.[83] On the other hand, supplementation with Lactobacillus GG during pregnancy and early infancy neither reduced the incidence of AD nor altered the severity of AD in affected children, but was associated with an increased rate of recurrent episodes of wheezing bronchitis.[84] A Cochrane review concluded that probiotics are not an effective treatment for eczema in children and that probiotic treatment carries a small risk of adverse events.[85] In contrast, a more recent meta-analysis of randomized controlled trials through 2011 that attempted to overcome some of the limitations of earlier reviews found a reduction of approximately 20% in the incidence of AD and IgE-associated AD in infants and children with probiotic use.[86] To add to the continued uncertainty, a study in pregnant women and infants up to age 6 months given a multistrain probiotic did not show any difference in diagnosis of eczema at 2 years compared to placebo.[87] However, the frequency of allergic sensitization and allergic eczema (defined as eczema with one or more positive allergy skin tests) was significantly reduced.

VITAMIN D

Vitamin D deficiency is being increasingly recognized in the US population and may play a role in various allergic illnesses.[88] Of interest, vitamin D may play an important role in regulation of antimicrobial peptides in keratinocytes as discussed in Chapter 50.[89] A trial with oral vitamin D supports this hypothesis.[90] In one small pediatric study, children with AD were treated with oral vitamin D in a randomized, controlled trial. Investigator Global Assessment (IGA) score improved by 1 IGA category in 4 of 5 subjects treated with vitamin D versus 1 of 6 on placebo. Similar improvements were seen for change in the eczema area and severity index (EASI) score.[91] The updated Practice Parameter states that patients with AD may benefit from supplementation with vitamin D, particularly if they have low vitamin D levels or low dietary intake.[1]

OMALIZUMAB

Anecdotal reports suggest clinical benefit in some patients with AD, including children treated for their asthma with monoclonal anti-IgE (omalizumab) subcutaneous injections.[92] Adult patients with severe AD and significantly elevated serum IgE levels did not show benefit when omalizumab was used as monotherapy.[93] In contrast, significant improvement in three adolescent patients was observed when omalizumab was added to the usual therapy.[94] In addition, in an open study of 7 patients (aged 6–19 years) with severe AD treated with omalizumab, baseline SCORAD was 75.4 (53–96.2) with mean serum IgE 16,007 IU/L (7,520–35,790 IU/L).[95] After 12 months of treatment, mean SCORAD was 30.0 (16.2–43), a mean improvement of 45.6 (31.6–59.6; $P < .0005$). Specific markers have not been found to identify potential responders although a recent study suggested that adult AD patients who respond are wild type for filaggrin mutations.[96] At present, omalizumab remains an investigational therapy in AD.

Conclusions

AD is a common, genetically transmitted inflammatory skin disease frequently found in association with respiratory allergy. Key management concepts include protection of the skin barrier, skin hydration, avoidance of irritants and proven allergic triggers and effective use of topical antiinflammatory agents (Box 51-2). Education of patients and caregivers is an essential part of treating AD patients of all levels of severity and a multidisciplinary approach to management may be the best approach for a number of patients. Better understanding of the complex genetic and immunoregulatory abnormalities underlying AD may allow for development of more specific treatments and suggest new paradigms for managing this disease.

BOX 51-2 THERAPEUTIC PRINCIPLES

ATOPIC DERMATITIS

- Proper skin hydration and moisturizers are needed to repair and help preserve skin barrier function.
- Topical antiinflammatory therapy can be used for both treatment of acute flares and prevention of relapses.
- Avoidance of proven food and inhalant allergens may prevent or lessen flares.
- Measures to decrease microbial colonization can improve atopic dermatitis.
- Sedating antihistamines may provide symptomatic relief through sedating side-effects.
- Addressing the psychosocial aspects of a chronic, relapsing illness and providing education with written skin care instructions can lead to improved outcomes.

52 Urticaria and Angioedema

BRUCE L. ZURAW

KEY POINTS

- The distinction between acute and chronic urticaria/angioedema has important diagnostic and therapeutic implications. Recurrent angioedema without urticaria suggests the possibility of hereditary angioedema.
- The most common type of swelling in children is acute urticaria/angioedema. The cause of acute urticaria can often be determined and is most likely to involve IgE-mediated reactions, viral infections or bites and stings.
- Chronic urticaria/angioedema is typically idiopathic; however, physical stimuli often contribute to the symptoms. Extensive diagnostic evaluation of chronic urticaria is usually not warranted.
- First-line treatment of urticaria/angioedema is nonsedating antihistamines with dosing up to four times the usual dose if necessary.
- Omalizumab or cyclosporine may be considered for patients with chronic urticaria who do not respond to high-dose antihistamines and do not have an underlying urticarial vasculitis.

Urticaria (hives or wheals) typically presents as a pruritic generalized eruption with erythematous circumscribed borders and pale, slightly elevated centers (Figure 52-1A). Angioedema is characterized by an asymmetric nondependent swelling that is generally not pruritic (Figure 52-1B). The pathophysiology of urticaria and angioedema is similar and is due to increased vascular permeability. However, the underlying mechanisms can be very distinct: mast cells are usually implicated in urticaria but bradykinin may be the cause in angioedema. Affected patients may manifest symptoms that range from transient and mildly annoying hives to severe and potentially fatal angioedema. Quality of life has been reported to be moderately to severely impaired in patients with chronic urticaria,[1–3] and children with chronic urticaria exhibit significantly greater psychiatric morbidity than controls.[4] An efficient and cost-effective approach to the management of urticaria and angioedema depends on a careful assessment of the characteristics and likely cause of the swelling. This chapter provides a framework to differentiate the various types of urticaria and angioedema, then outlines a directed evaluation and treatment plan based on the etiology (Box 52-1).

Epidemiology/Etiology

EPIDEMIOLOGY

Urticaria/angioedema is conventionally classified as either *acute* or *chronic,* the latter being defined as the continuous or frequent occurrence of lesions for longer than 6 weeks.[5] While arbitrary, this distinction has significant implications regarding the cause, course and treatment of the swelling. Most urticaria/angioedema is acute, particularly in children. Acute urticaria/angioedema can occur during anaphylaxis, and this possibility needs to be considered when urticaria or angioedema is associated with respiratory, gastrointestinal, cardiovascular or nervous system involvement. Approximately 50% of affected patients experience both urticaria and angioedema, 40% only urticaria, and 10% only angioedema.[6] Surveys have indicated that 15% to 23% of the population experience urticaria at least once during their lifetime,[7] while the prevalence of chronic urticaria is estimated to be 0.5% to 5%, with females over-represented.[8,9] Atopic individuals are at increased risk for acute urticaria/angioedema and some forms of physical urticaria; however, most patients with chronic urticaria/angioedema are not atopic.

The prevalence of hereditary angioedema (HAE) due to C1 inhibitor (C1INH) deficiency (HAE-C1INH) is approximately 1:50,000. The prevalence of HAE with normal C1INH (HAE-nlC1INH) is unknown but likely less than HAE-C1INH. Acquired C1INH deficiency is only seen in adults and has an estimated prevalence of 1:500,000. Bradykinin-mediated angioedema can also be associated with use of angiotensin-converting enzyme inhibitors and possibly with recurrent idiopathic angioedema.

ETIOLOGY

Most urticaria/angioedema is caused by mast cell degranulation with released mediators causing activation of sensory nerves, vasodilation, plasma extravasation, up-regulation of endothelial cell adhesion molecules and recruitment of inflammatory cells.[10–12] Basophils may also play an important role.[13] The causes of mast cell degranulation in urticaria/angioedema are variable. IgE-mediated mast cell degranulation is responsible for many cases of acute urticaria/angioedema in children, most commonly from drugs and foods. Many acute and most chronic urticaria/angioedema cases involve mast cell activation due to nonimmunologic or immune processes not involving IgE, such as direct mast cell degranulators, viral infections, anaphylatoxins, various peptides/proteins and several types of physical stimuli. Viral infections are the most common cause of acute urticaria in children.[14,15]

The underlying cause of mast cell degranulation in chronic urticaria/angioedema usually cannot be determined. Lesions demonstrate a nonnecrotizing mononuclear cell infiltrate around small venules, with increased numbers of basophils, eosinophils and T helper cells.[10,16] Filaggrin is overexpressed in urticarial lesions, the level correlating with urticaria severity.[17] Activation of thrombin with subsequent generation of C5a has also been suggested as a potential underlying mechanism in chronic urticaria.[18] Some children with celiac disease and severe

BOX 52-1 KEY CONCEPTS

Urticaria and Angioedema

- The distinction between acute and chronic urticaria/angioedema has important diagnostic and therapeutic implications.
- The most common type of swelling in children is acute urticaria/angioedema.
- The cause of acute urticaria can usually be determined and is most likely to involve IgE-mediated reactions, viral infections or bites and stings.
- The cause of chronic urticaria/angioedema is typically idiopathic; however, physical stimuli often contribute to the symptoms.
- Chronic urticaria/angioedema must be distinguished from urticarial vasculitis.
- Recurrent angioedema without urticaria suggests the possibility of hereditary angioedema.
- Most cases of chronic urticaria/angioedema resolve within 3 to 4 years.

chronic urticaria showed improvement of the urticaria following institution of a gluten-free diet.[19] At least 40% of patients with chronic urticaria have circulating autoantibodies with specificity for IgE or the high-affinity FcεR.[20–22] Skin testing with autologous serum or plasma may detect these antibodies.[23] Approximately 30% of children with chronic urticaria have positive autologous serum skin tests.[24,25] The functional and prognostic significance of these autoantibodies remains unclear.

An increased prevalence of thyroid antimicrosomal and antithyroglobulin antibodies has been described in urticaria/angioedema, with about half of these patients having goiters or abnormal thyroid function;[26–29] however, no causal relationship has been demonstrated.[30] Conversely, an increased cumulative prevalence of urticaria/angioedema has been found in thyroid disease patients with antimicrosomal and antithyroglobulin antibodies (primarily Hashimoto's thyroiditis) but not in patients with other types of thyroid disease.[31] Activation of complement by the complement controller domain of thyroperoxidase has been suggested to be an important contributor to development of urticaria/angioedema in patients with thyroid autoimmunity.[32] An association between urticaria and a variety of autoimmune diseases has also been described, although the nature of the relationship remains uncertain.[33,34]

Severe urticaria/angioedema associated with marked weight gain, pronounced leukocytosis and striking eosinophilia (Gleich syndrome) has been shown to involve increased serum levels of cytokines (including IL-5) during attacks.[35,36] Other cases of urticaria/angioedema have been reported in association with parathyroid disease, polycythemia vera, hemolytic uremic syndrome, Schnitzler syndrome (chronic urticaria, monoclonal IgM, arthralgia, fever and adenopathy) and pregnancy.[37] Cyclical urticaria occurring prior to menses may be an autoimmune progesterone-induced dermatitis.[38] Genetic causes of swelling include HAE, Muckle-Wells syndrome, vibratory angioedema, familial cold autoinflammatory syndrome, familial localized heat urticaria of delayed type, erythropoietic protoporphyria with solar urticaria, C3 inactivator deficiency with urticaria, and serum carboxypeptidase N deficiency with angioedema.

HAE-C1INH is an autosomal dominant disease caused by a functional deficiency of the plasma protein C1INH. Two major types of HAE-C1INH have been described: type I HAE comprises 85% of cases and is characterized by low C1INH antigenic and functional levels; type II HAE comprises the other 15% of cases and is characterized by normal C1INH antigenic levels with low C1INH functional activity due to secretion of a dysfunctional protein.[39] Type I and type II HAE are caused by mutations in the C1INH gene (*SERPING1*), resulting in increased plasma kallikrein activity and generation of the vasoactive mediator bradykinin.[39] Familial recurrent angioedema with normal C1INH gene and protein was originally called type III HAE,[40,41] but has now been named HAE-nlC1INH.[42] Initially thought to affect primarily women exposed to increased estrogen levels, it has become clear that both men and women are affected, with a variable effect of estrogens.[42] Several coagulation factor XII gene mutations have been found in a minority of HAE-nlC1INH kindreds;[43] however, the underlying cause of the disease remains unclear. C1INH deficiency may also be acquired; however, this occurs primarily in older adults and has not been reported in children.

Familial cold autoinflammatory syndrome and Muckle-Wells syndrome have been shown to be associated with mutations in a gene that encodes cryopyrin.[44] The family of autoinflammatory urticarial syndromes is referred to as cryopyrinopathies.[45] Neonatal-onset multisystem inflammatory disease (NOMID) is a particularly severe cryopyrinopathy. The IL-1 receptor antagonist anakinra has been used successfully to prevent attacks.[46,47] A hereditary cold urticaria syndrome due to genomic deletions of *PLCG2* has been shown to lead to a gain of phospholipase Cγ2 function associated with antibody deficiency, susceptibility to infection, and autoimmunity.[48,49]

Differential Diagnosis

Recognition of urticaria and angioedema on examination is generally straightforward. The single most important step in the differential diagnosis is to visualize the lesions during swelling. Individual urticarial lesions seldom last for more than a few hours (up to 24 hours), which distinguishes urticaria from almost all other skin diseases. In addition, urticarial lesions blanch with pressure and new hives frequently develop as the older ones fade. If the lesions do not itch, the diagnosis should be reconsidered. Angioedema is not dependent and is typically

https://CafePezeshki.IR

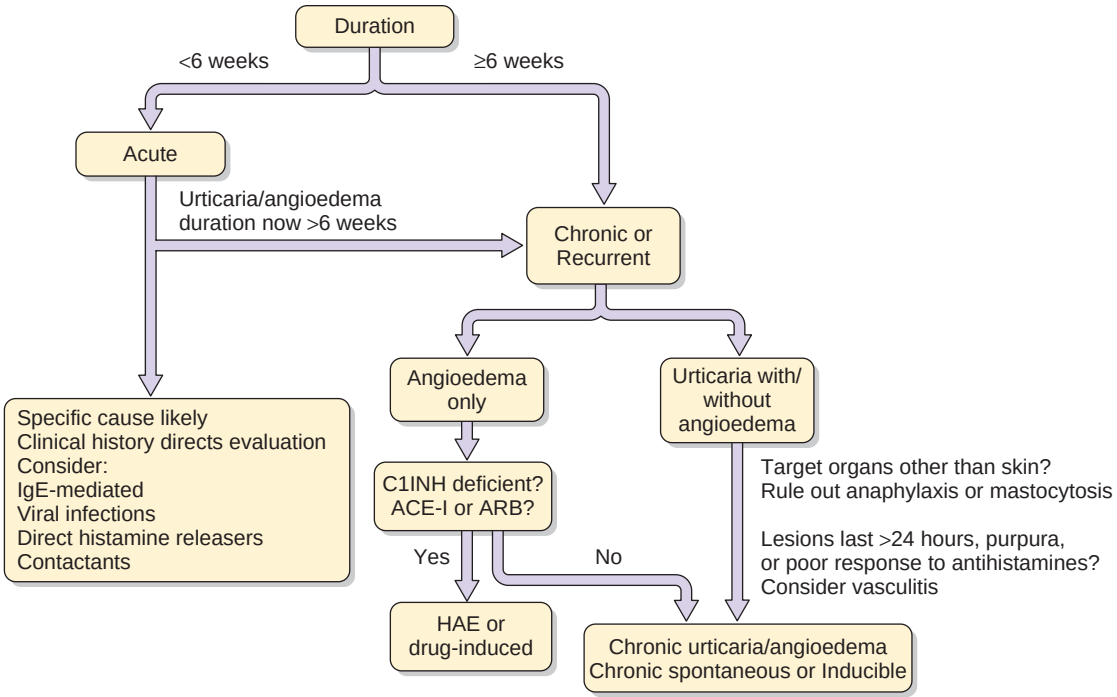

Figure 52-2 Diagnostic algorithm for urticaria/angioedema. *ACE-I* – Angiotensin-converting enzyme inhibitor, *ARB* – angiotensin II receptor blocker, *HAE* – hereditary angioedema.

not symmetrical. Figure 52-2 presents an algorithm for the approach to the differential diagnosis.

ACUTE URTICARIA/ANGIOEDEMA

Acute urticaria/angioedema by definition lasts less than 6 weeks and is most commonly caused by exposure to allergens, toxins or sensitizers, or infections. A cause for acute urticaria/angioedema can frequently be determined. Most cases in children will be secondary to IgE-mediated reactions or viral infections.[14,15] Penicillin and other antibiotics frequently cause urticaria/angioedema. The most common foods associated with IgE-mediated urticaria/angioedema vary with the age of the patient. In younger children, egg, milk, soy, peanut and wheat are the most common allergens, whereas fish, seafood, nuts and peanuts are common offenders in older children.[50] Acute urticaria can also be triggered by ingestion of fish containing high levels of bioactive amines in the absence of specific IgE (scombroid poisoning).[51] Urticaria and angioedema are the most common manifestations of anaphylactic reactions to insect stings and bites. Immunologic reactions to the saliva of bedbugs, fleas or mites can cause papular urticaria, especially on the legs of children. Recently, acute urticaria/angioedema occurring 3 to 6 hours following the ingestion of beef, pork, lamb or venison has been described in patients with IgE against galactose-α-1,3-galactose.[52] Urticaria multiforme (or acute annular urticarial hypersensitivity) is distinguished by transient annular urticarial lesions, often accompanied by angioedema, that respond to antihistamines.[53]

Urticaria/angioedema can also result from exposure to direct mast cell degranulators (such as strawberries, narcotic drugs, polymyxin antibiotics, D-tubocurarine or dextran volume expanders), penetrating substances (such as nettles, Portuguese man-of-war, other forms of sea life, moth and butterfly scales, tarantula hairs or caterpillar foot processes), or substances that can produce urticaria on contact with intact skin (such as latex, industrial chemicals, benzoic acid, sorbic acid and numerous other agents).[54] Aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) can provoke acute urticaria/angioedema in children and adults.[55,56]

CHRONIC URTICARIA/ANGIOEDEMA

This is a diagnosis of exclusion, based on history, examination and carefully selected testing. No clear relationship has been found between chronic urticaria and food allergy, ingestion of food additives or focal infections.[57,58] Parasitic infestations may be suggested by finding substantial eosinophilia, elevated IgE level, abdominal symptoms or a history of recent foreign travel. *Helicobacter pylori* infection has also been suggested as having a link to chronic urticaria.[59–61]

Chronic urticaria is further subdivided into chronic spontaneous urticaria (CSU, previously referred to as chronic idiopathic urticaria) or inducible urticaria (previously known as physical urticaria) based on whether there is a precipitating stimulus.[62] CSU has no identifiable cause and is the most common form of chronic urticaria/angioedema. Patients with CSU may have autoimmune features (see above). Inducible urticaria involves mast cell degranulation precipitated by discrete physical stimuli (Table 52-1). Inducible urticaria is often but not always encountered in the setting of co-existing CSU. The percentage of children in whom chronic urticaria also has a physical component ranges from 1% to >10%.[63] Patients may swell in response to one or several physical stimuli, including mechanical pressure or stroking, heat or cold, sunlight or water. Specific physical challenges can be performed to confirm inducible urticaria/angioedema. Dermographism may occur in up to 2% to 5% of the general population (Figure 52-3A), and can

https://CafePezeshki.IR

TABLE 52-1 Major Physical Urticaria Syndromes

Type	Provoking Stimuli	Diagnostic Test	Comment
Mechanically Provoked			
Dermographism (urticaria factitia)	Rubbing or scratching of skin causes linear wheals	Stroking the skin (especially the back) elicits a linear wheal	Primary (idiopathic or allergic) or secondary (urticaria pigmentosa or transient following virus or drug reaction)
Delayed dermographism	Same	Same	Rare
Delayed-pressure urticaria	At least 2 hr after pressure is applied to the skin, deep, painful swelling develops, especially involving the palms, soles and buttocks	Attach two sandbags or jugs of fluid (5–15 lb) to either end of a strap and apply over the shoulder or thigh for 10 to 15 min. A positive test exhibits linear wheals or swelling after several hours	Can be disabling and may be associated with constitutional symptoms such as malaise, fever, arthralgia, headache and leukocytosis
Immediate-pressure urticaria	Hives develop within 1 to 2 min of pressure	Several minutes of pressure elicit hives	Rare; seen in conjunction with hypereosinophilic syndrome
Thermally Provoked			
Acquired cold urticaria	Change in skin temperature rapidly provokes urticaria	Place ice cube on extremity for 3 to 5 min, then observe for pruritic welt and surrounding erythema as the skin rewarms over subsequent 5 to 15 min	Relatively common, may occur transiently with exposure to drugs or with infections; other rare cases may be associated with cryoproteins or may be transferable by serum
Familial cold autoinflammatory syndrome	Intermittent episodes of rash, arthralgia, fever and conjunctivitis occur after generalized exposure to cold	Symptoms occur 2 to 4 hr after exposure to cold blowing air	Autosomal dominant inflammatory disorder previously called familial cold 'urticaria'; results from mutation of *CIAS1* gene, coding for cryopyrin
Cholinergic urticaria	Heat, exertion or emotional upsets cause small punctate wheals with prominent erythematous flare. May be related more to sweating than to heat per se	Methacholine cutaneous challenge is sometimes helpful; better to reproduce the lesions by exercising in a warm environment or while wearing a wetsuit or plastic occlusive suit	Differs from exercise-induced anaphylaxis in that it features smaller wheals and is induced by heat as well as by exercise but does not generally cause patients to collapse. Relatively common in patients with chronic urticaria; can be passively transferred by plasma in some patients
Localized heat urticaria	Urtication occurs at sites of contact with a warm stimulus	Hold a test tube containing warm water against the skin for 5 min	Rare
Miscellaneous Provoked			
Solar urticaria	Urticaria develops in areas of skin exposed to sunlight	Controlled exposure to light; can be divided depending on the wavelength of light eliciting the lesions	Types include genetic abnormality in protoporphyrin IX metabolism as well as types that can be passively transferred by IgE in serum
Aquagenic urticaria	Tiny perifollicular urticarial lesions develop after contact with water of any temperature	Apply towel soaked in 37°C water to the skin for 30 min	Rare; systemic symptoms can occur; females affected more than males; familial form has been described

account for the majority of hives in some patients.[7] Delayed pressure urticaria is more angioedematous than urticarial and causes significant morbidity.[2] Primary and secondary acquired forms of cold urticaria have been described.[64] Primary acquired cold urticaria is often seen in children and is frequently associated with asthma, allergic rhinitis and progression to frank anaphylaxis.[65] Patients with acquired cold urticaria have drowned when exposed to cold water, and must be warned to avoid cold water and never to swim alone. Cold urticaria should be distinguished from familial cold autoinflammatory syndrome, which is marked by cold-induced erythematous rash, fever, arthralgias, leukocytosis and conjunctivitis.[44] Cholinergic urticaria (Figure 52-3B) is relatively common in children, may be confused with exercise-induced anaphylaxis, and can be associated with angioedema, wheezing or even syncope.[66] Persistent cholinergic erythema, a variant of cholinergic urticaria, can be mistaken for a drug eruption or cutaneous mastocytosis.[67] Many patients have combinations of different physical urticarias, such as cold and cholinergic urticaria, cold and localized heat urticaria, or dermographism with cold urticaria.

Idiopathic anaphylaxis often includes a prominent component of urticaria or angioedema and can be difficult to distinguish from severe urticaria/angioedema.[68] The angioedema of idiopathic anaphylaxis can also resemble HAE; however, a positive family history as well as complement abnormalities will clearly identify HAE-C1INH.

Urticarial vasculitis must be distinguished from chronic idiopathic urticaria/angioedema. When flagrant, urticarial

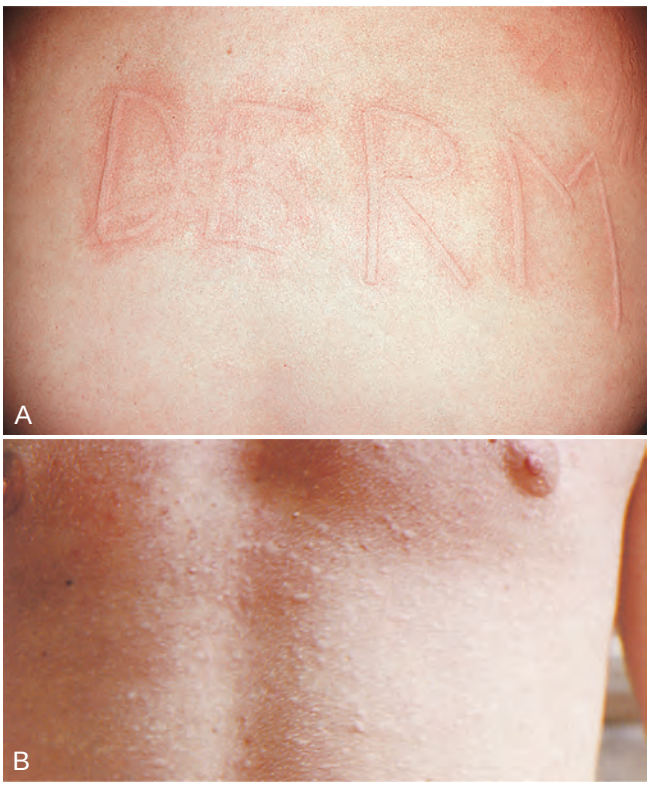

Figure 52-3 Examples of physical urticaria. (A) Dermographism. *(From Weston WL, Morelli JG, Lane A, editors. Color textbook of pediatric dermatology. 3rd ed. St Louis: Mosby; 2002.)* (B) Cholinergic urticaria. *(From Fireman P, Slavin R, editors. Atlas of allergies. 2nd ed. London: Mosby-Wolfe; 1996.)*

vasculitis is characterized by palpable purpura and bruising or discoloration that persists after the hive disappears. Persistence of individual urticarial lesions for more than 24 hours or a poor response to antihistamine therapy may suggest the possibility of urticarial vasculitis, which ranges from relatively benign cutaneous hypersensitivity vasculitis to the hypocomplementemic urticarial vasculitis syndrome.[69,70] In children, most cases of cutaneous vasculitis represent Henoch-Schönlein purpura or hypersensitivity vasculitis.[71] The hypocomplementemic urticarial vasculitis syndrome is rarely seen in children.[72]

ANGIOEDEMA

Angioedema is usually associated with urticaria that is nondependent, asymmetric and nonpruritic. When it occurs with urticaria, the diagnosis and treatment of angioedema mirrors the parameters described for urticaria. Recurrent angioedema without urticaria (including recurrent unexplained abdominal pain) should suggest a possible diagnosis of HAE. Accurate diagnosis of HAE is essential to avoid morbidity and mortality;[73] however, delays in HAE diagnosis are the rule rather than the exception. Repeated surveys have shown a 10- to 20-year interval between onset of symptoms and establishment of the correct diagnosis.[74] Half of all HAE patients begin swelling during the first decade of life, with almost all patients manifesting symptoms by age 18.[75]

Angioedema may also occur during the treatment of hypertension with angiotensin-converting enzyme (ACE) inhibitors or, less commonly, with angiotensin II receptor blockers.[76] ACE is a peptidase that degrades bradykinin (among other peptides), and the mechanism of ACE inhibitor-associated angioedema is suspected to be due to diminished catabolism of bradykinin.[77] There are also several forms of facial edema that can be confused with angioedema, including the granulomatous cheilitis accompanying Crohn's disease and the Melkersson-Rosenthal syndrome (a rare syndrome of recurrent orofacial swelling, relapsing facial paralysis and fissured tongue).

Evaluation and Management

HISTORY

A discerning history is the most important diagnostic procedure in the evaluation of urticaria/angioedema. One should determine whether the urticaria/angioedema is acute or chronic, the duration of the individual lesions, the presence of pruritus (a defining symptom for urticaria), *when* lesions occur, *where* the patient is when lesions occur, *what* has the patient suspected, and the response to prior treatment. Specific inquiry should be made about drugs (including over-the-counter products), foreign sera, foods, food additives, herbal or homeopathic treatments, psychologic factors, inhalants, bites and stings, direct contact of skin with various agents, connective tissue diseases and exposure to physical agents. Associated respiratory, gastrointestinal or musculoskeletal symptoms should be inquired about.

In many patients, the disease is aggravated by vasodilating stimuli such as heat, exercise, emotional stress, alcoholic drinks, fever and hyperthyroidism. Premenstrual exacerbations also are common. Aspirin and other cyclooxygenase (COX)-1 inhibiting NSAIDs can cause acute urticaria or lead to exacerbations in up to 30% of patients. A retrospective review of 1,007 charts of atopic children revealed that 41 (4.07%) had experienced NSAID-induced facial angioedema.[78] Intermittent use of NSAIDs was associated with a higher rate of angioedema than chronic regular use.[79] COX-2 inhibitors and acetaminophen do not typically trigger urticaria or angioedema.[55,80]

Angioedema attacks in HAE-C1INH have distinct manifestations, including: prolonged duration (typically 72 or more hours); frequently triggered by minor trauma or stress; often preceded by a prodromal syndrome; displaying periodicity with attacks of angioedema interspersed by periods of remission (daily episodes suggest an alternate diagnosis); swelling most commonly affecting the extremities, face, gastrointestinal tract or upper airway; and a history of lack of response to prior treatment with antihistamines, corticosteroids or epinephrine.[74] Virtually all HAE-C1INH patients experience extremity and gastrointestinal attacks during their lifetime. Abdominal attacks can be severe, and may resemble a surgical abdomen. Recurrent school absences because of abdominal pain may be a presenting symptom. It is not unusual to obtain a history of a normal exploratory laparotomy for presumed appendicitis. Laryngeal attacks are considerably less common, although over 50% of HAE-C1INH patients will experience a laryngeal attack at some point in their life. Angioedema of the larynx in HAE-C1INH can result in closure of the airway and asphyxiation. In the past, over 30% of HAE-C1INH patients died from airway attacks.[74] A positive family history of angioedema can usually be elicited although up to 25% of HAE-C1INH patients have de novo *SERPING1* mutations.[81]

https://CafePezeshki.IR

HAE-nlC1INH is also characterized by recurrent prolonged attacks of angioedema that can cause asphyxiation.[40,41,82] Attack frequency varies considerably between affected individuals, from carriers who are asymptomatic to patients with multiple attacks per year. There is a striking female preponderance of patients, and affected women tend to have more severe symptoms than affected men.[83,84] Like HAE-C1INH, the inheritance pattern of HAE-nlC1INH is autosomal dominant; however, the penetrance is often much lower with evidence of obligate asymptomatic carriers, particularly men. HAE-nlC1INH patients appear to manifest symptoms at a somewhat older age than HAE-C1INH patients.[85] They are also less likely to suffer abdominal attacks.

PHYSICAL EXAMINATION

Urticarial lesions typically are generalized and may involve any part of the body. Individual lesions often coalesce into large lesions. Angioedema is usually asymmetric and typically involves loose connective tissue such as the face or mucous membranes such as the lips or tongue. Occasionally, the appearance of the lesions gives a clue as to the type of urticaria being encountered: linear wheals suggest dermographism; small wheals surrounded by large areas of erythema suggest cholinergic urticaria; wheals limited to exposed areas suggest solar or cold urticaria; and wheals mainly on the lower extremities suggest papular urticaria or urticarial vasculitis.

DIAGNOSTIC PROCEDURES

The laboratory evaluation of patients with urticaria or angioedema must be tailored to the clinical situation. In most cases no specific etiology can be established, and the diagnostic approach should therefore be carefully selected and cost effective. If the history or examination provides clues to the cause of the urticaria/angioedema, the evaluation should be pursued using the appropriate tests (e.g. skin testing to confirm IgE-mediated food or drug allergy). In the absence of a specific likely cause, the laboratory evaluation should be minimal.[37,62] Box 52-2 summarizes a limited laboratory evaluation that could be performed in patients with chronic urticaria/angioedema. Because the cause of chronic urticaria or angioedema is not related to extrinsic allergen exposure in the vast majority of cases, routine skin testing is not cost effective.[37] Patients with a history suggestive of physical urticaria may be challenged to confirm the diagnosis (see Table 52-1).[37]

Patients with recurrent angioedema without urticaria should be evaluated for HAE with complement testing, which can readily establish the diagnosis of type I or type II HAE (Table 52-2). HAE-nlC1INH patients have a normal C4 as well as normal C1INH antigenic and functional levels. Consensus criteria for making a diagnosis of HAE-nlC1INH have recently been published.[42] A minority of HAE-nlC1INH patients may have a mutation in the *F12* gene, and testing for these mutations is warranted in suspected cases.

Treatment

Reassurance is an important aspect of therapy for urticaria/angioedema. Skin lesions are often more frightening in appearance than the generally favorable prognosis warrants and are self-limited. Most urticaria/angioedema spontaneously remits without any irreversible damage. Patients should, however, be made aware of the need for an emergency room visit if laryngeal edema occurs. If the patient has experienced laryngeal edema, many physicians would prescribe and instruct the patient in the use of self-injectable epinephrine. However, one should avoid generating undue anxiety about laryngeal edema because the only known fatalities from this cause have been in patients with HAE, angiotensin-converting enzyme inhibitor-associated angioedema or anaphylactic reactions.

Guidelines for treating patients with urticaria/angioedema are summarized in Box 52-3. Obviously the preferred treatment is avoidance of causative agents when these can be identified. An explanation of the disease process and its triggers should

BOX 52-2 SUGGESTED TESTING FOR CHRONIC URTICARIA/ANGIOEDEMA OF UNKNOWN ETIOLOGY

BASIC TESTS

Routine screening:
- Complete blood count (CBC) with differential
- Erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP)

Optional tests based on history and physical:
- Liver function tests
- Antimicrosomal antibodies, antithyroglobulin antibodies
- Anti-FcεR or anti-IgE antibodies or autologous skin testing
- Stool for ova and parasites
- Physical challenges
- C4, C1INH antigen, C1INH function

DISCRETIONARY TESTS BASED ON EVALUATION

If vasculitis is suspected:
- Antinuclear antibody
- Skin biopsy
- CH_{50}
- Rheumatoid factor
- Cryoglobulins

If liver function tests abnormal:
- Serology for viral hepatitis

If HAE-nlC1INH is suspected
- *F12* mutation

BOX 52-3 THERAPEUTIC PRINCIPLES

Treatment of Urticaria/Angioedema

- Avoidance of known provoking stimuli can greatly improve treatment outcomes.
- H_1 antihistamines are the mainstay of treatment, and second-generation H_1 antihistamines are preferred because they have fewer side-effects.
- Difficult cases may require treatment with various combinations of second-generation H_1 antihistamines, first-generation H_1 antihistamines, H_2 antihistamines and leukotriene receptor antagonists.
- Omalizumab and cyclosporine are often effective for antihistamine-resistant urticaria.
- Delayed-pressure urticaria does not generally respond well to antihistamines.
- Corticosteroids should be avoided whenever possible and in particular for the treatment of chronic urticaria/angioedema without delayed-pressure urticaria.
- The angioedema of hereditary angioedema does not respond to antihistamines, corticosteroids or epinephrine; oropharyngeal attacks of hereditary angioedema must be treated as a medical emergency.

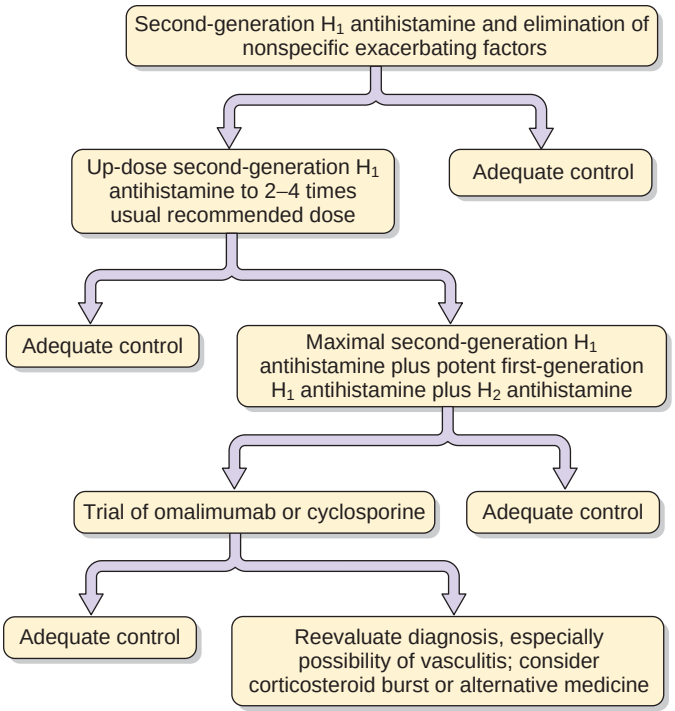

Figure 52-4 Therapeutic algorithm for chronic urticaria/angioedema.

also be helpful for patients with physical urticaria such as dermographism, cholinergic urticaria and delayed-pressure urticaria. Common sense avoidance measures should be reviewed with patients afflicted with cold or solar urticaria. Treatment of any discovered underlying disease is imperative, and genetic counseling should be provided to families with hereditary forms of these conditions. In addition, patients should avoid, to the extent feasible, potentiating factors such as alcoholic drinks, heat, exertion and aspirin.

Antihistamines are the mainstay of treatment for acute or chronic urticaria/angioedema (Figure 52-4).[37,62] Continuous use of antihistamines is justified by their actions as inverse agonists on the H_1 receptor, decreasing spontaneous receptor activity.[86] Used at a sufficient dose, they alleviate pruritus and suppress hive formation. Most first-generation H_1 antihistamines are effective in urticaria; however, common side-effects (particularly drowsiness and anticholinergic effects) are a substantial issue and have limited the usefulness of these drugs.[87] In addition, children may experience either sedation or a paradoxical agitation response to first-generation H_1 antihistamines.[88]

Second-generation H_1 antagonists cross the blood-brain barrier poorly, producing much less central drowsiness or agitation, and have much less anticholinergic effect. In general, first-generation antihistamines should be avoided for the treatment of urticaria, particularly in children.[62] Second-generation H_1 antagonists have thus become the preferred drugs for the first-line treatment of urticaria/angioedema, including for infants as young as 6 months.[37,62,89] The most commonly used second-generation H_1 antihistamines in the USA are cetirizine, loratadine, desloratadine and fexofenadine. Each of these has been shown to be well tolerated and effective for the treatment of urticaria/angioedema.[90] The recommended doses for the pediatric population are shown in Table 52-3. Up-dosing of second-generation antihistamines up to 4 times the usual dosage has been shown to be effective for control of urticaria in adults and children.[91]

Because the cutaneous vasculature expresses H_2 as well as the more abundant H_1 receptors, the addition of an H_2 antihistamine may provide significant benefit for patients who are refractory to H_1 antihistamines alone, although the evidence for their efficacy is weak.[37,62] Leukotriene receptor antagonists have shown some promise in the treatment of urticaria/angioedema, particularly in combination with an antihistamine regimen;[92] however, clear evidence of benefit from randomized, double-blinded studies is lacking.[93] The addition of ephedrine or terbutaline is another option but is generally not effective and is often associated with significant side-effects. While almost all patients will respond to antihistamine therapy, patient variability dictates an empiric approach to achieve optimal results.

Lack of response should raise the possibility of an underlying urticarial vasculitis, particularly when individual hives last for longer than 24 hours. It should be emphasized, however, that the physician must document the continuing hives by direct observation. Patients should be treated with high-dose second-generation H_1 antihistamines for at least one week before they are considered to be ineffective. Furthermore, it is often helpful to counsel the patient and patient's family that the goal of therapy is not to suppress the swelling totally, but rather to minimize the urticaria/angioedema to the point that it is tolerable. Addition of a potent first-generation antihistamine (hydroxyzine or doxepin) titrated to tolerance may help in patients who are not fully responsive to high-dose second-generation antihistamines.[94] Avoidance of dietary 'pseudoallergens' (substances that induce hypersensitivity/intolerance reactions such as food additives, vasoactive substances such as histamine, and some natural substances in fruits, vegetables and spices) has been reported to improve CSU in a minority of patients.[95]

In those patients who require additional therapy, third-line treatments for chronic urticaria are omalizumab or cyclosporine. Omalizumab has been shown in randomized placebo-controlled trials to be highly effective in antihistamine-resistant urticaria in adults and children.[96–100] Cyclosporine has also been

https://CafePezeshki.IR

TABLE 52-3 Dosing of Second-Generation H_1 Antihistamines in the Pediatric Population

Drug	Supplied As	Usual Dosage	Earliest Approved Age
Cetirizine	Tablets: 5, 10 mg Syrup: 1 mg/mL	6 mo to 1 yr: 2.5 mg/d 1 to 2 yr: 2.5 mg bid 2 to 5 yr: 2.5 mg bid or 5 mg qd 6 to 11 yr: 5–10 mg/d ≥12 yr: 10 mg/d	6 mo
Loratadine	Tablets/Reditabs: 10 mg Syrup: 1 mg/mL	2 to 6 yr: 5 mg/d ≥6 yr: 10 mg/d	2 yr
Fexofenadine	Tablets: 30, 60, 180 mg Oral suspension: 6 mg/mL	6 mo to 2 yr; 15 mg/d 2 to 11 yr: 30 mg bid ≥12 yrs: 60 mg bid or 180 mg/d	6 mo
Desloratadine	Tablets/Reditabs: 5 mg	6 mo to 1 yr: 1 mg/d 1 to 5 yr: 1.25 mg/d 6 to 12 yr: 2.5 mg/d ≥12 yrs: 5 mg/d	6 mo

shown to be effective for chronic urticaria in randomized placebo-controlled studies.[101,102] The safety of cyclosporine in children is less well established than in adults; however, it has also been shown to be efficacious in children with chronic urticaria.[103,104] Patients treated with cyclosporine need to be carefully monitored with cyclosporine serum concentrations and measures of renal function and blood pressure. A variety of other drugs (including dapsone, colchicine, hydroxychloroquine, methotrexate, sulfasalazine and intravenous gammaglobulin) have been reported to be helpful, although most of the reports are anecdotal.

In cases of severe antihistamine-resistant urticaria, a brief course of corticosteroids could be cautiously considered but the potential side-effects need to be discussed.[105] Parenteral corticosteroids are often effective in controlling severe urticaria/angioedema as well as urticarial vasculitis;[105] however, the potential side-effects from chronic use of corticosteroids mandate that they be used at the lowest possible dose for the shortest period of time.[106,107]

The treatment of HAE is distinct from that of allergic or idiopathic angioedema. Treatment of HAE is best considered as three separate goals: treatment of acute attacks, short-term prophylaxis and long-term prophylaxis.[108] It is crucial to recognize that standard angioedema treatment modalities, such as epinephrine, corticosteroids or antihistamines, do not have a significant impact on the swelling in HAE. Due to the complexity of treatment of HAE, involvement of an expert physician and extensive patient education are recommended.[108]

Acute HAE attacks should be treated with drugs that specifically and effectively target the pathophysiology of the disease (Table 52-4). Published guidelines concur that all HAE patients should have ready access to these drugs, that attacks at all sites are eligible for treatment, and that treatment is most effective when administered early in an attack.[73,108–111] Two different C1INH concentrates have been approved in the USA for treatment of HAE attacks – plasma-derived C1INH (Berinert) and recombinant human C1INH (Ruconest). Both are administered by intravenous injection and have been approved for use in adolescent and adult HAE patients. Home therapy with intravenous C1INH was also shown to be safe and effective in children.[112] Two other drugs that antagonize bradykinin generation or action have been approved for treatment of acute HAE attacks: a plasma kallikrein inhibitor (ecallantide) and a bradykinin B_2 receptor antagonist (icatibant). Ecallantide and icatibant have been approved for use in the USA for treatment of acute attacks in HAE patients age 16 and older, and 18 and older, respectively.

TABLE 52-4 Drugs Used for Treatment of Acute HAE Attacks in Children

Drug Class and Name	Dose	Side-Effects
C1INH Concentrates		
Berinert	20 units/kg, IV	*Common*: bruising and pain at site of injection *Uncommon*: thrombosis, allergic reaction
Ruconest	50 units/kg, IV	*Common*: bruising and pain at site of injection *Uncommon*: thrombosis, allergic reaction
Plasma Kallikrein Inhibitor		
Ecallantide	30 mg SC children ≥12	*Common*: none *Uncommon*: anaphylaxis
Bradykinin B_2 Receptor Antagonist		
Icatibant	30 mg SC children ≥18	*Common*: wheal and pain at injection site *Uncommon*: none

IV – Intravenous, *SC* – subcutaneous.

Prophylactic treatment of HAE is used to reduce the likelihood of swelling in a patient undergoing a stressor or procedure likely to precipitate an attack (short-term prophylaxis) or to decrease the number and severity of angioedema attacks (long-term prophylaxis). The extent of the local trauma may influence the decision on whether to treat the patient prophylactically. C1INH replacement given for short-term prophylaxis should be administered 1 to 12 hours prior to the stressor. High-dose anabolic androgens used for short-term prophylaxis in adults should be started 7 to 10 days prior to the stressor. It is critically important that effective on-demand treatment also be available whether the patient is given short-term prophylaxis or not.

There is little consensus regarding which patients should receive long-term prophylactic treatment. In general, the decision to start a patient on long-term prophylaxis should be

https://CafePezeshki.IR

TABLE 52-5 Drugs Used for Long-Term Prophylaxis of HAE in Children

Drug Class and Name	Usual Pediatric Dose (Typical Range of Doses)	Side-Effects
Antifibrinolytic Agents		
Epsilon aminocaproic acid	0.05 g/kg bid (0.025 g/kg bid–0.1 g/kg bid)	*Common*: nausea, vertigo, diarrhea, postural hypotension, fatigue, muscle cramps with increased muscle enzymes *Uncommon*: thrombosis
Tranexamic acid	20 mg/kg bid (10 mg/kg bid–25 mg/kg tid)	
17α-Alkylated Androgens		
Danazol	50 mg/d (50 mg/wk–200 mg/d	*Common*: weight gain, virilization, acne, altered libido, muscle pain/cramps, headache, depression, fatigue, nausea, constipation, menstrual abnormalities, increase in liver enzymes, hypertension, altered lipid profile *Uncommon*: decreased rate of growth in children, masculinization of female fetus, cholestatic jaundice, peliosis hepatis, hepatocellular adenoma
Stanozolol	0.5–1 mg/day for children <6 yr; up to 2 mg/d for children ≥6 yr	
Oxandrolone	0.1 mg/kg/d	
C1INH Concentrate		
Cinryze	1,000 units IV 2×/wk for adolescents	*Common*: bruising and pain at injection site *Uncommon*: thrombosis, allergic reaction

individualized, taking into account attack frequency, attack severity, co-morbid conditions, access to emergent treatment and patient experience and preference. The most commonly used medications for long-term prophylaxis of HAE are anabolic androgens and plasma-derived C1INH concentrate (Cinryze) (Table 52-5). Anabolic androgens, however, are relatively contraindicated in children under the age of 16.[113,114] Antifibrinolytic drugs, epsilon aminocaproic acid or tranexamic acid can also be used for long-term prophylaxis but are typically less effective.

Conclusions

Urticaria and angioedema are common clinical problems whose manifestations range from trivial and intermittent to life threatening. To minimize spending time and money unnecessarily on complicated work-ups, while simultaneously not overlooking important diagnoses, the clinician must be able to characterize urticaria/angioedema by chronicity, type and, increasingly, pathogenesis. With careful detective work, the cause of acute urticaria/angioedema can often be determined and appropriate interventions can be instituted that should lead to prompt resolution of the problem. A discrete cause of chronic urticaria, by contrast, is rarely established, forcing the clinician into the role of suppressing symptoms but not curing the problem. Although frequently frustrating for both the patient and the physician, the treatment of chronic urticaria can almost always achieve adequate results until the swelling disorder spontaneously remits. Hereditary angioedema is a rare but important cause of recurrent angioedema, and timely screening for HAE is the key to protecting these patients from potentially severe morbidity and mortality.

53 Contact Dermatitis

LUZ FONACIER | MARK BOGUNIEWICZ

KEY POINTS

- Allergic contact dermatitis (ACD) in children is not uncommon and should be suspected in patients with chronic dermatitis.
- Patch testing is the gold standard for the diagnosis of ACD even in children and should be considered for children with chronic or recurrent eczematous dermatitis including those with atopic dermatitis (AD) who fail to improve with standard treatment. The greatest abuse of patch testing is lack of use.
- Counsel the patient and/or family by identifying and providing a list of the chemicals they are sensitive to and giving synonyms and sources.
- Give patients a list of safe products to use, alternatives and substitutions if possible.
- Patients with a suggestive history or physical findings but negative results on the thin-layer rapid-use epicutaneous test (T.R.U.E. TEST®) should be considered for further evaluation in a patch testing clinic.

Contact dermatitis (CD) is a spectrum of inflammatory skin reactions induced by exposure to external agents. Clinically, CD most commonly manifests as a dermatitis or eczema, but it can present as urticaria, erythroderma, phototoxic or photoallergic reactions, hypopigmentation or hyperpigmentation, and even as an acneiform eruption. The more common type of CD results from tissue damage caused by contact with irritants (irritant CD), whereas contact with allergens causes allergic contact dermatitis (ACD). The former is seen commonly in infants as diaper dermatitis, whereas nickel and poison ivy are more frequent causes of ACD in the pediatric population.[1]

An estimated 85,000 chemicals exist in the world, and approximately 2,800 substances have been identified as contact allergens.[2] The majority of these agents, when applied to the skin, can induce an irritant CD (ICD).[3]

Epidemiology

It was previously thought that ACD occurs less frequently in children, possibly because of reduced exposure to contact allergens or because the immune system in children may be less susceptible to contact allergens. However, subsequent studies found a sensitization rate of 20% to 24%.[4–6] Two multicenter North American studies describing patch testing in pediatric patients with ACD found that allergen sensitivity rates were not different in children when compared to those of adults in the USA; however, the frequency of the relevant allergen reactions differed between the two populations.[7,8] Another striking difference was the finding that the frequency of the concomitant diagnosis of atopic dermatitis (AD) was higher (34%) in children with a relevant positive patch test reaction compared to only 11.2% in adults.[8]

ACD is considered rare in the first few months of life but has been reported as early as 1 week of age from a hospital ID bracelet.[9] The prevalence rises with increasing age and by 10 years of age the incidence reaches that seen in adults. Subsequently, variations for some allergens depend on the patterns of exposure. With advancing age, ACD diminishes in severity and in the loss of allergic response in previously sensitized individuals.[10]

In patients suspected of having ACD and referred for patch testing, the positive patch test rates ranged from 14% to 70%. Current relevance was reported at 56% to 93%. In a study by Seidenari et al[11] in Italian children, the highest percentage of positive responses was found in children less than 3 years of age, suggesting a higher sensitization rate in young children. In a study designed to look specifically at infants and young children, Bruckner and colleagues[12] found that 24.5% of asymptomatic children aged 6 months to 5 years were sensitized to one or more contact allergens. Approximately one half of the sensitized children were younger than 18 months. In the adolescent age group, females have significantly higher rates of ACD on the face, likely to be explained by increased exposure to nickel in piercing and to preservative and fragrance in cosmetic products. A USA-based study showed nickel, fragrance, cobalt, thimerosal, Balsam of Peru (BOP), potassium dichromate, neomycin, lanolin, thiuram mix and *p*-phenylenediamine (PPD) to be common allergens in children.[7] Less common, but emerging allergens include cocamidopropyl betaine in 'no tears' shampoos, baby washes and cleansers and disperse dyes in clothing materials. A different study looking at age-related specific allergens showed that, with increasing age, nickel takes the place of mercurials as the principal allergen.[13] With respect to race, in a large study of more than 9,000 individuals, De Leo and colleagues[14] found no difference in the overall response rate to allergens on patch testing between white and black patients.

Pathogenesis

IRRITANT CONTACT DERMATITIS

Irritant CD results from contact with agents that abrade or irritate the skin. Irritation is usually a cytotoxic event produced by a wide variety of chemicals, detergents, solvents, alcohol, creams, lotions, ointments and powders and by environmental factors such as wetting, drying, perspiration and temperature extremes. A major finding after exposure to skin irritants is perturbation of the skin barrier with an associated increase in

https://CafePezeshki.IR

transepidermal water loss. The mechanism associated with this barrier perturbation may include disorganization of the lipid bilayers in the epidermis.[15] In addition, these changes can stimulate an array of proinflammatory cytokine production in the epidermis.[16]

Although allergens are not implicated in ICD, the skin-associated immune system is clearly involved, and historically few differences were noted when ICD and ACD were compared immunohistopathologically.[17] An important difference between the two forms of CD is that ICD does not require prior sensitization and immunologic memory is not involved in the clinical manifestation. The cellular infiltrate includes $CD4^+$ T cells with a T helper cell type 1 (Th1)-type profile.[18] A number of studies have identified the epidermal keratinocyte as a key effector cell in the initiation and propagation of contact irritancy. Keratinocytes can release both preformed and newly synthesized cytokines, as well as up-regulate major histocompatibility complex (MHC) class II molecules and induce adhesion molecules in response to irritants.[19] These mediators can cause direct tissue damage, activating Langerhans cells, dermal dendritic cells and endothelial cells, which contribute to further cellular recruitment including neutrophils, lymphocytes and mast cells that also contribute to the inflammatory cascade. The 'final' cellular damage results from inflammatory mediators released by activated, nonsensitized T cells. The inflammatory response is dose and time dependent. Any impairment to the epidermal barrier layer (e.g. fissuring, overhydration) renders the skin more susceptible to an irritant effect. The clinical presentation of ICD is usually restricted to the skin site directly in contact with the offending agent, with little or no extension beyond the site of contact.

ALLERGIC CONTACT DERMATITIS

Allergic CD is recognized as the prototypic cutaneous cell-mediated hypersensitivity reaction, in which the epidermal Langerhans cell plays a pivotal role.[19] The offending agent, acting as an antigen, initiates the immunologic reaction at the site of contact with the skin. Most environmental allergens are haptens (>500 Da) that bind to carrier proteins to form complete antigens before they can cause sensitization. The thickness and integrity of the skin influence the allergic response. Thus thinner sites such as the eyelids, earlobes and genital skin are most vulnerable, whereas the thicker palms and soles are more resistant. Exposure patterns determine the clinical appearance and course of the dermatitis. An association of filaggrin gene (*FLG*) mutations with contact sensitization to nickel and contact sensitization to nickel combined with intolerance to fashion jewelry, but not with other contact allergens, has been demonstrated.[20] Thus, *FLG* deficiency may represent a risk factor for contact sensitization to allergens.

The immune response of ACD requires completion of both an afferent and an efferent limb. The afferent limb consists of the hapten gaining entrance to the epidermis, activating keratinocytes to release inflammatory cytokines and chemokines including tumor necrosis factor (TNF)-α, GM-CSF, interleukin (IL)-1β, IL-10 and macrophage inflammatory protein (MIP)-2. The latter in turn activate Langerhans cells, other dendritic cells and endothelial cells, leading to an accumulation of even more dendritic cells at the site of antigen contact. In addition, the release of IL-1β by epidermal Langerhans cells promotes their egress from the epidermis. After the uptake of antigen, Langerhans cells process it while migrating to regional lymph nodes, where they present it to naïve T cells. Hapten-specific T cells have been shown to include Th1, Th2, Th17 and T regulatory subsets.[19] An important property of Langerhans cells and dendritic cells is their ability to present exogenous antigens on both MHC class I and class II molecules. This cross-priming leads to the activation of both $CD4^+$ and $CD8^+$ hapten-specific T cells.[21]

Although classic delayed-type hypersensitivity reactions are mediated primarily by $CD4^+$ cells, CD to haptens is mediated primarily by $CD8^+$ cells with a Th1-type cytokine profile.[22,23]

On subsequent contact of the skin with a hapten, that is, during the elicitation phase of ACD, other antigen-presenting cells (APCs), including macrophages and dermal dendritic cells, may stimulate antigen-specific memory T cells and contribute to the initiation of the local inflammatory response (the dermatitis reaction). The sensitized T cells home in on the hapten-provoked skin site, releasing their inflammatory mediators, which results in epidermal spongiosis ('eczema'). Secondary or subsequent hapten exposure shortens the period of latency from contact to appearance of the rash.

INNATE IMMUNE RECOGNITION OF HAPTENS

A recent review of early events in ACD described the earliest event in ACD as the formation of hapten-self complexes:[24] pre-haptens oxidize before contact with the skin; pro-haptens such as urushiol are oxidized by the host after contact; complete haptens are directly active. Haptens induce the production of reactive oxygen species, which leads to release of ATP and other damage-associated molecular patterns (DAMPs), as well as to the generation of low-molecular-weight hyaluronic acid. The latter is sensed by neighboring cells via Toll-like receptor 2 (TLR2) and TLR4, resulting in increased expression of pro-IL-1β and pro-IL-18. Activation of the inflammasone by ATP with resultant caspase 1 activity generates active IL-1β and IL-18. Of interest, nickel has been found to directly bind histidine residues in the extracellular domain of TLR4, triggering the activation of this receptor.[25]

KERATINOCYTE APOPTOSIS AND ECZEMA

Spongiosis is a well-established histologic hallmark of the epidermis in eczema. It is characterized by the diminution and rounding of keratinocytes (condensation), and widening of intercellular spaces resulting in a spongelike appearance of the epidermis that can lead to formation of small intraepidermal vesicles. The function and integrity of the epidermis are dependent on specific cell surface adhesion molecules. Activated T cells infiltrating the skin in eczematous dermatosis induce keratinocyte apoptosis, resulting in spongiosis.[26] Resolution of epidermal spongiosis and cellular infiltrate can be demonstrated when ACD is successfully treated.[27]

T CELL RECRUITMENT IN ALLERGIC CONTACT DERMATITIS

The recruitment of T cells into the skin is regulated by the expression of the specific skin-homing receptor, cutaneous lymphocyte-associated antigen (CLA), which mediates rolling of T cells over activated endothelial cells expressing E-selectin.[28] In addition, chemokine receptors have been proposed as

https://CafePezeshki.IR

important regulators of the tissue targeting of T cells. In this respect, CLA^+ T cells co-express the chemokine receptor CCR4, the ligand for thymus and activation-regulated chemokine TARC (CCL17) and macrophage-derived chemokine (CCL22). CCR4 triggered by TARC exposed on the endothelial cell surface during inflammatory skin disorders is thought to augment integrin-dependent firm adhesion of T cells to endothelial intercellular adhesion molecule (ICAM)-1.[29] T cell migration into peripheral tissues mostly depends on their chemokine receptor profiles. Th1-type cells express high levels of CCR5 and CXCR3, interacting with MIP-1β (CCL4) and interferon gamma (IFN-γ)-inducible protein 10 (CXCL10), respectively, whereas Th2-type cells express primarily CCR3, CCR4 and CCR8 and interact with eotaxin (CCL11), TARC and MDC, and I-309 (CCL1).[30]

Epidermal keratinocytes have been shown to be an important source of inflammatory mediators for the initiation and amplification of skin immune responses. Treatment with IFN-γ or IFN-γ plus TNF-α induces keratinocytes to express ICAM-1 and MHC class II molecules and to release a number of chemokines and cytokines, including IL-1, TNF-α and GM-CSF.[31] IL-17 modulates many of the effects induced by IFN-γ. Of note, IL-4, a Th2 cytokine, acts synergistically with the Th1 cytokine IFN-γ to enhance keratinocyte ICAM-1 expression and release of the CXCR3 agonistic chemokines, IP-10, monokines induced by IFN-γ (Mig; CXCL9), and IFN-inducible T cell α-chemoattractant (I-TAC; CXCL11), thus augmenting both recruitment and retention of Th1-type cells in lesional skin.[32]

EFFECTOR T CELLS IN ALLERGIC CONTACT DERMATITIS

Both CD4 and CD8 T cells participate in ACD, with CD8 T cells predominating in effector mechanisms of tissue damage.[33] Budinger and colleagues[34] demonstrated that nickel-responsive peripheral T cells from patients with nickel-induced CD showed a significant overexpression of T cell receptor (TCR)-Vβ17, and the frequency of TCR-$V\beta17^+$ T cells correlated significantly with the in vitro reactivity of peripheral blood mononuclear cells to nickel. In addition, the cutaneous infiltrate of nickel-induced patch test reactions consisted primarily of $V\beta17^+$ T cells, suggesting that T cells with a restricted TCR-Vβ repertoire predominate in nickel-induced CD and may be crucial in the effector phase of nickel hypersensitivity. Of note, these nickel-specific T cells produced IL-5 but not IFN-γ, consistent with a Th2-type cytokine profile. Other studies have shown nickel-specific T cells with a Th1-type profile;[35] in addition, nickel-specific $CD4^+$ Th1-type cells have been shown to be cytotoxic (along with $CD8^+$ T cells) against keratinocytes, whereas Th2-type nickel-reactive T cells were not.[36] More recently, IL-17-producing TH17 cells have been shown to play a role in the immunopathology of ACD, including in both innate and adaptive immune responses to nickel.[37]

REGULATORY T CELLS IN ALLERGIC CONTACT DERMATITIS

Cavani and colleagues[38] described nickel-specific $CD4^+$ T cells from nickel-allergic subjects that secrete predominantly IL-10, which blocks the maturation of dendritic cells including IL-12 release, thus impairing their capacity to activate specific T effector lymphocytes. Thus regulatory T cells may limit excessive tissue damage and participate in the resolution of ACD.

Evaluation and Management

DIFFERENTIAL DIAGNOSIS

A number of both eczematous and noneczematous dermatoses should be considered in the evaluation of a child with suspected CD. Eczematous dermatoses such as seborrheic and atopic dermatitis occur commonly, whereas psoriasis and zinc deficiency are less common. Nummular eczema, neurodermatitis (lichen simplex chronicus) and adverse drug reaction should also be considered. Noneczematous dermatoses such as dermatophytosis, bullous impetigo, vesicular viral eruptions, urticarial vasculitis, mycosis fungoides and Sézary syndrome may mimic CD.

SPECTRUM OF CONTACT DERMATITIS

Contact dermatitis is traditionally divided into ICD, accounting for 80%, and ACD, accounting for 20% of these reactions. However, there are other diseases that are caused by an external inciting factor such as contact urticaria (CU) and protein contact dermatitis (PCD).[39]

The innate allergenicity or irritancy of the allergen, the site of contact, the degree of contact, the exposure time to contactants, the thickness and integrity of the skin involved, the environmental conditions, the immunocompetency of the patient and genetics affect the type, severity and location of the CD. However, there is frequent overlap between ACD and ICD because many allergens at high enough concentrations can also act as irritants. Impairment to the epidermal barrier layer such as fissuring may increase allergen entry into the epidermis.

CU, a type I immediate hypersensitivity reaction, manifests as pruritic wheals after contact with the triggering substance. CU can be nonimmunologic or immunologic; the latter requires a prior sensitization phase and can spread beyond the localized contact point.[40]

Protein CD manifests as chronic or recurrent eczematous dermatitis (rather than urticaria) upon exposure to specific proteins such as shrimp, fish, meat or latex[41,42] and is thought to be caused by a combination of type I and type IV reactions.[41] Both CU and PCD can be caused by contact to external allergens and can respond to antihistamines and topical corticosteroids.

ALLERGIC CONTACT DERMATITIS AND ATOPIC DERMATITIS

The relationship between ACD and AD is complex and controversial. Earlier literature suggested that patients with AD, especially severe AD, had a depressed Th1 immune system and therefore were less likely to become sensitized to allergens and develop ACD.[43,44] However, more recent literature suggests that development of ACD may be enhanced in patients with chronic moderate to severe AD.[45–47] Two later studies showed that the rates of ACD in patients are similar regardless of whether they have AD or not, the frequencies of positive patch test reactions in patients with AD being 63% to 74% and without AD 61.3% to 67%.[48,49] In 2010, Jacob et al reported that 95.6% of 69 children with suspected ACD had at least one positive patch test reaction, and of these, 76.7% had a history of AD.[50] Although

https://CafePezeshki.IR

many of the common allergens seen in AD, such as fragrances and lanolin, are similar to those seen in the general population there are certain topical agents that are especially relevant in AD such as topical antibiotics (neomycin and bacitracin) and topical corticosteroids. Interestingly, bacitracin is also reported to cause contact urticaria and anaphylactic reactions. Allergic reactions to topical steroids, the mainstay of treatment of AD, have been reported not only to components of the vehicle (e.g. preservative, fragrance, emulsifier) but to the actual corticosteroid itself. Thus, although the incidence of ACD in patients with AD remains unknown, newer recommendations include the consideration of patch testing in patients with AD who are refractory to standard therapies.[50]

Diagnosis of Contact Dermatitis

HISTORY

A careful, thorough and comprehensive, age-appropriate history should include possible contact exposure of the child such as diapers, hygiene products, perfume-containing products, moisturizers, cosmetics, sun blocks, tattoos, body piercing, textiles with dyes and fire retardant, medications, pets and pet products, school projects, recreational exposure, sports, work, etc. ICD may be the cause of the dermatitis or an aggravating factor. Frequent handwashing, use of water and soaps, detergents and cleansers should be noted. The evolution of the skin reaction is influenced by many factors, including the patient's skin, age, color, ambient conditions, the use of topical or other oral medication and response to all prior treatment. Because the majority of contact reactions present as eczematous eruptions, it is essential to note clinical evolution from acute vesiculation to chronic lichenification.

Unfortunately, although history can strongly suggest the cause of CD, relying solely on the history, other than with obvious nickel reactions and a few other allergens, may confirm sensitization in only 10% to 20% of patients with ACD. CD must be considered in patients with AD because they have an impaired epidermal barrier layer and use multiple medications, creams and other topical products that subject them to a greater risk for both allergic sensitization and irritation. Also, atopy amplifies the effects of contact irritants and allergens on the skin, and contact sensitization is an aggravating factor in AD.

PHYSICAL EXAMINATION

The diagnosis of ACD is suspected from the clinical presentation of the rash and the possible exposure to a contact allergen. CD can be described as acute, subacute or chronic. Acute dermatitis can present with erythematous papules, vesicles and even bullae. Chronic CD is generally pruritic, erythematous and may be associated with crusting, scaling, fissuring, excoriations and lichenification. ICD usually presents as well-demarcated, erythematous macules, papules and plaques confined to the area of the skin in direct contact with the offending agents, with little or no extension beyond the site of contact (Figure 53-1). ICD generally spares 'protected' areas such as the inguinal folds in diaper dermatitis. In ACD, the dermatitis can spread beyond the areas of contact and can even cause an activation of dermatitis at distant sites of prior dermatitis as in systemic CD.

Although geographic location of dermatitis can aid in the determination of the suspected allergen, other factors may influence the location of the dermatitis. In connubial dermatitis, the product may be transferred to the child by the parent/caregiver or to the patient by a partner. Clinically, it is difficult to differentiate CD from AD, especially in the common areas of involvement such as the eyelids, lips, hands, flexural areas of the neck, and even dermatitis with scattered generalized distribution.

Figure 53-1 Irritant contact dermatitis of the arms.

A broader spectrum of ICD, including *acute, acute delayed, cumulative, traumatic* and *subjective,* has been described.[51]

REGIONAL CONSIDERATIONS IN CHILDREN

Hand Dermatitis

Hand dermatitis in children is extremely common.Its differential diagnosis can be challenging and it is not often studied with patch testing. Hand dermatitis may be due to ICD or ACD, AD, dyshidrosis or psoriasis. Because the skin on the palm is much thicker than that on the dorsum of the hands, ACD rarely involves the palms, occurring most often on the thinner skin between the fingers and the dorsum of the hands (Figure 53-2). However, because of significant overlap, it may be difficult to distinguish the etiology of hand dermatitis. In a study by Toledo et al,[52] 36% of the children with hand eczema had ACD, supporting the recommendation of patch testing of children with chronic hand eczema, independently of age, sex, personal history of atopic dermatitis or distribution of the eczema.

Patch tests in patients with hand eczema showed that relevant allergens included nickel sulfate (17.6%), potassium dichromate (7.2%), rubber elements including thiuram mix, carba mix, *p*-phenylenediamine (PPD) and mercaptobenzothiazole (MBT) (19.6%) and cobalt chloride (6.4%).[53,54] A

https://CafePezeshki.IR

Figure 53-2 Allergic contact dermatitis of the hand.

Swedish study of 5,700 patients showed that patients whose entire hands were involved were more likely to react to thiuram mix, *p*-phenylenediamine, chromate and BOP, while those with involvement of the fingers and interdigital spaces or palm were more likely to react to nickel, cobalt and 5-chloro-2-methyl-4-isothiazolin-3-one/2-methyl-4-isothiazolin-3-one.[55]

The prevalence of hand eczema in patients with AD is 2- to 10-fold higher than in nonatopics. Involvement of the dorsal aspect of the hand and fingers, combined with volar wrist involvement, suggests AD as a contributing etiologic factor. Irritant CD commonly presents as a localized dermatitis without vesicles over webs of fingers extending onto the dorsal and ventral surfaces ('apron' pattern), dorsum of the hands, palms and ball of the thumb. In contrast, ACD is often associated with vesicles and tends to favor the fingertips, nail folds and dorsum of the hands; less commonly it involves the palms. Since ICD of the hands can precede ACD, pattern changes such as increasing dermatitis from web spaces to fingertips or from palms to dorsal surfaces should prompt patch testing.[56]

Face and Eyelid Dermatitis

Eyelid dermatitis may be due to ACD (55–63.5%), ICD (15%), AD (<10%) and seborrheic dermatitis (4%).[57] The eyelid is susceptible to ACD because of higher exposure to allergens, greater sensitivity to allergens including aeroallergens, and easy accessibility to touch, facilitating the transfer of chemicals from other areas of the body (e.g. nails, scalp) to the eyelid. Although CD is considered to be the most common cause of eyelid dermatitis, it is believed that 25% of patients with AD may have chronic eyelid dermatitis.

Pure eyelid dermatitis may be distinct from dermatitis with other areas of involvement.[58] Common allergens causing eyelid dermatitis are fragrances (facial tissues, cosmetics), preservatives, nickel (eyelash curlers), thiuram (rubber sponges, masks, balloons, toys), cocamidopropyl betaine and amidoamine (shampoos), tosylamide formaldehyde resin (nail polish) and gold.[59] Facial tissues may contain fragrances, formaldehyde or benzalkonium chloride. PPD and ammonium persulfate can cause urticaria and/or eyelid edema.

Facial dermatitis may also occur secondary to allergens transferred to the face from other regions of the body. The cosmetic industry markets heavily to children, especially the adolescent population. Cosmetics and personal products such as moisturizers, sunscreens, foundations and powders can cause ACD which tends to be symmetrical but can be patchy. The products most likely to cause ACD in the peripheral face (pre-auricular, submental and jawline areas) are shampoos, conditioners and facial cleansers. In contrast, the products most likely to cause a central facial dermatitis (cheeks, forehead) are make-up and moisturizers. ACD that affects the lateral neck is most likely secondary to perfumes/colognes and nail cosmetics. Preservatives and fragrances are the most common allergens in patients with ACD of the face.[60] Rubber-sensitive individuals may react to rubber sponges, masks, balloons, children's toys and other products that are in contact with the face.

The scalp skin is relatively resistant to allergens in shampoos and hair dyes; shampoos, conditioners, hair sprays, gels and mousses may cause eyelid or facial dermatitis without causing scalp or forehead lesions. Severe burns of the scalp and hair can be caused by the misuse of hair straighteners and relaxers. The manufacturers of hair dyes recommend patch testing with the product before each application.

Oral Mucous Membranes, Perioral Dermatitis and Cheilitis

Perioral dermatitis and cheilitis are common in children and are associated with lip licking, lip chewing, thumb sucking or excessive drooling. Objectively, changes may be barely visible or may vary from a mild erythema to a fiery red color, with or without edema. Juices of foods and even chewing gum may contribute to skin irritation of these areas. Cinnamon flavorings and peppermint are the most common causes of allergic cheilitis from toothpastes.[61]

Contact allergy of the mucous membrane is rare and use of patch testing to evaluate patients with mucosal involvement is controversial. In a series of 331 patients with different oral diseases (burning mouth syndrome, cheilitis, gingivitis, orofacial granulomatosis, perioral dermatitis, lichenoid tissue reaction and recurrent aphthous stomatitis), metals (nickel and gold) were most frequently positive on patch testing.[62] Metals, including mercury, chromate, nickel, gold, cobalt, beryllium and palladium, have been used in orthodontic materials and are important allergens in patients with dental implants or orthodontic devices presenting with oral lichenoid lesions. Other allergens with a high percentage of positive reactions on patch testing include flavorings and preservatives. 'Fragrances' are used as flavoring in food products, skin care products and dentifrices. Balsam of Peru is found in dentifrice, mouthwash, lipstick and food. Dodecyl gallate is a preservative used to extend the shelf life of oil-based foods such as peanut butter, soups and pastries. Toothpaste, fluoride mouth washes, chewing gum and other foods may contain cinnamic aldehyde, flavorings and peppermint, which are common causes of allergic cheilitis. Thus, an oral antigen screening series in patients with cheilitis should include not only metals but also an even more comprehensive panel of flavorings, preservatives, medications and dental acrylates. The usefulness of patch testing in the evaluation of orofacial granulomatosis and recurrent aphthous stomatitis is questionable.[62]

Flexural Areas of Neck and Axillary Dermatitis

The thin intertriginous skin of the neck is vulnerable to irritant reactions from 'perms', hair dyes, shampoos and conditioners. 'Berloque' dermatitis from certain perfumes or nail polish presents as localized areas of eczema. Nickel-sensitive individuals may react to wearing a necklace or to zippers.

ACD can be caused by deodorants but is rarely due to antiperspirants, the latter usually causing ICD. These agents

https://CafePezeshki.IR

generally cause a dermatitis involving the entire axillary vault, whereas textile ACD spares the apex of the vault. However, sweat and perspiration may cause increased deodorant allergen in the periphery, giving a dermatitis that is less intense in the apex of the axillae. ACD due to disperse dyes such as disperse Orange 1, disperse blue 106 and disperse blue 124 in clothing can elicit eczematous eruptions in the axillae, arms and groin.[63–65]

Diaper Dermatitis

Eruptions in the diaper area are the most common dermatologic disorder of infancy.[66] Friction, occlusion, maceration and increased exposure to water, moisture, urine and feces[67] contribute to ICD. The prevalence of diaper dermatitis, an ICD, in infants has been estimated to be 7% to 35% with a peak incidence between ages 9 and 12 months.[68] However, a large-scale study in the UK demonstrated an incidence of 25% in the first 4 weeks of life alone.[69]

Allergic CD to rubber chemicals (mercaptobenzothiazole, cyclohexyl thiophthalimide) or glues (*p*-tertiary butylphenol-formaldehyde resin) has been called 'Lucky Luke' CD.[70] The characteristic dermatitis is predominantly located on the outer buttocks and hips in toddlers ('gun holster' pattern) and is caused by the elastic bands that hold tightly on the thighs to prevent leaking. Treatment usually involves increasing the frequency of diaper changes, using superabsorbent disposable diapers and applying low-potency corticosteroids and barrier ointments or creams. A topical antifungal agent is beneficial in secondary *Candida albicans* infection. There has been a definite decrease in the incidence of diaper dermatitis due to the availability of newer and improved diapers, including those with superabsorbent gel.[71]

Medication, douches, spermicides, sprays and cleaners can cause CD in the genital area. Fragrances found in liners, toilet paper, soap and bubble baths can cause a reaction in sensitized patients. Contraceptive devices can affect rubber- and latex-sensitive individuals. Ammonia and/or the acidity of urine may cause ICD, especially in incontinent patients. The ingestion of spices, antibiotics or laxatives may cause anal itching.

Leg and Foot Dermatitis

Shaving agents, moisturizers and rubber in the elastic of socks can cause allergic reactions in children. Romaguera and Vilaplana[72] found that the foot was the most frequent localization of CD in children. Irritant dermatitis of the feet may occur in children because of excessive perspiration or the use of synthetic footwear. More commonly, children can develop ACD to rubber accelerators (MBT mix, thiuram mix, carba mix, and PPD mix), dichromates (Figure 53-3) or glues used in the manufacture of shoes. Chrome used in the tanning and dyeing processes of leather, and colophony used in glues in soles and insoles, may be sensitizing. Other chemicals in footwear (e.g. leather, adhesives, glues and dyes) or in topical medications (e.g. creams, ointments and antiperspirants) can cause ACD. Reactions to nickel sulfate were also frequent with metal in footwear buckles, eyelets and ornaments.[73] In ACD, the involvement of the dorsal aspect of the foot and toes, especially the hallux, and sparing of the interdigital areas is characteristic. Irritant dermatitis can involve either the dorsum or the sole. Patients with hyperhidrosis or 'sweaty sock' dermatitis should be encouraged to wear cotton socks and to change them frequently, along with wearing breathable footwear.

Figure 53-3 Chronic dermatitis on dorsa of feet and toes caused by potassium dichromate allergy from chronic exposure to leather tennis shoes. *(From Weston WL, Lane AT, Morelli JG. Dermatitis. Color textbook of pediatric dermatology. 4th ed. Mosby; 2007.)*

Generalized Dermatitis

Dermatitis with scattered generalized distribution (SGD) is a difficult diagnostic and therapeutic challenge because it lacks the characteristic distribution that gives a clue as to the possible diagnosis of ACD. Interestingly, the most common body location of dermatitis for both children and adults reported by the NACD in 2013 was scattered/generalized pattern, followed by the hands and then the face.[74] Zug and colleagues[75] reported that approximately half (49%) of patients with SGD referred for patch testing had a positive patch test deemed at least possibly relevant to their dermatitis, the prevalence being higher in patients with a history of AD. The two allergens most commonly identified were nickel and BOP. Hjorth[76] reported two children who were patch test positive to BOP whose eczema flared after oral intake of naturally occurring balsams. Other relevant positive patch test reactions included preservatives (formaldehyde, quaternium 15, methyldibromoglutaronitrile/phenoxyethanol, diazolidinyl urea, 2-bromo-2-nitropropane-1, 3-diol, imidazolidinyl urea, and DMDM hydantoin) and propylene glycol. Dyes such as disperse blue 106 in synthetic fibers in children's garments have also been implicated.[11]

Advising patients to use skin care products without the most frequent, relevant allergens (formaldehyde-releasing preservatives, fragrances and propylene glycol) is one strategy that may be helpful while awaiting definitive patch testing results. However, 8% to 10% of patients with SGD remain in the unclassified eczema category.[75]

Systemic CD should be considered as a possible cause of dermatitis with SGD. It manifests as a localized or generalized inflammatory skin disease that occurs in sensitized individuals when they are exposed to the specific allergen orally, transcutaneously, intravenously or by inhalation. There are a variety of manifestations of systemic CD reactions including a reactivation of a previous dermatitis, reactivation of a previously positive patch test (localized 'recall reactions'), a systemic inflammatory skin disease such as the 'baboon syndrome'[77–81] and/or oral lichenoid reactions. Patients allergic to ethylenediamine may react to systemic aminophylline and antihistamines of the piperazine or ethanolamine families. Similar reactions have been reported to glucocorticoids, diphenhydramine,

https://CafePezeshki.IR

TABLE 53-1 Reported Causes of Systemic Allergic Contact Dermatitis

Contact Sensitizer	Systemic Reaction to
Glucocorticoids	Oral hydrocortisone
Benadryl cream®	Oral diphenhydramine
Neomycin	Oral neomycin
Penicillin	Oral penicillin
Sulfonamide	Para-amino sulfonamide hypoglycemics (tolbutamide, chlorpropamide)
Thiuram	Antabuse
Colophony, Balsam of Peru, fragrance mix	Spices: clove, nutmeg, cinnamon, cayenne pepper Citrus fruits: oranges, lemon, tangerines Tomatoes
Ethylenediamine	Aminophylline (alternative: oral theophylline, IV theophylline) Piperazine and ethanolamine (Atarax®, Antivert®) (alternatives: diphenhydramine, chlorpheniramine, fexofenadine)
Nickel	Nickel in tap water, utensils and food high in nickel content such as soy, chocolate, lentils, cashews
Chromate	Inhaled chromium: oral potassium dichromate

neomycin, penicillin, sulfonamides, thiuram, colophony, BOP, fragrance mix and nickel (Table 53-1).

Patch Testing

Unfortunately, even with an extensive history and physical exam, only about 10% to 20% of patients with ACD can be diagnosed accurately without patch testing. Patch testing is needed to identify the responsible allergens, is helpful in young children suspected of ACD and remains the gold standard for confirming ACD. Although the application of antigens for patch testing is rather simple, antigen selection and patch test interpretation require an experienced clinician (Table 53-2).

SELECTION OF APPROPRIATE SUBJECTS TO TEST

The higher the index of suspicion, the more frequent the diagnosis of ACD. Patch testing should be considered for children with a chronic, pruritic or recurrent eczematous dermatitis, especially those with eyelid or hand involvement,[82] those with uncontrollable or worsening chronic dermatitis of greater than 2 months duration and those who fail to improve following standard treatment protocols including a preliminary avoidance regimen of formaldehyde and fragrance. Indeed, the observation that the greatest abuse of patch testing is its lack of use holds true even for the pediatric population. Immunocompromised patients, including those on oral steroids or those on cancer chemotherapy or immunosuppressive drugs, are not appropriate candidates for patch testing. Ideally, the patient's dermatitis should be quiescent because flare-up reactions may be elicited during patch testing. The patch test site should have had no potent topical immune modulators or steroid applied for 5 to 7 days before testing. Patients should avoid sun or ultraviolet light exposure for 96 hours. Systemic antihistamines have no effect on patch test results. However, not all children with suspected ACD can have patch testing. Given the smaller surface area for patch testing, especially in young children, if comprehensive patch testing cannot be done, a detailed exposure history may guide the choice of potential allergens to test based on the history of exposures and the patient's own personal care products.

TABLE 53-2 Patch Test Interpretation Based on The Recommendation of The International Contact Dermatitis Research Group

Grade	Patch Test Grading
(–)	Negative reaction
(?+)	Doubtful reaction with faint erythema only
1+	Weak positive reaction with nonvesicular erythema, infiltration, possible papules
2+	Strong positive reaction with vesicular erythema, infiltration and papules
3+	Extreme positive reaction with intense erythema and infiltration coalescing vesicles, bullous reaction
IR	Irritant reaction

SOURCES OF ALLERGENS

Commercially available standardized patch testing allergens have been calibrated with respect to nonirritant concentrations and compatibility with the test vehicle. Test systems currently available in the USA are the T.R.U.E. TEST® and the standardized allergens loaded in patch test chambers. Certain screening panels such as the NACD recommended series or the American Contact Dermatitis Society Core Allergen Series, with a range from 65 to 70 allergens are not approved by the US Food and Drug Administration (FDA) but conform to standards of care recommended by CD experts. Commercial sources of customized patch test materials include Smart Practice Canada (1.866.903.2671), SmartPractice Europe +49 (0)40 6701768 and Dormer Laboratories, Inc. (416-242 6167) (chemotechnique@dormer.com).

ALLERGENS

The German Contact Dermatitis Group (GCDG)[83] recommends that children under 6 should only be subjected to patch testing if there is a high degree of clinical suspicion and that only the suspected allergens should be used. Some authors suggest dose adjustment in younger children for allergens such as nickel, formaldehyde, formaldehyde releasers, mercaptobenzothiazole, thiuram and potassium dichromate to avoid irritant false-positive reactions.[84,85] Jacob et al recommend a reduced concentration of nickel, formaldehyde and rubber additives in children under 5, especially in those who also have AD.[86] Children over the age of 12 can be tested in the same manner as adults and most studies to date suggest that the same test concentrations as in adults can be used.[87]

The ideal number of patch tests to be applied depends on the patient. The usefulness of patch testing is enhanced with the number of allergens tested. Allergens not found on commercially available screening series in the USA frequently give relevant reactions, and personal products are a useful supplement especially in facial or periorbital dermatitis.

https://CafePezeshki.IR

A 2011 Pediatric Research Equity Act (PREA)-1 found that the T.R.U.E. TEST® test with 29 patches was efficacious and safe, in a study of 102 children aged 6 to 18 years.[88] Since then seven more allergens have been added to the T.R.U.E. TEST®, whose safety and efficacy in pediatric age groups are still being studied (Table 53-3). Comparative results of the T.R.U.E. TEST® and Finn Chamber method have shown a 64% to 98% concordance, depending on the allergen.

However, a further study suggested that false-negative results may occur with the T.R.U.E. TEST®, particularly with fragrance mix and rubber additives (thiuram and carba mix),[89] as well as to neomycin, cobalt and lanolin.

Other standardized allergens can be tested individually with a loading chamber such as the Finn Chamber but clinicians need to be aware of the limitations of each system of patch testing for individual allergens.[90] Caution should be exercised when testing for nonstandardized antigens to avoid adverse effects and false-positive or -negative responses. Ideally, at least two control subjects should be tested with any nonstandardized allergen. 'Leave-on' cosmetics (make-up, perfume, moisturizer, nail polish), clothing and most foods are tested 'as is', whereas 'wash-off' cosmetics (soap, shampoo) are tested at 1 : 10 to 1 : 100 dilution.

Patch testing should never be performed with an unknown substance. Photopatch tests should be performed by physicians with expertise in ultraviolet radiation if photocontact dermatitis is suspected. Additional guidelines for patch testing, including strength of recommendations and quality of evidence, have been published by the British Association of Dermatologists' Therapy Guidelines and Audit Subcommittee.[91] The T.R.U.E. TEST® may serve as triage or a screening tool in an allergist's practice but occupational exposures may benefit from early referral for supplemental testing.

SELECTION OF ALLERGENS IN CHILDREN

The North American Contact Dermatitis Group (NACDG) seeks to determine the frequency of positive and relevant patch tests in children referred for patch testing in North America and to compare results of patch testing in children and adults, as well as results with international data on contact allergy in children. No significant difference in the overall frequency of at least one relevant positive patch test reaction was noted in children (51.2%) compared with adults (54.1%).[8] In a more recent meta-analysis, the top five most prevalent allergens in the pediatric population that should have priority for inclusion in standardized testing are nickel sulfate, ammonium persulfate, gold sodium thiosulfate, thimerosal and toluene-2,5-diamine (*p*-toluenediamine).[92]

The top ten most commonly positive allergens in the pediatric population in North America are nickel, neomycin, cobalt, fragrance, *Myroxylon pereirae* (BOP), gold, formaldehyde, lanolin/wool alcohols, thimerosal and potassium dichromate.[8] Eight of these allergens are also in the top 10 allergens seen in adults.[74] The two allergens in children but not in adults are lanolin/wool alcohols, which can be found in healing ointments, aftershave, baby and bath oil, hand sanitizers and creams, and thimerosal, which is likely a sensitization due to previous vaccination and is not a relevant allergen.

There are additional highly relevant allergens in children which correlate with unique exposures such as (1) methylchlorosiothiazolinone/ methylisothiazolinone (MCI/MI), a chemical preservative found in infant products such as wet wipes, protective creams, liquid soaps and shampoos; (2) cocamidopropyl betaine (CAPB), a surfactant used in cleansing products (e.g. No More Tears™ formulations); (3) disperse dyes found in diaper material and colored garments such as school and athletic uniforms; (4) carbamates and thiuram used in rubber production found in gloves, garments, shoes and toys; (5) dialkyl thioureas; and (6) *p-tert*-butyl formaldehyde resin found in rubber and neoprene components in shin guards, protective pads and wetsuits.

Thus Jacob et al[93] recommend a basic North American Standard Series for children aged 6 to 12 years to include 20 selected allergens that are the most prevalent in the pediatric population with the highest clinical relevance and therefore would be the highest yield as a basic series. An additional five other allergens could be tested for if there is a relevant exposure history. Table 53-3 gives the most common source of exposure for some significant allergens. Similarly, due to the limited surface available for testing and the potential risk of active sensitization, the GCDRG[83] recommends an even more limited panel of 12 contact allergens as a standard series in children from 6 to 12 years of age. When history suggests exposure to shoe allergens, *p-tert*-butylphenol-formaldehyde resin and potassium dichromate are added. Wool alcohols/lanolin is added when there is exposure to skin care products, disperse blue if clothing dermatitis is suspected and *p*-phenylenediamine if there is exposure to henna, tattoos and hair dyes. Table 53-4 compares the recommended allergens for patch testing in children 6 to 12 years of age and the secondary allergens to test based on the recommendations of Jacob and the GCDRG. Of note, 15% and 39% of children had relevant allergens not included in the NACDG series or T.R.U.E. TEST®, respectively, hence the need for supplemental allergens as well as the patient's personal products in some cases. It is important to remember that the majority of patients will be allergic to a single allergen or a single group of allergens and that there is a risk of false-positive patch test results. Ideally, one needs to know the value of all the clinical data before patch testing, in predicting a clinically relevant response to any of the allergens tested.

PATCH TESTING PROCEDURE

Standardized criteria for patch testing have been set by the Task Force on Contact Dermatitis of the American Academy of Dermatology. All results are dependent on the recommended protocol for application, removal and interpretation of results.

Patch tests are typically applied to the upper- or mid-back areas (2.5 cm lateral to a mid-spinal reference point) which must be free of dermatitis and hair and are kept in place for 48 hours. Patients are instructed to keep the area dry and avoid activities that will cause excessive sweating or excessive movement that may cause displacement of the patches. In infants and small children, the patch test can be covered with fabric adhesive tape or a stockinet vest. Patch tests are removed after 48 hours and read 30 minutes after to allow resolution of erythema and irritative effect from the tape and/or chamber if present. A second reading should be done 3 to 5 days after the initial application. Thirty percent of relevant allergens negative at the 48-hour reading become positive in 96 hours. Irritant reactions tend to disappear by 96 hours. Metals (gold, potassium dichromate, nickel, cobalt), topical antibiotics (neomycin, bacitracin), topical corticosteroids and PPD may become positive after 7

https://CafePezeshki.IR

TABLE 53-3 Thin-layer Rapid Use Epicutaneous Test (T.R.U.E. TEST®) Antigens

Antigen	Common Exposures
PANEL 1.2	
Nickel sulfate	Snaps, jewelry, food
Wool alcohols (lanolin)	Cosmetics (lipstick, hair spray), skin care products (creams, ointments, lotions, moisturizer, baby oil, diaper lotion), personal hygiene items (soaps, cleansers, shampoos), facial masks, sunscreens, over-the-counter and prescription medications for skin rashes, pet grooming aids
Neomycin sulphate	Topical antibiotics
Potassium dichromate	Chrome-tanned leather products (shoes, boots, gloves), cement, pigments in inks and paints, make-up
Caine mix	Topical anesthetics
Fragrance mix	Fragrances, scented household products
Colophony	Cosmetics, sunscreens, adhesives, household products, diapers, feminine napkins, wax depilatories, match tips
Paraben mix	Preservative in topical formulations, cosmetics
Negative control	
Balsam of Peru	Cosmetics, fragrances, dental hygiene products, topical medications, food
Ethylenediamine dihydrochloride	Topical medications, piperazine-related antihistamines, aminophylline, hydroxyzine hydrochloride
Cobalt dichloride	Metal-plated objects (utensils, keys, magnets, clothing fasteners, jewelry), paints, cobalt-based pigments, vitamin B_{12} supplements
PANEL 2.2	
p-tert-Butylphenol-formaldehyde resin	Fabrics, glued rubber (rubber-containing footwear, handbags, watchbands, belts, bras), sports gear, leather goods
Epoxy resin	Two-part adhesives and paints, art and sculpture materials, manufacture of tennis racquets, skis, circuit boards, lightweight equipment
Carba mix	Rubber products, shampoos, disinfectants
Black rubber mix	All black rubber products (tires, playgrounds), some hair dyes
CL+ ME– Isothiazolinone (MCI/MI)	Cosmetics (foundations, powders, blush, mascaras, eye shadows, eyeliners and pencils), skin care products (creams, lotions, moisturizers, soaps, cleaners, bubble baths, wipes), hair care products (conditioners, shampoos, coloring agents), laundry products (detergents, fabric softener)
Quaternium-15	Preservative in cosmetics and skin care products
Methyldibromo glutaronitrile	Skin care products such as body creams, facial/hand lotions, sun screens, and baby lotions Personal hygiene products such as moist toilet paper, shampoos, conditioners and shower gels
p-Phenylenediamine	Permanent or semipermanent hair dyes, cosmetics, printing ink, black henna tattoo
Formaldehyde	Fabric finishes, cosmetics
Mercapto mix	Rubber products, glues for leather and plastics
Thimerosal	Preservative in contact lens solutions, cosmetics, injectable drugs
Thiuram mix	Rubber products, adhesives
PANEL 3.2	
Diazolidinyl urea	Products for personal care, hygiene and hair care; cosmetics; pet shampoos
Quinoline mix	Paste bandages; prescription and non-prescription topical antibiotics and antifungal creams, lotions, ointments; animal food
Tixocortol-21-pivalate	Antiinflammatory preparations
Gold sodium thiosulfate	Gold or gold-plated jewelry, dental restorations
Imidazolidinyl urea	Products for personal care, hygiene and hair care; cosmetics; liquid soaps; moisturizers
Budesonide	Corticosteroid creams, lotions and ointments, nasal corticosteroid spray; asthma controller medication in inhaler, nebulized suspension and dry powder forms
Hydrocortizone-17-butyrate	Antiinflammatory preparations
Mercaptobenzothiazole	Rubber products, nitrile or neoprene, such as rubber bands, ear- and headphones, masks, condoms and diaphragms, goggles, shoes, utility gloves, swimwear, toys, hoses, tubing and elastic Sports equipment made with natural rubber, butyl rubber, nitrile or neoprene such as shoes, wetsuits, boots, masks, racquet and club handles
Bacitracin	Prescription and in over-the-counter preparations such as topical antibiotic creams, lotions, ointments, bandages, ophthalmic and otic products
Parthenolide	Plants and gardens, herbal teas containing sesquiterpenes, supplements, tablets or tinctures
Disperse blue 106	Synthetic fabrics such as polyester, acetate, nylon with black or navy blue color; dark-colored polyester velour and in children's diapers and exercise garments; dyed fabrics such as bedding, clothing, nylon stockings, swimming suits, tights, velour, children's diapers
2-Bromo-2-nitropropane-1,3-diol (Bronopol)	Topical antibiotic/antifungal creams/ointments, finger paints, kitty litter, detergents, toiletries and cleansers, cleansing lotions, creams, foundations, hair conditioners, mouthwash, shampoos

para-phenylenediamine[2,9,12,13,17]	Secondary	Secondary
p-tert-butylphenol formaldehyde resin[2,9,13]	Secondary	Secondary

*Primary allergens: most prevalent in the pediatric population with the highest clinical relevance and therefore would be the highest yield as a basic series.
†Secondary allergens: additional significant allergens that could be tested for if there is a relevant exposure history.
GCDRG – German Contact Dermatitis Research Group; *MCI/MI* – methylchloroisothiazolinone/methylisothiazolinone.

TABLE 53-5 Relevance

Definite	If a use test with the putative item containing the suspected allergen is positive or positive patch to object/product
Probable	If the substance identified by patch testing can be verified as present in the known skin contactants of the patient
Possible	If the patient is exposed to circumstances in which skin contact with materials known to contain the putative allergen will likely occur
Past	If the patient had previous exposure but is currently not exposed
Unknown	

BOX 53-1 STRUCTURAL GROUPS OF CORTICOSTEROIDS: CROSS-REACTIVITY BASED ON TWO IMMUNE RECOGNITION SITES – C 6/9 AND C16/17 SUBSTITUTIONS

Class A (hydrocortisone and tixocortol pivalate: has C17 or C21 short chain ester)
Hydrocortisone, -acetate, tixocortol, prednisone, prednisolone, -acetate, cloprednol, cortisone, -acetate, fludrocortisone, methylprednisolone-acetate
Class B (acetonides: has C16 C17 *cis*-ketal or -diol additions)
Triamcinolone acetonide, -alcohol, budesonide, desonide, fluocinonide, fluocinolone acetonide, amcinonide, halcinonide
Class C (nonesterified betamethasone; C16 methyl group)
Betamethasone sodium phosphate, dexamethasone, dexamethasone sodium phosphate, fluocortolone
Class D1 (C16 methyl group and halogenated B ring)
Clobetasone 17-butyrate, -17-propionate, betamethasone-valerate, dipropionate, alclometasone dipropionate, fluocortolone caproate, -pivalate, mometasone furoate
Class D2 (labile esters w/o C16 methyl nor B ring halogen substitution)
Hydrocortisone 17-butyrate, -17-valerate, -17-aceponate, -17-buteprate, methylprednisolone aceponate

Wilkinson, SM. Corticosteroids cross reactions: an alternative view. Contact Dermatitis 2000;42:59–63.

days. More than 50% of positive patch testing to gold was delayed for about 1 week.

The International Contact Dermatitis Research Group has developed a grading system that is almost universally recognized and continues to be widely used (Table 53-2).

DETERMINING CLINICAL RELEVANCE

The relevance of positive reactions to clinical ACD can only be established by carefully correlating the history, including exposure to the allergen. A positive patch test reaction may be relevant to present or previous dermatitis, multiple true-positives can occur, and mild responses may still represent allergic reaction. Conversely, patients with negative results may need to be referred for more complete testing to a patch testing clinic. Thus, understanding the sources of antigen in the patient's environment is required to be able to advise the patient adequately regarding avoidance and alternatives in ACD. A positive patch test is considered to be a 'definite' reaction of ACD if the result of a 'use test' with the suspected item was positive or the reaction of the patch test with the object or product was positive. It would be 'probable' if the antigen could be verified as present in known skin contactants and the clinical presentation was consistent, and 'possible' if the patient is exposed to circumstances in which skin contact with materials known to contain allergen was likely (Table 53-5). Multiple sensitivities are possible if different allergens are present in different products used simultaneously, or concomitant sensitization occurs if allergens are present in the same products and both induce sensitization. Cross-sensitization can also occur. Common combinations of a

https://CafePezeshki.IR

positive patch test are: PPD and benzocaine (cross-sensitizer); thiuram mix, carba mix and mercapto mix (rubber products); quaternium 15 and paraben (quaternium-15, a formaldehyde releaser, and paraben are preservatives that are frequently combined and cosensitize); cobalt and nickel (cobalt is used in alloys with nickel and chromium and cosensitize). Polysensitization is common in children.

The repeat open application test (ROAT) or exaggerated use test may be done to confirm the presence or absence of ACD. The suspected allergen (for 'leave-on' but not 'wash-off' products) is applied to the antecubital fossa twice daily for 7 days, and observed for dermatitis. The absence of a reaction makes CD unlikely. If eyelid dermatitis is considered, ROAT can be carried out on the back of the ear.

Additional tests used less frequently in the diagnosis of CD include skin biopsy to differentiate from other diseases. Prick or intradermal testing may be helpful, especially in the evaluation of contact urticaria. Contact urticaria can also be evaluated with an 'open' patch test. Potassium hydroxide preparation for fungal hyphae or cultures may be needed to identify fungal disease.

Allergens of Particular Importance in Children

NICKEL

Nickel is a more common cause of ACD than all other metals combined, even in children. Of 391 children aged 18 years or less who were patch tested by the NACDG, 28% had a positive patch test to nickel, and 26% were deemed to have a nickel allergy of either current or past relevance.[94] Nickel allergy is more common in adolescents, girls more than boys, and ear piercing is the most important predisposing factor. The prevalence of nickel allergy among children with pierced ears was 13% compared to 1% among those without.[95] The risk of sensitization to nickel appears higher when earlobes are pierced before the age of 20 years ($P < .05$)[96] and is increased with the number of piercings.[97] Thus, some authors recommend that ear piercing be delayed until after 10 years of age, presumably to allow for the development of immune tolerance.[98]

Nearly 5 million people in the USA and Canada undergo orthodontic treatment. In patients with contact allergy to orthodontics, nickel is the most common allergen. Nickel is commonly used in orthodontics; stainless steel, which contains about 8% nickel that is not normally biologically available, is generally considered safe in nickel-allergic patients. Certain flexible titanium-nickel arch wires used in orthodontics release increased amounts of nickel compared to stainless steel and may need to be avoided in patients with known nickel sensitivity.[99] A Finnish study of adolescents found that 35% of the girls who had their ears pierced prior to orthodontic treatment were nickel allergic versus none of the girls who had orthodontic treatment prior to ear piercing.[100] The mechanism responsible was suggested to be oral tolerance.[101] In females, nickel sensitivity may increase the risk of developing hand eczema.[102] The presence of releasable nickel from the surface of any object can be detected using the dimethylglyoxime spot test; a pink color indicates the presence of releasable nickel. Despite some studies suggesting benefit,[103,104] the evidence for dietary avoidance of nickel is not strong (quality of evidence IV, strength of recommendation C).[91]

CHROMATE

Chromates are commonly found in products made of chrome and stainless steel, cement and leather. They are found in shoes and gloves, where chromium salts are used in the tanning process. Chromate sensitivity can be associated with hand or foot dermatitis, which can persist even after chromate avoidance.

THIMEROSAL

Thimerosal is a mercuric derivative of thiosalicylic acid used as a preservative in vaccines, cosmetics, tattoo inks, eye drops and contact lens solutions as well as a disinfectant (e.g. merthiolate).[105,106] It may cross-react with mercury, which is used as a preservative material in shoe manufacturing. The NACDG reported thimerosal as the fifth most common allergen, inducing allergic reactions in 11% of patch-tested patients,[107] with only 17% of the positive patch tests considered clinically relevant, ranking thimerosal last in relevance among the 50 allergens tested. Sensitization to thimerosal is associated with routine vaccination and this sensitization is lifelong. Thus a positive patch test to thimerosal may not have current relevance. However, thimerosal can still be found in ophthalmic solutions and some eye make-up and may have relevance in eyelid dermatitis. Because of its potential toxicity and allergenicity in children, precautionary measures are underway to remove thimerosal from vaccines.[108] Notably, sensitization to thimerosal is not a contraindication to vaccination[109–111] and the only vaccine for children under 6 years of age that still contains thimerosal is the inactivated influenza vaccine in the multi-dose units; the single-dose units do not contain thimerosal.[112] Thimerosal's removal from the allergy patch testing screening tray has been recommended.[113]

Aside from thimerosal, reactions to adjuvants (e.g. aluminum hydroxide), stabilizers (e.g. gelatin), preservatives and antibiotics (e.g. neomycin) in vaccines have been reported.

ALUMINUM

Aluminum may cause cutaneous granulomas in response to vaccines containing aluminum hydroxide. These tend to resolve spontaneously, although children subsequently have positive patch tests to metallic aluminum or its salts.[114] The aluminum sensitivity appears to be lost with time as it occurs rarely in adults.

RUBBER CHEMICALS

Rubber chemicals (thiuram mix, mercaptobenzothiazole, mercapto mix) are used in the manufacturing of both dipped (e.g. balloons, gloves) and molded (e.g. pacifiers, handle bars) rubber products. Mixed dialkyl thioureas (MDTU), a mixture of two thiourea chemicals, is used for rubber acceleration and as an antioxidant in the manufacturing of neoprene. Large quantities of thioureas have been shown to leach from neoprene compounds and the levels were sufficient to elicit ACD.[115] This allergen mixture has one of the highest relevancy rates in the NACDG database. ACD from neoprene includes cases caused by orthopedic braces, prostheses, splints and foot supports; athletic shoes; rubber masks, swim goggles and wet suits; computer wrist rests; neoprene gloves; and rubber-based materials in automobiles.

https://CafePezeshki.IR

Special Considerations

PLANT DERMATITIS (PHYTODERMATOSES)

A number of plants can cause irritant reactions through mechanical or chemical injury. Most mechanical injury from plants is trivial, although inoculation of cactus hairs can cause pruritus. 'Itching powder' from rose hip hairs has caused maculopapular, and sometimes pustular, eruptions at sites of contact. Chemical irritation caused by oxalate crystals results from contact with mustard, horseradish and capsaicinoids in chili peppers. Contact with stinging nettles injects a mixture of inflammatory mediators, including histamine, causing a hive, and an unidentified neurotoxin that causes localized numbness and tingling.

Plants of the *Toxicodendron* group, including poison ivy and poison oak, are the most common causes of allergic plant dermatitis in children in the USA. Even newborns can be sensitized to the oleoresin (urushiol). The clinical reaction is typically vesicles and bullae, often with a characteristic linear appearance. Although the fluid content of vesicles is not antigenic, the oleoresin can be transferred by handling exposed pet dander, clothing or sports equipment. Soap and water inactivate the antigen. Urushiol is also found in cashew nut trees, Japanese lacquer, *Ginkgo biloba* and mango skin, and the ingestion of cashews or contact with mango skin can cause a similar rash. Rhus patch testing is not recommended because it has a significant sensitizing capacity.

The Compositae family (Asteraceae), the second largest plant family, represents approximately 10% of the world's flowering plants. ACD to Compositae may manifest as acute or chronic dermatitis of exposed sites. Although ACD to Compositae is typically seen in florists, farmers and professional gardeners, recent studies indicate that it may be more common in children than previously believed. Patch test reactions on screening with two different Compositae mixes detected 4.2% and 2.6% positives among children and adolescents, with significantly higher positive results in children with AD.[116] The dermatitis has an airborne contact pattern distribution in the exposed areas of the hands and face with symptoms worse in late spring or summer and worse after picking daisies, dandelions or playing outdoors. Belloni Fortina and colleagues[117] suggested adding Compositae mix to the pediatric screening series when investigating dermatitis of air-exposed areas in children with AD; however, this carries the risk of false-positive results or sensitization. Cross-reactivity between fragrance terpenes and Compositae plant extracts may be a cause of false-positive patch testing to Compositae.[118] In summary, ACD to Compositae should be suspected in children with a family or personal history of atopy, summer-related or -exacerbated dermatitis and a history of plant exposure.

Ambrosia species, which include ragweed, can cause allergic plant dermatitis when pollinating, in both atopic and nonatopic individuals. Repeated contact with ornamental cut flowers, including *Alstroemeria* (the lily and tulip family of plants), can result in an ACD that presents with a fissured dermatitis of the fingertips. Plants that contain furocoumarins (psoralens), including parsley, parsnips and wild carrots, can cause phototoxic reactions, especially in summer when psoralens are most abundant in the plants where children are playing. These reactions occur when the skin, contaminated with psoralens, is exposed to ultraviolet A light.

DERMATITIS FROM TOPICAL MEDICATIONS

The topical application of anesthetics, antihistamines, antibiotics and even antiinflammatory drugs along with preservatives or fragrances has been implicated in sensitization and contact reactions. Neomycin and topical diphenhydramine are frequent and potent sensitizers in children. Contact allergy to topical corticosteroids can be difficult to diagnose[119] and should be suspected in patients whose dermatitis worsens with the application of a corticosteroid. There have been reports of contact allergy in the nasal mucosa to budesonide nasal spray and stomatitis with budesonide for oral inhalation.[120] Patch testing to some corticosteroids is commercially available but because of concurrent antiinflammatory action, delayed readings beyond 72 hours have to be done. Corticosteroids representative of different structural groups A-D with cross-reactivity based on two immune recognition sites – C 6/9 and C16/17 substitutions – are typically used in patch testing[121] (Box 53-1). Cross-reactivity within a group is higher than between agents in different groups. The currently available T.R.U.E. TEST® contains tixocortol (Class A), budesonide (Class B) and hydrocortisone-17-butyrate (Class D2).

CONTACT DERMATITIS TO COSMETICS

An average adult applies 12 personal hygiene products daily and, in the course of using these products, is exposed to 168 discrete chemicals. Children, especially adolescents, may be exposed to similar numbers. Exposure to multiple potential allergens occurs repeatedly with the use of cosmetics and it is not unusual for these products to manifest as contact allergy distant from the sites of application (termed *ectopic contact dermatitis*).

Fragrance is the most common causes of ACD from cosmetics in the USA. Fragrances can be found in cosmetics, personal hygiene products, diapers and even scented toys, either overtly to add an appealing scent or to mask unpleasant odors.

The term *unscented* can erroneously suggest that a product does not contain fragrance when, in fact, a masking fragrance can be present. *Fragrance-free* products are typically free of classic fragrance ingredients and generally acceptable for the allergic patient. However, if a fragrance-based chemical (such as the preservative benzyl alcohol) is added for a purpose other than to act as a fragrance, the product can still claim that it is fragrance free. The addition of botanical and natural chemicals can also alter the smell of the product. The fragrance mix that is popularly used for patch testing contains eight different fragrances and together with BOP will diagnose approximately 60-70% of fragrance-allergic individuals. Fragrance Mix II is one of the top 10 most frequently positive allergens of the NACD 2009–2010 patch test but is not included in the current T.R.U.E. TEST® and may therefore be missed.

Preservatives, present in most aqueous-based cosmetics and personal hygiene products to prevent rancidity, are grouped into two broad categories: formaldehyde releasers and non-formaldehyde releasers (Table 53-6). Individuals who are allergic to formaldehyde cannot use any of the formaldehyde releasers. Paraben is the most commonly used preservative in cosmetic, pharmaceutical and industrial products because of its broad spectrum of activity against yeasts, molds and bacteria.

Excipients, including propylene glycol, ethylenediamine and lanolin, serve to solubilize, sequester, thicken, foam or lubricate

https://CafePezeshki.IR

TABLE 53-6 Cosmetic Preservatives

Formaldehyde Releaser	Nonformaldehyde Releaser
Quaternium 15	MCI/MI
Diazolidinyl urea	Parabens
Imidazolidinyl urea	Chloroxylenol
Bromonitropropane	Iodopropynyl butylcarbamate
DMDM hydantoin	Benzalkonium chloride
	Thimerosal

Note: Paraben, quaternium-15 and formaldehyde preservatives are frequently combined and cosensitize.

the active component in a product. They can cause ACD or, in higher concentrations, can act as irritants. Lanolin is a common component of consumer products whose composition has not been fully characterized. Medicaments containing lanolin are more sensitizing than lanolin-containing cosmetics. Lanolin is a weak sensitizer when applied on normal skin but a stronger sensitizer on damaged skin.

Hair products are second only to skin care products as the most common cause of cosmetic allergy. Allergy to routine hair care products is usually due to fragrance and cocoamidopropyl betaine, an amphoteric surfactant often found in shampoos, bath products, eye and facial cleaners, roll-on deodorants and other skin and hair care products. Cocoamidopropyl betaine is less irritating (e.g. baby shampoo) than the older polar surfactants such as sodium lauryl sulfate,[122] but is more allergenic.

New trends in permanent and temporary tattoos have emerged in our adolescent population. Black henna mixtures, containing indigo, henna and PPD and/or diaminotoluens, to temporarily paint the skin are used in some cultures, primarily before major events. There is increasing use of PPD to give henna (auburn to red color) a darker shade of brown to black for body painting, and the need for a policy for use in children has been suggested.[123] Adolescents working in hair salons may be exposed to PPD, the most common allergen affecting hairdressers. A number of chemicals may cross-react with PPD[124] such as PABA in sunscreens, sulfonamides, *p*-aminosalicylic acid, benzocaine and related 'caines' anaesthetics, azo dyes and black rubber mix.

Glycerol thioglycolate, the active ingredient in permanent wave solutions, is a more common cause of occupational ACD in hairdressers than consumers. Unlike PPD, thioglycolates may remain allergenic in the hair long after it has been rinsed out, thus allergic individuals may continue to have skin eruptions weeks after application of the perm, and allergic hairdressers may be unable to cut permanent waved hair.

Nail cosmetics have become increasingly popular and fashionable and ACD to acrylics can present locally at the distal digit or ectopically on the eyelids and face. The currently marketed products contain various methacrylate ester monomers, dimethacrylates and trimethacrylates as well as cyanoacrylate-based glues.

Sunscreens are frequently present in cosmetics such as moisturizers, lip preparations and foundations. As a group they are the most common cause of photoallergic CD. *Chemical-free* sun blocks use physical blocking agents instead of photoactive chemicals and include titanium dioxide and zinc oxide, which are rarely sensitizers.

CONTACT DERMATITIS IN ATHLETES

The skin of athletes is exposed to repeated trauma, heat, moisture and numerous allergens and chemicals and is predisposed to ICD or ACD. Early recognition can facilitate appropriate therapy and prevention.[125]

In swimmers, chemicals such as chlorine used to disinfect swimming pools can cause both ICD and ACD. The dermatitis may spare the area under the swimwear. However, swimwear and equipment including goggles, nose plugs, nose clips, ear plugs, fins and swim caps may also cause CD. Although ACD from swimming goggles usually presents with well-demarcated, bilateral periorbital edema and erythema with varying degrees of pruritus, exudate and scaling, conjunctival injection and hypopigmentation have been reported.[126,127] Patch testing to rubber products should ideally include a piece of material taken from the suspected goggles. Allergens include rubber and chemicals used in manufacturing (neoprene, benzoyl peroxide, phenol-formaldehyde resin, thioureas and antioxidants).

'Jogger's nipples' are painful, erythematous and crusted erosions representing an ICD caused by friction from the running shirt.[128] Other skin and nail problems are associated with ICD and ACD from shoes, shirts and topical medications. Contact allergens include components of rubber, leather, glues or dyes used in the manufacture of running shoes. Sweat helps leach out the chemicals from the shoes. Rubber insoles containing mercaptobenzothiazole and dibenzothiazyl disulfide have been reported to cause recurrent eczematous eruptions of the feet, which can be prevented by switching to new insoles made of materials such as polyurethane.[129] In a large case series of student athletes, benzocaine and lanolin (found in topical anesthetics and massage creams) were the most prevalent allergens responsible for CD in runners.[130]

CD in soccer or football players is usually caused by equipment or chemicals used on the field. 'Cement burns' presenting as erythematous, edematous plaques, bullae and erosions on the upper inner thighs are due to the lime component used in field markings. The characteristic rash, a history of exposure to wet field lines, and worsening of symptoms after taking a hot shower point to the diagnosis. Treatment includes removing contaminated clothing, cleaning the areas with water and applying topical antibiotics or petroleum jelly.

Like runners, soccer players may develop ACD from topical anesthetic creams, epoxy resins, nickel in certain athletic shoes and tincture of benzoin used in conjunction with athletic tape.[125]

Urea-formaldehyde resin in shin pads has caused ACD in soccer players.

Ball handling in baseball and basketball can cause both ICD and ACD. 'Basketball pebble fingers', manifesting as small petechiae and abrasions on a shiny denuded surface of the fingertips and pads, is an ICD resulting from mechanical irritation from the ball's pebbled surface. An eczematous rash on both palms, the palmar fingertips and base of the thumbs may be due to rubber allergy.[131] Protective knee padding and adhesives in athletic tape contain rubber accelerators and formaldehyde resins.

Tennis players can develop ICD due to friction of the medial thighs. This manifests as erythematous eruptions over the opposing areas. ACD can be caused by isophorone diamine and epoxy resin used in the manufacture of tennis rackets, neoprene splints for tennis elbow, squash balls with

https://CafePezeshki.IR

N-isopropyl-*N*′-phenylparaphenylenediamine, rubber and anesthetic sprays with ethyl chloride.

Fiberglass in hockey sticks, epoxy resin adhesives in a face mask and dyes used in the manufacture of hockey gloves have caused ACD.[132] Weightlifters have developed ACD to the nickel and palladium in weights or bars[133] and the chalk used to achieve a better grip.[134]

In summary, the young athlete is constantly exposed to allergens in clothing, equipment, environment and medications. The unique presentation of the rash, a careful sports-directed history and allergen-directed patch testing enhances the ability to diagnose and care for the young athlete with dermatitis.

Treatment and Prevention

Identification of the allergen to improve avoidance of contact to the allergen and education of patients and/or families is the mainstay of treatment for ACD. All other measures are palliative and temporary. Compliance with allergen avoidance is frequently difficult. Once the offending agent is identified, patients and/or caregivers must be educated regarding the nature of the dermatitis, triggering agents and irritant factors. A list of potential exposure alternatives and substitutes should be offered to the patient to increase compliance (see textbooks such as Fisher's *Contact Dermatitis*[135] or Marks et al's *Contact and Occupational Dermatitis*).[136] There are two US databases of products free of allergens the patient is allergic to: the Contact Allergen Management Program (CAMP) of the American Contact Dermatitis Society (www.contactderm.org) and the Contact Allergen Replacement Database (CARD) of the Mayo Clinic (www.AllergyFreeSkin.com).

Topical corticosteroids are the first-line treatment for ACD and are most effective when treating localized dermatitis. Low-potency corticosteroids are recommended for the thinner skin of the face and flexural areas, and high-potency corticosteroids are indicated for thickened, lichenified lesions. Ointments are generally more potent, more occlusive and contain fewer sensitizing preservatives than creams and lotions. Patients with sensitivity to preservatives can use preservative-free corticosteroids such as fluocinolone (Synalar®) ointment, triamcinolone (Aristocort®) ointment or betamethasone dipropionate (Diprosone®) ointment. Of note, high-potency corticosteroids should not be used for diaper dermatitis, yet the results of one survey revealed that a combination antifungal-corticosteroid product containing betamethasone dipropionate was used in 6% of encounters.[137]

Cool compresses with aluminum subacetate (Burrow's solution), calamine or colloidal oatmeal may help acute, oozing lesions. Excessive handwashing should be discouraged in patients with hand dermatitis, and nonirritating or sensitizing moisturizers must be used after washing. Soaps and nonalkaline cleansers should be avoided.

For extensive and severe CD, systemic corticosteroids may offer relief within 12 to 24 hours.

Topical calcineurin inhibitors, approved for children with AD, have been used in both animal models and patients with ACD.[138,139] These agents do not induce skin atrophy and may be especially valuable in treating facial or eyelid dermatitis, although use in CD would be off-label at the present time.

Antihistamines may offer some benefit in contact urticaria and some relief from pruritus. Oral diphenhydramine should not be used in patients with ACD to diphenhydramine in a calamine base (Caladryl®) or hydroxyzine hydrochloride (Atarax®) in ethylenediamine-sensitive patients. Other treatments include ultraviolet light as well as immunomodulating agents such as methotrexate, azathioprine and mycophenolate mofetil.

Mechanical barriers such as protective gloves and clothing and barrier creams are helpful in some cases. For nickel-allergic patients, barriers such as gloves, covers for metal buttons and identification of nickel by the dimethylglyoxime test can be prescribed but results can be disappointing.[136]

Frequency of diaper changes using improved product design features, such as superabsorbent disposable diapers, is believed to explain the decline in diaper dermatitis among infants.[140] Low-potency corticosteroids and barrier ointments or creams can be used for a limited period of time.[141] A topical antifungal agent should be used in secondary *C. albicans* infection. A gentle cleansing routine, frequent diaper changes and a thick barrier cream help control this condition.[142]

Patient education regarding the nature of the dermatitis, triggering agents and irritant factors plus instruction for avoidance and appropriate substitutes will not only aid in clearing the dermatitis but also prevent or minimize recurrences. At present, hyposensitization of patients with ACD is not a viable therapy.[143]

Conclusions

Contact dermatitis includes irritant and allergic forms and can affect patients of any age. Identification and avoidance of the allergen is key to the successful treatment of ACD. Patch testing remains the gold standard for diagnosis of ACD even in children, and negative results in the face of a convincing clinical presentation should prompt further evaluation by a specialist in CD. A limited number of interventions effectively prevent or treat ICD and ACD, but well-controlled, outcome-blinded studies, particularly in the area of ACD prevention, are needed.[144] New insights into the immune mechanisms involved may lead to better treatment strategies, including induction of tolerance, especially with difficult-to-avoid allergens.[145]

54 Allergic and Immunologic Eye Disease

LEONARD BIELORY | BRETT P. BIELORY | RUDOLPH S. WAGNER

KEY POINTS

- The hallmark of allergic conjunctivitis is itching. Bacterial and viral conjunctivitis do not commonly present with pruritus.
- Bacterial and viral conjunctivitis generally have a self-limited course ranging from 5 to 14 days. Signs and symptoms of acute allergic conjunctivitis wax and wane of over longer periods of time coinciding with the circulating allergen (e.g. seasonal pollens).
- Chronic conjunctival vascular injection, 'red or pink eye', may occur in children with dry eye disease related to intense viewing of cell phones and other electronic devices.
- Disorders of the tear film as in meibomian gland disease (MGD) can result in chronic blepharoconjunctivitis.
- Topical steroids should be used with caution in treating conjunctivitis in children because they may raise the intraocular pressure (glaucoma) or exacerbate a herpes simplex virus (HSV) keratoconjunctivitis.
- Some systemic antihistamines may produce dry eye symptoms that confound the diagnosis of allergic conjunctivitis.

Allergic disease affects as many as 25% of the pediatric population. The direct costs of upper airway allergies are approximately $5.9 billion, with children < 12 years accounting for 38% ($2.3 billion) of the total.[1] In a study of 5,000 allergic children, ocular allergy was reported in 32% as the single manifestation of their allergies.[2] In the USA ocular allergy symptoms have doubled over the past 25 years with up to 40% of the population reporting ocular symptoms in the NHANES study,[3] coinciding with the international market growth in the treatment of anterior ocular inflammatory disorders with anti-allergics occupying 25% of the market.[4] This chapter provides an overview of pediatric 'red eye' eye disease and a focus on the approach to proper diagnosis and management of allergic disorders.

Eye Anatomy, Histology and Immune Function

The eye is a common target of local and systemic inflammatory disorders that impact on the patient's quality of life, due to its considerable vascularization and vessel sensitivity, and the potential for visual loss. Anterior ocular inflammatory disorder can pose a formidable diagnostic challenge to clinicians, and thus a solid understanding of the eye's anatomy, histology and immune function is essential.

The eye is essentially constructed of two immunologically active portions (Figure 54-1):

1. Anteriorly the eyelids, conjunctiva (palpebral and bulbar) and tear fluid layer provide the primary barrier against environmental aeroallergens, chemicals and infectious agents and are contiguous with the collagenous sclera, involved in autoimmune disorders.
2. Internally the highly vascular uvea is involved in immune complexes and cell-mediated systemic inflammatory disorders and is contiguous with the retina, which is an extension of the central nervous system.

Immunologic hypersensitivity reactions involving the eye incorporate the spectrum of the classic Gell and Coombs classification[5] (Table 54-1).

EYELIDS

The eyelids are the first line of defense for the eye as they provide a mechanical barrier that maintains moisture and cleanses the anterior ocular surface. However, the palpebral skin is extremely thin compared to the dermis elsewhere (0.55 mm thick compared to the 2 mm integument of the face), and is also commonly involved in fluid retention, such as in periorbital edema and anasarca.

CONJUNCTIVA

The conjunctiva is an active immunologic tissue as it consists of a thin mucous membrane that extends from the eyelid margin to the limbus of the eye. It is divided into: (1) the palpebral conjunctiva lining the inner surface of the eyelids; (2) the bulbar conjunctiva covering the sclera; and (3) the fornix or conjunctival sac at the junction between the bulbar and palpebral conjunctiva. The conjunctiva consists of two distinct histologic layers: the epithelium composed of two to five layers of stratified columnar cells, with interspspersed mucin producing goblet cells and the substantia propria composed of connective tissue.

Inflammatory cells such as mast cells, eosinophils and basophils normally do not reside in the ocular epithelium. In the substantia propria, mast cells (~6,000/mm^3) are present, predominantly (>95%) of connective tissue type (MC_{TC}).[6–8] However, in the more chronic forms of allergic conjunctivitis, an increase in mucosal type mast cells (MC_T) can be found in the epithelial layer.[7] Epithelial cells have also been found to have an extensive proinflammatory capability in the production of various cytokines, such as tumor necrosis factor alpha (TNF-α),

https://CafePezeshki.IR

interleukin (IL)-6 and IL-10 as well as various adhesion molecules, such as intracellular adhesion molecules (ICAM-1).

Various mononuclear cells, including Langerhans cells, $CD3^+$ lymphocytes and $CD4^+/CD8^+$ lymphocytes, are also an active component of the anterior surface immune response and are primarily found in the epithelial layer. Langerhans cells, which serve as antigen-presenting cells in the skin, have a similar role in the eye.[6] The primary lymphoid organ for intraocular reactions is the spleen. Although lymphatics do drain from the lateral conjunctiva to the preauricular nodes (e.g. parotid node) just anterior to the tragus of the ear, the nasal conjunctival lymphatics drain to the submandibular nodes. It is generally believed that activated conjunctival lymphocytes travel first to these regional lymph nodes, then to the spleen, and ultimately back to the conjunctiva.

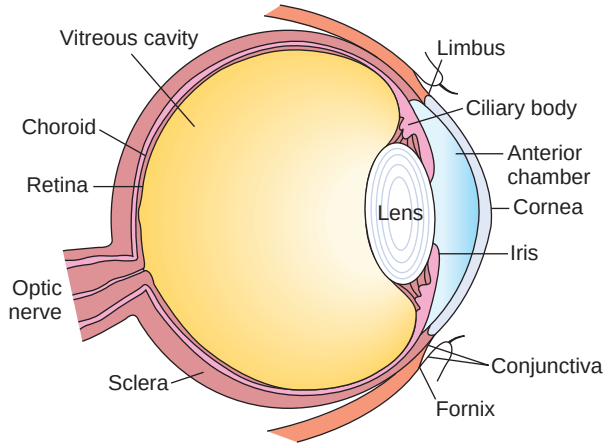

Figure 54-1 Sagittal cross-sectional view of the human eye revealing the parts commonly involved in immunologic reactions: eyelids (blepharitis and dermatitis); conjunctiva (conjunctivitis); cornea (keratitis); sclera (episcleritis and scleritis); optic nerve (neuritis); iris (iritis); vitreous (vitreitis); choroid (choroiditis); and retina (retinitis). The last four parts constitute the inner portion of the eye (the uveal tract) and are classified as forms of uveitis.

TEAR FILM

The conjunctival surface is bathed in a thin layer of tear film that appears approximately 2 to 4 weeks after birth. A recent model of tear film structure describes an aqueous layer with a gradient of mucin that decreases from the ocular surface to the overlying lipid layer.[9] Goblet cells distributed along the conjunctival surface produce this mucin, which decreases the surface tension of the tear film, thus maintaining a moist hydrophobic corneal surface. The outermost lipid component of the tear film decreases the evaporation rate of the aqueous tears. The aqueous portion of the tear film contains a variety of solutes, including electrolytes, carbohydrates, ureas, amino acids, lipids, enzymes and tear-specific prealbumin, and immunologically active proteins, including immunoglobulin A (IgA), IgG, IgM, IgE, tryptase, histamine, lysozyme, lactoferrin, ceruloplasmin, vitronectin and cytokines.

UVEAL TRACT

The uveal tract comprises the iris, ciliary body and choroid, each of which possesses a rich vascular architecture and pigment. The pigment acts as a filtering system. The ciliary body is involved in the production of aqueous humor and is a common site for the deposition of immune complexes. In addition, disturbances in the production or outflow of aqueous humor may lead to increased intraocular pressure (IOP; i.e. glaucoma). There are congenital forms of glaucoma that are not specifically associated with immunologic disorders but must be considered in the differential diagnosis of pediatric conjunctivitis ('pink eye' or 'red eye').

Differential Diagnosis

The differential diagnosis of the pediatric red eye can be broadly divided into four categories: allergic, infectious, immunologic and nonspecific (Figure 54-2). Each category possesses distinct signs and symptoms.[10] These indicators are summarized in Table 54-2 and can be used as a guide to delineate pediatric red eye.

TABLE 54-1 Categories of Pediatric Ocular Inflammation

Category	Recognition Component	Soluble Mediators	Time Course	Cellular Response	Clinical Example
IgE/mast cell	IgE	Leukotrienes Arachidonates Histamine	Seconds Minutes	Eosinophils Neutrophils Basophils	Allergic conjunctivitis Anaphylaxis Vernal keratoconjunctivitis
Cytotoxic antibody	IgG IgM	Complement	Hours Days	Neutrophils Macrophages	Mooren's ulcer Pemphigus Pemphigoid
Immune complex	IgG IgM	Complement	Hours Days	Neutrophils Eosinophils Lymphocytes	Serum sickness uveitis Corneal immune rings Lens-induced uveitis Behçet's syndrome Kawasaki's disease Vasculitis
Delayed hypersensitivity	Lymphocytes Monocytes	Lymphokines Monokines	Days Weeks	Lymphocytes Monocytes Eosinophils Basophils	Corneal allograft rejection Sympathetic ophthalmia Sarcoid-induced uveitis

https://CafePezeshki.IR

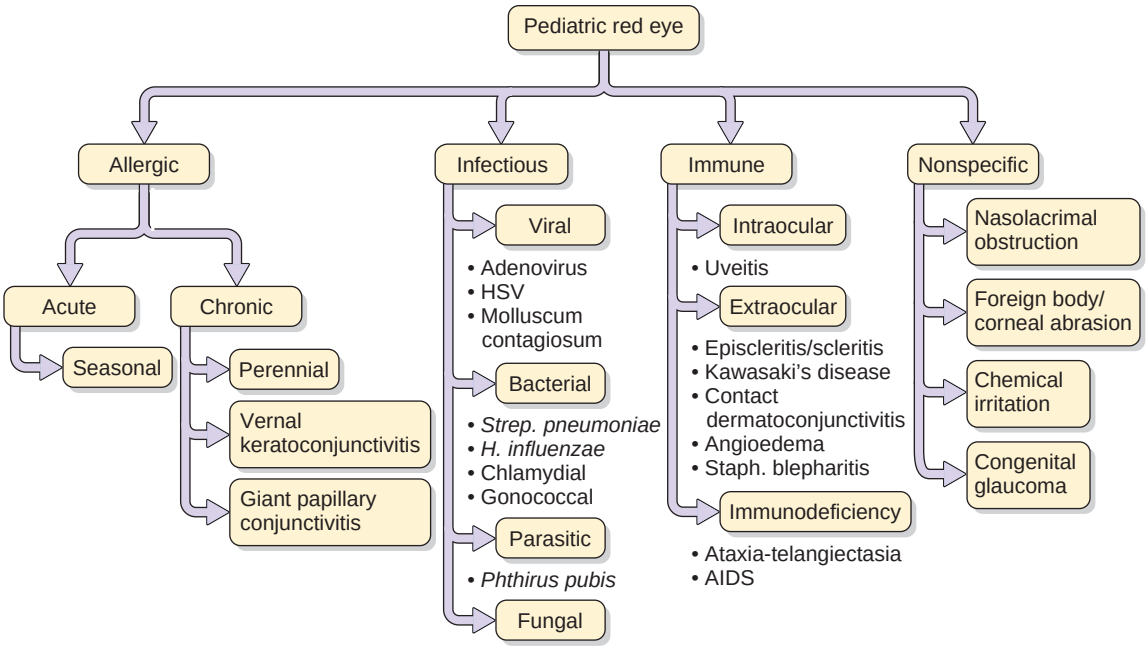

Figure 54-2 The differential diagnosis of pediatric 'red eye' includes infectious agents (e.g. chlamydial disease, adenovirus), allergic conditions (e.g. SAC, PAC, GPC, VKC), immunologic disorders (e.g. Kawasaki's disease, uveitis, ataxia-telangiectasia) and nonspecific causes (e.g. foreign body, chemical irritation, nasolacrimal obstruction).

History

A detailed and accurate history is the most important element in distinguishing allergic from nonallergic causes of pediatric conjunctivitis. When evaluating a newborn, a full prenatal history, including developmental delays and maternal infections (e.g. HSV, *Chlamydia* or human immunodeficiency virus [HIV]), needs to be obtained. Ocular trauma from forceps or vacuum delivery has been known to occur. In addition, ocular medications such as silver nitrate and erythromycin given at childbirth may cause chemical irritation. In the older child, recent exposure to individuals with conjunctivitis or upper respiratory tract infection, either within the family or at school, may suggest exposure to adenovirus infection in an endemic area. The conjunctivitis-otitis media syndrome, occurring frequently in preschool children, is usually caused by nontypable *Haemophilus influenzae* or *Streptococcus pneumoniae*.[11,12] Family history is particularly important when inherited disorders are suspected. Accidental trauma resulting in corneal abrasions or ocular foreign bodies may also occur, especially in the curious and mobile toddler. Yet, while accidents occur frequently, child abuse must also be considered; in these circumstances a thorough social history is merited. In teenagers, a sexual history may suggest a chlamydial or neisserial infection. Patient use and abuse of over-the-counter topical medications (e.g. vasoconstrictors, artificial tears, cosmetics or contact lens wear) has the potential to produce inflammation (conjunctivitis medicamentosa or toxic keratopathy). As with all allergies, environmental factors and time of onset must be addressed, including seasonal variation and exposure to tobacco smoke, cleaning supplies, pets, air-conditioning, carpets and other sources of irritants.

Many of the signs and symptoms of allergic conjunctivitis are nonspecific as they involve the four classical signs of inflammation (calor, dolor, rubor and tumor), originally recorded by the Roman encyclopedist Celsus in the 1st century AD, and include heat, pain, redness, swelling, tearing, irritation, stinging, burning and photophobia. The hallmark of allergic conjunctivitis is itching. Pruritus can be mild or prominent and may last from hours to days. A stringy or ropy discharge is also characteristic of a persistent ocular allergy, and may range from serous to purulent. While a purulent discharge may be present, morning crusting and difficulty opening the lids are more characteristic of bacterial causes, especially Gram-negative organisms (e.g. *Neisseria* and *Haemophilus*). Environmental allergens affect both eyes at once, although a unilateral reaction may result if one eye is inoculated with animal hair or dander. Ocular pain is not typically associated with allergic conjunctivitis and suggests an extraocular process such as a corneal abrasion, scleritis or foreign body, or an intraocular process such as uveitis.

Eye Examination

The eye should be carefully examined for evidence of eyelid involvement such as blepharitis, dermatitis, swelling, discoloration, ptosis or blepharospasm (Table 54-3). Conjunctival involvement may present with chemosis, hyperemia, cicatrization or formation of papillae on the palpebral and bulbar membranes. The presence of increased or abnormal secretions should also be noted. A fundoscopic examination should be performed to detect such conditions as uveitis (often associated with autoimmune disorders) and cataracts (associated with atopic disorders and chronic steroid use).

The examination starts with an inspection of the face and area surrounding the eye. A horizontal skin crease on the nose (nasal salute) suggests a history of allergic rhinitis. Allergic shiners are ecchymotic-looking areas beneath the eyes thought to result from impaired venous return from the subcutaneous tissues (Figure 54-3). Angioedema commonly involves the conjunctiva, but it more commonly affects the periorbital space and is more prominent around the lower lids secondary to gravity.

TABLE 54-2 Differential Diagnosis of Pediatric Conjunctivitis

	Predominant Cell Type	Chemosis	Lymph Node	Cobblestoning	Discharge	Lid Involvement	Pruritus	Gritty Sensation	Pain	Seasonal Variation
ALLERGIC										
AC	Mast cell EOS	+	–	–	Clear mucoid	–	+	+/–	–	+
VKC	Lymph EOS	+/–	–	++	Stringy mucoid	+	++	+/–	+/– if cornea is involved	+
GPC	Lymph EOS	+/–	–	++	Clear white	–	++	+	–	+/–
INFECTIOUS										
Bacterial: Strep., Staph., *Haemophilus*	PMN	+/–	+	–	++ Mucopurulent	–	–	+	+/–	+/–
Viral	PMN Monolymph	+/–	++	+/–	Clear mucoid	–	–	+	+/–	+/–
Chlamydial	Monolymph	+/–	+/–	+	++ Mucopurulent	–	–	+	+/–	+/–
IMMUNOLOGIC										
Kawasaki's disease	PMN, lymph	+/–	++	–	Serous mucoid	–	–	+/–	+/–	–
Uveitis	Lymph	–	–	–	–	–	–	–	++	–
Sarcoidosis	Lymph	–	–	–	–	Grey flat papules	–	–	+/–	–
JIA	Lymph	–	–	–	–	–	–	–	+/–	–
Episcleritis	Lymph	–	–	–	–	–	–	–	++	–
Contact dermatoconjunctivitis	Lymph	–	–	–	+/–	++	+	–	+/– if cornea is involved	–
Angioedema	Mast cell	++	–	–	–	+++	+/–	–	–	–
Ataxia-telangiectasia	–	–	–	–	–	–	–	–	–	–
Staphylococcal blepharitis	Monolymph	+/–	–	–	++ mucopurulent	++	+	++	+/– if cornea is involved	–
NONSPECIFIC										
Congenital entropion epiblepharon	–	–	–	–	Serous watery	++	–	+	+++	–
Congenital glaucoma	–	–	–	–	Serous	+/–	–	+/–	+++	–
Corneal abrasion	–	–	–	–	Serous watery	+	–	+/–	+++	–
Chemical	–	–	–	–	Serous mucoid	++	–	+/–	+++	–
Nasolacrimal obstruction	PMN if secondary infection	–	–	–	Mucopurulent	+	–	+/–	+/–	–

AC – Allergic conjunctivitis, *EOS* – eosinophils, *VKC* – vernal keratoconjunctivitis, *GPC* – giant papillary conjunctivitis, *PMN* – polymorphonuclear leukocytes, *JIA* – juvenile idiopathic arthritis.

https://CafePezeshki.IR

TABLE 54-3 Ocular Clinical Signs

Disorder	Description
Blepharitis	Inflammation of the eyelids; sometimes associated with the loss of eyelashes (madarosis)
Chalazion	A chronic, granulomatous inflammation of the meibomian gland
Chemosis	Edema of the conjunctiva due to transudate leaking through fenestrated conjunctival capillaries
Epiphora	Excessive tearing; may be due to increased tear production or more commonly congenital obstruction of the nasolacrimal drainage system. This may occur in as many as 20% of infants, but resolves spontaneously in most cases before 1 year of age.[13] Children with chronic sinusitis and/or rhinitis may have intermittent nasolacrimal duct obstruction since the distal nasolacrimal duct drains below the inferior meatus. Congenital glaucoma may also present with epiphora but has other characteristic findings (e.g. corneal enlargement, photophobia and eventually corneal edema presenting as a corneal haze) usually within the first year of life*
Hordeolum	Synonymous with a stye
Keratitis	Inflammation and infection of the corneal surface, stroma and endothelium, with numerous causes
Leukocoria	A white pupil; seen in patients with Chédiak-Higashi syndrome (a neutrophil defect), retinoblastoma, cataracts and retrolental fibroplasia
Papillae	Large, hard, polygonal, flat-topped excrescences of the conjunctiva seen in many inflammatory and allergic ocular conditions
Phlyctenule	The formation of a small, gray, circumscribed lesion at the corneal limbus that has been associated with staphylococcal sensitivity, tuberculosis and malnutrition
Proptosis	Forward protrusion of the eye or eyes
Ptosis	Drooping of the eyelid, which may have neurogenic, muscular or congenital causes. Conditions specific to the eyelid that may cause a ptotic lid include chalazia, tumors and preseptal cellulitis
Scleritis	Inflammation of the tunic that surrounds the ocular globe. Episcleritis presents as a red, somewhat painful eye in which the inflammatory reaction is located below the conjunctiva and only over the globe of the eye. The presence of scleritis should prompt a search for other systemic immune-mediated disorders
Trichiasis	In-turned eyelashes; usually results from the softening of the tarsal plate within the eyelid
Trantas' dots	Pale, grayish-red, uneven nodules made up of eosinophils with a gelatinous composition seen at the limbal conjunctiva in vernal conjunctivitis

*Data from Seidman DJ, Nelson LB, Calhoun JH, et al. Pediatrics 1986;77:399–404.

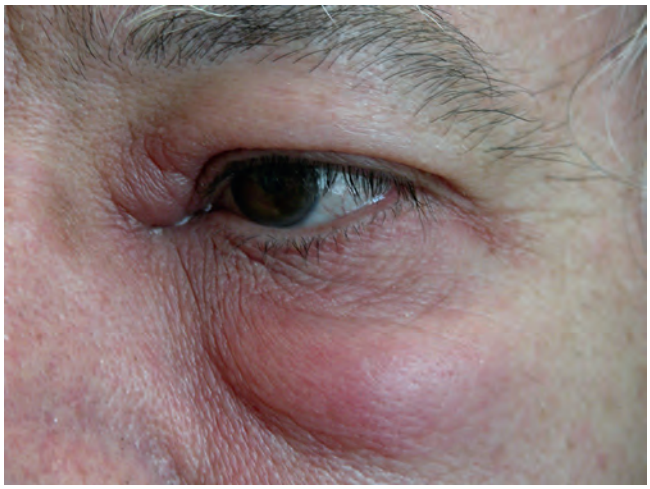

Figure 54-3 Patient with periorbital swelling.

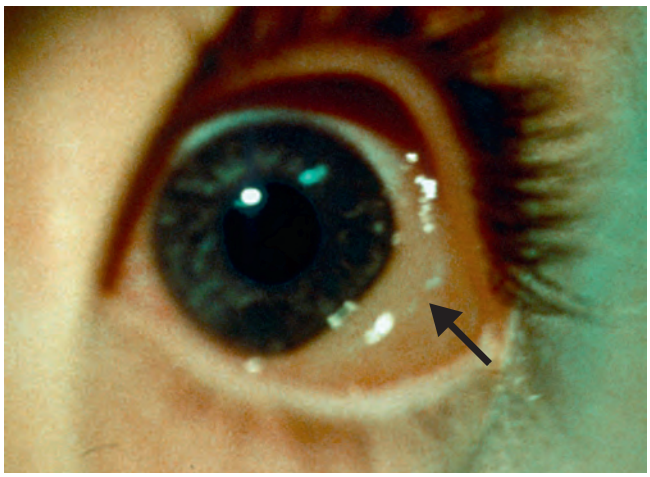

Figure 54-4 Conjunctival edema or chemosis with milky appearance obscuring conjunctival vessels in an acute allergic reaction.

Eyelid or nasal vesicular eruptions are often seen in ophthalmic zoster, but can also reflect recurrent bacterial infection-associated staphylococcal blepharoconjunctivitis due to constant rubbing of the eyelids. Scratches and scars on the face or eyelid suggest ocular injury. In addition, palpation of the sinuses and the preauricular and cervical chain lymph nodes is of diagnostic importance.

Next, the conjunctiva should be thoroughly inspected. The bulbar conjunctiva examination is performed by looking directly at the eye and asking the patient to look up and then down, while gently retracting the opposite lid. Examine the palpebral (tarsal) conjunctiva by grasping the upper lid at its base with a cotton swab on the superior portion of the lid while gently pulling the lid out and up as the patient looks down. To return the lid to its normal position, have the patient look up. The lower tarsal conjunctiva is examined by placing a finger near the lid margins, everting the lower eyelid and drawing downward. A 'milky' appearance of the conjunctiva is characteristic of allergy and is the result of the obscuring of blood vessels by conjunctival edema (Figure 54-4). In contrast, a velvety, beefy-red conjunctiva with purulent discharge suggests a viral or bacterial etiology, while follicular or papillary

https://CafePezeshki.IR

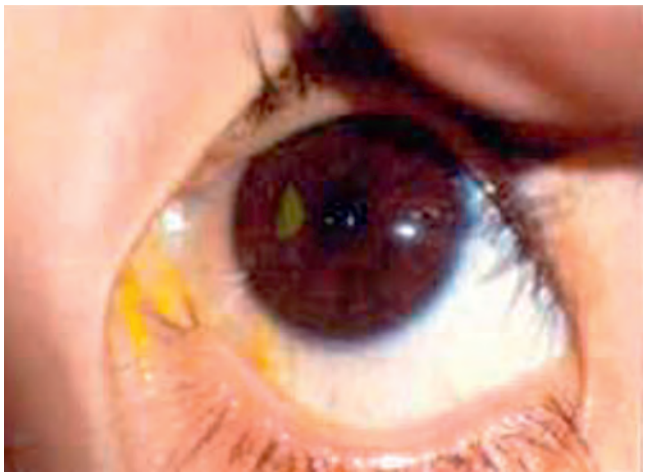

Figure 54-5 Triangular corneal abrasion highlighted with fluorescein dye.

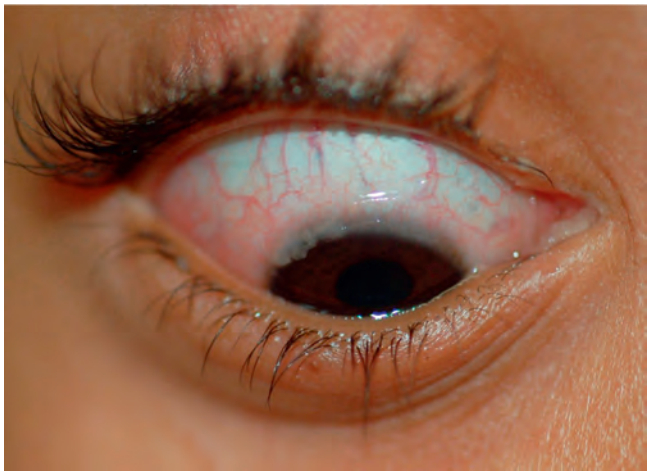

Figure 54-6 Limbal conjunctivitis (a form of vernal conjunctivitis).

hyperplasia of the conjunctival surface reflects a more persistent or chronic inflammatory condition. Follicles appear as grayish, clear or yellow bumps varying in diameter from a pinpoint to 2 mm, with conjunctival vessels on their surface, while papillae contain a centrally located tuft of vessels. Although a fine papillary reaction is nonspecific, giant papillae (greater than 1 mm) on the upper tarsal conjunctiva indicate an allergic source. Papillae are generally not seen in active viral or bacterial conjunctivitis. The presence of follicles, a lymphocytic response in the conjunctiva, is a specific finding that occurs primarily in viral and chlamydial infections, but is also seen in chronic and persistent forms of ocular allergy.

The cornea is best examined with a slit lamp biomicroscope, although many important clinical features can be seen with the naked eye or with the use of an ophthalmoscope. The cornea should be perfectly smooth and transparent. Dusting of the cornea may indicate punctate epithelial keratitis. A localized corneal defect may suggest erosion or a larger ulcer that could be related to major basic protein deposition. Surface lesions can best be demonstrated by applying fluorescein dye to the eye, preferably following the instillation of a topical anesthetic drop (Figure 54-5). The end of the fluorescein strip is touched to the marginal tear meniscus. When the patient blinks, the dye is dispersed throughout the ocular surface and stains wherever an epithelial defect exists, as in a corneal or conjunctival abrasion. A light utilizing a cobalt filter, found on most modern ophthalmoscopes, will best demonstrate abnormal accumulations of the dye. Mucus adhering to the corneal or conjunctival surfaces is considered pathologic.

The limbus is the zone immediately surrounding the cornea that becomes intensely inflamed with a deep pink coloration in cases of anterior uveitis or iritis, the so-called 'ciliary flush'. Discrete swellings with small white dots are indicative of degenerating cellular debris, which is commonly seen in vernal conjunctivitis (Figure 54-6). The anterior chamber is examined for clearness or cloudiness of the aqueous humor and for the presence of blood, either diffuse or settled out (i.e. hyphema) or the settling out of pus (i.e. hypopyon). A shallow anterior chamber suggests narrow-angle glaucoma and is a contraindication for the use of mydriatic agents. An estimation of the anterior chamber depth can be made by illuminating it from the side with a pen light; if the iris creates a shadow on the far side from the light, then there is a high index of suspicion for increased IOP (i.e. glaucoma).

Allergic Disorders

Conjunctivitis caused by IgE-mast cell-mediated reactions is the most common hypersensitivity response of the eye. Direct exposure of the ocular mucosal surface to the environment stimulates these mast cells, clinically producing the acute- and late-phase signs and symptoms of allergic conjunctivitis.[14,15] In addition, the conjunctiva is infiltrated with inflammatory cells such as neutrophils, eosinophils, lymphocytes and macrophages. Interestingly, acute forms of allergic conjunctivitis lack an eosinophilic predominance, as seen in asthma. However, eosinophils and other immunologically active cells are prevalent in the more chronic forms.

SEASONAL ALLERGIC CONJUNCTIVITIS

Seasonal allergic conjunctivitis (SAC) is the most common allergic conjunctivitis, representing over half of all cases. As its name implies, SAC is characterized by symptoms that are seasonal and related to specific aeroallergens. Symptoms predominate in the spring and in some areas during the fall (Indian summer). Grass pollen is thought to produce the most ocular symptoms. Patients report itchy eyes and/or a burning sensation with watery discharge, commonly associated with nasal or pharyngeal symptoms. A white exudate may be present that turns stringy in the chronic form of the condition. The conjunctiva appears milky or pale pink and is accompanied by vascular congestion that may progress to conjunctival swelling (chemosis). Symptoms are usually bilateral but not always symmetric in degree of involvement. SAC rarely results in permanent visual impairment but can interfere greatly with daily activities.

PERENNIAL ALLERGIC CONJUNCTIVITIS

Perennial allergic conjunctivitis (PAC) is considered a variant of SAC that persists throughout the year. Dust mites, animal dander and feathers are the most common allergens. Symptoms are analogous to those of SAC, and 79% of PAC patients have

https://CafePezeshki.IR

seasonal exacerbations. In addition, both PAC and SAC are similar in distribution of age, sex and associated symptoms of asthma or eczema. The prevalence of PAC has been reported to be lower than that of SAC (3.5:10,000) although it is subjectively more severe,[16] but with the increasing prevalence of allergies as reported in the International Study of Asthma and Allergies in Childhood this may be underrepresented; in fact, perennial forms of ocular allergy may be more common than pure seasonal forms.

VERNAL KERATOCONJUNCTIVITIS

Vernal keratoconjunctivitis (VKC) is a severe, bilateral, recurrent, chronic inflammatory process of the upper tarsal conjunctival surface. It has a marked seasonal incidence, and its frequent onset in the spring has led to use of the term 'vernal catarrh'. It occurs most frequently in children and young adults who have a history of seasonal allergy, asthma and eczema. The age of onset for VKC is usually before puberty, with boys being affected twice as often as girls. After puberty it becomes equally distributed between the sexes and 'burns out' by the third decade of life (about 4 to 10 years after onset). VKC may threaten sight if the cornea is involved and is more common in persons of Asian or African origin.

Symptoms of VKC include intense pruritus exacerbated by time and exposure to wind, dust, bright light, hot weather or physical exertion associated with sweating. Associated symptoms involving the cornea include photophobia, foreign body sensation and lacrimation. Signs include: conjunctival hyperemia with papillary hypertrophy ('cobblestoning') reaching 7 to 8 mm in diameter in the upper tarsal plate; a thin, copious milk-white fibrinous secretion composed of eosinophils, epithelial cells and Charcot-Leyden granules; limbal or conjunctival 'yellowish-white points' (Horner's points and Trantas' dots) lasting 2 to 7 days; an extra lower eyelid crease (Dennie's line); corneal ulcers infiltrated with Charcot-Leyden crystals; or pseudomembrane formation of the upper lid when everted and exposed to heat (Maxwell-Lyon's sign; Figure 54-7). Although VKC is a bilateral disease, it may affect one eye more than the other.

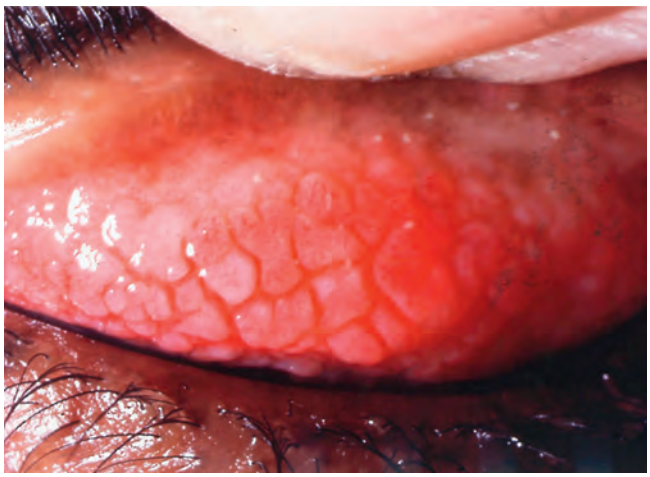

Figure 54-7 Conjunctival hyperemia with papillary hypertrophy (cobblestoning) on the everted palpebral conjunctiva of the upper eyelid in a patient with vernal conjunctivitis.

VKC is characterized by conjunctival infiltration by eosinophils, degranulated mast cells, basophils, plasma cells, lymphocytes and macrophages. Degranulated eosinophils and their toxic enzymes (e.g. major basic proteins) have been found in the conjunctiva and in the periphery of corneal ulcers, a fact that may suggest their etiopathogenic role in many of the problems associated with VKC.[15,16] MC_T cells are increased in the conjunctiva of these patients.[8] Tears from VKC patients have been found to contain higher levels of leukotrienes and histamine (16 ng/mL) when compared to controls (5 ng/mL).[17] Tears from VKC patients also contain major basic protein, Charcot-Leyden crystals, basophils, IgE and IgG specific for aeroallergens (e.g. ragweed pollen) and eosinophils (in 90% of cases).[18] The tear-specific IgE does not correlate with the positive immediate skin tests that VKC patients may have, thus it represents more than a chronic allergic response as reflected in a study that suggested that exposure to house dust mite allergen aggravates VKC symptoms.[19]

GIANT PAPILLARY CONJUNCTIVITIS

Giant papillary conjunctivitis (GPC) is associated with the infiltration of basophils, eosinophils, plasma cells and lymphocytes. GPC has been directly linked to the continued use of contact lenses with a seasonal increase of symptoms during the spring pollen season, including itching. Signs include a white or clear exudate upon awakening that chronically becomes thick and stringy. Patients may develop Trantas' dots, limbal infiltration and bulbar conjunctival hyperemia and edema. Upper tarsal papillary hypertrophy ('cobblestoning') has been described in 5% to 10% of soft and 3% to 4% of hard contact lens wearers. The contact lens polymer, the preservative (thimerosal) and proteinaceous deposits on the surface of the lens have been implicated in GPC, but this remains controversial. Analysis of the glycoprotein deposits on disposable soft contact lenses has revealed that the higher the water content, the higher the protein integration (lysozyme, tear-specific prealbumin and the heavy chain components of IgG) into the lens.[20]

Immunologic Disorders

KAWASAKI'S DISEASE

Kawasaki's disease (KD) (*mucocutaneous lymph node syndrome*) is the most common systemic vasculitis after Henoch-Schönlein purpura and the most common cause of acquired heart disease in the pediatric population. KD is an acute exanthematous illness that almost exclusively affects children: 50% of cases occurring in males less than 2 years of age, with an increased prevalence in individuals of Japanese ancestry. Five of the following six criteria must be present for diagnosis: (1) fever, (2) bilateral conjunctival injection, (3) changes in upper respiratory tract mucous membrane, (4) changes in skin and nails, (5) maculopapular cutaneous eruptions, and (6) cervical lymphadenopathy. The cutaneous eruption characteristically involves the extremities and desquamates in the later stages. The disease may occur in cyclic epidemics, supporting an infectious hypothesis. It was originally associated with toxin-producing *S. aureus*,[21] but more recently *Rickettsia*-like organisms have been demonstrated by electron microscopy. KD is usually benign and self-limited, although 2% of Japanese KD cases (nearly all male) experience sudden cardiac death[22] due to an acute thrombosis

https://CafePezeshki.IR

of aneurysmally dilated coronary arteries secondary to direct vasculitic involvement.

The most typical ocular finding is bilateral nonexudative conjunctival vasodilatation, typically involving the bulbar conjunctiva, with medium to large sized blood vessels being tortuous and engorged. No ocular discharge or pretragal lymph nodes are noted. However, there appears to be an increase in neutrophilic infiltration in conjunctival epithelial cells.[23] Anterior uveitis is seen in up to 80% of patients and is usually mild, bilateral and symmetric without ciliary injection (most common in children >2 years of age);[24] superficial punctate keratitis is seen in 12% of patients. Vitreous opacifications and papill-edema have been reported. Choroiditis has been reported in a case of infantile periarteritis nodosa, which may be indistinguishable from KD (see Chapter 12).

UVEITIS

Uveitis may be anatomically classified as anterior, intermediate, posterior or diffuse. Patients typically complain of diminished or hazy vision accompanied by black floating spots. Severe pain, photophobia and blurred vision occur in cases of acute iritis or iridocyclitis. The major signs of anterior uveitis are pupillary miosis and ciliary/perilimbal flush (a peculiar injection seen adjacent to the limbus) that can be easily confused with conjunctivitis. Vitreous cells and cellular aggregates are characteristic of intermediate uveitis and can be seen with the direct ophthalmoscope. Cells, flare, keratic precipitates on the corneal endothelium, and exudates with membranes covering the ciliary body can be visualized with the slit lamp and indirect ophthalmoscopy.

Anterior uveitis may be confused with conjunctivitis because its primary manifestations are a red eye and tearing; ocular pain and photophobia are also present. Anterior uveitis may be an isolated phenomenon that presents to an ophthalmologist or may be associated with a systemic autoimmune disorder that presents to a general practitioner. It is found in approximately 50% of cases of HLA-linked spondyloarthropathies (HLA-B27, e.g. ankylosing spondylitis [sacroiliitis], Reiter's syndrome); infections, such as *Klebsiella* bowel infections (resulting from molecular mimicry), brucellosis, syphilis and tuberculosis; HLA B5, Bw22, A29, and D5 genotypes; and inflammatory bowel diseases (e.g. Crohn's disease). The inflammatory response in the anterior chamber of the eye results in an increased concentration of proteins (flare [i.e. Tyndall effect]), a constricted pupil (miosis) with afferent pupillary defect (a poor response to illumination), or cells in the aqueous humor. White cells can pool in the anterior chamber, forming a hypopyon, or stick to the endothelial surface of the cornea, forming keratic precipitates. The sequelae of anterior uveitis may be acute, resulting in synechia (adhesions of the posterior iris to the anterior capsule of the lens), angle-closure glaucoma (blockage of the drainage of the aqueous humor) and cataract formation.

Posterior uveitis commonly presents with inflammatory cells in the vitreous, retinal vasculitis and macular edema, which threatens vision. Posterior uveitis caused by toxoplasmosis occurs as a result of congenital transmission. Serologic assays for toxoplasmosis (enzyme-linked immunosorbent assay or immunofluorescent antibody) assist in the diagnosis.[25]

Panuveitis is the involvement of all three portions of the uveal tract, including the anterior, intermediate (pars plana) and posterior sections. In an Israeli study it was clearly linked (over 95% of cases) to a systemic autoimmune disorder, such as Behçet's disease.[26]

SARCOIDOSIS

Sarcoidosis is rare in children; 50% to 80% have ocular involvement associated with anterior, intermediate, posterior or diffuse nongranulomatous uveitis. Classically, noncaseating granulomas appear as 'mutton fat precipitates', obstructive glaucoma, Koeppe nodules at the pupillary margin, or sheathing of vessels ('candle wax drippings'). The ocular inflammatory response may occur independently of any evidence of systemic involvement. Diagnostic tests include biopsy of the conjunctival or lacrimal granulomas, serum angiotensin-converting enzyme and lysozyme, chest radiograph for hilar adenopathy, and gallium scan. Biopsy of the lacrimal gland, the conjunctiva or the periocular skin is only useful when direct visualization reveals a nodule. Other granulomatous processes involving the eye include toxocariasis, tuberculosis and histoplasmosis, which may occur months to years after the primary infection.

JUVENILE RHEUMATOID ARTHRITIS

Juvenile rheumatoid arthritis (JRA), now more commonly referred to as juvenile idiopathic arthritis (JIA) and accounting for 70% of chronic arthritis in children, exists as three subtypes: (1) systemic JIA (10–20%), usually characterized by a febrile onset, lymphadenopathy and evanescent rash; (2) polyarticular JIA (30–40%), characterized by involvement of multiple (>4) joints with few systemic manifestations; and (3) pauciarticular JIA (40–50%), characterized by no more than four joints involved, usually larger joints, and a positive antinuclear antibody (≈75%). Anterior uveitis can develop in all types although it is seen most often in pauciarticular JIA (≈25%). JIA is associated with chronic bilateral iridocyclitis and Russell bodies (large crystalline deposits of immunoglobulin in the iris). Ocular manifestations do not parallel the patient's arthritis; instead, onset generally occurs within 7 years after joint inflammation, so frequent screening and early detection are crucial to decrease the risk of vision loss.

BLEPHARITIS (TABLE 54-4)

Blepharitis, inflammation of the eyelid margin, is one of the most common causes of pediatric red eye and is often misdiagnosed as an ocular allergy. It may be either anterior, involving the lash line, or posterior, involving a dysfunction of the meibomian glands; both are strongly associated with dermatologic disorders including atopic dermatitis and rosacea. Anterior and posterior blepharitis often occur together due to their common association with dermatologic disorders.

A specific form of anterior blepharitis involves colonization of the lid margin by *Staphylococcus aureus.* Coagulase-negative staphylococci colonize the normal lid without causing blepharitis (positive cultures of normal lid 6-15%) and thus a cultures is not sufficientfor diagnosis. However, it is known that 76% of blepharitis cases are associated with atopic dermatitis, while ulcerative blepharitis is almost exclusivley associated with atopic dermaititis. Staphylococci may contribute to the development of conjunctivitis via direct infection as well as enterotoxin[27] or, indirectly, lipids because the bacteria release esterases and lipases generating fatty acids that can act as direct irritants.

https://CafePezeshki.IR

TABLE 54-4 Blepharoconjunctivitis: Inflammation of the Eyelid Can Involve Different Portions of the Anterior and Posterior Eyelid (Either Alone or in Combination)

	ANTERIOR		Posterior Meibomian Gland Dysfunction	Anterior and Posterior Blepharo-Keratoconjunctivitis
	Staphylococcal	Seborrheic		
Lashes	Soft scales around roots	Soft greasy scales in between eyelashes	Unremarkable	Crusty
Lid margin	Ulceration Notching microabscesses	Shiny	Posterior oil capping with occlusion of meibomian glands	Chronic anterior and posterior involvement
Tear film	Dry	Dry	Dry and frothy	Dry
Conjunctiva	Papilla Phlyctenules	Unremarkable	Unremarkable	Follicular and papillary hypertrophy
Cornea	Punctate erosions Marginal infiltrates	Punctate erosions Peripheral infiltrates	Punctate erosions	Punctate erosion, vascularizations
Associated dermatitis	Atopic dermatitis	Seborrheic dermatitis	Acne rosacea	None
Cysts	Hordeolum		Meibomian	Styes (often multiple) and meibomian gland blockage

Patients typically complain of persistent burning, itching, tearing and a feeling of 'dryness'. These symptoms tend to be more severe in the morning and an exudative crust may be present leading to a child's eye becoming 'glued shut'. The signs of staphylococcal blepharitis include conjunctival injection, dilated blood vessels, erythema, scales, collarettes of exudative material around the eyelash bases, crusting, lid ulceration, folliculitis, foamy exudates in the tear film, telangiectasias, the loss of eyelashes (madarosis) in more chronic forms and even chronic papillary conjunctivitis. In addition, corneal immune deposits may cause severe photophobia. Treatment is directed toward eyelid hygiene with detergents (baby shampoo) and steroid ointments applied to the lid margin.

Posterior blepharitis is primarily manifested by meibomian gland obstruction that may result in an acute infection (internal hordeolum or stye) but more commonly produces a chalazion (a localized granulomatous inflammation caused by an accumulation of lipids and waxes within the meibomian gland). Chalazion clinically results in edema, erythema and burning of the eyelid that evolves into a firm, painless nodule. Bilateral eye involvement and conjunctivitis may also be present, which further contribute to allergic mimicry; once again, eyelid hygiene is the mainstay of therapy. In the ophthalmologic literature, 'hyposensitization' has been proposed for the subset of cell-mediated associated staphylococcal blepharoconjunctivitis.

Phthirus pubis, the pubic or crab louse, has a predilection for eyelash infestation[29] and may also cause blepharitis. Often the lice may be visualized with direct inspection. Involvement of the eyelashes in prepubertal children should raise the suspicion of sexual abuse.

Ocular rosacea is a rare cause of blepharitis in children, although it is believed to be underdiagnosed due to its typically mild symptoms.[30,31] The majority of cases are unilateral and present with a chronic red eye or recurrent chalazia with a female : male ratio of 3 : 1. Conjunctival phlyctenules that appear as clear vesicles are pathognomonic for this condition, and are thought to arise from inflammation directed against the bacterial flora of the eyelids. Treatment with lid hygiene, antibiotics, topical corticosteroids and topical cyclosporine may prevent serious complications including corneal involvement.

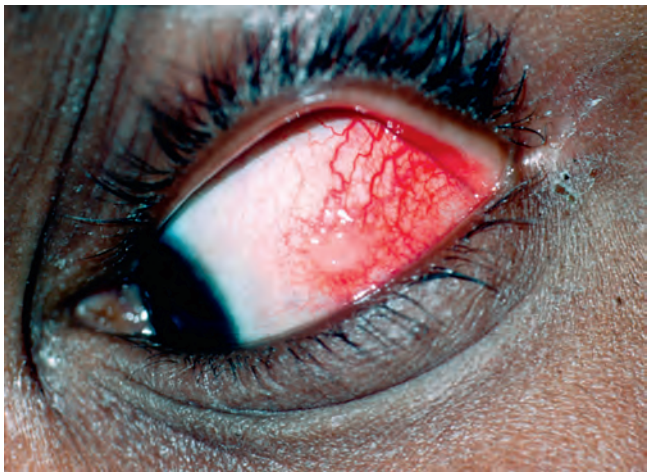

Figure 54-8 Localized bulbar conjunctival vascular injection in a patient with nodular episcleritis.

EPISCLERITIS

Inflammation of the scleral surface is termed *episcleritis*. It occurs mainly in adolescents and young adults, presenting as a localized injection of the conjunctiva around the lateral rectus muscle insertion (Figure 54-8). Typically, the inflammation is bilateral and accompanied by ocular pain. The presence of pain and absence of pruritus distinguishes episcleritis from allergic conjunctivitis. Episcleritis is self-limited and usually not associated with systemic disease.

CONTACT DERMATOCONJUNCTIVITIS

Contact dermatitis involving the eyelids frequently causes the patient to seek medical attention for a cutaneous reaction that elsewhere on the skin would be of less concern. The eyelid skin, being soft, pliable and thin, has an increased susceptibility to contact dermatitis. Initially there is erythema and edema associated with ipsilateral conjunctivitis with thickening and crusting noted in cases of longer standing. Cosmetics are a major offender, but in the pediatric population it may be due

https://CafePezeshki.IR

to ophthalmic medications or preservatives. Ophthalmic lubricants such as thimerosal, which are found in contact lens cleaning solutions and other topical agents, have been shown by patch tests to be among the culprits. Because of the high incidence of irritant false-positive reactions, patch testing is generally used only as a confirmatory tool.

ANGIOEDEMA

Angioedema is the swelling of the dermis, and the conjunctiva is one of the most commonly involved sites in a variety of systemic hypersensitivity reactions. A documented local IgE-mast cell sensitization has been reported to papain enzyme in contact lens cleaning solution in which serum specific IgE to papain and chymopapain was detected.[32] The anatomy of the eyelid consists of loose epidermal tissue that provides an extensive reservoir for edema to even minor allergic reactions, but the differential diagnosis of periorbital cellulitis, which may be life-threatening, should also be considered.

ATAXIA-TELANGIECTASIA

Louis-Bar's Syndrome

Ataxia-telangiectasia presents with large tortuous vessels on the bulbar conjunctiva, most prominent in the exposed canthal regions[33] (Figure 54-9), that typically become evident between 1 and 6 years of age and progress with time. There are no other signs or symptoms of conjunctivitis. These children eventually develop ataxia, hypogammaglobulinemia (with absent or deficient IgA) and recurrent sinopulmonary infections.[34]

ACQUIRED IMMUNODEFICIENCY SYNDROME

Children stricken with acquired immunodeficiency syndrome (AIDS) rarely have eye involvement. Cytomegalovirus retinitis is the most frequently encountered disorder, affecting approximately 7% of children with AIDS, and can lead to permanent vision loss if untreated. It is characterized by regions of intraretinal hemorrhage and white areas of edematous retina. HIV cotton-wool spots retinitis, herpes zoster retinitis and toxoplasmosis retinitis have also been documented in children.

Figure 54-9 Tortuous conjunctival vessels on the bulbar conjunctiva in a patient with ataxia-telangiectasia.

INFECTIONS

Conjunctivitis

With increasing contact lens wear in the pediatric population there has been an increase in bacterial conjunctivitis and thus parents and children should be vigilant with eyelid hygiene and contact lens procedures.[35]

Cellulitis

Orbital cellulitis is an infectious process that involves the extraocular contents and presents with a key symptom of 'pain' as well as lid edema, proptosis and diplopia due to involvement of extraocular muscles, in contrast to other allergic disorders affecting the eye. A majority of cases are due to extension of sinusitis with the most common pathogens being *Streptococcus pyogenes*, *Staphylococcus aureus* and *Haemophilus influenzae*. Preseptal cellulitis may resemble orbital cellulitis with intense lid swelling except that there is normal ocular movement and there is no inflammation of the globe. However, delay in diagnosis may lead to extension of infection into the orbit. The infectious agents are the same as in orbital cellulitis. A more lethal form of a deep subcutaneous infection of the eyelid that evolves into a necrotizing fasciitis is caused by beta-hemolytic *S. pyogenes* Lancefield group A, C and G and *S. aureus* in 25% of cases. The underlying process is associated with septic thrombophlebitis of the dermal vessels that can lead to septicemia and is considered a medical emergency.

TRANSPLANTATION

Bone marrow transplantation is associated with the development of xerophthalmia.

Corneal transplantation is one of the most frequently performed transplant procedures, in which a diseased cornea is replaced by a cadaveric cornea that must be harvested within 24 hours of death. Tissue typing is not required for initial transplants as the cornea is avascular. Repeated transplants may require tissue typing. The primary indication for corneal allografts is maintaining optical integrity. Keratoconus is the most common indication, but other keratopathies (e.g. interstitial keratitis, corneal scars or ulcers, herpetic keratitis) and endothelial dystrophies may also necessitate transplantation.

Ocular complications involving the conjunctiva and the lacrimal system are noted in patients undergoing bone marrow transplantation. In acute graft versus host disease (GVHD), conjunctival involvement progresses from erythema to chemosis, serosanguineous exudate, and ultimately to the sloughing of the conjunctiva and potentially the cornea (pseudomembranous conjunctivitis) (Table 54-5).[36] The lacrimal gland may develop a stasis picture with inspissated blockage of the

TABLE 54-5 Clinical Staging of Conjunctival Acute GVHD

Stage 1	Hyperemia
Stage 2*	Hyperemia, chemosis, serosanguineous exudate
Stage 3	Pseudomembranous conjunctivitis
Stage 4	Pseudomembranous conjunctivitis with corneal epithelial sloughing

*Occurs in 12% of patients and is associated with increased mortality ~90%.[38]

https://CafePezeshki.IR

ductules. These complications are not commonly seen in solid heart/lung organ transplantation.[37] In chronic forms of GVHD there is increased scarring of the conjunctiva and lacrimal inflammation with over 50% of patients developing a dry eye and a Sjögren-like syndrome.

Treatment

Once an allergic etiology is identified, treatment is approached in a stepwise fashion. Treatment can be divided into primary, secondary and tertiary interventions (Table 54-6), as well as acute (seasonal) versus chronic (persistent).

Current treatment is primarily aimed at restoring the patient's quality of life and may require at least 2 weeks of therapy.

PRIMARY INTERVENTION

Nonpharmacologic interventions are commonly the first line of treatment to be considered. Interventions include minimizing or avoiding contact with environmental allergens, application of cool compresses to the eye, lubrication and use of disposable contact lenses, and the use of preservative-free lubricants.[39,40]

Environmental Control

Avoidance of allergens remains the first option in the management of any ocular disorder.

Cold Compresses

Cold compresses provide considerable symptomatic relief, especially from ocular pruritus. In general, all ocular

TABLE 54-6 Overview of the Treatment of Pediatric Ocular Allergic Disorders in a Stepwise Format

Therapeutic Intervention	Clinical Rationale	Pharmaceutic Agents	Comments
PRIMARY			
Avoidance	Effective, simple in theory, typically difficult in practice		>30% symptom improvement
Cold compresses	Decrease nerve c-fiber stimulation, reduce superficial vasodilation		Effective for mild-to-moderate symptoms
Preservative-free tears	Lavage, dilutional effect	Artificial tears	Extremely soothing, recommend refrigeration to improve symptomatic relief, inexpensive OTC, safe for all ages, comfortable, use as needed
SECONDARY			
Topical antihistamine and decongestants	Antihistamine relieves pruritus, vasoconstrictor relieves injection	Antazoline naphazoline, pheniramine naphazoline	No prescription required, quick onset, more effective than systemic antihistamines, limited duration of action, frequent dosing required
Topical antihistamine and mast cell stabilizer (plus other mechanisms)	Single agent with multiple actions, has immediate and prophylactic activity, eliminates need for 2-drug therapy, comfort enhances patient compliance	Olopatadine (Patanol), ketotifen (Zaditor), azelastine (Optivar), bepotastine (Bepreve)	Twice-daily dosing, dual-acting agents, antihistamine, mast cell stabilizer, inhibitor of inflammatory mediators, more effective at relieving symptoms than other classes of agents, longer duration of action, safe and effective for 3 years and older
Topical mast cell stabilizers	Safe and effective for allergic diseases, especially those associated with corneal changes	Cromolyn (Crolom), lodoxamide (Alomide), nedocromil (Alocril), pemirolast (Alamast)	Cromolyn relieves mild-to-moderate symptoms of vernal keratoconjunctivitis, vernal conjunctivitis, vernal keratitis. Lodoxamide is highly potent
Topical antihistamines	Relieves signs and symptoms of pruritus and erythema	Levocabastine (Livostin), emedastine (Emadine)	Dosing 1–4 times daily, safe and effective for 3 years and older
Topical NSAIDs	Relieves pruritus	Ketorolac (Acular)	Stinging and/or burning on instillation experienced up to 40% of patients
TERTIARY			
Topical corticosteroids	Relieves all facets of the inflammatory response including erythema, edema and pruritus	Loteprednol (Lotemax, Alrex), rimexolone (Vexol), fluorometholone (FML)	Appropriate for short-term use only, contraindicated in patients with viral infections
Immunotherapy SCIT SLIT	Identify and modulate allergen sensitivity		Adjunctive, although may be considered in secondary treatment in conjunction with allergic rhinitis
ANCILLARY			
Oral antihistamines	Mildly effective for pruritus	Loratadine, fexofenadine, cetirizine	May cause dry eyes, worsening allergy symptoms; may not effectively resolve the ocular signs and symptoms of allergy

NSAID – Nonsteroidal antiinflammatory drug, *OTC* – over the counter.

https://CafePezeshki.IR

medications provide additional subjective relief when refrigerated and immediately applied in a cold state.

Lubrication

Many conditions require the use of lubricants for either temporary relief (e.g. seasonal ocular allergy, corneal abrasion) or for more long-term complications (e.g. keratoconjunctivitis sicca in patients undergoing bone marrow transplantation). Tear substitutes consist of a viscosity agent in three formulations in order to increase the length of action while decreasing the length of time vision is blurred after instillation: aqueous (seconds), gel (a few minutes) and ointment (~30 minutes). Ointments are best tolerated overnight. Most are buffered to pH 7.7–7.8 and contain a preservative. Artificial tears can be applied topically 2 to 4 times daily as necessary. If drops are used more than 4 times a day then a preservative-free preparation should be considered. Lubrication primarily assists in the direct removal and dilution of allergens that may come in contact with the ocular surface. Ocular lubricants vary by class, osmolarity and electrolyte composition; no product has yet emerged as a clear favorite. Parents should be given the name of one or two brands from each class of lubricant to try until a suitable product or combination of products is found.

Contact Lenses

In general, adolescent patients who have seasonal allergy should avoid contact lens use during seasonal flare-ups. The need for clean lenses with minimal deposit build-up must be stressed, and the use of daily wear lenses with rigid disinfecting and cleaning techniques is recommended. Alternatively, daily disposable lenses should be used.[41,42] When such individuals wear contact lenses (CLs), a special set of circumstances arises that increases the risk of ocular infection. The risk is greatest if the lenses are soft and, therefore, provide for little tear exchange beneath their surface. Under such circumstances, limited tear flow allows for a greater build-up of lens deposits and metabolic wastes, while permitting increased tear evaporation from the lens surface.[43]

In a study evaluating the impact of daily disposable lenses versus patient's standard chronic wear lenses, 67% reported that the 1-day disposable lenses provided improved comfort in comparison to the lenses they wore prior to the study. This compared with 18% agreeing that the new pair of habitual lenses provided improved comfort, suggesting that the use of 1-day disposable lenses may be an effective strategy for managing allergy-suffering contact lens wearers.[44] Overall, the newer soft silicone lenses with increased gas permeability have had a higher comfort satisfaction rate (56%) than the rigid gas-permeable lens (14%), while 63% of nonatopic and only 47% of atopic subjects described their lenses as very comfortable to wear.[45,46]

SECONDARY INTERVENTION – A STEP APPROACH[47]

The development of therapeutic agents to specifically address the various signs and symptoms of allergic inflammation of the conjunctival surface is ongoing. In the search for more effective medications for ocular allergy, the conjunctival allergen challenge (CAC), also known as the conjunctival provocation test (CPT), has been critical as a standardized model for the assessment of efficacy and duration of effect that new agents have on the allergy signs and symptoms of erythema (redness), pruritus (itching), epiphora (tearing), lid swelling and conjunctival swelling (chemosis). Many of the newer agents are also being evaluated for potential treatment of the more chronic ocular allergy-associated disorders, such as atopic keratoconjunctivitis, or the potential to treat both ocular and nasal symptoms as the medication drains down the nasolacrimal duct onto the nasal mucosa.

Decongestants

Topical decongestants act primarily as vasoconstrictors that are highly effective in reducing erythema and are widely used in combination with topical antihistamines. The decongestants are applied topically 2 to 4 times daily as necessary. They have no effect in diminishing the allergic inflammatory response. Vasocon-A is the only antihistamine/decongestant proven to be effective in treating the signs and symptoms (itch and redness) of allergic conjunctivitis. The usual dose is 1 to 2 drops per eye every 2 hours, up to four times daily. The primary contraindication is narrow-angle glaucoma. Excessive use of these agents has been associated with an increased conjunctival hyperemia known as the rebound phenomenon (a form of conjunctivitis medicamentosa).[48]

Antihistamines

Initially, oral antihistamines were extensively employed to systemically control the symptoms of allergic rhinoconjunctivitis, although with an obvious delayed onset of action on the ocular domain when compared to topical antihistamine agents. However, oral antihistamine appears to have a longer biological half-life and can have a longer-lasting effect. Information on oral antihistamine use in the treatment of allergic conjunctivitis is commonly buried within studies on allergic rhinitis instead of *rhinoconjunctivitis.* Oral antihistamines, especially the older generation (e.g. chlorpheniramine), appear to have an effect on excessive tearing (lacrimation and epiphora).[49] Another assessment tool has been ocular challenge testing (OCT), which has shown that oral antihistamines, such as terfenadine or loratadine, can increase several-fold the tolerance to a dose of specific allergen treatment in children and adults.[50,51] Oral antihistamines can offer relief from the symptoms of ocular allergy but have a delayed onset of action. Newer, second-generation H_1 receptor (nonsedating) antagonists are less likely to cause unwanted sedative or anticholinergic (dry eye) effects compared to earlier compounds.[52] It has therefore been suggested that the concomitant use of an eye drop may treat ocular allergic symptoms more effectively.[53]

H_1 stimulation principally mediates the symptom of conjunctival pruritus whereas the H_2 receptor appears to be clinically involved in vasodilation.[54–57] Although topical antihistamines can be used alone to treat allergic conjunctivitis, they have been shown to have a synergistic effect when used in combination with a vasoconstrictor or when the agents themselves have been shown to have effects on other mediators of allergic inflammation. Dosing is 1 to 4 times daily and is safe for children 3 years and older.

In general, the older topical antihistamines are known to be irritating to the eye, especially with prolonged use, and may be associated with ciliary muscle paralysis, mydriasis, angle-closure glaucoma and photophobia, especially those that are nonselective and block muscarinic receptors. Interestingly, this effect is more pronounced in patients with lighter irides and has not been reported with the newer topical agents.

https://CafePezeshki.IR

The newer topical antihistamines have also been found to have other potential antiinflammatory actions, such as mast cell stabilization, cytokine expression or interleukin release (discussed later in the chapter).

Antihistamines with Multiple Antiinflammatory Activities (Table 54-7)

Olopatadine. Olopatadine 0.01% (Patanol and Pataday) possesses antihistaminic activity and mast cell stabilizing effects. Olopatadine was approximately 10 times more potent as an inhibitor of cytokine secretion (50% inhibitory concentration 1.7–5.5 nmol/L) than predicted from binding data whereas antazoline and pheniramine were far less potent (20–140 times) in functional assays, including TNF-α mediator release from human conjunctival mast cells. Olapatadine has been shown to be significantly more effective than placebo in relieving itching and redness for up to 8 hours.[58] In a comparison study with another multiple-action agent, ketotifen, olopatadine fared only slightly better over 2 weeks.[59] In a reformulated form it has been approved for once a day treatment of ocular allergy (Pataday).[60]

Epinastine. Epinastine 0.05% (Elestat) is another topical antihistamine with other antiinflammatory properties that include H_2-receptor antagonism, mast cell stabilization and inhibition of cytokine production. Pretreatment by epinastine differentially reduced histamine, TNF-α and -β, IL-5, IL-8 and IL-10. In vivo, epinastine and olopatadine pretreatment significantly reduced clinical scores and eosinophil numbers while epinastine also reduced neutrophils ($P < .02$), reflecting that there are different patterns of inhibition of inflammation.[61] The role of the histamine H_1, H_2 and H_3 receptor affinities is unclear in the actual treatment, but from past clinical experience it would appear that having such multiple binding would be beneficial. In an animal model of histamine-induced vascular leakage, epinastine, azelastine and ketotifen had a shorter duration of effect than olopatadine.[62] In CAC placebo trials, multiple signs and symptoms (ocular itching, eyelid swelling, conjunctival and episcleral hyperemia, and chemosis) of allergic conjunctivitis were significantly reduced by instillation of epinastine compared with vehicle.[63]

Bepotastine. Bepotastine 1.5% (Bepreve) is the newest of the FDA-approved ophthalmic antihistamines. There is evidence for multiple antiinflammatory properties that include H_1-receptor antagonism, mast cell stabilization and inhibition of cytokine production including IL-5.[58,64,65] Pretreatment by bepotastine differentially reduced IL-5 as well as itching associated with LTB-4 injection in an animal model.[65,66] The agent also appears to have the highest selectivity for H_1.[67] Bepotastine besilate was originally developed in Japan by Tanabe in conjunction with Ube Industries and was approved in Japan as an oral preparation (Talion) in July 2000 for the treatment of allergic rhinitis and subsequently approved for the treatment of pruritus/itching accompanying urticaria and other skin conditions in January 2002. Since bepotastine relieves antihistamine-resistant pruritus, it is possible that mechanisms of action other than H_1 receptor antagonism are also responsible for the antipruritic effects of this agent. In CAC placebo trials, multiple signs and symptoms (ocular itching, eyelid swelling, tearing, total nonocular symptoms score, nasal congestion and rhinorrhea) of allergic conjunctivitis were significantly reduced by instillation of bepotastine compared with vehicle.[68,69]

Ketotifen. Ketotifen 0.025% (Zaditor) is a benzocycloheptathiophene that has been shown to display several antimediator properties, including strong H_1 receptor antagonism and inhibition of leukotriene formation.[70,71] Ketotifen has also been shown to have pronounced antihistaminic and antianaphylactic properties that result in moderate to marked symptom improvement in the majority of patients with asthma, atopic dermatitis, seasonal or perennial rhinitis, allergic conjunctivitis, chronic or acute urticaria and food allergy. Ketotifen is distinguished from the sodium cromolyn and nedocromil, by a conjoint mast cell stabilizer with, several antimediator properties including strong H_1 receptor antagonism and inhibition of leukotriene formation.[72] It is now available as an over-the-counter therapy for ocular allergy.

Azelastine. Azelastine 0.05% (Optivar) is a second-generation H_1 receptor antagonist. It was demonstrated in a pediatric SAC

TABLE 54-7 Topical Multiple Action Agents for Treatment of Ocular Allergy

	Azelastine HCl 0.05% (Optivar)	Epinastine HCl 0.05% (Elestat)	Ketotifen Fumarate 0.25% (Zaditor)*	Olopatadine HCl 0.2% (Pataday)	Bepotastine Besilate 1.5% (Bepreve)	Alcaftadine 0.25% (Lastacaft)
Indication	Relief of itching associated with allergic conjunctivitis	Relief of itching associated with allergic conjunctivitis	Temporary prevention of itching of the eye caused by allergies	Relief of itching associated with allergic conjunctivitis	Treatment of itching associated with allergic conjunctivitis	Prevention of itching associated with allergic conjunctivitis
Dosage	1 drop in each affected eye twice a day	1 drop in each affected eye twice a day (age 3 yr and older)	1 drop in each affected eye every 8–12 hr	1 drop in each affected eye once a day	1 drop in each affected eye twice a day (age 2 yr and up)	1 drop in each eye daily (2 years or older)
Adverse event	Transient sting (≈30%) Headache (≈15%) Bitter taste (≈10%)	Cold symptoms (≈10%) Upper respiratory infection (≈10%)	Headache (≈10–25%) Conjunctival injection (≈10–25%) Rhinitis (≈10–25%)	Cold syndrome (≈10%) Pharyngitis (≈10%)	Taste (≈25%)	Eye irritation, burning and/or stinging upon instillation (<4%)

*Ketotifen (Zaditor) is now available over the counter in the USA.

https://CafePezeshki.IR

study that the response rate in the azelastine eye drops group (74%) was significantly higher than that in the placebo group (39%) and comparable with that in the levocabastine group.[73] Apart from the ability to inhibit histamine release from mast cells and to prevent the activation of inflammatory cells, it is likely that the antiallergic potency of azelastine is partially the result of down-regulation of ICAM-1 expression during the early- and late-phase components of ocular allergic response, probably leading to a reduction of inflammatory cell adhesion to epithelial cells and confirming the prophylactic properties of azelastine.[74] It is safe to use in children 3 years and older.

Alcaftadine. Alcaftadine 0.25% (Lastacaft) is an antihistamine with affinity to H_1, H_2 and less to H_4 receptors that is superior to placebo and as effective as olopatadine 0.1% in preventing ocular itching and conjunctival redness at 15 minutes and 16 hours after administration.[75] Interestingly, in an animal model for allergic conjunctivitis, alcaftadine demonstrated a decrease of eosinophil infiltration when compared to controls and olopatadine.[76] It is approved for children 2 years and older.

Mast Cell Stabilizers

Cromolyn. Cromolyn 4% (Crolom) is the prototypic mast cell stabilizer. The efficacy of this medication appears to be dependent on the concentration of the solution used (i.e. 1% – no effect, 2% – possible effect, and 4% solution – probable effect).[40,77] Sodium cromolyn was originally approved for more severe forms of conjunctivitis with corneal involvement (e.g. GPC, VKC) but many physicians have used it for the treatment of SAC and PAC with an excellent safety record, although the original studies reflecting its clinical efficacy were marginal when compared to placebo[51,54] and in some animal models.[78] Cromolyn sodium 4% ophthalmic solution requires application 4 to 6 times daily for effectiveness. It is approved for children 3 years and older. The major adverse effect is burning and stinging, which has been reported in 13% to 77% of patients treated.

Lodoxamide. Lodoxamide 0.1% (Alomide) is a mast cell stabilizer that is approximately 2,500 times more potent than cromolyn in the prevention of histamine release in several animal models.[79] Lodoxamide is effective in reducing tryptase and histamine levels and the recruitment of inflammatory cells in the tear fluid after allergen challenge,[54,55] as well as tear eosinophil cationic protein[80] and leukotrienes (BLT and $CysLT_1$) when compared to cromolyn. In early clinical trials lodoxamide (0.1%) was shown to deliver greater and earlier relief in patients with more chronic forms, such as VKC, including upper tarsal papillae, limbal signs (papillae, hyperemia and Trantas' dots) and conjunctival discharge, and to improve epithelial defects seen in the chronic forms of conjunctivitis (VKC, GPC) than cromolyn.[81] In patients with allergic conjunctivitis, it is approved for the treatment of VKC at a concentration of 0.1% four times daily. Lodoxamide may be used continuously for 3 months in children older than 2 years of age.

Pemirolast. Pemirolast potassium 0.1 % (Alamast) is a mast cell stabilizer for the prevention and relief of ocular manifestations of allergic conjunctivitis. It was originally marketed for the treatment of bronchial asthma and allergic rhinitis and then registered in Japan as an ophthalmic formulation for the treatment of allergic and vernal conjunctivitis.[82] It has been studied in children as young as 2 years of age, with no reports of serious adverse events. In various animal and in vitro studies it was found to be superior and, in others, equivalent to cromolyn.[83] The usual regimen is 1 to 2 drops four times daily for each eye.

Nedocromil. Nedocromil 2% (Alocril) is a pyranoquinoline derivative of cromolyn that inhibits various activities on multiple cells involved in allergic inflammation including eosinophils, neutrophils, macrophages, mast cells, monocytes and platelets. Nedocromil inhibits activation and release of inflammatory mediators such as histamine, prostaglandin D_2 and leukotriene C4 from eosinophils. The mechanism of action of nedocromil may be due partly to inhibition of axon reflexes and release of sensory neuropeptides, such as substance P, neurokinin A and calcitonin gene-related peptides. Nedocromil does not possess any antihistamine or corticosteroid activity.[84] Nedocromil has been shown to improve clinical symptoms in the control of ocular pruritus and irritation in the treatment of SAC.[85–92] Its safety profile is similar to that of sodium cromolyn, but it is more potent and can be given just twice daily. The results of several placebo-controlled studies have shown that nedocromil is effective in alleviating the signs and symptoms of SAC and provides relief in approximately 80% of patients.[86] In a study comparing nedocromil (2%) with cromolyn eye drops, nedocromil was more efficacious in its impact on hyperemia, keratitis, papillae and pannus formation with less time to have an effect on itching, grittiness, hyperemia and keratitis.[87]

Nonsteroidal Antiinflammatory Drugs

Topically applied inhibitors of the cyclooxygenase system (1% suprofen)[88] have been used in the treatment of VKC.[87,88] Ocufen (diclofenac) is one of three topical NSAIDs approved for the treatment of intraocular inflammatory disorders. Another topically applied NSAID (0.03% flurbiprofen) has been examined for the treatment of allergic conjunctivitis and was found to decrease conjunctival, ciliary and episcleral hyperemia and ocular pruritus when compared to the control (vehicle-treated eyes). Pruritus is associated with prostaglandin release. It has been shown that prostaglandins can lower the threshold of human skin to histamine-induced pruritus, which may also be the primary benefit of these medications in the eye.

Ketorolac Tromethamine. Ketorolac tromethamine (Acular, Allergan) was approved for the treatment of SAC with a primary mechanism of action on the inhibition of cyclooxygenase, thus blocking the production of prostaglandins but not the formation of leukotrienes. Clinical studies have shown that prostanoids are associated with ocular itching and conjunctival hyperemia and thus inhibitors can interfere with ocular itch and hyperemia produced by antigen-induced and seasonal allergic conjunctivitis.[89–91] NSAIDs (e.g. ketorolac) do not mask ocular infections, affect wound healing, increase IOP or contribute to cataract formation, unlike topical corticosteroids. A recent study compared diclofenac sodium with ketorolac tromethamine and the results for both agents were similar.[92] Treatment group differences were observed for the pain/soreness score with an advantage observed for the diclofenac sodium group over ketorolac tromethamine (20.7% versus 3.2%). Keterolac and other NSAIDs are classically associated with a low-to-moderate incidence of burning and stinging upon instillation into the eye.

TERTIARY INTERVENTION

Topical Corticosteroids

When topically administered medications such as antihistamines, vasoconstrictors, cromolyn sodium and other multiple-action agents are ineffective, mild topical steroids are a consideration. Topical corticosteroids are highly effective in the treatment of acute and chronic forms of allergic conjunctivitis and are even required for control of some of the more severe variants of conjunctivitis including VKC and GPC. However, local administration of these medications is not without possible localized ocular complications including increased IOP (e.g. in glaucoma), viral infections and cataract formation. Topically or systemically administered steroids will produce a transient rise in IOP in susceptible individuals; this trait is thought to be genetically influenced.[91,93–95] Unlike efficacy, which varies among the steroid esters, IOP effects are consistent among the different esters of the same corticosteroid base.

Loteprednol. Loteprednol 0.2% (Alrex) is an ophthalmic suspension approved for the treatment of ocular allergy. One of its unique features is its claim to be a site-specific steroid (i.e. the active drug resides at the target tissue long enough to render a therapeutic effect but rarely long enough to cause secondary effects such as increased IOP and posterior subcapsular cataract development). The higher dose loteprednol (0.5%) formulation has been shown to be effective in reducing the signs and symptoms of GPC, acute anterior uveitis and inflammation following cataract extraction with intraocular lens implantation,[91] and as prophylactic treatment for the ocular signs and symptoms of SAC administered 6 weeks before the onset of the allergy.[93]

It is recommended that only patients with more chronic forms of allergic conjunctivitis use topical steroids in a routine manner. Ophthalmologic consultation should be obtained for any patient using ocular steroids for more than 2 weeks to assess cataract formation or increased IOP. Consultation is also merited for any persistent ocular complaint or if the use of strong topical steroids or systemic steroids is being considered.

Immunotherapy

The efficacy of allergen immunotherapy is well established, although it appears that allergic rhinitis may respond better to treatment than allergic conjunctivitis.[96] Similarly, for allergic patients who had asthma and rhinoconjunctivitis when exposed to animal dander (Fel d-I allergen), immunotherapy clearly improved the overall symptoms of rhinoconjunctivitis, decreased the use of allergy medications and required a 10-fold increase in the dose of allergen to induce a positive OCT reaction after 1 year of immunotherapy with the specific cat allergen.[97] Symptom assessment post challenge for ragweed-sensitive patients treated for at least 2 years with specific ragweed immunotherapy revealed improvement in nasal more than ocular symptoms when compared with controls.[98] The effect of immunotherapy specific for Japanese cedar (*Cryptomeria japonica*) pollenosis had reduced the daily total symptom medication score, not only in cedar but also in the cross-allergenic Japanese cypress (*Chamaecyparis obtusa)* pollination season, but not significantly.[99] Thus immunotherapy plays more of an important role in the 'long-term' control of SAC.

New Directions and Future Developments

Cyclosporine was FDA approved in 2002 as an ophthalmic solution to increase tear production in patients with tear film dysfunction. The safety and efficacy of ophthalmic cyclosporine, however, has not been established in patients under 16 years of age. This agent acts on IL-2, which has an immunomodulatory effect on the activation of T lymphocytes. Studies and reports on the use of topical cyclosporine in cases of VKC have demonstrated marked and lasting improvement in symptoms.[13] Likewise, tacrolimus has been shown to improve the signs and symptoms of VKC when administered as an ophthalmic solution or ointment, with results occurring in as little as 1 week.[100,101] Tacrolimus is a macrolide antibiotic that acts primarily on T lymphocytes by inhibiting the production of lymphokines, particularly IL-2. It has been effective in the treatment of immune-mediated ocular diseases such as corneal graft rejection, keratitis, scleritis, ocular pemphigoid and uveitis. The drug is approximately 100 times as potent as cyclosporine. Both tacrolimus and cyclosporine have been shown in vitro to inhibit histamine release.[102]

Alternative delivery systems for topical agents are also under investigation. Immunization approaches using 'naked plasmid' DNA (pDNA) are being pursued. This approach induces an altered antiallergic immune state in which there is a preference for the T helper cell type 1 response, producing primarily IgG2a whereas allergens would normally induce an IgG1 and IgE response.[102,103] Additional areas of future research include cytokine antagonists and anti-IgE therapy.[15]

Sublingual immunotherapy has been approved for use in Europe and appears to have potential for patients with single allergen-induced symptoms. It is undergoing multiple clinical studies for its efficacy and cost effectiveness in studies in the USA.[103–105]

Recent studies have demonstrated the potential of the positive impact of intranasal treatment (intranasal steroids and possibly intranasal antihistamines) on allergic rhinitis and its associated ocular allergy symptoms.[106–108] It appears that this treatment would be best for mild-to-moderate cases, such as in seasonal allergic conjunctivitis (more than in perennial allergic conjunctivitis). Such patients would still benefit the most from topical allergy medications.

Evidence shows that herbal remedies (e.g. butterbur, *Urtica dioica*, citrus unshiu powder), dietary products (e.g. *Spirulina*, cellulose powder), Indian Ayurvedic medicine and Traditional Chinese medicine have an effect on the symptoms of allergic rhinoconjunctivitis.[109,110] Randomized, placebo-controlled trials are needed to evaluate the safety and efficacy of complementary and alternative medicine in both children and adults.

Conclusions

Ocular disorders in children seen in the clinical subspecialty of allergy and immunology are increasing as our basic understanding of underlying mechanisms of the eye's immune response coupled with a stepwise diagnostic approach facilitates proper diagnosis and treatment, especially for allergic disorders (Boxes 54-1 and 54-2). As we develop a greater understanding of the biomolecular mechanisms of these disease states, treatment will continue to progress from symptomatic relief to more directed therapeutic interventions.

BOX 54-1 KEY CONCEPTS

Allergic Eye Disease

- Conjunctivitis caused by IgE mast cell-mediated reactions is the most common hypersensitivity response of the eye.
- Seasonal allergic conjunctivitis is the most common allergic conjunctivitis, representing over half of all cases.
- Grass pollen, dust mites, animal dander and feathers are the most common allergens.
- Most environmental allergens affect both eyes at once.
- The hallmark of allergic conjunctivitis is pruritus.
- A stringy or ropy discharge may also be characteristic of allergy.
- A detailed history is the cornerstone of proper diagnosis.
- Eye examination: simple observation alone may be diagnostic.
- Ocular inflammation caused by systemic immunologic diseases is frequently observed in children.
- Immunologic disorders of the eye commonly affect the interior portion of the visual tract and are associated with visual disturbances.

BOX 54-2 THERAPEUTIC PRINCIPLES

Allergic Eye Disease

- Approached in a stepwise fashion:
  Primary: avoidance, cold compresses, artificial tears
  Secondary: topical antihistamines, decongestants, mast cell stabilizers, nonsteroidal antiinflammatory drugs, multiple action agents
  Tertiary: Topical corticosteroids, immunotherapy (immunotherapy may be considered in the secondary category for some cases)
- Novel approaches: cyclosporine, tacrolimus, liposomal drug delivery systems, cytokine antagonists, anti-IgE therapy, complementary and alternative medicine
- Ophthalmology consultation is merited for any persistent ocular complaint or if the use of strong topical steroids or systemic steroids is being considered

55 Drug Allergy

ANCA M. CHIRIAC | PASCAL DEMOLY

KEY POINTS

- While true drug hypersensitivity is relatively uncommon, many children are labeled as being 'allergic' to various medications, particularly antibiotics. They end up carrying this label into adulthood and are likely to be treated with alternative antibiotics, which may be less effective, more toxic, more expensive and lead to the development and spread of certain types of drug-resistant bacteria.
- In children, the drugs most frequently involved in suspected drug hypersensitivity reactions are similar to those in the adult population: β-lactam antibiotics, nonsteroidal antiinflammatory drugs, other antibiotics, acetaminophen/paracetamol and others.
- The entire spectrum of drug hypersensitivity reactions can be seen in children, even the most severe cutaneous and organ-specific types.
- Most of the lessons learnt from drug hypersensitivity reactions in adults can be and have been extrapolated and applied to the pediatric population. However, some peculiarities arise in children in terms of prevalence and involved classes as well as practical aspects of the drug allergy work-up.
- Certain approaches such as simplifying and reducing the protocol steps in highly selected pediatric populations seem increasingly attractive to groups working in pediatric settings. It remains to be seen whether they will stand the test of time and be accepted as a general rule in drug allergy work-up in children.

Introduction

Drug hypersensitivity reactions (DHRs) are adverse effects of pharmaceutical formulations (including active drugs and excipients) that clinically resemble allergy.[1] Iatrogenic by nature, drug allergy goes against the ultimate purpose of prescribing a drug, which is to alleviate, and not to induce a disease. DHRs represent a public health problem whose burden arises from:

- misdiagnosis: both underdiagnosis (due to underreporting[2,3]) and overdiagnosis (due to an over-use of the term 'allergy', e.g. in the presence of symptoms due to co-existing factors such as infections[2,4]);
- prevalence: affecting more than 7% of the general population;[2]
- misbeliefs: not only is the suspicion of DHRs long lasting, with patients carrying the 'allergy' label into adulthood, but the field of DHRs must be one of the very few in medicine where the suspicion of a condition may persist even after the diagnosis has been discarded with the best available means.[5,6]

The work of numerous groups dealing with DHR management has provided a growing body of evidence leading to guidelines and/or consensus documents to support medical decision making on several aspects of DHR. These documents vary in scope and methodology in that they: (1) are national,[7–11] regional, or international;[12–23] (2) concern one specific drug class;[8,9,15–17,19,21,22,24] (3) focus specifically on evaluation tools/management;[12–14,18,20,24,25] or (4) are more general.[7,9,26,27] Recently, the International Collaboration in Asthma, Allergy and Immunology (iCAALL)[28] contributed to the issue of an International Consensus (ICON) on drug allergy,[29] a comprehensive reference aimed at highlighting the key messages that are common to the existing guidelines, while critically reviewing and commenting on any differences. As for the ICON on pediatric asthma,[30] unmet needs, research and guideline update recommendations were generated.

Most of the lessons learnt from DHR in adults have been extrapolated and applied to the pediatric population. However, some peculiarities arise in terms of prevalence and involved classes as well as practical aspects of drug allergy work-up. For instance, a shorter algorithm of testing has been recently proposed by some groups in highly selected pediatric patients with a suspicion of β-lactam (BL) allergy. Nevertheless, there are hardly any specific recommendations for the pediatric population. Currently, a Task Force on Paediatric Drug Allergy is ongoing within the European Academy of Allergy and Clinical Immunology (EAACI) drug allergy interest group (DAIG) and its core group, the European Network of Drug Allergy (ENDA).

Clinicians and researchers working in the field of DHR are aware that there is a risk of iatrogenesis in subjects with histories that suggest, but do not always confirm, DHR. Proper identification of a DHR, and all the steps leading to it, upholds the principle of '*primum non nocere*'.

Due to space limitation, the entire spectrum of DHRs cannot be addressed and, for this, the reader is referred to the previously mentioned guidelines. This chapter will focus on the most clinically relevant reactions: to antibiotics, aspirin (acetylsalicylic acid; ASA) and other nonsteroidal antiinflammatory drugs (NSAIDs) and vaccines. There is an emphasis on novel approaches in drug allergy work-up in children.

Epidemiology

Patients and physicians commonly refer to all adverse drug reactions (ADRs) as being 'allergic'. This causes confusion and misconception with regards to drug hypersensitivity. Drugs can indeed induce several different types of immunologic reactions that, together with nonallergic DHRs, comprise 15% of all ADRs.[29] Nonallergic DHRs resemble allergy, but have no proven immunologic mechanism.

While true DHR is relatively uncommon, many children are labeled as being 'allergic' to various medications, particularly

https://CafePezeshki.IR

antibiotics such as penicillins (or more widely, BL). They end up carrying this label into adulthood. These patients are more likely to be treated with alternative antibiotics, which may be less effective, more toxic, more expensive and lead to the development and spread of certain types of drug-resistant bacteria.

Estimates of the prevalence of DHR in the pediatric population vary widely between studies. Recent cross-sectional surveys revealed that the incidence of self-reported DH ranged between 2.5% and 10.2% of children.[31]

A systematic review and meta-analysis[32] concluded that the overall incidence of ADRs in hospitalized children was 9.5%, and that for outpatient children it was 1.5%. A large study from the USA found that the overall incidence of self-reported antibiotic allergy was 15.3%, and that increasing age had a significant correlation with antibiotic allergy prevalence.[33] Nonetheless, these data are based on studies that, in most cases, have addressed ADRs in general, ignoring the underlying mechanism. Indeed, a study on children in Portugal[34] highlighted the fact that although ADRs were frequently reported in an outpatient pediatric survey (10.2%), after a complete evaluation very few (4.5%) of these reactions could be attributed to DHRs.

It is assumed that in children most skin reactions are attributable to infectious diseases or interactions between drugs and infectious agents rather than to the drugs themselves.[35–37]

Whether or not children carry a drug hypersensitivity into adulthood is not known; there are no follow-up studies addressing this aspect of the natural history of DHRs. While there is little or no evidence regarding nonallergic DHRs, we do have some insight with respect to allergic DHRs: the IgE response (to BL) is known to decrease with time (in adults),[38] while T cell mediated response is long lasting.[19,39] Proven DHR seems to be less common in children compared with adults. However, the validity of a negative drug allergy work-up performed in adults who have had a reaction suggesting drug hypersensitivity in childhood can be questioned because of the time that has elapsed since the occurrence of the reaction. In a study involving 3,275 patients, Rubio and colleagues[40] reported that when the first reaction occurred during childhood, the prevalence rate of positive tests was similar whether the test was carried out during childhood (10.6%) or adulthood (10.6%). It could be therefore extrapolated that drug hypersensitivity in childhood does not resolve with time, although prescription habits have dramatically changed over the last 20 years, with increasing use of antibiotics in particular.

In children, the drugs most frequently involved in suspected DHRs are similar to those in the adult population: BL antibiotics, NSAIDs, other antibiotics, acetaminophen/paracetamol and local anesthetics.[40]

Clinical Manifestations

Drug hypersensitivity reactions are classified artificially into two types, according to the delay in onset of the reaction after the last administration of the drug: (1) immediate reaction, occurring less than 1 hour after the last drug intake, and (2) non-immediate reaction, with variable cutaneous symptoms occurring after more than 1 hour and up to several days after the last drug intake.

The entire spectrum of DHRs (Table 55-1) can be seen in children, even the most severe cutaneous and organ-specific types.[41,42]

Drug Allergy Work-Up

EVALUATION OF THE CLINICAL HISTORY

The suspicion of DHR arises from several factors elicited from the clinical history. The following details should be

TABLE 55-1 Classification of Drug Allergies

Type	Type of Immune Response	Pathophysiology	Clinical Symptoms	Typical Chronology of the Reaction
I	IgE	Mast cell and basophil degranulation	Anaphylactic shock Angioedema Urticaria Bronchospasm	Within 1–6 hours after the last intake of the drug
II	IgG and complement	IgG and complement-dependent cytotoxicity	Cytopenia	5–15 days after the start of the eliciting drug
III	IgM or IgG and complement or FcR	Deposition of immune complexes	Serum sickness Urticaria Vasculitis	7–8 days for serum sickness/urticaria 7–21 days after the start of the eliciting drug for vasculitis
IVa	Th1 (IFNγ)	Monocytic inflammation	Eczema	1–21 days after the start of the eliciting drug
IVb	Th2 (IL-4 and IL-5)	Eosinophilic inflammation	Maculopapular exanthem (MPE), DRESS	1 to several days after the start of the eliciting drug for MPE 2–6 weeks after the start of the eliciting drug for DRESS
IVc	Cytotoxic T cells (perforin, granzyme B, FasL)	Keratinocyte death mediated by CD4 or CD8	Maculopapular exanthem, SJS/TEN, pustular exanthem	1–2 days after the start of the eliciting drug for fixed drug eruption 4–28 days after the start of the eliciting drug for SJS/TEN
IVd	T cells (IL-8/CXCL8)	Neutrophilic inflammation	Acute generalized exanthematous pustulosis	Typically 1–2 days after the start of the eliciting drug *(but could be longer)*

DRESS – Drug reaction with eosinophilia and systemic symptoms; *SJS* – Stevens-Johnson syndrome; *TEN* – toxic epidermal necrolysis.

https://CafePezeshki.IR

TABLE 55-2 Severity/Danger Signs in Drug Hypersensitivity Reactions

	Visible Severity Signs	Invisible Severity Parameters
Immediate reactions	Sudden onset of multisystem symptoms (respiratory, skin and mucosal) Reduced blood pressure Dyspnea Dysphonia Sialorrhea	High levels of serum tryptase*
Non-immediate reactions	General Lymphadenopathy Fever > 38.5°C Organ specific Painful skin Skin extension > 50% Atypical target lesions Erosions of mucosa Skin blisters, bullae Centrofacial edema Purpuric infiltrated papules, cutaneous necrosis	Changes in blood count† Cytopenia Eosinophilia Alteration of liver function tests† Alteration of kidney function†

*No clinical utility in the acute setting.
†If a severe delayed DHR is suspected, all patients should have complete blood count and liver and kidney function tests.
(With permission from Chiriac AM, Demoly P. Drug allergy diagnosis. Immunol Allergy Clin North Am 2014;34:461-71.)

addressed: (1) the timing of the reaction (with respect to drug administration), (2) the nature of the drugs involved, (3) the history of a previous exposure to the same drug or to cross-reactive drugs, (4) the medical/genetic background, (5) the circumstances of the occurrence of the reaction and (6) differential diagnosis.[29] If possible, these details should be compiled in a standardized manner.[12] Documentation of the presence of severity signs (Table 55-2) is mandatory since they will tailor the drug allergy work-up and establish contraindications to re-exposure.

SKIN TESTS

General Aspects of Skin Tests

Skin tests are the first step in in vivo re-exposure to the drug, and are therefore of utmost importance. If positive at validated, nonirritant concentrations, they confirm the diagnosis of sensitization to the culprit and/or cross-reactive drugs and avoid the need for a drug provocation test (DPT). The tests should follow standard operating procedures and should be performed by personnel trained in their practice and interpretation. They have to be applied according to the suspected pathogenetic mechanism of the DHR, with immediate and/or late-reading prick tests and intradermal tests according to the initial clinical presentation (patch tests can also be used to explore delayed DHRs, but late-reading intradermal tests are preferred whenever possible, because of their demonstrated higher sensitivity for BL in adults).[19] The diagnostic value of skin tests is limited by several factors:

1. They only address true allergic reactions, providing evidence for type I and type IV drug allergies.
2. For most drug allergens, standardized and validated test concentrations and vehicles have not been elucidated. The European Network of Drug Allergy/Drug Allergy Interest Group (ENDA/DAIG) network took on the task of reviewing the literature for evidence to support the recommendation of specific appropriate drug concentrations for systemically administered drugs. Their conclusions and recommendations have recently been published.[23]
3. Sometimes the drug is not available in an adequately reactive form (generally because it is a metabolic derivative that is immunogenic and not the parent drug).

Peculiar Aspects of Skin Tests in Children

The pain of intradermal tests may limit their use in young children and, in the absence of therapeutic necessity, a 'waiting approach' is generally adopted until the patient is older. On the other hand, viral infections are thought to be the most common cause of maculopapular or urticarial eruptions in children[36] and this hypothesis is strongly favored after a negative drug allergy work-up. With these two considerations in mind, a shorter algorithm of testing, i.e. bypassing skin tests, in highly selected pediatric patients has been proposed by some groups. In the first prospective study of its kind, Caubet et al[36] performed DPT in 88 children with benign delayed eruptions (maculopapular exanthema or urticaria) to BL antibiotics, irrespective of skin test results. The lack of any criteria of severity had been confirmed by a trained allergist in the acute phase of the reaction. Six out of 88 children (6.8%) had a positive DPT (4 of them also had immediate positive intradermal tests but, interestingly, none had positive patch tests or delayed-reading intradermal tests). The authors found that the group with positive intradermal tests did have a significantly higher rate of positive DPT ($P < .05$), but that none of the 6 patients with a positive DPT developed a more severe reaction than the index event. They thus concluded that skin tests had a limited value in the diagnosis of these benign cutaneous eruptions in children and suggested performing DPT without previous skin testing in these selected patients.

DRUG PROVOCATION TESTS

General Aspects of Drug Provocation Tests

The DPT is performed at the end of a stepwise approach in the drug allergy work-up. There is general agreement that this procedure has better sensitivity than all the other available diagnostic tools, and that it may considerably improve patient management. However, its use as the 'gold standard' to establish (or exclude) the diagnosis of DHR is not unanimously accepted or widespread in the medical community, due to its inherent risks. Interestingly, however, a study carried out in three European centers dealing with the patient's perspective and satisfaction with regard to DPT revealed that most patients accepted DPT for diagnostic purposes, irrespective of the final test results. Furthermore, 95% of them believed that it was useful and stated that they would recommend it to others.[43] Similar findings were observed across other centers, in adults as well as in children.

Although not well established, the negative predictive value (NPV) of DPTs is important for both the patient and the physician. One of the main limitations of DPT is that a negative test

https://CafePezeshki.IR

does not prove beyond any doubt tolerance for the drug in the future, but rather that there is no DHR at the time of the test. Studies regarding the NPV of DPTs are, however, encouraging and display virtually the same results in both adult and pediatric populations. A high NPV of BL DPT of 94% to 98% was found in a large study involving 256 children,[44] and most of the reactions reported by the patients were mild and non-immediate. This information should reassure the patients and their doctors about prescription of drugs after negative DPT.

General considerations on DPTs, with regard to indications, contraindications, methods, limitations and interpretation, have been thoroughly addressed[14] and protocols published.[4,15,16,19,45] Nevertheless, the precise DPT procedure may vary considerably from one team to the next. Moreover, in pediatric settings, novel approaches arise, awaiting either validation or refutation by larger studies in the future.

Particular Aspects of Drug Provocation Testing in Children

(1) Methodology of DPT. Technical aspects vary between published studies in terms of initial dose, number of and interval between protocol steps, and duration of DPT. In a child with negative testing and in the absence of contraindications, drug hypersensitivity should be ruled out or confirmed by administering an age- and weight-appropriate cumulative dose of the drug to which the patient initially reacted. An observation period should then follow, before discharging the child, in order to ensure that no life-threatening reaction occurs. Informed consent should be obtained (ideally from both parents).

A maximum single dose of the specific drug must be achieved and the administration of the defined daily dose is desirable.

(2) Duration of the DPT. Depending on the type of the drug itself, the severity of the DHR under investigation and the expected time latency between application and reaction, the DPT may take hours, days or, occasionally, weeks before it is complete.[14]

There is controversy among different groups as to whether one full therapeutic dose (of the tested drug) is sufficient to elicit reactions in non-immediate responders, particularly in children. Hence, prolonged[36,46] courses have been suggested to increase the sensitivity of DPTs. However, this suggestion is still subject to debate and must be considered with caution in terms of diagnostic improvement, cost and medical implications.

Another matter for discussion concerning non-immediate reactions is the duration of the DPT, and also, for some authors, the location. Theoretically, DPT should be performed in the hospital, under medical supervision. In the study of Ponvert et al,[46] DPTs were carried out either in a hospital setting (for immediate reactors) or at home (for a group of children with a clinical history of mild to moderately severe non-immediate reactions). The latter group was prescribed the daily therapeutic dose for up to 10 days, according to the chronology of the index reaction. Eighty-eight reactions were reported for DPT performed at home, accounting for 6.1% of the 1,431 tested patients. One urticaria with asthma exacerbation and two severe serum sickness-like reactions (SSLR) were elicited by DPT performed at home.

(3) Step Dosing. Based on their initial results in the prospective study of 88 children with benign delayed cutaneous reactions during BL treatment (challenged irrespective of skin test outcome), Caubet et al[36] concluded that, in these patients, performing a single-dose DPT can be considered safe. The group is currently generating data with this practice (single-dose protocol, followed by 30-minute observation). The authors emphasize that this procedure requires careful primary evaluation by an experienced allergist and cannot be performed in patients suspected of having a more severe reaction. Such a level of certainty about the initial reaction history is only possible if the clinician has observed the reaction first hand, or if there is clear documentation of the reaction in the medical record. Otherwise, in case of doubt, the group recommends performing a complete drug allergy work-up, including skin testing, prior to a more progressive DPT.

Other authors have also performed DPT with or without skin testing. Chambel et al[47] implemented this practice and reported a 6-year experience of drug allergy work-up in children with clinical histories of either immediate or delayed reactions to BL antibiotics. However, in this study, patients with positive skin tests were not challenged, and in about one third of the patients (32 out of 114, 28%) who underwent DPT directly, an alternative cross-reactive drug was used. Of the 68 patients not skin tested to BL and submitted to a DPT with the culprit antibiotic, almost two thirds (62.5%) could not specify the chronology of the initial reaction. In this study, there were more DPT reactors in the subgroup with immediate index reactions than in the delayed-type reaction group (36.4% vs 16.9%). Conversely, there were more DPT negative patients in the delayed group (19.7% vs 9% who had presented immediate reactions in their clinical history), although this difference did not reach statistical significance in simple univariate analysis.

Regarding these practices (bypassing skin testing, single-dose DPT), no recommendation has been issued by the national or international allergology societies. A growing body of evidence regarding (1) standardization of the various protocols, (2) precise identification of the selected pediatric patients that could benefit from it, and (3) safety profile must be provided before its possible acceptance and adoption as a standard practice in the diagnosis of BL allergy in children.

(4) DPT Contraindications. Drug provocation testing should never be performed on patients who have experienced severe, life-threatening immunocytotoxic reactions, vasculitic syndromes, exfoliative dermatitis, erythema multiforme major/Stevens-Johnson syndrome, drug-induced hypersensitivity reactions (with eosinophilia)/DRESS, toxic epidermal necrolysis or organ involvement. In a large retrospective study regarding BL allergy in children, Ponvert et al[46] suggested that SSLR, erythema multiforme and Stevens-Johnson syndrome in children are mainly due to viral infections and that in such patients, with a negative allergologic work-up based on late-reading intradermal and patch tests, DPT might be considered for essential (future necessity) BL. However, this course of action must be regarded with the utmost caution, given that supporting evidence is lacking and due to the high risk of recurrence of such reactions.[48]

DESENSITIZATION

In order to confirm or rule out DHR, elective testing, i.e. performing a drug allergy work-up in children labeled 'allergic' to important drugs (BL, NSAIDs, local anesthetics), is always preferred to testing during situations of acute need. However, in

https://CafePezeshki.IR

cases where testing could not be performed before the situation that required therapeutic administration, and in the absence of contraindication, desensitization is an option. Referral to successfully applied existing protocols is recommended because there are no generally accepted protocols for drug desensitization in immediate DHRs,.[20,29] For non-immediate DHRs the literature is more controversial and desensitization should be restricted to uncomplicated exanthems or fixed drug eruption, due to the unpredictability and limited therapeutic options in severe DHRs.[25]

Beta-lactam Antibiotics

Beta-lactam antibiotic DHRs are explored as described above, by a thorough clinical history, standardized skin tests, and DPTs if necessary.

There is still an ongoing debate on whether to recommend a fixed panel of haptens to be included in the diagnostic evaluation of BL allergy due to: (1) different experiences, (2) different drug prescription habits and (3) different patterns of sensitization (which certainly follow past and present patterns of antibiotic use). However, classically, a certain number of reagents are considered to be essential for the diagnosis of BL allergy. The current recommended reagents used for skin testing[7,19] comprise, when available, a combination of PPL (the penicillin major determinant benzylpenicilloyl conjugated to poly-L-lysine), MDM (mixture of minor determinants), and/or penicillin G (in cases of unavailability of PPL/MDM or if skin tests to PPL/MDM are negative) in addition to the suspected determinants that bring their side-chain structures into the panel (i.e. amoxicillin and culprit drugs such as cephalosporins). Of note, a few recent reports pointed out the role of selective clavulanic acid hypersensitivity in reactions attributed to the combination of amoxicillin and clavulanic acid.[49] Selective immediate and delayed-type DHRs to clavulanic acid were diagnosed based on positive skin tests (or DPT) with amoxicillin associated with clavulanic acid, whereas skin tests (and DPT) with amoxicillin remained negative. Some authors[49,50] performed skin tests with purified clavulanic acid alone (the drug is unstable in solution, requiring the use of excipients and limiting its availability) and obtained positive results at concentrations that proved negative in exposed controls. In the largest retrospective study to date on BL allergy in children (1,431 patients evaluated over a 20-year period), Ponvert et al[46] observed that up to 37 of the 87 (42.5%) children diagnosed as hypersensitive (by means of positive DPT) to combined amoxicillin/clavulanic acid were actually selective responders to the latter and tolerated amoxicillin. However, in another large pediatric European study, tackling immediate drug hypersensitivity reactions to penicillins and cephalosporins in 1,170 children,[51] no such case was mentioned.

Beta-lactam skin tests have been used for decades and systemic reactions (ranging from generalized cutaneous reactions to anaphylactic shock, including a few cases of fatalities) have been described, especially in relation to IgE-mediated allergy. In a predominantly adult population, the prevalence of such reactions was up to 8.8% to 9.4% of the positive skin-tested patients (1.2–1.3% of the tests).[52,53] The safety of skin tests to BL in children appears to be better, with an overall prevalence ranging between 0 and 1.2%[51,54] of the tested patients and 2.6% and 3.8% of the allergic children.[46,54]

The prevalence of BL DHR varies greatly between large series, from 7.92%[55] to 58.3%.[51] As with adults, skin tests are of greater diagnostic value in confirming immediate rather than delayed-type DHR to BL, with a sensitivity ranging from 86%[46] for the former to 3.77%[55] for the latter. Overall, most of the cases, whether immediate or non-immediate, are confirmed by DPT.[46,55]

Some groups focussed on the use of specific BL in particular pediatric settings, i.e. in patients suffering from cystic fibrosis.[56–59]

Non-β-lactam Antibiotics

Children suspected of having DHRs for antibiotics other than BL are not generally subjected to elective testing. The attitude most frequently adopted by physicians is definitive avoidance, mainly because these drugs are rarely used as a first-line treatment. Apart from BL, the two antibiotic classes most commonly involved in pediatric DHRs are sulfonamides and macrolides.[37,60] Because they are not systematically studied, the bulk of the data derives from case reports, case series or studies in specific populations (i.e. HIV-infected subjects for sulfonamides). Moreover, the true prevalence of DHRs to these antibiotics is difficult to determine due to certain issues interfering with the drug allergy work-up:

1. The lack of standardized, nonirritating concentrations for skin tests, most of the diagnosis relying therefore upon DPTs.
2. The relative use of DPT as a diagnostic procedure, because of alternative approaches:
   a. for macrolides, the use of an alternative drug, as a matter of principle in most cases, without prior confirmation of DHRs to the culprit macrolide
   b. for sulfonamides, the use of desensitization for therapeutic purposes.

SULFONAMIDES

Antibacterial sulfonamides (sulfamethoxazole, sulfadoxine and sulfapyridine) – which are derivates of sulfanilamides – are of allergenic importance. Patients with an allergy to a sulfanilamide might cross-react with other sulfanilamides with a different side chain, but not with sulfonamides in general.[61] Although they can induce a broad spectrum of DHRs (including type I and type II allergies, i.e. hemolytic anemia), they are known and feared elicitors of severe cutaneous adverse reactions (SCARs) such as DRESS, Stevens-Johnson syndrome and toxic epidermal necrolysis. The drug allergy work-up obeys the general rules, but with a few peculiarities:

1. Positive skin tests have been described[61] but their sensitivity is low and certain groups support the use of in vitro tests (the lymphocyte transformation test) to increase sensitivity (with the advantage of using compounds that are not available for in vivo testing).
2. In a clinical situation requiring treatment and in the absence of contraindications, desensitization has been an option for many years (it is extensively used in the HIV-infected population) and protocols have been published.[25,62]

MACROLIDES

Macrolide antibiotics are considered to be one of the safest antibiotic treatments available, with a DHR prevalence of 0.4% to 3% of all treatments.[45,63] Their chemical structure is

https://CafePezeshki.IR

characterized by a large lactone ring, which can vary from 12 to 16 atoms, with one or more sugar chains attached. Cross-reactivity among different macrolides has not been extensively studied, but when it was tested, a majority of patients with a demonstrated DHR to a certain macrolide could tolerate another macrolide with a different number of atoms in the lactone ring. Moreover, macrolide antibiotics are unlikely to cross-react with macrolide immunosuppressants such as 23-C tacrolimus and 29-C sirolimus. Published series reveal that, after performing DPT, DHRs to macrolides are confirmed in only 2.7% to 17% of cases.[45,63]

Nonsteroidal Antiinflammatory Drugs (NSAIDs)

Together with BL, NSAIDs are the most common elicitors of DHRs in children, as well as in adults.

Some considerations are worth mentioning with regard to the pediatric population:

1. The infrequent use of acetyl salicylic acid (ASA) because of concerns about Reye's syndrome in children.
2. The use of NSAIDs that are known to be generally well-tolerated alternatives in adults is regulated by prescription restrictions. Nimesulide was removed from the market in several countries due to concerns about hepatic ADRs, and oxicams and coxibs are only approved for children older than 15 years and adults, respectively.

Five major clinical entities are recognized in the new nomenclature proposed by the EAACI[64] although overlaps may exist: (1) NSAID-exacerbated respiratory disease (NERD); (2) NSAID-exacerbated cutaneous disease (NECD), (3) NSAID-induced urticaria/angioedema (NIUA); (4) single NSAID-induced urticaria/angioedema or anaphylaxis (SNIUAA); (5) NSAID-induced delayed hypersensitivity reactions (NIDHR). These entities underpin two reactive patterns: the cross-reactive types (1, 2 and 3), or cross-intolerant (CI), involving nonallergic mechanisms, and the single drug-induced types (4 and 5), presumably allergic in nature, involving putative IgE and T cell mediated mechanisms.

Several studies have confirmed that isolated angioedema is the most common manifestation of confirmed NSAID DHRs in children, with ibuprofen being the most frequently involved drug in the clinical history,[55,65] as well as in proven NSAID DHRs.

As with adults, the diagnosis is mainly based on clinical history and DPT. For nonallergic type 1–3 DHRs, neither skin nor laboratory tests are of value. However, for patients experiencing type 4 and 5 allergic reactions, skin tests and some in vitro tests can be of value, although with limitations.

Some authors perform ASA challenge, in order to confirm or discard cross-reactive status, in patients whose clinical history is not reliable, i.e. patients who developed a reaction with 1 or 2 NSAIDs. However, when challenged with ASA, ibuprofen-sensitive children reacted faster and at a lower total cumulative dose, and occasionally with more severe reactions (including respiratory symptoms such as rhinoconjunctivitis and also asthma) than their index reactions.[55]

Corzo et al[66] studied paracetamol and etoricoxib tolerance in 41 children with DHR (proven by means of DPT) to ASA and ibuprofen and found that all of them tolerated these alternative drugs. All but two patients had clinical histories of NIUA (83.3% with angioedema). When challenged with meloxicam, only two patients (4.9%) reacted. The authors concluded that there was better tolerance to these drugs than in the adult NSAID hypersensitive population.[67] However, it cannot be ruled out that, in the natural evolution of NSAID DHR, reactions to these drugs may appear in initially tolerant children. Moreover, although their results indicate that paracetamol can be a safe alternative in these children, the authors underline that this needs to be verified by a DPT, because the estimated reaction to paracetamol varies in other studies and may be as high as 40%.[65,68,69] This high cross-reactive rate was found in a pediatric study (carrying the pitfall of a smaller sample size with only a few DPTs to find safe alternatives), where the tolerability rate for nimesulide was 88.8%.[65]

The clinical phenotype of NERD is less common in children. Reactions to COX-1 inhibitors can be life-threatening.[70]

Vaccines

Vaccines are complex preparations and hold a special place in preventive medicine by generating a protective immune response against various infectious diseases. Withholding vaccination from patients with histories of possible or even confirmed DHRs to any component of the culprit vaccine may result in significant individual and social consequences because of the need for vaccination coverage of the population. Generally, the risks of vaccinating are outweighed by the risks of not vaccinating.[8,71] Given these considerations, as well as the growing body of evidence about the rarity of true DHRs to vaccines, recommendations regarding the re-administration of vaccines to a patient with a clinical history are somewhat different and more critical than in other areas of DHR.

Allergic-like reactions elicited by vaccines can be attributed to the microbial components, the residual components of the culture medium or the preservatives, stabilizers and adjuvants added to the vaccines.[71] Both food (gelatin, egg) and drug (i.e. neomycin, gentamicin, polymyxin B and streptomycin) hypersensitivities must be considered when evaluating vaccine DHRs. Local reactions are by far the most frequent adverse event after immunization, whereas systemic reactions (either immediate or non-immediate) occur with an estimated incidence ranging between 1 and 3 reactions per million vaccine doses.[72,73] Systemic reactions carry the risk of life-threatening anaphylaxis if the patient is re-exposed. Drug allergy work-up is therefore mandatory before the patient is re-exposed.

Vaccination is subject to immunization schedules but 'catch-up' booster doses can be administered to children whose vaccination has been delayed due to a suspicion of DHR. If skin testing, especially intradermal testing, to the vaccine itself is unreliable (because it may cause false and clinically irrelevant positive reactions), measuring levels of IgG antibodies to the immunizing agents in a vaccine suspected of causing a serious DHR can be considered as a step in the drug allergy work-up in these patients.[8,71] Determining whether or not they are at protective levels can help to determine whether subsequent doses of the vaccine are required. If the patients reach the established level associated with protection from disease, consideration can be given to withholding additional doses, although the induced immunity might be lower than if all doses were injected. Follow-up of levels of protection is then recommended.

https://CafePezeshki.IR

DIAGNOSIS AND MANAGEMENT OF A PATIENT WITH A CLINICAL HISTORY OF LOCAL REACTION AFTER VACCINE ADMINISTRATION

Patients developing local reactions after vaccine administration do not have a higher rate of systemic reactions upon re-exposure, so tests are not usually needed except in patients with a large local inflammatory reaction. If there is a suspicion of Arthus reaction, measurement of serum vaccine-specific antibodies (IgM/IgG) is indicated in order to detect a hyperimmunized status.

Patch tests can be useful in patients developing eczema or persistent nodules after vaccine administration. They can demonstrate a delayed DHR to preservatives or adjuvants and guide the physician to avoid vaccines and other products containing these incriminated components. However, a positive patch test is not accurate for the purpose of assessing a patient's ability to tolerate a vaccine and is not a contraindication to administering the vaccine following a risk-benefit analysis.[8] There are no contraindications for booster injections in relevant infectious agent seronegative subjects, even if they are aluminum or thimerosal patch test positive.[8,71]

GENERAL MANAGEMENT OF PATIENTS WITH A HISTORY OF SYSTEMIC REACTION TO VACCINES

In children with systemic reactions, skin testing (and/or specific IgE) to the vaccine itself but also to the potential single components that may have caused the reaction (when commercially available) is required. Although the sensitivity and specificity of skin tests with the vaccine itself have not been studied, and false-positive reactions occur, the result can guide the approach. Patients with negative skin tests can receive the full dose of vaccine, while in patients with positive skin tests to the vaccine itself (or with confirmed allergy to one of its components) the ratio between risk and therapeutic benefit should be assessed (including measurement of protective antibody levels) and the physician should determine whether subsequent doses of the suspected vaccine, or other vaccines with similar components, are required. If needed, the vaccine can still be administered following the protocol proposed by the American Academy of Pediatrics.[8]

Multiple Drug Hypersensitivity Syndrome

About one third of the patients seen in a drug allergy consultation report multiple drug allergies.[51,74] True multiple drug hypersensitivity syndrome (MDH), as opposed to self-reported MDH, is rare and has been estimated in the range of 0.3% to 0.6% in large series of patients presenting with a suspicion of DHR.[74,75] However its incidence is definitely higher in delayed-type reactions, including SCARs.[76,77] Interestingly, although the prevalence of proven DHR in children is lower than in adults, Atanaskovic-Markovich et al[51] reported MDH in 7 of 279 children (2.5%) evaluated for suspected DHR over a 5-year period. In this series, one patient had a history of SCAR, namely SJS.

Conclusions

Drug allergy work-up in children faces the same issues, challenges and unmet needs as in adults. Certain approaches (e.g. simplifying and reducing the protocol steps in highly selected pediatric populations) seem increasingly attractive to the groups working in pediatric settings. It remains to be seen whether they will stand the test of time and be accepted as a general rule in drug allergy work-up in children.

56 Latex Allergy

KEVIN J. KELLY | BRIAN T. KELLY

KEY POINTS

- Natural rubber latex (NRL) is contained in thousands of consumer and medical products and is responsible for an epidemic of IgE-mediated latex allergy in the past three decades. Products made by a dipping method (e.g. gloves, condoms) have the highest content of allergenic protein that may result in urticaria, angioedema, asthma, rhinoconjunctivitis and anaphylaxis. Latex finished products contain multiple chemicals that may induce cell-mediated contact dermatitis, although this is uncommon in pediatric practice.
- Latex proteins may have clinical cross-reactivity with multiple foods and lead to clinical allergic responses, especially to banana, avocado and/or kiwi, in nearly 50% of latex-allergic subjects. A small subset of patients with fruit and vegetable allergies may develop allergic reactions from cross-reactions to latex but these occur in less than 15% of patients.
- Patients with spina bifida are at highest risk of developing latex allergy. Occupational asthma is a common problem seen in adult workers exposed to latex materials that use a cornstarch donning powder, which may carry latex protein into the ambient environment.
- Diagnosis is best achieved by performance of a history, physical examination and allergy tests using skin test, serologic tests and provocation tests, although standard reagents are lacking. Serologic tests may produce false-positive results by a variety of mechanisms while up to 25% of serologic tests may be falsely negative.
- Avoidance of latex through 'latex safe precautions' is essential for the treatment of latex allergy.

Introduction

In the 1980s a worldwide epidemic of immunoglobulin E (IgE)-mediated allergy to natural rubber latex (referred to as NRL or latex) occurred. A marked increase in personal exposure to latex with the implementation of healthcare standard precautions and manufacturing changes in latex production resulted in sensitization to protein allergens retained in finished products. This chapter reviews the clinical presentation of latex allergy (LA), production of latex products, patterns of latex use in the context of clinical symptoms, allergens, diagnosis, clinical and laboratory cross-reactivity with foods and pollens, and treatment options.

Clinical Manifestations – Initial Observations

The clinical circumstances in patients who develop LA are highly variable and may not be readily recognized by patients. This requires clinicians to have a high index of suspicion and astute diagnostic skills.

In 1927, a single case of chronic urticaria from contact with rubber prosthetics was reported in the German literature.[1] It was not until 1979 that the first clear case of LA was reported in a homemaker.[2] The diagnosis was confirmed by a medical history of intense pruritus and atopic dermatitis after the use of rubber gloves, with confirmation by patch test and prick test-induced hives from a latex glove. The clinical spectrum of LA was broadened by the first report of latex exposure in a healthcare worker causing urticaria, rhinitis and ocular symptoms.[3]

The introduction of standard precautions saw an exponential rise in latex exam glove use, paralleling a rise in reporting of LA but latex is now being replaced by nitrile butadiene rubber (Figure 56-1) in exam gloves. A 1987 prevalence study confirmed the presence of LA in 15/512 (2.9%) hospital employees screened by prick test to latex.[4] A subset of individuals (operating room personnel) had the highest prevalence at 6.2%. Atopy was found to be a strong contributing factor to LA development with 10/15 (66.7%) of subjects having environmental allergies. In 1987, Axelsson et al reported five individuals with systemic reactions to latex gloves; only one was a healthcare worker.[5] Seaton and Cherrie completed the medical literature spectrum of latex allergy manifestations a decade after the first modern publication, when a case of occupational asthma caused by latex gloves was confirmed, and suggested that latex exposure came from airborne allergen.[6] Previous mucosal reactions of conjunctivitis and rhinitis were believed to have come from direct allergen transfer by hand contact. This report moved the medical community toward an understanding that the environment could be contaminated by allergen-carrying glove powder.

After these earliest observations, specific risk groups emerged with common exposures. Throughout the first decade of reporting this disorder, women, healthcare workers and atopic individuals were identified as being at risk. Reports identified individuals undergoing surgical operations having severe allergic reactions during anesthesia. Two children with spina bifida suffered anaphylactic reactions when undergoing anesthesia in two completely different clinical scenarios. One child experienced systemic symptoms within 15 minutes of anesthesia induction and prior to surgical incision while the other child's reaction occurred at the time of closure of the surgical incision. These reactions were characterized by generalized flushing, expiratory wheezing, marked increase in airway pressure needed to mechanically ventilate, and severe hypotension requiring epinephrine for symptom reversal. These observations were confirmed in the next 3 years by multiple clinical observations of allergic reactions in spina bifida patients undergoing surgery.[7–9]

SPINA BIFIDA

Children with spina bifida (SB) emerged in the early 1990s as the group at highest risk for developing LA.[10] Recurrent

https://CafePezeshki.IR

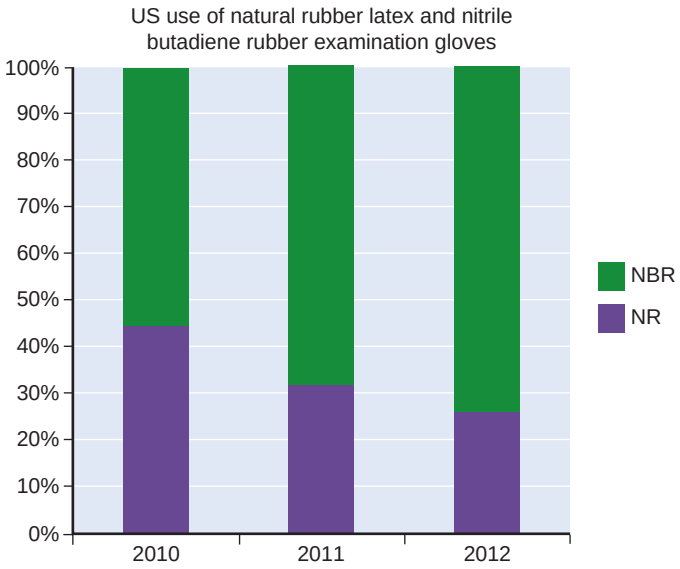

Figure 56-1 The introduction of standard precautions saw an exponential rise in use of latex examination gloves but not sterile surgical latex gloves. After 2009, a marked buying change of latex examination gloves occurred in the USA with nitrile butadiene rubber (NBR) replacing natural rubber (NR) as the most common source for latex gloves. In addition, powdered latex examination gloves now constitute a small proportion of latex examination gloves. *(Adapted from Whitfield A. Synthomer Investor Day pdf presentation on November 19, 2013 at http://www.synthomer.com/fileadmin/content_investor/2013/Investorday 2013.pdf.)*

exposure to latex products in their daily care, multiple surgeries, atopic disposition and epigenetic factors may all contribute to this response. Patients with SB seem exceptionally capable of mounting an IgE response to latex proteins, with subjects undergoing surgery in a prior year having a 68% prevalence of NRL sensitization. Alarmingly, one of every eight patients with SB in one hospital, prior to the use of latex avoidance precautions in the operating room, developed systemic allergic reactions during anesthesia, representing a 500-fold higher rate of anaphylaxis than expected during general anesthesia and surgery. Two case series reported anaphylaxis occurring 40 to 220 minutes into surgery with direct mucosal glove contact, while another series noted anaphylaxis within 30 minutes of the induction of anesthesia.[9,10] One case series compared differences between SB patients who developed intraoperative anaphylaxis and those who did not, while a second case series compared SB to atopic and nonatopic control groups. SB groups developed LA more frequently than atopic subjects (40.5% vs 11.4%) and at >20 times the rate of healthy controls (40.5% vs 1.9%). Other case series without control groups suggest that atopy, >5 surgeries, high antilatex IgE (>3.5 kU/L), and skin test reactivity to foods (kiwi, pear or tomato) are important factors.[11–15]

Recently, sensitization to latex in SB patients has declined significantly (5% vs 55%) with the introduction of latex safe conditions.[16] Therefore, latex avoidance measures have been extremely successful in reducing sensitization and allergy in patients with SB.

LATEX ALLERGY IN PATIENTS WITH UROLOGIC OR NEUROLOGIC DEFECTS

In addition to patients with SB, patients with cloacal anomalies, chronic renal failure or bladder anomalies are at risk for latex anaphylaxis. Two studies published in the same year reached opposite conclusions about the risk of LA or sensitization in patients with spinal cord injuries. Konz et al performed a cross-sectional study of 36 SB patients, 50 patients with spinal cord injury, 10 patients with cerebrovascular accidents and 10 healthy control patients.[17] While 72% of the SB subjects had clinical histories and confirming tests compatible with LA, no positive histories were identified in either of the other two groups with neural disease. Antilatex IgE was noted in 4% of spinal cord-injured patients despite no history of latex-induced reactions. Vogel et al reported only 2/67 spinal cord-injured patients with a clinical history of latex reactions, but 10 (15%) with evidence of latex sensitization, a historically higher rate than the general population.[18] Regardless, there appear to be significant differences between neurologically injured patients and patients with SB.

HEALTHCARE WORKERS

The clinical manifestations of healthcare workers' (HCW) disease are quite different from other groups.[19–23] While most children with LA do not have irritant dermatitis or contact dermatitis, the majority of latex-allergic healthcare workers show evidence of dermatitis, with the irritant type being the most prevalent. Hand symptoms have been correlated closely with latex sensitization. In fact, HCW with more than two hand symptoms are 11 times more likely to have positive skin prick tests.[24] Dermatitis often heralds the development of IgE-mediated symptoms of urticaria, angioedema, occupational asthma, rhinoconjunctivitis and anaphylaxis, but is not a prerequisite for the development of LA. The prevalence of HCW disease has ranged from 5% to 17% with >50% having latex-induced asthma. Several reasons for LA development in this group include frequent use of latex gloves, manufacturing changes that lead to higher allergen content of gloves, processing changes or manufacturing changes. Airborne antigen exposure has been found to be a significant source of latex sensitization among HCWs. The use of powder-free examination gloves reduces the risk of sensitization 16-fold.[25]

SURGERY

Multiple reports suggest that surgical intervention increases LA risk.[12,26] In addition, children with cerebral palsy, esophageal atresia, gastroschisis and omphalocoele may be at higher risk. Since these diseases are confounded by frequent latex glove use and multiple surgeries, the contribution of each variable is unclear.

LATEX ALLERGY IN THE GENERAL POPULATION

Multiple reports and clinical experience have shown that individuals with no apparent risk factors of exposure, SB, healthcare work or surgery may develop LA. The symptoms in these individuals are usually predicted by the route of exposure: rhinitis, conjunctivitis and asthma occur after inhalation, while anaphylaxis occurs after abdominal mucosa or intravenous exposure. The most dramatic presentations were the first cases of anaphylaxis seen after rectal mucosal surface exposure to latex balloons, glove or condom materials. In the 1980s, air contrast barium enema procedures used a catheter that was inflated to help retain the air and barium in the colon.[27,28] Rectal

https://CafePezeshki.IR

manometry with a catheter tipped with a balloon or covered by condom material was common. Case series described severe anaphylaxis, including deaths, associated with these procedures. Only in retrospect were these cases identified as LA, with most occurring in non-healthcare workers, although some were atopic or had had prior surgery. One particular catheter was implicated in barium enema-induced anaphylaxis (E-Z-Em Company) with as many as 148 episodes of anaphylaxis and 9 deaths. Most of these subjects were not from identified risk groups, raising significant concern about the risk in the general population.

Two large studies[26,29] showed a prevalence of LA in children of 0.7% to 1.1%, well below the reported prevalence in children with SB and healthcare workers. These observations were contrasted by serologic studies from blood donors, non-healthcare workers, and consecutive emergency department patients that demonstrated antilatex IgE presence in the blood of 4% to 8% of these subjects.[29–34] Whether this represents a predictable rate of false-positive tests in low-prevalence populations, or accurate results in subjects at risk of latex-allergic reactions following future exposures, is unclear.

FRUIT ALLERGY AND CONCURRENT LATEX ALLERGY

Clinical observations raised the question of pan-allergens and clinical cross-reactivity of fruit and latex. Multiple clinical reactions to bananas, kiwi, avocado, mango, chestnut, papaya and stone fruits such as cherries or peaches have been published in known latex-allergic subjects.[34–41] In addition, individuals with primary food allergy have had clinical reactions to latex, but much less frequently than might have been expected from the initial frequency of in vitro allergen cross-reactions. This syndrome has been termed the 'latex-fruit syndrome' and was extended to the 'latex-vegetable syndrome' when cross-reactions were found between a number of vegetables and latex proteins.

Over 50% of individuals with LA may have clinical reactions to fruit (Table 56-1) due to specific cross-reacting allergens.[31] A common tertiary structure of Hev b 6 (hevein) is shared with two banana proteins, avocado and chestnut. Kiwi has significant homology with Hev b 5.[42–44] While Hev b 7 has structural similarity to patatin from potato, the clinical relevance may be minor. Hev b 8, a profilin, may cross-react with other plant profilins. Hev b 2 is a pathogen-related protein β-1,3-glucan with cross-reactive homology. Hev b 12 is a lipid transfer protein that has been a common protein type to cause clinical reactions to vegetables and fruit in patients who are pollen reactive.

Latex-fruit syndrome was investigated from the perspective of whether individuals with primary fruit allergy have concurrent LA. Of 57 subjects with primary fruit allergy, 49 (86%) had IgE reactivity in serum and/or skin test. Only 6 (12.2%) reported prior symptoms from latex exposure; however, fruit allergy symptoms preceded these.[45]

The concern of hidden food allergen has been brought to light by multiple reports of transfer of allergen to food (a bagel, cheese, lettuce and doughnut) by handlers wearing latex gloves.[46,47]

TABLE 56-1 Foods that Cross-React with *Hevea brasiliensis* Latex

Primary Food Allergies Causing Latex Reactions	Clinical Cross-Reacting Foods
Bananas	Avocados
Melons	Bananas
Peaches	Chestnuts
	Kiwi
	Papaya
	Potato
FOODS WITH IN VITRO CROSS-REACTIVITY BUT UNCOMMON IN VIVO SYMPTOMS IN LATEX ALLERGY	
Apple	Passion fruit
Bell pepper	Pear
Celery	Pineapple
Cherry	Tomato
Fig	Turnip
Mango	Wheat

DIABETES AND LATEX ALLERGY

The development of LA in patients with type 1 diabetes was unexpected.[48] In 1995, anaphylaxis was reported during surgery and was presumed to be from latex contamination of injectable medication drawn from a latex rubber-topped bottle during anesthesia. A series of case reports[49–51] and a prevalence study investigating the risk of LA in individuals who require insulin injection were subsequently reported. Local allergic reactions at the site of insulin injection occurred after the needle used to draw up the insulin was inserted through a rubber-stopped bottle containing latex. Removal of the latex top and subsequent drawing up of the insulin into the syringe did not produce allergic reactions in any of these cases. These observations suggest that the latex stopper does not contaminate the medication vial, but does contaminate the needle during insertion. One report in the pharmacy literature found that multiple needle punctures of multidose vials did not elute allergen in sufficient quantity to result in allergic reactions. Serum samples from children with type 1 diabetes demonstrated that latex-specific IgE was detectable only in atopic diabetic children, but was not more prevalent than in nondiabetic atopic subjects. In this study, 7/112 (6%) of subjects had IgE antibody and were all derived from the atopic group of 42 subjects (17%). In contrast, none (0/70) of the nonatopic subjects had antilatex IgE antibody detected in the serum.[52]

Latex Production

Produced by nearly 2,000 lactiferous plants and trees, the polymer cis-1,4 polyisoprene has been exploited for broad commercial use from the tree *Hevea brasiliensis* and recently from other lactiferous plants such as guayule latex.[53–57] Charles Goodyear's critical discovery of sulfur heat vulcanization, a method that effectively cross-links the rubber polyisoprene while reducing the tackiness and sensitivity to temperature change of latex, catapulted NRL use into one of the most important industries in the world. Worldwide latex consumption has increased dramatically, with nearly 6 million tons/year produced in 1995 and over 21 million tons/year utilized, mainly due to China's spectacular economic growth. Latex demand for NRL in Japan, Europe and North America has remained stable. Whether a new epidemic of LA will emerge in China is unknown.

https://CafePezeshki.IR

Rubber hydrocarbon (cis-1,4 polyisoprene) makes up the majority of the latex suspension while protein, carbohydrate, lipids, inorganic constituents and amino acids are a minor percentage of the mix. Despite proteins being a minor portion of NRL, the retention of these proteins in finished products is the cause of IgE-mediated reactions in humans. During the manufacturing of latex products, over 200 different chemicals have been utilized and fall into broad categories of accelerators of cross-linking, antioxidants, antiozonates, biocides, colorants, epoxies and plasticizers. It is the accelerator class of chemicals, including thiurams, thiazoles and carbamates, that most frequently causes type IV cell-mediated contact dermatitis of the skin from latex. Synthetic rubber materials and alternative medical glove materials may retain these same chemicals, resulting in contact dermatitis. Gloves made of polyvinyl chloride, styrene butadiene rubber or Tactylon® (styrene ethylene butylene styrene) may not contain these accelerators.

LATEX COLLECTION

NRL flows through a circulation system of the tree and is collected when bark is shaved off just short of the cambium layer. Latex is treated with a stabilizer such as sodium sulfite, formaldehyde, ammonia (0.05–0.2%) or ammonia with a 1 : 1 mixture of zinc oxide and tetramethylthiuram disulfide (TMTD). A number of chemicals can be used to enhance the yield of latex. Such chemicals (e.g. 2-chloroethylphosphonic acid or ethepon) may enhance the quantity and type of allergenic proteins. Demand to produce more medical-grade latex with the advent of standard precautions in the 1980s resulted in more frequent tapping of trees and reduced storage time of latex. As many allergenic proteins are defense proteins, their production may have been enhanced.

LATEX PRODUCT MANUFACTURING

Approximately 88% or more of the world's harvested latex is acid coagulated, prepared as dry raw rubber in sheets or crumbs of technically specified rubber and dried at 60°C or higher temperature. Allergic IgE reactions have been rarely reported from this type of rubber but contact reactions may be seen.

The other 10% to 12% of NRL is produced in a latex concentrate by centrifugation or creaming to make products such as gloves and condoms from a dipping method. Most latex is concentrated to 60% isoprene, stabilized in either a high concentration of ammonia (0.7%) or low ammonia (0.2%) with TMTD and zinc oxide and stored in tanks for at least 2 to 3 weeks and often longer before being shipped to manufacturers. After shipping, the latex is prepared by the manufacturer, with proprietary methods, for dipping of forms (e.g. gloves) coated with a surface coagulant into latex slurry. The latex adheres to the form, is wet leached, heat vulcanized and dried, and various methods are used to prevent the latex products from sticking to each other. In the past, the most common agent used to prevent sticking was highly cross-linked cornstarch powder or talc. Given its ability to act as a carrier of latex allergen, cornstarch powder has fallen out of favor. Talc was found to induce granulomatous inflammation and decrease wound healing and has mostly been abandoned in medical-grade gloves. Halogenation or surface coating with a synthetic polymer has been useful in replacing donning powder.

Latex Allergens

Field latex varies in its protein content by clonal origin of the rubber plant, climatic factors, soil types, fertilizers and yield enhancers used for the rubber cultivation. Latex-producing trees are susceptible to invasion by a variety of microorganisms, especially fungi, and insects that can injure and kill the tree. NRL contains numerous defense-related proteins and enzymes that are integral in the protection of the plant, biosynthesis of polyisoprene and coagulation of latex, but which cause allergic sensitization and clinical reactions in susceptible hosts. Proteins present in freshly harvested latex are detected in finished latex products, either in their natural configuration or an altered configuration, which may lead to the formation of neoantigens.[53] Based on their IgE-binding properties, the Allergen Nomenclature Subcommittee of the International Union of Immunological Societies (IUIS) has accepted 13 proteins as latex allergens (http://www.allergen.org).

IMMUNOLOGIC PROPERTIES

The immunologic properties of individual latex allergens have been evaluated by immune responses in either healthcare workers or patients with SB since those individuals make up the majority of subjects found to have clinical disease. The allergens that the general population reacts to are likely to parallel these current observations (Table 56-2).

Functional Properties of Latex Allergens

Latex proteins are involved in rubber biosynthesis (Hev b 1, 3, 6, 7), plant defense (Hev b 2, 4, 6.01–6.03, 7, 11, 12, 13), enzyme actions and structural formation (Hev b 5, 8, 9). Some of these proteins have multiple functions and elicit variable IgE responses in humans who contact them.[44,54]

IMMUNE RESPONSES TO RUBBER BIOSYNTHESIS PROTEINS

The four allergens most involved in rubber biosynthesis include Hev b 1, Hev b 3, Hev b 6.01–6.03 and Hev b 7. What is most interesting is the dichotomy of reactions seen between healthcare workers and SB patients to this particular group of allergens. SB patients react more frequently to Hev b 1 and Hev b 3 than other risk groups, possibly due to genetic differences, surgical exposure, timing or route of exposure to the allergens.

Hev b 1 (Rubber Elongation Factor or REF)

A tetramer with a molecular mass of 58 kDa and tightly bound on large rubber particles (>350 nm in diameter), Hev b 1 is a major allergen, inducing IgE reactions in 13% to 32% of latex-sensitive healthcare workers and 52% to 100% of SB patients. This very important allergen must be present in sufficient quantity for diagnosis in patients with SB.[58–60]

Hev b 3 (REF Homolog)

This protein, with strong IgE-binding reactivity in patients with SB and LA, is associated with the small rubber particles (<75 nm) in latex. Clinical and immunologic reactivity of Hev b 3 with serum IgE in healthcare workers is less frequent and weaker than

https://CafePezeshki.IR

TABLE 56-2 *Hevea brasiliensis* Latex Allergens

Allergens	Allergen Name	Molecular Weight kDa	Function	Significance as Allergens
Hev b 1	Elongation factor	14.6	Rubber biosynthesis	Major
	Tetramer	58		
Hev b 2	1,3-glucanase	34/36	Defense protein	Major
Hev b 3	Elongation factor	23	Rubber biosynthesis	Major
Hev b 4	Microhelix complex	50–57	Defense protein	Major
	Dimer	100–115		
Hev b 5		16	Enzyme	Major
Hev b 6.01	Prohevein	20	Defense protein	Major
Hev b 6.02	Hevein	4.7	Defense protein	Major
Hev b 6.03	C-terminal hevein	14	Defense protein	Major
Hev b 7	Patatin homolog	42.9	Defense protein Inhibit rubber biosynthesis	Minor
Hev b 8	Latex profiling	14	Structural protein	Minor
Hev b 9	Latex enolase	51	Enzyme	Minor
Hev b 10	Mn superoxide dismutase	26	Enzyme	Minor
Hev b 11	Class 1 chitinase	33	Defense protein	Minor
Hev b 12	Lipid transfer protein	9.3	Defense protein	Major
Hev b 13	Latex esterase	42	Enzyme	Major

in SB patients. The amino acid sequence homology is 47% when compared to Hev b 1. Preincubated latex-allergic sera with Hev b 1 show >80% enzyme linked immunosorbent assay (ELISA) inhibition to solid phase Hev b 3, indicating the presence of similar conformational allergens in these proteins.[59–61]

Hev b 7 (Patatin-Like Protein)

An important potato storage protein allergen (Sol t 1), Hev b 7, a 46 kDa protein with patatin storage protein homology, inhibits rubber biosynthesis but also has defense hydrolase and esterase activity that inhibits the growth of invertebrate pests. IgE-binding reactivity occurs in 23% of healthcare workers with LA but Hev b 7 has not been demonstrated to be a major allergen for patients with SB.[62]

Hev b 6.01–6.03

Hev b 6.01–6.03 has latex coagulation activity but will be presented under defense-related proteins.

IMMUNE RESPONSES TO PLANT DEFENSE-RELATED PROTEINS

The Hevea latex allergens that have defense-related functions include Hev b 2, 4, 6.01–6.03, 7 (see above), 11, 12 and 13. Most latex-allergic patients recognize one or more of these allergens and their potential cross-reactions with fruit proteins account for the serious allergic reactions after ingestion of a food with such proteins. In addition, hevamine, a common protein that is not officially accepted as an allergen, is also a defense-related protein that some individuals develop IgE antibody against.[37,38,41–43,62–64]

Higher plants have a defense system of proteins that is compared frequently to the immune system of animals, but in reality is significantly different. Static defense proteins (e.g. storage proteins) may exert antifungal activity (e.g. lectins) or antimicrobial activity. Pathogenesis-related proteins (PR proteins) are encoded by the host plant but are induced only in pathologic situations (e.g. tapping of a latex tree). There are 14 identified families of PR proteins with defense functions and many are associated with food allergy cross-reactions in pollen-induced food allergy and the latex-fruit syndrome. Thus it is important to understand the type of defense proteins that are allergens in NRL in order to predict which fruit and environmental allergens will cause clinical cross-reactivity.

Hev b 2

This basic β-1,3-glucanase exhibits significant IgE binding in latex-sensitized SB and healthcare workers.[63] IgE reactivity may range from 20% to 61% of patients with clinical symptoms from latex allergen content. Foods such as banana, potato and tomato may contain β-1,3-glucanase activity, but it is not clear if this is truly the protein resulting in cross-reactions.[65,66]

Hev b 4

This microhelix component of latex is an acidic protein (50–57 kDa) and 65% of healthcare workers are found to have IgE against this component. However, only 14% of these patients showed peripheral blood mononuclear cell (PBMC) stimulation to Hev b 4.

Hev b 6 (Prohevein)

Hev b 6.01, one of the most abundant latex proteins, has two distinct domains: a 4.7 kDa C-terminal domain (Hev b 6.02) and an N-terminal 14 kDa peptide (Hev b 6.03).[41–44] Prohevein has strong reactivity with IgE from healthcare workers and SB patients with LA. The 43 amino acid-long N-domain exhibits IgE binding with a significantly higher number of latex-sensitized patients when compared to the 144 amino acid-long C-domain of Hev b 6. Skin test reactions correlate well with the in vitro IgE to latex allergens. Epitope mapping of the prohevein molecule revealed more IgE-binding regions near the N-terminal end of the protein.

https://CafePezeshki.IR

Hev b 11 (Endochitinase)

The class 1 chitinase shares homology with N-terminal hevein domain (resulting in cross-reactivity and the latex-fruit syndrome) and also shares epitopes with chitinases from avocado, chestnut and banana. They appear to be minor contributors to disease.[38,40,41]

Hev b 12 (Lipid Transfer Protein)

Lipid transfer proteins with antifungal and antibacterial activity are named for their ability to transfer phospholipids from liposomes to mitochondria, and are widely distributed in the plant kingdom.[64,67] This class of proteins is the most important allergen in the Prunoideae fruits such as peach, cherry, apricot and plum, which may help explain the cross-reactivity seen with stone fruits in latex-allergic healthcare workers.

Hev b 13 (Latex Esterase)

The biologic role of this protein is not as well defined, but it is one of the major allergens found in natural and finished latex products to which healthcare workers react. This important allergen correlates well with the allergenic content of finished latex gloves and has been proposed to be one of four allergens used in a standard to measure immunologic allergenic content of manufactured products.[68]

IMMUNE RESPONSES TO COMMON ENZYMES AND STRUCTURAL PROTEINS

Hev b 5

A proline-rich protein with a 46% amino acid sequence homology to an 18.9 kDa acidic protein from kiwi, Hev b 5 has been cloned and expressed with a molecular mass of 16 kDa.[68,69] It is presumed to be partially responsible for clinical reactions to kiwi in LA patients. This protein is a major allergen with strong IgE-binding reactivity in both healthcare workers (92%) and SB (56%) patients.

Hev b 8 (Profilin)

Profilin, an actin binding protein, is involved in the formation of the actin network of plant exoskeleton. Purified latex profilin, when used in skin prick testing, showed positive reactions in 100% (24/24) of SB patients and 6/17 healthcare workers with LA, but its role in the clinical induction of symptoms is unclear, due to carbohydrate binding in vitro.[70–73]

Hev b 9 (Enolase)

A high degree of cross-reactivity can be expected because of the homology of enolases present in different organisms. However, unpublished work from our laboratory on sera from 26 healthcare workers with LA failed to demonstrate any IgE binding with the recombinant latex Hev b 9 and fungal enolases.

Hev b 10 (Manganese Superoxide Dismutase)

This highly conserved enzyme (MnSOD) has been reported from a number of fungi and bacteria, as well as from human beings, but its role in cross-reactive allergenicity is unclear.[37,38,41,64]

Diagnosis of Latex Allergy

The diagnosis of LA in a patient requires a medical provider to take a complete medical history, perform a physical examination and then supplement the clinical conclusions with appropriate testing. An algorithm that outlines one method of approaching the diagnosis is shown in Figure 56-2. Epicutaneous skin testing or serologic testing for antilatex IgE in the absence of a clinical history and physical exam is inadequate for an accurate diagnosis of LA, since each of those tests has variable sensitivity, specificity, positive predictive values and negative predictive values. Testing for LA has been hindered in the USA by lack of a standard reagent clearance through the US Food and Drug Administration (FDA).

SKIN TESTING

Skin testing has been the most sensitive and predictive test for confirming a diagnosis.[11,74–77] Achieving the highest sensitivity has required the use of more than one source material for latex (e.g. natural latex nonammoniated and a latex glove extract).[11,75] In one series using two source materials, the sensitivity was 100%, specificity 99%, and a negative test had 100% predictive value in concluding that a patient was not allergic to latex.[11] Failure of a skin test reagent to be approved in the USA may relate to the frequency of adverse reactions to epicutaneous testing with latex allergen.[11,74,78] Early information demonstrated that skin testing resulted in a high rate of systemic reactions not seen with other allergens approved for skin testing. This high rate of reaction was confirmed in a comparative retrospective study from the Mayo Clinic where the rate of systemic reactions to latex was 228/100,000 latex skin tests, while the rate of reactions of this nature to other allergens was 72/100,000 penicillin skin tests and 23/100,000 aeroallergen tests.[78] This represents a 10-fold elevated risk of systemic reactions to latex skin testing in comparison to aeroallergen tests. Even the multicenter skin test study with cloned latex resulted in 16% of subjects having systemic, albeit mild, reactions to skin testing.[74] Comparisons of latex extracts made using different techniques indicated that the protein content obtained from a latex glove can vary widely, depending on the extraction method.[75] In addition, the stability of the different latex antigens is variable. The antigen content of gloves can vary several 100-fold, therefore nonstandardized extracts may contain vastly different amounts of latex protein. Some of the risk associated with latex skin tests can be attributed to uncharacterized extracts. Although the algorithm in Figure 56-2 recommends skin testing, it may be safest to perform such tests with a commercial latex standardized reagent such as the Stallergenes S.A. (Marseilles, France) used in Europe.

IN VITRO TESTING FOR LATEX ALLERGY

Detection of antilatex IgE in serum of patients has been the most widely accepted testing method in the USA.[76,78–83] Tests include research laboratory prepared enzyme linked immunosorbent assays (ELISA) or commercial tests from Pharmacia, UniCAP FEIA (Pharmacia, Peapack, NJ), AlaSTAT (Diagnostic Products Corporation, Los Angeles, CA) and Hycor HYTECH (Hycor Biomedical, Inc., Garden Grove, CA) systems.

Comparative performance of the three commercially available serologic assays for latex-specific IgE was studied in 117 clinically allergic individuals and 195 clinically nonallergic controls. When compared to skin test, both the Pharmacia CAP and AlaSTAT had similar sensitivities of 76% and 73% respectively with 97% specificity. Unfortunately, 25% of the latex-sensitized

https://CafePezeshki.IR

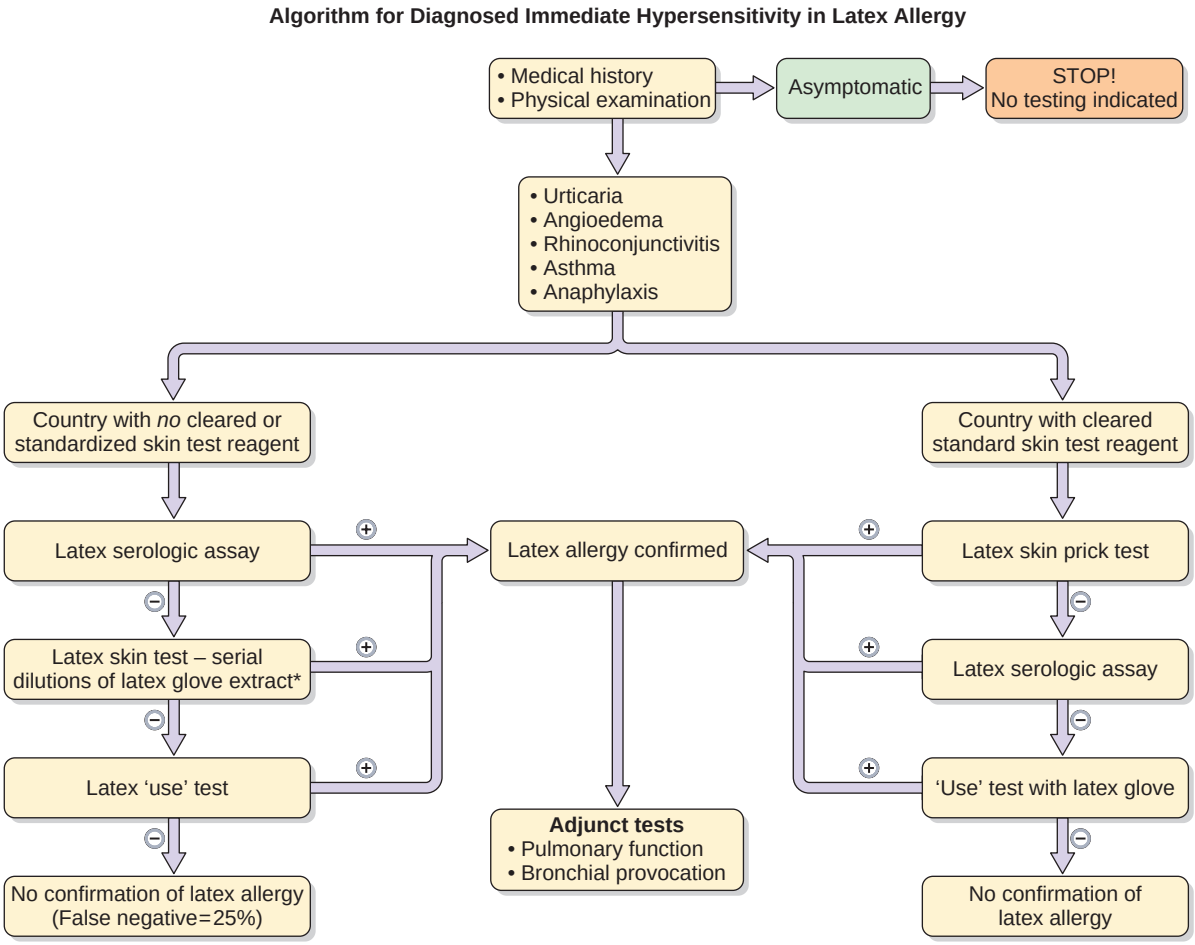

Figure 56-2 This algorithm outlines the common decision analysis for the diagnosis of latex allergy. Countries that lack an FDA cleared skin test reagent, such as the USA, are significantly hindered from making a diagnosis, especially with a 25% rate of false-negative serologic assays. Patients with histories and physical examinations inconsistent with latex allergy should not undergo testing. This is due to the high rate of false-positive serologic assays in populations with a low prevalence of disease.

cases had false-negative results. HyTECH had a significantly lower specificity of 73%, which indicates that 27% of the positive results are erroneous.[79] Thus, screening studies for LA in a population with a low prevalence of disease may result in a significant number of false-positive reactions. In addition, 25% of patients with disease may have a false-negative test. These characteristics make these tests undesirable for screening without a follow-up definitive test. Analysis of the three available methods performed using an unselected at-risk group of patients determined that the FDA-cleared Pharmacia CAP sensitivity was lower than reported, and that this method should only be used for confirmation of LA, not screening.[84]

Other in vitro methods of diagnosing LA have included basophil histamine release, CD63 activation of basophils and lymphocyte proliferation methods.[85–87] These assays are more specific but lack sensitivity. Their most useful activity has been to identify specific IgE epitopes and T cell epitopes. These tests have not become useful clinical tools although genetic altering of strongly allergenic epitopes may be useful in down-regulating and inducing tolerance by immunotherapy in latex-allergic subjects.[88]

IN VIVO PROVOCATION TESTING

In addition to using serologic testing or skin prick testing in diagnosing LA, it is sometimes necessary to understand whether a specific allergen or latex product reported by the clinical history is truly responsible for the symptoms, or to clarify discordant serum and skin test results. Provocation tests for diagnosing LA have included 'glove use tests', utilizing standardized gloves as described in the multicenter latex skin test study.[81] In addition, multiple investigations have used a 'latex glove wearing' test with or without a coupled inhalation test. The critical value of the provocation test is making certain that objective measurable or observable reactions are measured.[89] These may include such things as urticaria, angioedema or pulmonary function changes.

Some investigators have used inhalation provocation challenges alone or mucous membrane allergen contact. These have been progressive, graded challenges and are currently only standardized in research settings. Assuring standard allergen content in the provocation may be helped by the LEAP© assay or equivalent.[90]

Prevention and Treatment of the Patient with Latex Allergy

Prevention of LA has focussed on avoidance strategies for children who have SB, individuals who require multiple surgeries, and workers in health care and other occupations that require contact with natural rubber latex gloves.[91–97] The prototype patient for prevention of LA is the infant born with SB. Avoidance measures include complete abstinence from use of latex materials in the care of these patients from birth. This means preventing contact with latex gloves, catheters, dressings, tape or other medical devices that contain latex in the hospital and home setting. Given the level of disability and the vast number of surgeries in these subjects, an opinion article to vastly change care and prevent LA was published in 1996. Over 40,000 devices and materials contained natural rubber latex as a component, therefore stopping all use of latex-containing materials became impractical. Avoiding the use of latex materials that were made by a dipping process with short vulcanization times and low heat was the most likely strategy to prevent allergic reactions. Indeed, the concept of 'latex-safe' environments vs 'latex-free' environments turned out to be safe, practical and ideal for patients with LA.

Further observations in Canada, Europe and the USA noted that airborne latex was created by cornstarch donning powder from latex gloves which continued to sensitize and cause allergic reactions, not only in patients but also in healthcare workers.[93–97] This has led to a change in manufacturing and possibly in the prevalence of LA in healthcare workers through powder-free glove use, reduced airborne latex exposure and reduction in product allergen content.

The care of the patient with LA requires that individuals avoid personal contact of the skin and mucous membranes with latex materials. In addition, they should only enter areas where airborne latex allergen is controlled by use of nonpowdered latex products. If the individuals are healthcare workers, they should use nonlatex gloves and only work in areas where either powder-free latex gloves are used routinely or nonlatex gloves are used.

Rarely, immunotherapy is a consideration for the cure of LA. However, the side-effects of such therapy, length of time to achieve tolerance and lack of a standardized reagent make this therapy relatively futile.[98,99] The promise of modified allergens to make immunotherapy safer and more effective is on the horizon.[88]

57 Insect Sting Allergy

HANNEKE (JOANNE) N.G. OUDE ELBERINK

KEY POINTS

- The majority of insect sting reactions in children are mild and frequently only dermal (hives, angioedema).
- Children who have only dermal reactions have a very benign prognosis and generally do not retain their allergic sensitivity.
- Children with more severe reactions have a 30% to 40% risk of recurrent anaphylaxis.
- Venom immunotherapy (VIT) provides more than 95% protection against subsequent re-sting reactions in children, and if there are reactions, they are milder.
- For most individuals, 3 to 5 years of therapy appears adequate despite the persistence of specific IgE.
- VIT is associated with an improvement in quality of life in contrast to use of an epinephrine autoinjector (EAI).
- In children, the prescription of an EAI should carefully take into account the risks of the disease versus the risks of having an EAI (diminished quality of life) versus the benefits (preparedness for treating a potentially life-threatening event).

Introduction

Allergic reactions to insect stings are common. An allergic reaction can occur at any age, often after a number of uneventful stings. It is estimated to affect at least 0.3% to 3% of the population.[1] The severity of the reaction ranges from a local reaction to anaphylaxis. Children tend to suffer from less serious reactions, a large local reaction being the most common presentation in this age group. The incidence of insect anaphylaxis in children is estimated to constitute 0.3% to 1.0% of all cases of childhood anaphylaxis, in contrast to adults where anaphylaxis to insect stings makes up 3% to 34% of all adult anaphylaxis cases. Stinging insect allergy is responsible for considerable anxiety that is detrimental to lifestyle.

This chapter reviews the general concepts relating to insect sting allergy and, in particular, addresses those aspects that are more relevant to children.

The Insects

Biting insects are different to stinging insects. The former primarily cause reactions due to the saliva they inject when feeding, while stinging insects inject venom with the stinging apparatus at the back of their abdomen. Salivary gland secretions have no relation to venom allergens. While the venom of a sting typically causes an intense, burning pain, the saliva of a biting insect is a chemical cocktail of substances designed to make blood flow quickly and painlessly to avoid being squished. Unlike insect stings, insect bites rarely cause anaphylaxis.

BITING INSECTS

The most common biting insects are mosquitoes, flies, midges, gnats, fleas, ticks and bedbugs.

Itching and a wheal may develop immediately and mostly disappear after about 2 hours, but they are often followed by a small itchy lump (papule) that develops up to 24 hours later and may last for several days before fading away. Large local reactions from mosquito bites are more common in young children.[2] Over time, and with repeated exposure, the reactions become less intense and are less frequent problems in adolescents and adults. Anaphylaxis has been described after the bites of mosquitoes,[3,4] deer flies,[5] bed bugs and black flies.

Mosquito bites may be associated with IgE and perhaps IgG antibodies. Elevated titers correlate with the intensity of the local reactions and appear to be the immunologic mediators responsible for the reactions.[2]

Skeeter syndrome describes a localized (allergic) reaction to mosquito bites masquerading as cellulitis and accompanied by lethargy, fever and general malaise.[2] Skeeter syndrome usually progresses over the course of hours while cellulitis typically will evolve over the course of several days. Diagnosis can therefore be made clinically by the course of the symptoms and can be confirmed by measuring IgE and IgG antibodies to mosquito saliva antigens.

A mild reaction to an insect bite will probably resolve itself within a day or two without any need for treatment. In some cases, the use of a topical steroid may assist in reducing inflammation and an antipruritic may relieve itchiness. There is a scarcity of quantitative scientific studies into the various treatments for insect bite reactions.

STINGING INSECTS

Insects that sting are members of the order Hymenoptera of the class Insecta. It is almost exclusively the social Aculeata of the families Apidae, Vespidae and Formicidae that cause significant allergic reactions in human beings. Aculeata from other families can cause painful stings to people, but repeated stings from the same species are so unlikely that allergy to them is practically unheard of. There are three major subgroups: Vespidae, which include the yellow jacket, hornet and wasp; Apidae, which include the honeybee and bumblebee; and the Formicidae (Figure 57-1). An overview of the Hymenoptera is given in Figure 57-2.

The Aculeata share in common a stinging apparatus that originates in the abdomen of the female insect and actually is a modified ovipositor; therefore only female insects can sting.

https://CafePezeshki.IR

The sting consists of a sac containing venom attached to a barbed stinger. The honeybee's stinger has multiple barbs, which usually cause the stinging apparatus to detach from the insect, leading to its death. In contrast, the stingers of vespids have few and finer barbs than the Apidae, and do not commonly autotomize, so vespids can inflict multiple stings (Figure 57-3).

Vespidae

The Vespidae are divided into the subfamilies Vespinae (yellow jackets and hornets) and Polistinae (wasps). The Vespinae are split into three genera: *Vespula* (yellow jackets), *Dolichovespula* and *Vespa* (hornets). The common names in general usage can be misleading: in Europe the term 'wasps' refers generally to any of the social wasps rather than just to Polistes species (Table 57-1).

In most parts of the USA and Europe, yellow jackets are the principal cause of allergic reactions, whereas Polistes are more commonly implicated in the Gulf Coast areas of the USA and along the Mediterranean coast of Europe. In Australia yellow jackets were only introduced around 20 years ago, but are already found in every state.[6]

The Vespula (yellow jackets) preferably build their nests underground, but can also be found under the roof and in window shutters. They live mostly in proximity to humans. Their nests are often encountered by children playing in the garden, or are disturbed by lawn mowing, gardening or other outdoor activities. Yellow jackets are scavengers and are often encountered at outdoor events when food and drinks abound. Most stings occur in summer.[7,8]

Figure 57-1 The common stinging insects. Shown clockwise from the top right portion of the figure are a yellow jacket, honeybee, bumblebee, Polistes wasp and two hornets. *(From Reisman RE. Insect stings. N Engl J Med 1994;331:523–7. Copyright 1994 Massachusetts Medical Society. All rights reserved.)*

TABLE 57-1 Popular Names for Vespids in Europe and the USA

Genus	Europe	USA
Vespula	Wasp	Yellow jacket
Dolichovespula	Wasp	Hornet, white-faced hornet, aerial yellow jacket
Vespa	Hornet	European hornet
Polistes	Paper wasp	Wasp

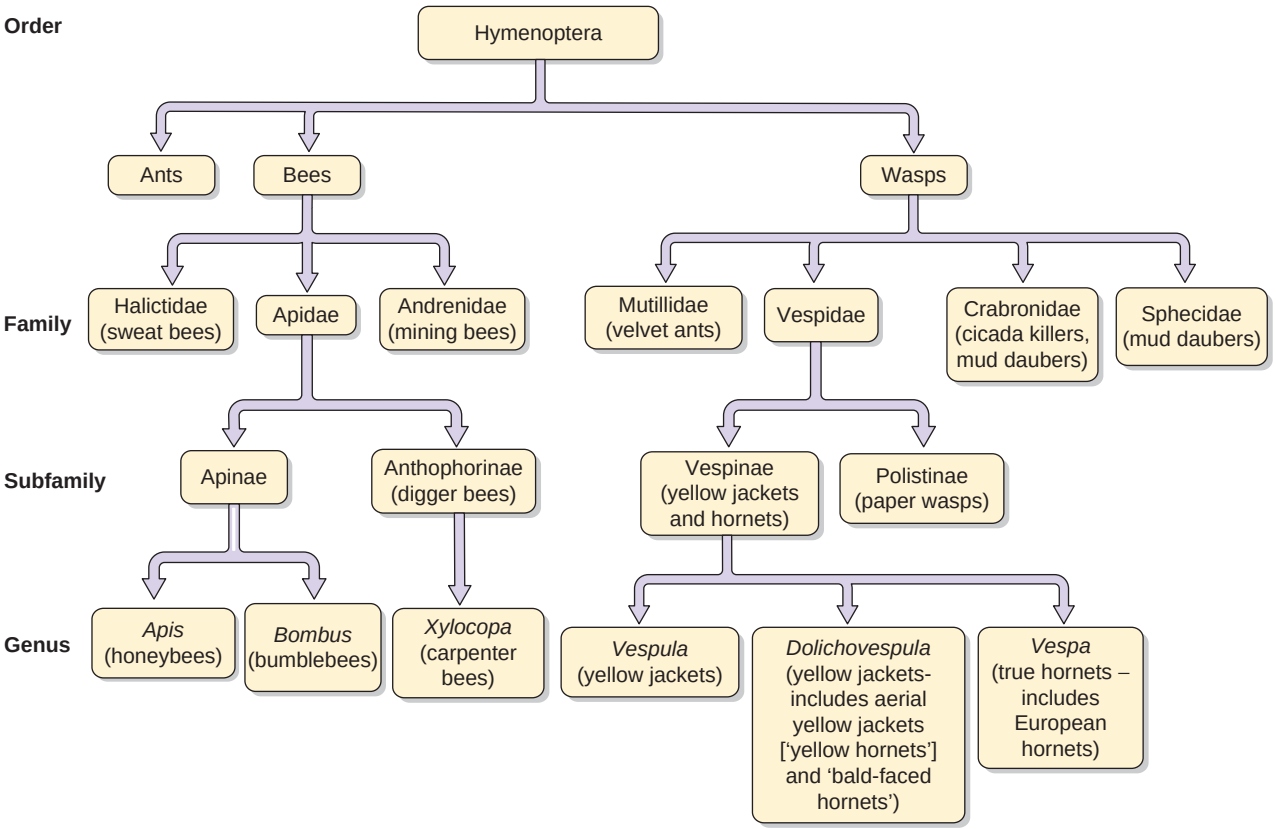

Figure 57-2 Overview of taxonomy of common Hymenoptera (stinging insects).

https://CafePezeshki.IR

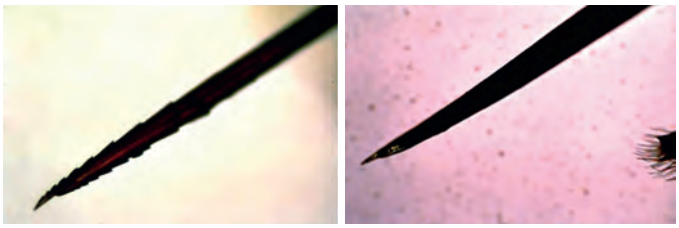

Figure 57-3 The honeybee stinger on the left has multiple barbs. The yellow jacket stinger on the right is smooth.

Vespa include the European hornet (*V. crabro*) which also exists in significant numbers in eastern North America, and the Asian hornet (*V. orientalis*). Hornets nest in shrubs, trees and birds' nest-boxes. Near their nests, hornets are very aggressive. However, they are attracted much less to meat and sweet foodstuffs than the *Vespula*. Therefore hornet stings are rare.

The common paper wasps (*Polistes*) build honeycomb nests in shrubs or under the eaves of houses. Their nests are generally limited to a single layer of open cells (or comb) with minimal outer covering. They are important predators, preying on agricultural and horticultural pests. Important *Polistes* species in Europe are *P. dominula* and *P. gallicus*, whereas in North America other species such as *P. annularis, P. apachus, P. exclamans, P. fuscatus* and *P. metricus* are dominant. In the last decades, *P. dominula* has increasingly spread across the North American continent and central and northern parts of Europe. The coloring of wasps varies greatly: they can be brown, black, red or striped. The European species, the Mediterranean wasp (*P. dominula*), is difficult to distinguish from a yellow jacket because it has the same bright yellow and black stripes. Outwardly they are distinguishable by differences at the junction of thorax and abdomen: the waist becomes thicker more rapidly in the Vespinae compared to the Polistinae and they have characteristic dangling legs when in flight (Figure 57-4). *Polistes* are more prevalent early in the summer season. In some areas of the USA, such as Texas, they are the most frequent cause of sting reactions.

Apidae

The Apidae are divided into the genera *Apis* (honeybees) and *Bombus* (bumblebees). Honeybees and bumblebees are docile and sting only when provoked. The most significant species in causing allergic reactions is the domesticated *A. mellifera*, cultured all over the world for honey production and to pollinate fruit trees.

Africanized honeybees, or 'killer bees', have received much publicity.[9] They are a cross between the European *A. mellifera mellifera* and the African *A. mellifera adansoni*. They were introduced into Brazil from Africa in 1956 for the purpose of more productive pollination and have gradually spread north into the USA. The venom components of the Africanized honeybees and the domesticated European honeybees are similar. African honeybees are much more aggressive. Massive stinging incidents have occurred, leading to death from venom toxicity.

Members of the genus *Bombus,* the bumblebees, also live in colonies. The nests are usually in the earth. Most bumblebee species are bigger than honeybees, more heavily built and more hairy. Bumblebees are not aggressive; children can incur stings when walking on grass. Systemic reactions occur in particular in owners of greenhouses where bumblebees are kept for pollination of plants (e.g. tomatoes).[10]

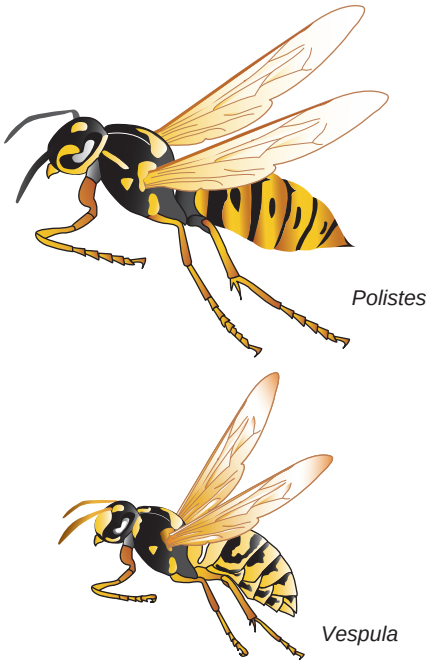

Figure 57-4 Polistes compared to Vespula: thicker waist and dangling legs when in flight. *(From:* http://crawford.tardigrade.net/bugs/BugofMonth16.html.*)*

Formicids

The family *Formicidae* has a subfamily *Myrmicinae*, which subsequently can be divided in two genera: *Myrmecia* (jack jumper ants [JJA] and bull ants) and *Solenopsis* (imported fire ants [IFA]). *Myrmecia* are solitary roamers, do not appear in ant trails, and attack when aggravated. JJA cause the highest rate of anaphylaxis in the world from a single insect sting/bite.[11]

The main two members of the *Solenopsis* genus are the red fire ant (*S. invicta*) and the black fire ant (*S. richteri*). Fire ants build characteristic nests, which can grow to 40 cm in height, and often migrate in trails.

Red fire ants are found in the southeastern and south central USA, especially along the Gulf Coast. They have now spread to California. In Australia they are only found in Brisbane.

Stings occur most frequently in summer, most commonly in children and typically on the lower extremities. The fire ant attaches itself to a person by biting with its powerful mandibles to hold onto the skin. It then pivots around its head and stings at multiple sites in a circular pattern with the stinger located at the tip of its abdomen. Within 24 hours a sterile pustule develops, which is diagnostic of the fire ant's sting. Allergic reactions to fire ant stings are becoming increasingly common in the southern USA.[12,13]

Insect Venoms

Venoms contain vasoactive amines (e.g. histamine, dopamine, norepinephrine), acetylcholine and kinins, which account for the burning, pain and itching normally experienced from a sting. They increase permeability, allowing the spread of the venom through the body of the victim. The different venom components known to date are listed in Table 57-2.[14]

The major allergenic components of Hymenoptera venoms are phospholipase A in honeybee venom and antigen 5 in vespids.

Sol i 4, Sol g 4		12		0	–

CRR – Carbohydrate-rich protein, *DPP IV* – dipeptidyl peptidase IV, *DW* – dry weight, *MRJP* – major royal jelly protein.
*Inactive iso form.

https://CafePezeshki.IR

The venom of fire ants differs markedly from the other venoms by consisting approximately of 95% water-insoluble alkaloids. The alkaloids produce a sterile pustule. The protein content is only 5%, with a higher content in summer.[15]

Commercial Hymenoptera venom products are available in many countries as lyophilized protein extracts of honeybee, yellow jacket and *Polistes* wasp venoms.

CROSS-REACTIVITY

A common problem of in vivo and in vitro diagnosis of insect venom allergy using venom extracts is that patients may have double positive test results for honeybee venom (HBV) and yellow jacket venom (YJV).[14] This double positivity may reflect true double sensitization to HBV and YJV, or may be based on IgE cross-reactivity.

Cross-reactivity may be based on IgE reactivity to homologous single venom allergens present in venoms of different families or on IgE reactivity to cross-reactive carbohydrate determinants (CCD).[15] Causative for the latter are IgE antibodies that are directed against an alpha 1,3-linked fucose residue of the *N*-glycan core established by insects and plants. Most HBV and YJV allergens are glycoproteins with one or more such carbohydrate structures (Table 57-2). CCD-specific IgE antibodies have been reported to be responsible for more than 50% of double sensitizations to HBV and YJV.[16] The clinical relevance of CCD-reactive IgE antibodies in the case of insect venom allergy appears to be low or nonexistent.[14,17,18] *Polistes* species seem to lack the alpha 1,3-linked fucose residue that is responsible for IgE reactivity to CCDs.[19]

Recombinant allergens lack CCDs, allowing for a more precise distinction between true double sensitization and cross-reactivity between different venoms.[20] By using CCD-free, correctly folded Ves v 2.0101 and Ves v 2.0201, it could also be demonstrated that hyaluronidases – contrary to previous assumptions – do not play a significant role as major allergens of YJV.[16]

Vespid venoms have been extensively analyzed. Venom allergens of diverse *Vespidae* species such as the white-faced hornet (*Dolichovespula maculata*) or the European hornet (*V. crabro*) are fairly similar to those of the yellow jacket,[21] allowing *V. crabro* allergic patients to be treated with yellow jacket venom.[22]

The IgE cross-reactivity between European and American *Polistes* species is described as low because they belong to different subgenera. In contrast, cross-reactivity between Polistinae and Vespinae (*Vespula*, *Dolichovespula* and *Vespa*) venoms and purified venom proteins[23] is frequently observed, especially for *Vespula* and both American and European *Polistes* venoms.[24] *Polistes* VIT is not necessary. The converse is also true: half of the people who have had *Polistes* sting reactions have positive skin tests to yellow jacket or hornet venom and require treatment with *Polistes* venom only.

Within the *Apidae* there is cross-reactivity in that people initially sensitized to honeybee venom then react to bumblebee venom due to cross-reactive allergens. Honeybee venom should be effective immunotherapy. Bumblebees have particular importance for pollination industry workers; it has turned out that some of these patients need to be treated with specific bumblebee venom.[10,25]

Little is known of immunologic cross-reactivity between fire ant and vespid venom.

Sol i 1 shares sequences with the venom phospholipases of *Vespula maculifrons*.[26]

Epidemiology/Etiology

Demographic studies suggest that the incidence of insect sting allergy in the general population ranges between 0.4% and 3%.[1] The majority of reactions that do occur are in younger individuals, although the fatality rate is greater in adults.[9–12] Data on fatal reactions are scarce. It is estimated that 40 to 50 deaths per year occur in the USA as the result of insect sting anaphylaxis[27] and in France 16 to 38.[28] Most of these individuals have had no warning or indication of their allergies and had tolerated earlier stings with no difficulty. Fatal reactions are particularly associated with mastocytosis.[29]

DEVELOPMENT OF INSECT STING ALLERGY

Hymenoptera stings are frequently encountered in the population. The younger the child, the more often they are (re)stung; in contrast, prevalence of systemic reactions to field stings was significantly lower in preschool (3.4%) and school-age children (4.3%) compared with adolescents (15.6%).[20]

No immunologic criterion, such as skin test reactivity or titers of serum venom-specific IgE or IgG, distinguishes or identifies sting reactors from nonreactors.[30]

The chance of developing an allergy increases with sting frequency.[1] In general, no time relationship exists between the last uneventful sting and the subsequent sting that leads to an allergic reaction[31] although multiple stings or repeated stings in close temporal proximity (only weeks apart) have been associated with a greater risk of developing an allergic reaction.[32] A confusing observation is the occurrence of initial insect sting anaphylaxis after the first known insect sting, primarily in children, raising the issue of the cause of sensitization or the pathogenesis of this initial reaction.[26,33]

Classification of Reactions

NORMAL REACTION

The usual reaction to an insect sting consists of localized pain, slight swelling, and erythema at the site of the sting. This reaction usually subsides within several hours. Little treatment is needed other than analgesics and cold compresses.

LARGE LOCAL REACTIONS

More extensive local reactions are common. Large local reactions are defined as reactions extending from the sting site over a large area, often peaking at 24 to 48 hours and taking 5 to 10 days to resolve. For example, the swelling from a sting on the finger may extend to the wrist or elbow. Fatigue and nausea may develop in addition. For a general clinician it might be difficult to distinguish large local reactions from cellulitis, resulting in misdiagnosis and unnecessary antibiotic treatment.

The cause of these large local reactions has not been established, but it is thought to be an IgE-mediated late-phase reaction.[34]

TOXIC REACTIONS

Large numbers of simultaneous stings (50–100) may result in a toxic reaction due to the vasoactive properties of the venom. Symptoms can have the same clinical characteristics as

https://CafePezeshki.IR

anaphylaxis, including nausea, vomiting, diarrhea, headache, vertigo, syncope, convulsions and fever. Hemolysis, cardiac complications, renal failure and rhabdomyolysis have also been described.[35,36]

As insect venom is highly sensitizing, most patients will develop specific IgE, making the differentiation from an allergic reaction difficult.

UNUSUAL REACTIONS

There have been rare reports of vasculitis, nephrosis, neuritis, encephalitis and serum sickness occurring in a temporal relationship to insect stings.[37] The symptoms usually start several days to several weeks after the sting and may last for a long period. Serum sickness, characterized by urticaria, joint pain and fever, may occur approximately 7 to 10 days after an insect sting.[22]

Some patients develop cold-induced urticaria days to weeks after Hymenoptera stings, not necessarily accompanied by an allergic reaction to the sting.[38]

Systemic Reactions

A systemic allergic reaction consists of signs and symptoms distant from the site of the sting, and may range from mild to life-threatening in one or more anatomic systems. Symptoms usually start within 10 to 15 minutes; the more severe the reaction, the earlier it begins.[39] On occasion, reactions can occur as long as 72 hours later.

The clinical features of anaphylaxis from an insect sting are the same as those of anaphylaxis from any other cause. Diagnosis of the acute reaction can be quite difficult if hypotension or cardiac manifestations occur with no other signs or symptoms.[39]

Studies from children with venom allergy usually report a milder clinical presentation (predominantly isolated cutaneous symptoms) than in adults.[40–42] In a study[43] including more than 500 children, more than 60% suffered only from mild cutaneous reactions. In a more recent study, however, half of the children suffered from respiratory or cardiovascular symptoms.[44]

Natural History

To assess appropriate intervention, it is necessary to understand the natural history of any disease process. This is particularly true of insect sting allergy. Observations of individuals who have been stung without suffering a reaction, as well as from individuals who had allergic reactions from insect stings and who did not receive VIT, have provided insight into the natural history of this allergy and suggest that insect sting allergy is a self-limiting process for many people, especially children.[43]

IgE SENSITIZATION

Insect venom is a strong IgE inducer. In the general population, 27.1% to 40.7% have detectable specific IgE (sIgE) to Hymenoptera venoms.[45] In 30% to 50% of these individuals these tests become negative after 2 to 5 years.[46] In a study evaluating the risk to normal adults with positive venom skin tests, there was a 17% incidence of systemic reactions to subsequent stings.[47] In a recent study of asymptomatic patients sensitized to venom who were sting challenged, only 5% experienced a systemic reaction, whereas >40% had a large local reaction.[30]

Specific IgE for venom, either measured by skin test or serologically, without a history of an allergic reaction therefore does not indicate a risk for venom anaphylaxis.

NATURAL HISTORY OF LARGE LOCAL REACTIONS

In the past, there was a common misconception that large local reactions after insect stings, particularly those that increased in size with each sting, might precede an anaphylactic reaction. Clinical observations in more recent years indicate that these large local reactions tend to be repetitive.

In children, the risk of anaphylaxis is between 2% and 7%.[45,48] This risk has remained unchanged over a period of 10 to 20 years, and where systemic reactions occurred they were mild to moderate; none was severe.

People who have had large local reactions do not require venom skin tests and they generally are not candidates for VIT, although VIT might be helpful in reducing size and duration of the large local reaction as demonstrated in a placebo-controlled study.[49] In an earlier study the occurrence of subsequent large local reactions was not affected by VIT.[34]

NATURAL HISTORY OF INSECT STING ANAPHYLAXIS

The majority of children outgrow their allergy, as has been documented in a long-term study of children who were not treated with VIT.[43]

Several factors increase the risk for a repeated systemic reaction. The first is age: the risk for recurrence is higher in adults than in children.[42,43,50] In adults the risk varies between 23.5% and 73%.[31,51–55] The second is the culprit insect: those who are allergic to honeybee venom have a higher risk compared to those with a vespid allergy.[52,54] A third risk factor is the time interval between the stings: there appears to be a gradual decline in the chance of a systemic reaction over time, from almost 50% after a recent reaction to 25% some 7 to 10 years later.[26,31] However, the risk never seems to disappear in some patients having severe reactions to stings, even after decades without an intervening sting.[55] Also, in untreated children, the frequency of systemic allergic reactions declines only slowly over a 20-year period.[43] Even in the same patient the outcome of the next sting may be somewhat unpredictable in that systemic reactions may occur on some occasions and not on others.[56] In a sting challenge study where no reaction occurred at the first sting, a repeated sting caused a systemic reaction in 20% of the patients.[55] It is hypothesized that this variability may be due as much to variation of the allergen during the season,[15] variation in the insect species[57] or the delivery of the allergen[58,59] as to the variations in the patient's physiology or immune status.

THE SEVERITY OF THE REACTION IS OF PARTICULAR PROGNOSTIC VALUE

Children who have dermal reactions (urticaria, angioedema) only, without other allergic symptoms, are a specific subgroup. These children have a particularly low reaction rate to re-stings, varying from 13%[43] to 18%,[42,50] and when a reaction does occur it tends to be of similar intensity. In adults with dermal

https://CafePezeshki.IR

reactions not treated with VIT the risk varies from 9.1% to 33.3% in wasp venom allergic patients and up to 40% in bee venom allergic patients.[54,60–62] In children with more severe reactions (moderate to severe) the risk is about 40%,[31,43] again with generally milder or similar symptoms to those that had occurred previously. Overall, these data suggest that children who only have dermal reactions have a very benign prognosis and generally do not retain their allergic sensitivity.

In contrast to winged Hymenoptera venom allergy, the natural history of imported fire ant venom allergy is not well known. The prevalence of allergic sensitization to imported fire ant (IFA) has been studied in183 children living in an imported fire ant endemic area.[63] Serum IFA-specific IgE was detected in 7.1% of children aged less than 1 year, 57.1% of those aged 2 to 5 years and 64.4% of those aged 6 to 10 years. Despite this high sensitization rate, the number of anaphylactic reactions to imported fire ant stings was low. These limited data suggest a benign prognosis for children who have had large local or generalized cutaneous reactions only from IFA stings, analogous to experience with winged Hymenoptera.[64]

In an observational study[39] of 657 patients, of which 73% suffered from yellow jacket allergy, four significant indicators and risk factors were identified: elevation of basal serum tryptase (BST), the absence of urticaria or angioedema during anaphylaxis, a time interval of less than 5 minutes from sting to onset of symptoms, and senior age. The absence of urticaria/angioedema was significantly related to BST elevation, suggestive for mastocytosis. In children with preexisting insect venom hypersensitivity, minor increases in BST levels (>5 µg/L) within the normal range are associated with a higher risk of severe systemic reactions.[44]

Diagnosis and Detection of Venom-Specific IgE

The diagnosis of potential allergy to Hymenoptera venom requires both a history of a sting event that resulted in a systemic allergic reaction and the presence of venom-specific IgE sensitization, assessed either by skin testing or in vitro testing (e.g. IgE immunoassay). Both of these components are necessary to document the diagnosis of insect sting allergy and the possibility of administering VIT.

HISTORY

As insect stings always cause pain, the history in this regard seems reliable. A comprehensive history should review the patient's past stings and risk for future stings and determine whether the patient's reaction was local or systemic. Relevant questions are listed in Box 57-1.

VENOM SKIN TESTS

For diagnostic (as well as for therapeutic) purposes, generally refined venom preparations are used because whole body extracts contain little or no venom.[51,56] The exception is fire ant, where skin tests with extracts prepared from whole bodies appear to be reliable.[11,12]

Skin tests can be performed either as prick or intradermal tests. A disadvantage of the skin prick test is its low sensitivity.[30]

BOX 57-1 RELEVANT QUESTIONS IN ELICITING A HISTORY OF INSECT VENOM REACTIONS

- When did the sting event occur?
- How many stings were sustained?
- Where was the patient when stung? (e.g. On the terrace, in a wood, on vacation in the south, etc.)
- Could the patient identify the insect? (Notoriously unreliable part of the history)
- Where on the body did the sting occur? (As an example, a sting on the face could cause extensive facial angioedema as part of a local reaction, but the same symptoms from a sting on the leg would indicate a systemic response)
- Which symptoms occurred? (Ask about all symptoms, not only the major symptoms)
- Was the patient taking any medication that might have aggravated the reaction? (e.g. β-blockers, ACE inhibitors)
- Were there any previous or subsequent stings? If so, what symptoms developed?
- Is there regular exposure to Hymenoptera insects? (e.g. Beekeeper, or occupational activities)

Intradermal skin tests are performed starting with venom doses usually around 0.001 µg/mL and testing up to a concentration of 1 µg/mL.[65] Greater venom concentrations may cause irritant reactions that are not immunologically specific. Simultaneous testing of all concentrations of two venoms (bee and wasp) is safe.[66] The skin test should be performed with a fixed amount of allergen (0.02 or 0.03 mL) and also include a negative diluent (human albumin-saline) control and a positive histamine control. A wheal at least half the size of the positive control is considered positive (histamine equivalent wheal size of 3 mm), while others consider a wheal size 3 mm greater than the negative control as positive.

Skin tests are clearly positive in the majority of patients with a convincing history but might be falsely negative if patients are tested too soon after a systemic reaction (attributable to a refractory period of 'anergy'),[67] in patients with mastocytosis[68] or due to lack of particular allergens that are lost or degraded during processing.[58] Generally, guidelines recommend sIgE determination and skin testing no earlier than 2 weeks after the sting because sIgE levels could be decreased or even undetectable.[69] However, there is only weak evidence in the literature for this recommendation.

IN VITRO MEASUREMENT OF VENOM-SPECIFIC IgE

Venom sIgE can be measured in the serum by in vitro tests, performed by many commercial laboratories with variable assays and variable outcomes. Therefore, especially in the USA, skin tests remain the preferred test for the diagnosis of venom allergy, and are considered to be more sensitive than the in vitro test.[41,70] ImmunoCAP is recognized as a reliable commercial assay and is generally used in Europe.

False-negative results might be partly due to the same problems as in a skin test with loss or degradation of particular allergens during the processing.[58] Of patients with a well-documented history of yellow jacket sting anaphylaxis but negative IgE test results to YJV extract, 84% subsequently were diagnosed using recombinant Ves v 5 as allergen. This discrepancy could be resolved by spiking the venom extract with rVes v 5.[71]

https://CafePezeshki.IR

OTHER DIAGNOSTIC TESTS

Tryptase

A baseline serum tryptase should be measured to screen for an underlying mast cell disorder, particularly if urticaria/angioedema was absent.[68] Reports about the relevance of mast cell disorders in insect venom allergic children are lacking. BST levels are found to be significantly higher in younger infants compared with older ones, with a gradual decrease to levels similar to those in adults.[72]

Tryptase can also be measured in connection with signs and symptoms of anaphylaxis: an increase from baseline serum tryptase is highly suggestive of IgE-mediated mast cell activation. Concentrations of serum tryptase peak at 60 to 90 minutes after anaphylaxis and decrease to baseline levels over subsequent hours. Total tryptase levels >11.4 in serum are consistent with systemic anaphylaxis.[73] The tryptase measured immediately after the anaphylactic reaction should preferably be compared with a baseline tryptase sample collected several days after all signs and symptoms have been resolved.

Other mast cell metabolites that can be used either to screen for mastocytosis or to determine anaphylaxis are urinary histamine metabolites.[74,75]

STING CHALLENGE TESTS

A live sting challenge has been assumed to be the gold standard, especially to evaluate the efficacy of venom immunotherapy. Live sting challenges are mainly performed in research settings. Routine use of a live sting challenge as a diagnostic procedure for selection of patients for immunotherapy has drawbacks, partly ethical[76] but also due to its limited significance because of the lack of reproducibility of one sting.[55,77]

Therapy

LARGE LOCAL REACTION

The treatment of large local reactions is symptomatic. There are no studies comparing different treatments. Cold compresses can be used to soothe. Antihistamines can be used to reduce pruritus. Nonsteroidal antiinflammatory drugs can reduce pain and additional flu-like symptoms of nausea and fever. Oral corticosteroids can be used, preferably as quickly as possible after the sting, to reduce significant swelling. They can also be used to prevent large local reactions in individuals with predictable local reactions.

ACUTE REACTION

The medical treatment for acute anaphylaxis is the same as that for anaphylaxis from any cause and is detailed in Chapter 58.

As venom is deposited very quickly after the sting, prompt removal of the stinger is not able to prevent an allergic reaction. An insect stinger that remains in the skin should be gently flicked off to avoid squeezing the sac, which might inject more venom.

Prior to discharge from the acute care setting, patients should receive a prescription for an EAI, with instructions about how and when to use it, and a referral to an allergist to determine if they are really at risk and need to carry an EAI and whether they are candidates for VIT.

Prevention of Acute Reactions

The optimal approach in the prevention of any IgE-mediated disease is avoidance of the antigen. Although insect venom allergic patients are able to reduce the frequency of their stings,[36,78,79] this is difficult in practice (e.g. yellow jackets live in close proximity to humans and have unpredictable and pugnacious behavior). Avoidance advice is not evidence based (Box 57-2).

EPINEPHRINE AUTOINJECTOR

Individuals at risk are advised to carry epinephrine, available in preloaded syringes for self-administration.

Current practice regarding prescribing of EAIs varies widely before, as well as during and/or after stopping VIT,[69,80,81] with some practitioners prescribing them lifelong and also during and/or after stopping VIT. Findings from studies evaluating effects on quality of life suggest the adoption of a more selective approach to prescribing an EAI.

In a randomized study evaluating VIT versus EAI in adults, patients randomized to treatment solely carrying an EAI deteriorated in health-related quality of life,[79] and carrying an EAI was associated with a significant burden.[82] After 1 year of carrying an EAI, almost 80% of the patients preferred to start VIT. The same results were found in dermal reactors,[83] a subgroup of patients who are often prescribed an EAI without being given the option of starting VIT.[69,80] It is not known if the reduced quality of life relates to the prescription of an EAI or actually having to carry one.

The effects of the different treatment options on health-related quality of life have not been studied so far in children with an insect venom allergy. In children with a food allergy it has been shown that carrying an EAI can have a detrimental effect on quality of life, independent of other factors that can also impact quality of life such as whether they have previously suffered anaphylaxis.[84] These studies emphasize that physicians prescribing an EAI should carefully take into account the risks of the disease versus the risks of having an EAI (diminished quality of life) versus benefits (preparedness for treating a potentially life-threatening event).

VENOM IMMUNOTHERAPY

Therapy with venom is remarkably effective, preventing subsequent allergic reactions in the great majority of treated patients and, in many instances, providing a permanent 'cure'. Whole venom preparations should be used because whole body extracts contain little or no venom.[51,56] However, immunotherapy with whole body fire ant extract appears to be quite effective.[85–87] In

BOX 57-2 OPTIONAL PRECAUTIONS TO AVOID SUBSEQUENT STINGS

- Wear slacks, long-sleeved shirts and shoes when outside, especially when involved in activities that might increase insect exposure such as gardening.
- Cosmetics, perfumes and hair sprays might attract insects.
- Light-colored clothing is less likely to attract insects.
- Take care outside around food and garbage, which especially attracts yellow jackets.

https://CafePezeshki.IR

jack jumper ant allergy, venom is used and is as effective as honeybee therapy.[88]

Major remaining issues relate to the refining of the selection process for people requiring VIT, choosing the right venom and refining criteria for duration of treatment.

Indications

Potential candidates for VIT are people who have had an allergic reaction to an insect sting and have a positive venom skin test or elevated levels of serum venom-specific IgE (Table 57-3). As noted, studies of the natural history of insect sting allergy have shown that only approximately 60% or less of these individuals will have a subsequent reaction when re-stung;[31,51] in children the rate is even lower.

Children with only dermal (hives, angioedema) reactions have a very benign prognosis and they do not require immunotherapy.[31,43,50] The risk to both adults and children, including very young children, who have had severe allergic reactions is increased.

Anaphylactic reactions following insect stings can have a great impact on the quality of life of insect sting allergic patients, both adults and children.[79,89] Health-related quality of life is an important therapeutic target in the treatment of allergic patients, as re-sting rates are generally low[22,43] and mortality is surprisingly low, especially in children. In a recent review evaluating the cost-effectiveness of VIT, Hockenhull et al[90] concluded that VIT is only cost-effective if it is able to improve health-related quality of life (HRQL), or in the case of a high re-sting rate.

VIT has been shown to improve HRQL in contrast to EAI prescription only.[79] In a randomized study evaluating VIT versus EAI in adults, VIT – with information about the risks and benefits of the treatment – was preferred by most patients and shown to improve health-related quality of life[82] in patients with moderate-to-severe reactions as well as those with only dermal reactions,[83] even if patients are not re-stung. The effect of VIT on health-related quality of life has not been studied so far in children. It is not known what the burden of this treatment (e.g. receiving injections in addition to frequent visits to the doctor) will be for children.

Venom Selection

There is general agreement that a positive skin test cannot be used as the sole criterion to start VIT, because at least 25% of the population has specific IgE to one or more venoms without a history of anaphylaxis.[69,80,81] Unnecessary use of additional venoms should be prevented. The administration of a single venom is much better tolerated than the administration of three or four venoms, especially in children, and VIT is a costly treatment.

Knowledge of cross-reactions is necessary to select the correct venom (see Cross-reactivity).

Dosing Schedule

Treatment is initiated in small doses; the starting dose can be based on the intensity of the skin test reaction and/or the nature of the allergic symptoms. Incremental doses are given until the maintenance dose is reached, traditionally 100 µg. In the USA mixed vespid venom preparations are available for therapy containing the two hornet venoms and yellow jacket venom with a top dose of 300 µg.

There is agreement about the efficacy of 100 µg, originally selected based on the estimated venom protein content of 2 to 4 stings. However, the amount of venom of the different species is different. The amount of honeybee venom is in the range of 50 µg; the amount of vespids is less consistent, ranging from 2 to 20 µg.[91] Patients who are not adequately protected might be protected with higher doses.[92]

A number of dosing regimens are used with different numbers of injections during weekly build-up phases and commonly reaching a maintenance dose in 4 to 6 weeks. VIT can also be given according to a rush desensitization program with multiple doses administered, often in a hospital setting, over a period of 2 or 3 days to 1 week. For some examples of schedules see Table 57-4.

TABLE 57-3 Indications for Venom Immunotherapy in Patients with Positive Venom Skin Tests or Serologically Positive sIgE

Previous Reaction		Skin Test or RAST	Risk of a Systemic Reaction	Advice
No reaction	Children and adults	Unknown	1–3%[1]	None
		Positive	5%[30] to 17%[47]	None
Large local	Children	Not relevant (negative or positive)	2%[43]	None
	Adults	Not relevant (negative or positive)	5–10%[13]	None
Systemic reaction – dermal	Children	Positive	1–13%[43]	No VIT, no EAI*
	Adults	Positive	9.1–33% (YJ)[60–62] 40% (bee)[54]	EAI* and VIT†[83]
Systemic reaction – grade II–IV	Children <5 yr	Positive	>20%/?[43]	EAI* and VIT – controversial due to age
	Children >5 yr	Positive	>32%[43]	EAI* and VIT
	Adults (>15 yr)	Positive	25–70%[31,52–55]	EAI* and VIT
		Negative	?	Further diagnostics: • repeat skin test • sIgE • consider other insects • consider mastocytosis • consider other diagnosis • consider sting challenge

*The decision to provide an EAI will depend on the practice patterns in each country.
†Quality of life is an important target.
RAST – radioallergosorbent test.

*Starting dose may vary depending on patient's skin test sensitivity. Subsequent doses are modified by local or systemic reactions. Doses expressed in micrograms.
†Sequential venom doses administered on the same day at 20- to 30-minute intervals.
‡50 µg may be used as the top dose.

Once the top maintenance dose is reached, it can be administered every 4 to 6 weeks.

Preventive medication with antihistamines can be used during VIT, especially during the initial phase. It has been demonstrated to significantly reduce large local and generalized cutaneous reactions in double-blind placebo-controlled trials.[93] This pretreatment affects the expression of histamine receptor and cytokine production of allergen-specific cells. It might also increase the efficacy of VIT,[94] although this could not be proven in the prospective study,[93] probably due to type II error.

BOX 57-3 APPROACHES IN THE CASE OF SIDE-EFFECTS

LARGE LOCAL REACTION

- The venom dose can be split into two injections, limiting the amount delivered at one site.
- Administration of an antihistamine 30–60 minutes before the venom injection.
- Addition of a small amount of epinephrine to the venom may minimize immediate local swelling.
- In the case of extensive delayed-onset swelling, corticosteroids are usually effective, either locally applied or by the addition of a small amount of steroid to the venom.
- In the case of fatigue, successful treatment is usually accomplished with the administration of aspirin approximately 30 minutes before the injection and every 4 hours thereafter for 1–2 days, if needed.

SYSTEMIC REACTION

- Dose reduction to 20% with subsequent slow increase.
- Pretreatment with antihistamine 30–60 minutes before the venom injection.
- A few patients require the maintenance dose every 2–3 weeks to avoid a systemic reaction.
- If individuals are receiving multiple venoms, it might be advisable to administer single venoms on separate days.
- Concomitant administration of β-adrenergic blocking drugs can increase the severity of anaphylaxis. ACE inhibitors also have been suggested as potentially exacerbating the severity of allergic reactions.[95]
- Check (again) for mastocytosis.

Side-Effects

Reported immunotherapy reaction rates with both rapid and slower schedules vary but are not significantly different. The critical issue is to reach the top maintenance dose.

Local swelling may occur, as may generalized fatigue and aching. Several approaches are available to minimize these reactions (Box 57-3).

Systemic reactions to VIT are unusual and much less common than those induced by pollen immunotherapy. Honeybee venom as compared to vespid venoms is associated with a higher incidence of systemic reactions during the build-up phase. Adverse reactions are no more common in the ultra rush regimen as compared to the modified rush regimen.[96]

There have been no identified adverse reactions caused by long-term VIT. Injections appear to be safe during pregnancy with no effect on the pregnancy or the fetus.

Results

VIT is highly effective in preventing subsequent anaphylaxis in children at risk, with comparable efficacy as in adults. In a follow-up study of children, 84.4% of those with anaphylaxis to honeybee and 94.1% to Vespula venom were completely protected.[36] In a study by Golden et al in 512 patients the efficacy was 95% in more than dermal reactors, and 100% in dermal reactors; the culprit insects were not mentioned.[43]

Graft et al[97] reported that during a 3- to 6-year period, 200 re-stings in 49 VIT-treated children resulted in only four mild systemic reactions (98% efficacy). Another study of children receiving bee VIT reported five reactors in 55 children after field re-stings.[98]

A recent study by Ruëff et al included more than 1,500 adults receiving a sting challenge 1 year after start of VIT, with a protection rate of 84% for bee VIT and 96% for yellow jacket VIT.[99]

https://CafePezeshki.IR

This difference in honeybee versus yellow jacket VIT has been known for decades. Recent studies demonstrated that more than 50% of HBV-allergic patients display IgE reactivity to low-abundance proteins such as Api m 3, Api m 5 and Api m 10.[14,59] Two of these allergens, Api m 3 and Api m 10, are present in the crude venom abstract but absent or under-represented in therapeutic venom preparations.[58] Based on these findings, it is tempting to speculate that the relative lack of these two allergens in therapeutic venom preparations may account for the reduced efficacy of VIT in bee venom-allergic patients, a hypothesis that is currently under investigation.

Treatment Duration

The question of duration of treatment or when it is safe to discontinue VIT has been a persistent issue. The re-sting reaction rate after cessation of VIT is low, generally in the range of 5% to 15%. The risk of a recurrent systemic reaction to a sting after stopping venom immunotherapy decreases the longer VIT has lasted.[100]

It appears that 3 to 5 years of VIT is adequate for the large majority of individuals who have had mild-to-moderate anaphylactic reactions, despite the persistence of a positive skin test.[60–64] One year of VIT does not provide sufficient protection for nearly 25% of patients.[28] After 3 years of VIT, 83% to 100% of patients are protected against recurrent systemic reactions in the first 1 to 3 years after stopping, and most of these reactions were only mild.[47,101–107] Studies evaluating more than 5 years of treatment show slightly higher rates of protection.[101,107]

There are several risk factors that are associated with lower efficacy or increased recurrence of systemic reactions (see Box 57-4).

BOX 57-4 RISK FACTORS FOR INCREASED INEFFICACY OF VIT TREATMENT

- Mastocytosis[29,68]
- Severe anaphylactic symptoms, such as loss of consciousness, caused by insect sting;[31,101,105] might also be due to mastocytosis
- Systemic reactions to venom immunotherapy;[47] might also be due to mastocytosis
- Honeybee venom allergy (compared with vespid venom allergy)[101]
- Presence of significant medical problems, such as cardiovascular disease
- High sting frequency[47,101]

Anaphylaxis: Assessment and Management

F. ESTELLE R. SIMONS

KEY POINTS

- Most episodes of anaphylaxis occur in the community, not in healthcare settings. Food is by far the most common trigger. Concomitant asthma increases the risk of severe or fatal anaphylaxis.
- Diagnosis of anaphylaxis is based on recognition of symptoms and signs that occur suddenly (minutes to a few hours) after exposure to a known or likely trigger.
- Prompt treatment of anaphylaxis is essential: call for assistance, inject epinephrine IM in the mid-outer thigh, and place the patient supine or in a position of comfort. Provide oxygen, IV fluids, and other interventions as needed.
- Patients at risk of anaphylaxis should carry one or more epinephrine auto-injectors and a written, personalized, anaphylaxis emergency action plan, and wear medical ID.
- Anaphylaxis triggers should be confirmed and vigilantly avoided. Immunotherapy effectively prevents venom anaphylaxis. Regular follow-up and anaphylaxis education are important aspects of long-term management.

Introduction

The areas covered in this chapter on anaphylaxis in infants, children and teenagers include: epidemiology, patients at increased risk, mechanisms, triggers, diagnosis, treatment of the acute anaphylactic episode, and long-term management.

Anaphylaxis is defined as a serious generalized allergic or hypersensitivity reaction that is rapid in onset and might cause death. It typically occurs minutes to a few hours after exposure to the trigger and involves two or more body organ systems (Box 58-1). The presence of hypotension or shock is not required in order to make the diagnosis. The term 'anaphylactoid' is no longer recommended for use.[1–4]

EPIDEMIOLOGY

The rate of occurrence of anaphylaxis is increasing, yet underdiagnosis and under-coding remain a problem. In the general population, the incidence doubled from 21 per 100,000 person years in the 1980s to 49.8 per 100,000 person years in the 1990s, and the highest rate (70 per 100,000 person years) was reported in patients 0.8 to 19 years of age.[6,7]

The hospitalization rate for anaphylaxis in patients under 20 years old increased more than 4-fold between 1990 and 2006, with peaks in the very young (0–4 years) and in teenagers. The incidence of emergency department (ED) visits and hospitalizations for anaphylaxis increased by 8.8% per year between 1993/4 and 2004/5, with a steep increase in hospitalizations for food-triggered anaphylaxis in children less than 5 years of age. The hospitalization rate for food-induced anaphylaxis more than doubled between 2000 and 2009, from 0.60 to 1.26 per 1,000 total hospitalizations, with corresponding increases in associated healthcare costs.[6–10]

In addition to the increase in ED visits and hospitalizations, critical care unit admissions are also increasing; however, in hospitalized patients, the case fatality rate is low.[11]

Most anaphylaxis fatalities occur in community settings.[12–14] Indeed, most anaphylaxis episodes occur in such settings, where they predominate in boys and in atopic patients. Foods are by far the most common trigger, followed by insect stings and drugs.[15–20]

PATIENTS AT INCREASED RISK OF SEVERE ANAPHYLAXIS

Severity of concomitant atopic diseases is a predictor of life-threatening anaphylactic episodes. Persistent asthma, especially if not optimally controlled, is an important risk factor for fatal anaphylaxis. Urticaria pigmentosa with extensive (>90%) involvement of the skin or blistering increases the risk of anaphylaxis in infants and children. Concurrent use of antihypertensive medications such as beta-adrenergic blockers and angiotensin-converting enzyme (ACE) inhibitors potentially makes anaphylaxis more severe.[2,21–26] Additionally, infants, teenagers and pregnant teens can be uniquely vulnerable in anaphylactic episodes because of issues with under-recognition and under-treatment.[2,27,28]

Co-factors that can amplify anaphylaxis include exercise, ethanol, NSAIDs (nonsteroidal antiinflammatory drugs), colds or other acute infections, fever, perimenstrual status and emotional stress. Some amplification mechanisms are better understood than others; for example, exercise, ethanol and NSAIDs increase food allergen bioavailability from the gastrointestinal tract, and acute viral infections decrease the mast cell activation threshold.[2,29–31]

PATHOLOGIC MECHANISMS IN ANAPHYLAXIS

In the pediatric population, anaphylaxis typically involves IgE specific to food, venom or other allergen, high-affinity IgE receptors (FcεR1 receptors), mast cells and basophils and release of mediators of inflammation. These include preformed histamine and tryptase, and newly generated mediators such as platelet-activating factor, leukotrienes, prostaglandins, cytokines and chemokines[2,3] (Figure 58-1).

https://CafePezeshki.IR

BOX 58-1 CLINICAL CRITERIA FOR DIAGNOSIS OF ANAPHYLAXIS

Anaphylaxis is highly likely when any *one* of the following three criteria is fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g. *generalized* hives, pruritus or flushing, swollen lips-tongue-uvula)
   AND AT LEAST ONE OF THE FOLLOWING:
   - Respiratory compromise (e.g. dyspnea, wheeze-bronchospasm, stridor, hypoxemia)*
   - Reduced BP† or associated symptoms of end-organ dysfunction (e.g. hypotonia [collapse], syncope, incontinence)
2. Two or more of the following that occur rapidly after exposure to a *likely allergen for that patient* (minutes to several hours):
   - Involvement of the skin-mucosal tissue (e.g. generalized hives, itch-flush, swollen lips-tongue-uvula)
   - Respiratory compromise (e.g. dyspnea, wheeze-bronchospasm, stridor, hypoxemia)*
   - Reduced BP† or associated symptoms (e.g. hypotonia [collapse], syncope, incontinence)
   - Gastrointestinal symptoms (e.g. crampy abdominal pain, *persistent* vomiting)
3. Reduced BP† after exposure to a *known allergen for that patient* (minutes to several hours):
   - Infants and children: low systolic BP† (age-specific) or greater than 30% decrease in systolic BP†
   - Adults: systolic BP† or less than 90 mm Hg or greater than 30% decrease from that person's baseline

References: 2,4,5.

BP – Blood pressure.

*Another example is reduced peak expiratory flow.

†Low systolic blood pressure for children is defined as less than 70 mm Hg from 1 month to 1 year, less than (70 mm Hg + [2 × age]) from 1 to 10 years, and less than 90 mm Hg from 11 to 17 years.

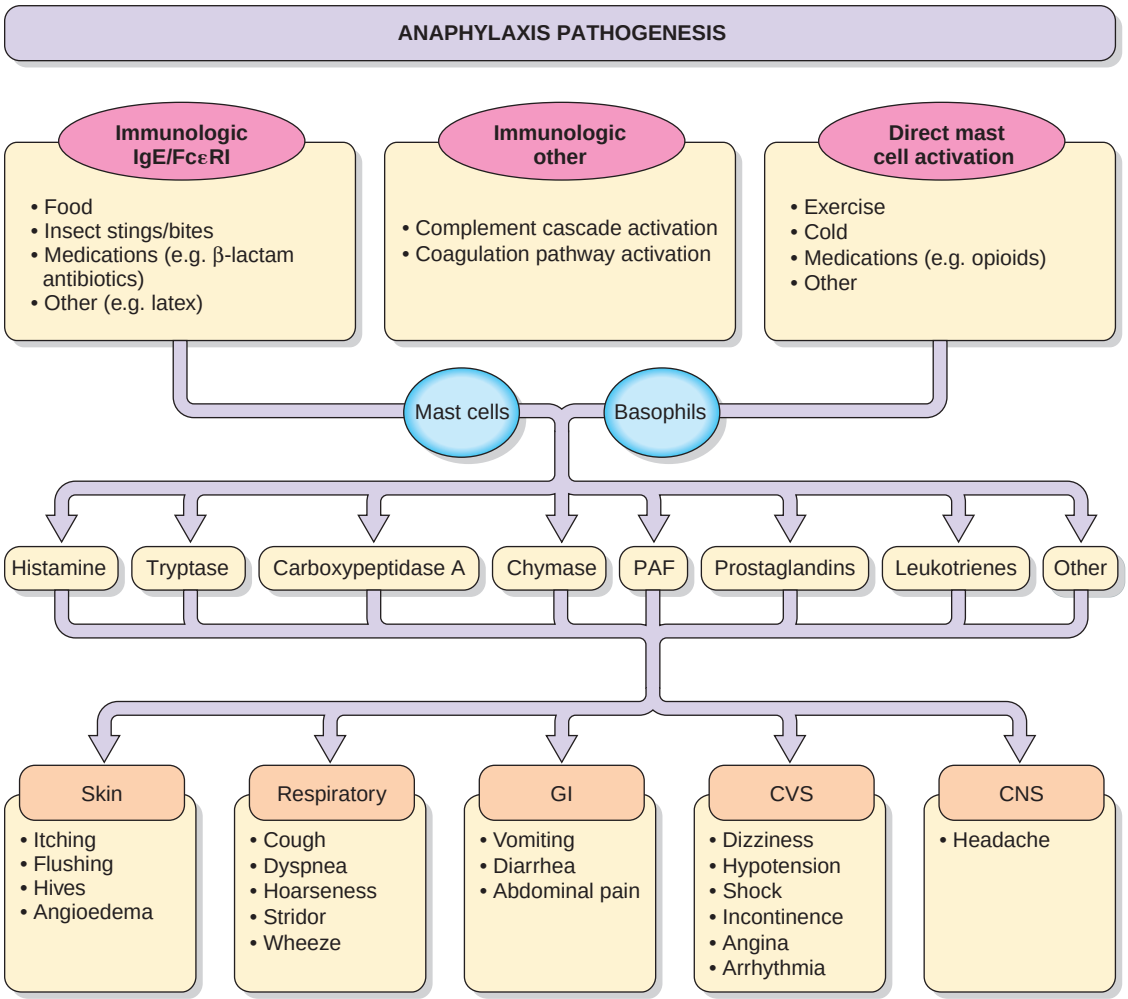

Figure 58-1 Summary of the pathogenesis of anaphylaxis. Details about mechanisms, triggers, key cells and mediators are found in the text. Two or more target organ systems are typically involved in anaphylaxis. *(Adapted from references 1,3.)*

https://CafePezeshki.IR

Recruitment of other inflammatory pathways has been reported. These include activation of the complement cascade leading to formation of C3a, activation of the coagulation pathway, and activation of the kallikrein-kinin system pathway with kinin formation. Direct activation of mast cells by physical factors such as exercise, exposure to cold water or cold air, or ingestion of medications such as opioids can also trigger anaphylaxis.[1–3,32,33]

IgG-mediated anaphylaxis is reported after administration of high molecular weight dextran or monoclonal antibodies such as infliximab.[1–3,32,34]

Triggers

In the pediatric population, food is by far the most common trigger of anaphylaxis. Milk, egg, peanut, tree nuts such as cashew, crustacean shellfish such as shrimp, and finned fish are the predominant food triggers in many geographic areas, while sesame, wheat and peach predominate in others. The relative importance of food triggers also differs with age; for example, in infants, milk, egg and peanut are the common concerns[12–20,35–40] (Box 58-2).

Potential food triggers include hidden, substituted, cross-reacting or cross-contacting foods, additives such as spices and colorants, novel food allergens (for example, red meats containing the carbohydrate allergen galactose-α-1,3,-galactose), contaminants such as storage mites in flour, and food parasites such as the live nematode *Anisakis simplex* in fish. Rarely, anaphylaxis is triggered by skin contact from food as such, vomited food, or inhalation of odors or cooking vapors, e.g. from fish.[1,2,35–37,41–49]

Other anaphylaxis triggers include venom from stinging insects such as bees, yellow jackets, wasps, hornets and ants, and less commonly, saliva from biting insects such as mosquitoes, caterpillars and ticks.[15–20,50–56]

Medication triggers include penicillins, cephalosporins and other antibiotics, NSAIDs such as ibuprofen, and antineoplastic agents. Contaminants in medications, including traces of food, can also trigger anaphylaxis. Peri-operative anaphylaxis can be triggered by antibiotics or by neuromuscular blockers/muscle relaxants such as suxamethonium, but any inhaled, injected or topically applied agent can be implicated, including antiseptics such as chlorhexidine.[15–20,57–65]

Natural rubber latex in medical equipment and supplies can trigger anaphylaxis in healthcare settings, and latex found in some infant pacifiers, bottle nipples, teethers, toys, balloons, sports equipment including balls and racquet handles, and condoms can trigger it in community settings.[2,66]

Other potential triggers include biologic agents such as the monoclonal antibodies infliximab and omalizumab, allergen skin tests (especially intradermal tests), allergen challenge tests, and allergen immunotherapy by any route.[67–69]

Vaccines that protect against infectious diseases seldom trigger anaphylaxis. If they do, the culprit is usually an excipient (such as gelatin, yeast, dextran, polysorbate-80), egg (influenza and yellow fever vaccines), neomycin or polymyxin B, *not* the microbial content.[34,70]

In exercise-induced anaphylaxis, common co-triggers/co-factors include foods (wheat, shrimp, celery), NSAIDs, ethanol, and concurrent exposure to cold water or cold air, which can also trigger anaphylaxis independently of exercise.[30]

Idiopathic anaphylaxis is uncommon in infants, children and teenagers[15–20,71] (see also Idiopathic Anaphylaxis, pages 534 and 535, and Box 58-6).

BOX 58-2 ANAPHYLAXIS TRIGGERS

ALLERGEN TRIGGERS (IgE-DEPENDENT IMMUNOLOGIC MECHANISMS)

- Foods, e.g. milk, egg, peanut, tree nut, finned fish, crustacean shellfish, soy, and wheat
- Food additives, e.g. spices, colorants, vegetable gums, and contaminants
- Stinging insects: *Hymenoptera* species, e.g. bees, yellow jackets, wasps, hornets and ants
- Medications, e.g. penicillins, cephalosporins and other antibiotics, ibuprofen and other NSAIDs, and chemotherapeutic agents
- Biologic agents, e.g. monoclonal antibodies, and allergens (challenge tests, allergen-specific immunotherapy)
- Natural rubber latex
- Inhalants (rare), e.g. horse dander, and grass pollen
- Uncommon triggers*
- Novel allergens

DIRECT MAST CELL ACTIVATORS

- Physical factors
  - Exercise†
  - Cold water or cold air
  - Heat
  - Sunlight/ultraviolet radiation
- Medications, e.g. opioids

IDIOPATHIC ANAPHYLAXIS‡

Adapted from references 1,2.
NSAIDs – Nonsteroidal antiinflammatory drugs.
*In the pediatric population, uncommon triggers include vaccines to prevent infectious disease.
†With or without co-triggers/co-factors such as foods, ethanol, NSAIDs, cold water or cold air.
‡Idiopathic anaphylaxis is uncommon in children. The possibility of a novel trigger or a mast cell activation syndrome should be ruled out.

Diagnosis

In the pediatric population, diagnosis of anaphylaxis depends almost entirely on the history and physical findings.

CLINICAL DIAGNOSIS

Diagnosis of anaphylaxis is based on recognition of the sudden onset of characteristic symptoms and signs within minutes to hours after exposure to a known or likely trigger or activity (Figure 58-2). Clinical criteria for diagnosis have been developed and validated as an instrument for rapid assessment of patients who present with a possible diagnosis of anaphylaxis in EDs and other medical settings, or those who present to their primary care physician after the acute event, and for use in epidemiologic studies (Box 58-1). These criteria have high sensitivity for identification of anaphylaxis, good specificity and a high negative predictive value.[4,5,73]

Anaphylaxis is under-reported in the pediatric population,[7] especially in infants.[27,74] First episodes might not be recognized as such, especially if symptoms are mild and/or transient. Skin involvement (itching, flushing, generalized urticaria and/or

https://CafePezeshki.IR

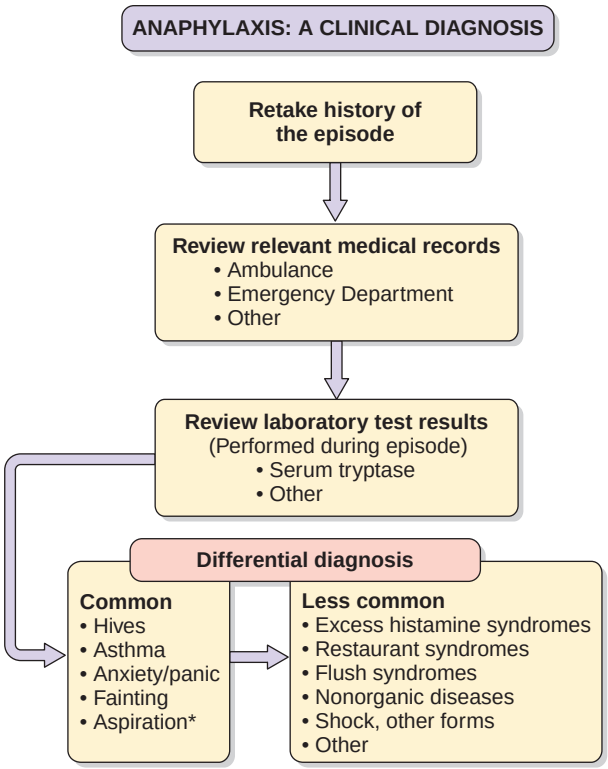

Figure 58-2 *of a foreign body. Algorithm for confirming the clinical diagnosis of anaphylaxis. Details about the supreme importance of the history, the role of serum tryptase levels and other laboratory tests, and the differential diagnosis are found in the text and in Box 58-3. *(Adapted from references 1–3,36,72.)*

angioedema) is helpful in making the diagnosis; however, it is absent or unrecognized in 10% to 20% of anaphylactic episodes and can be missed if itching is absent, if a partial skin examination is performed or if an H_1 antihistamine has been given. Patients with dysphonia, dyspnea or shock might not be able to describe their symptoms. Anaphylaxis might not be recognized as such in an asthmatic with acute respiratory symptoms if concomitant symptoms such as itching, vomiting or dizziness are not reported. Lack of recognition or delayed recognition of anaphylaxis due to patient or caregiver depression or substance abuse might also be relevant.[15–20,27]

In infants, a high index of suspicion is needed in order to diagnose anaphylaxis. They cannot describe their symptoms, and some of their signs can be difficult to interpret because they also occur in healthy babies (Table 58-1). A typical presentation includes skin signs such as generalized urticaria, gastrointestinal signs such as persistent vomiting, and/or respiratory symptoms and signs. Hypotension is often undocumented, for example in settings where infant-size blood pressure cuffs are unavailable.[27,74–76]

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of anaphylaxis in infants includes age-unique entities[27,74] (Box 58-3). The differential diagnosis of anaphylaxis in children and teens includes common entities such as acute generalized hives associated with viral infection, acute asthma, syncope (faint), anxiety or panic attack, and aspiration of a foreign body. It also includes less common entities such as excess histamine syndromes (e.g. mast cell activation syndromes, ruptured or leaking hydatid cyst); restaurant (post-prandial) syndromes (e.g. food poisoning, scombroid poisoning); and nonorganic diseases (e.g. vocal cord dysfunction, Munchausen syndrome or Munchausen syndrome by proxy). Flush syndromes are rare in the pediatric population except for nonallergic red man syndrome triggered by vancomycin. Seizures and stroke and other forms of shock (septic, hypovolemic or cardiogenic) should also be considered in the differential diagnosis.[1–3,15–20]

LABORATORY TESTS TO SUPPORT THE CLINICAL DIAGNOSIS

In the pediatric population, laboratory tests (Figure 58-2) are seldom helpful in confirming the clinical diagnosis of anaphylaxis. The most widely used test, measurement of serum or plasma total tryptase levels,[72] takes several hours to perform and is not available on an emergency basis. Even in blood samples obtained promptly (between 15 minutes and 3 hours) after symptom onset, tryptase levels are seldom elevated in children and in food-induced anaphylaxis. Lack of availability of tryptase measurements is *not* a barrier to prompt clinical diagnosis of anaphylaxis. A tryptase level in the normal reference range *cannot* be used to refute the clinical diagnosis of anaphylaxis. Initial treatment of anaphylaxis should *never* be delayed in order to obtain a blood sample for tryptase measurement.[1–4,72,77–79]

In young infants, interpretation of tryptase levels presents additional complexities, because *baseline* tryptase levels are elevated due to an increased mast cell burden in the developing immune system. At age 3 months, median *baseline* tryptase levels are reported as 14.2 ± 10.2 μg/L in atopic infants and 6.1 ± 3.54 μg/L in healthy infants. Levels gradually decline, and by age 9 to 12 months, they reach those found in older infants and young children.[80,81]

Plasma histamine levels and 24-hour urine levels of histamine and its metabolite, *N*-methylhistamine, are measured in some clinical laboratories. Other mast cell mediators such as platelet-activating factor are measured only in research laboratories.[72,77–79]

Treatment of the Acute Anaphylactic Episode

The essentials of prompt initial anaphylaxis treatment are outlined in Box 58-4. It is important to have a printed protocol that is posted and rehearsed regularly, to have the essential medications, supplies and equipment for emergency treatment readily available, and to pre-designate staff responsibilities. Remove any suspected relevant trigger. Rapidly assess the patient's airway, breathing, circulation, skin and body weight (mass). Simultaneously, call to request help from a resuscitation team in a healthcare setting or from emergency medical services (EMS) in a community setting, inject epinephrine promptly, and place the patient supine or semi-reclining in a position of comfort.[1–4,82,83,91–93]

EPINEPHRINE (ADRENALINE)

Epinephrine has life-saving α_1-adrenergic vasoconstrictor effects that prevent and relieve airway obstruction, hypotension

https://CafePezeshki.IR

TABLE 58-1 Symptoms and Signs of Anaphylaxis in Infants

Anaphylaxis Symptoms that Infants Cannot Describe	Anaphylaxis Signs that May be Difficult to Interpret/Unhelpful in Infants, and Why	Anaphylaxis Signs in Infants
GENERAL		
Feeling of warmth, weakness, anxiety, apprehension, impending doom	Behavioral changes such as persistent crying, fussing, clinging, irritability, fright	
SKIN/MUCOUS MEMBRANES		
Itching of lips, tongue, palate, uvula, ears, throat, nose, eyes, etc.; mouth tingling or metallic taste	Flushing (may also occur with fever, hyperthermia or crying spells)	Sudden onset of generalized hives (potentially difficult to discern in infants with acute atopic dermatitis; scratching and excoriations will be absent in young infants); also, angioedema (face, tongue, oropharynx)
RESPIRATORY		
Throat tightness; chest tightness; shortness of breath	Hoarseness, dysphonia (common after a crying spell); drooling/increased secretions (common in teething infants)	Sudden onset of coughing, stridor, wheezing, dyspnea, apnea, cyanosis
GASTROINTESTINAL		
Dysphagia, nausea, abdominal pain/cramping	Drooling, spitting up/regurgitation (common after feeds), loose stools (normal in infants, especially if breastfed); colicky abdominal pain	Sudden onset of persistent vomiting
CARDIOVASCULAR		
Feeling faint or dizzy (pre-syncope), confusion, blurred vision, difficulty in hearing	Hypotension (need appropriate size blood pressure cuff; low systolic blood pressure for infants is defined as less than 70 mm Hg from 1 month to 1 year, and less than (70 mm Hg + [2 × age]) in years in the first and second years of life; tachycardia, defined as greater than 120–130 beats per minute from 3 months to 2 years, inclusive; loss of bowel and bladder control (ubiquitous in infants)	Weak pulse, arrhythmia, diaphoresis/sweating, collapse/unconsciousness
CENTRAL NERVOUS SYSTEM		
Headache	Behavioral changes (see above), drowsiness, somnolence (common in infants after feeding)	Sudden onset of lethargy, hypotonia, unresponsiveness or seizures

Adapted from reference 27.

and shock, and life-saving β_2-adrenergic effects, including bronchodilation and suppression of mediator release from mast cells and basophils[1–4,82–84,94–98] (Box 58-4, Table 58-2).

Epinephrine should be promptly injected intramuscularly in the mid-outer thigh (vastus lateralis muscle) to achieve peak plasma and tissue concentrations rapidly. The epinephrine dose is 0.01 mg/kg IM for first aid treatment (maximum 0.15 mg in an infant; maximum 0.3 mg in a child; maximum 0.5 mg in a teenager). It needs to be injected *before* anaphylaxis progresses to severe respiratory or cardiac symptoms. If indicated, it can be repeated several times at 5–15 minute intervals. Failure to inject it promptly increases the risk of hypoxic-ischemic encephalopathy and death. There is no absolute contraindication to epinephrine treatment[1–4,12–14,82–84,93,94] (Box 58-4).

The severity of an anaphylactic episode can differ from one patient to another, and in the same patient from one episode to another. At the onset, it is impossible to predict whether the patient will respond promptly to treatment, die within minutes or recover spontaneously due to endogenous secretion of epinephrine, angiotensin II and endothelin I.[2]

Rates of epinephrine injection in anaphylaxis are improving in some pediatric emergency departments. In one study that included prospective data collection, 79% of all pediatric patients with anaphylaxis (and 100% of those with severe anaphylaxis) received epinephrine injections as initial treatment.[95]

Fewer than 20% of pediatric patients with food-induced anaphylaxis treated with epinephrine receive a second dose, either because of failure to respond to the initial dose or because of biphasic anaphylaxis, defined as recurrence of symptoms hours after resolution of the initial symptoms, despite no further exposure to the trigger.[96]

In a retrospective review of ED patients with anaphylaxis, most of whom were children, 17% of those who received one epinephrine injection required one or more additional injections; however, the need for subsequent injections did not correlate with obesity or overweight status. In some patients, the heights and weights used for body mass index calculations were estimated, not measured during the ED visit.[97]

Epinephrine seldom causes serious adverse events in the pediatric population. In patients of all ages, IM epinephrine is 10 times safer than an IV bolus dose of epinephrine. IV injection can be associated with delayed epinephrine administration due to difficult venous access, and with overdose due, for example, to overly rapid infusion or use of a 1:1,000

https://CafePezeshki.IR

BOX 58-3 DIFFERENTIAL DIAGNOSIS OF ANAPHYLAXIS IN INFANTS

SKIN

Acute episode of urticaria, urticaria pigmentosa/mast cell activation syndrome, hereditary angioedema

RESPIRATORY (UPPER OR LOWER RESPIRATORY TRACT)

Acute onset of symptoms due to obstruction, which can be congenital (e.g. laryngeal web, vascular ring, malacias) or acquired (e.g. aspiration of foreign body*, croup, bronchiolitis, asthma); asphyxiation/suffocation, breath-holding

GASTROINTESTINAL TRACT

Acute onset of symptoms due to obstruction, which can be congenital (e.g. pyloric stenosis, malrotation) or acquired (e.g. intussusception), food protein-induced enterocolitis syndrome with an acute presentation

CARDIOVASCULAR SYSTEM

Apparent life-threatening event/sudden infant death syndrome; different forms of shock: septic, hypovolemic, cardiogenic, distributive (other than anaphylaxis)

CENTRAL NERVOUS SYSTEM

Seizure, postictal state, stroke, trauma, child abuse, increased intracranial pressure

OTHER, INCLUDING

Metabolic disorders
Infectious diseases: pertussis, gastroenteritis, meningitis
Ingestion of: drug overdose, poison or toxin (e.g. food, chemical, plant)
Munchausen syndrome by proxy (Meadow's syndrome)

Adapted from reference 27.
*Peanuts and tree nuts are commonly associated with both foreign body inhalation and anaphylaxis.

epinephrine solution that has not been appropriately diluted 10-fold or 100-fold.[98] Unless cardiopulmonary arrest is imminent or has occurred, IV epinephrine should be given by physicians skilled in vasopressor administration through an infusion pump with dose titration based on the clinical information obtained by continuous electronic monitoring of blood pressure and cardiac rate and function. Reasons for failure to inject epinephrine promptly and reasons for occasional apparent failure of response to epinephrine injections are listed in Box 58-5.[1–4,82–84,93–98]

OTHER LIFE-SAVING MEASURES

Supplemental oxygen should be administered by face mask at a flow rate of 8–10 L/minute to patients receiving repeated doses of epinephrine, and those with moderate or severe respiratory symptoms or concomitant asthma.[1–4]

Isotonic (0.9%) saline is preferred for IV fluid resuscitation in anaphylaxis[1–4,36,50] (Box 58-4). A Cochrane review of randomized controlled trials (RCT) of IV fluid resuscitation in more than 20,000 critically ill patients (including infants and children) with distributive shock found that administration of colloids such as hetastarch or albumin conferred no survival advantage over crystalloids such as 0.9% saline.[114]

For patients with cardiopulmonary arrest, in addition to rescue breathing at a rate of 15–20 breaths/minute, CPR guidelines now emphasize chest compressions at a rate of at least 100/minute and a depth of 4 cm in infants and 5 cm in children. In teens, they should be performed at a rate of 100–120/minute and a depth of 5–6 cm. Interruptions should be minimized[85] (Box 58-4).

BOX 58-4 TREATMENT OF AN ACUTE ANAPHYLACTIC EPISODE

Have a printed, posted emergency protocol for recognition and treatment of anaphylaxis, and rehearse it regularly
Rapidly assess airway, breathing, circulation, skin and weight (body mass)
Call for help: emergency medical services (e.g. 9-1-1) in community settings, or resuscitation team in healthcare settings*
Inject epinephrine (adrenaline) intramuscularly in the mid-outer thigh in a dose of 0.01 mg/kg (up to a maximum dose of 0.15 mg in an infant, 0.3 mg in a child, or 0.5 mg in a teenager); if there is minimal or no response, it can be repeated several times at 5–15 minute intervals*†‡
Place the patient supine (or in a position of comfort if dyspneic or vomiting) and elevate the lower extremities*; the patient should not suddenly sit up or stand and should not walk or run
When indicated:
Administer high-flow oxygen (8–10 L/minute) by face mask
Give nebulized albuterol (salbutamol), 1.25–2.5 mg every 20 minutes or continuously to relieve bronchospasm that persists despite epinephrine injection
Give IV fluids (child: 0.9% [isotonic] saline, up to 10–20 mL/kg in the first 5–10 minutes§; teen: 0.9% [isotonic] saline, 1–2 liters rapidly (5–10 mL/kg in the first 5 minutes)§
Start cardiopulmonary resuscitation
Start continuous electronic monitoring of cardiac rate and function, blood pressure, respiratory rate, and monitor oxygen saturation (by pulse oximetry)‖
Consider second-line medications¶:
methylprednisolone IV, 1–2 mg/kg/day (single dose)
H_1 antihistamines such as cetirizine by mouth, 0.25 mg/kg to a maximum of 10 mg, or diphenhydramine IV, 1 mg/kg (to a maximum of 50 mg) to relieve itch/hives persisting despite epinephrine injection

Adapted from references 1–4,82–98.
*Simultaneous steps: call for help, inject epinephrine and position the patient.
†The epinephrine solution for intramuscular injection is 1 mg/mL (1:1,000).
‡Patients with anaphylaxis refractory to intramuscular injection of epinephrine and fluid resuscitation should preferably be transferred to the care of an emergency medicine team with the training, experience and equipment to provide skilled management of the airway and ventilation, and to provide optimal shock management by administering vasopressors safely through an infusion pump, with frequent dose titrations based on continuous electronic monitoring of cardiac rate and function and blood pressure, and monitoring of oxygenation using pulse oximetry.
§Titrate the rate of volume expansion to the cardiac rate and blood pressure; monitor for volume overload; in many pediatric emergency departments, hand-held ultrasound units are now used to monitor for and prevent volume verload.
‖If continuous monitoring is not available, monitor vital signs every 1–5 minutes.
¶These second-line medications do not replace epinephrine.

https://CafePezeshki.IR

TABLE 58-2 Medications for Anaphylaxis Treatment: Why Epinephrine is the Initial Medication of Choice

Medications	Epinephrine*	β_2-Adrenergic Agonist	H_1 Antihistamine†	Glucocorticoid
Pharmacologic effects	At α_1-receptor ↑ vasoconstriction ↑ peripheral vascular resistance ↑ blood pressure ↓ mucosal edema, e.g. in larynx At β_1 receptor ↑ heart rate ↑ force of cardiac contraction At β_2 receptor ↓ release of mediators ↑ bronchodilation	At β_2 receptor ↑ bronchodilation	At H_1 receptor ↓ itch (skin, mucous membranes) ↓ hives and flushing	At glucocorticoid receptor Given to prevent or diminish the late-phase response and biphasic, multiphasic or protracted symptoms associated with ongoing mediator release
Potential adverse effects when given in standard doses	Transient anxiety, pallor, restlessness, tremor, palpitations, headache, dizziness	Tremor, tachycardia, dizziness, jitteriness	First-generation H_1 antihistamines sedate, impair cognitive function, and cause other adverse effects	Adverse effects are unlikely after 1 or 2 doses
Current recommendations	Treatment of first choice	*In addition to epinephrine*, an inhaled bronchodilator, e.g. albuterol (salbutamol) can be given for bronchospasm	Not life-saving; *in addition to epinephrine* can be given for relief of itching and hives, if needed; not for initial or sole treatment	Not life-saving; *in addition to epinephrine*, can be given for the reasons stated above; not for initial or sole treatment

Adapted from references 1–4,82–84,86–90.
*Epinephrine by IM injection in the mid-outer thigh is the initial treatment of choice in healthcare settings and in community settings.
†Cetirizine 0.25 mg/kg to a maximum of 10 mg by mouth; for intravenous use, diphenhydramine 1 mg/kg, maximum 50 mg.

SECOND-LINE MEDICATIONS

H_1 antihistamines, H_2 antihistamines, glucocorticoids and β_2-adrenergic agonists are second-line medications in anaphylaxis and should not be substituted for epinephrine in initial treatment or given as the only treatment because they do not prevent or relieve life-threatening laryngeal edema, hypotension or shock[1–4,36,86–90] (Box 58-4, Table 58-2).

In a Cochrane systematic review, no high-quality evidence from RCTs was found to support the use of H_1 antihistamines in the treatment of anaphylaxis. H_1 antihistamines relieve itching, urticaria, flushing and angioedema, but do not relieve life-threatening respiratory or cardiovascular symptoms. Onset of action of an oral liquid formulation of cetirizine takes 30 minutes for relief of itch and 40 minutes for relief of hives. Impairing, nonsedating H_1 antihistamines can interfere with recognition of anaphylaxis symptoms[86–88] (Box 58-4, Table 58-2).

In another systematic review, no high-quality evidence from RCTs was found to support H_2 antihistamine use in anaphylaxis. If given in addition to H_1 antihistamines, they provide slightly increased relief of hives and flushing, but they do not relieve itching or life-threatening respiratory or cardiovascular symptoms.[89]

In other Cochrane systematic reviews, no high-quality evidence from RCTs has been found to support glucocorticoid use in anaphylaxis treatment.[90] These medications do not relieve acute symptoms and signs. Based on limited evidence, they are given to prevent biphasic anaphylaxis symptoms, which are reported to occur in 6% of pediatric patients with anaphylaxis.[115] As their onset of action through transcription of genes encoding pro-inflammatory proteins is relatively slow (hours, not minutes), corticosteroids are good candidates for investigation in RCTs[116] (Box 58-4, Table 58-2).

An inhaled β_2-adrenergic agonist such as albuterol (salbutamol) can be given to patients with wheezing that persists after epinephrine injection[1–4] (Box 58-4, Table 58-2).

REFRACTORY ANAPHYLAXIS

Patients with anaphylaxis refractory to epinephrine, supplemental oxygen and IV fluids should, if possible, be transferred to the care of a specialist team for ventilatory and inotropic support and continuous electronic monitoring of blood pressure, cardiac rate and function, and respiratory rate and oxygenation (by using pulse oximetry). Where continuous electronic monitoring and pulse oximetry are not available, vital signs should be measured at frequent regular intervals (every 1–5 minutes).[1–4] Based on case reports in adults, methylene blue infusion is life-saving in anaphylaxis refractory to conventional treatment; however, there are no pediatric studies.[117]

OBSERVATION AND MONITORING

Duration of observation and monitoring in healthcare settings should be individualized; for example, patients with moderate or severe respiratory or cardiovascular symptoms require monitoring for at least 6 to 8 hours. Recommendations for safe observation periods are supported by the finding that mediators measured at intervals during anaphylaxis peak at different times, and some mediators such as histamine, tryptase, IL-6 and IL-10 correlate with delayed deterioration.[77] At discharge, patients should be equipped with an anaphylaxis emergency action plan listing common symptoms, given (or prescribed) an EAI, with information about when, why and how to use it, and instructed to seek follow-up care[1–4] (Box 58-4).

Long-term Management of Anaphylaxis

Anaphylaxis can lead to impaired quality of life, psychosocial burdens, disrupted activities and anxiety, as assessed by using

https://CafePezeshki.IR

BOX 58-5 EPINEPHRINE IN ANAPHYLAXIS: POINTS TO PONDER

WHY HEALTHCARE PROFESSIONALS FAIL TO INJECT EPINEPHRINE PROMPTLY

- Lack of recognition of anaphylaxis symptoms/failure to diagnose anaphylaxis
- Episode appears mild, or there is a history of previous mild episode(s)*
- Inappropriate concern about transient mild pharmacologic effects of epinephrine, e.g. tremor
- Lack of awareness that serious adverse effects are nearly always attributable to epinephrine overdose or to IV administration, especially IV bolus, rapid IV infusion or IV infusion of a 1 : 1,000 epinephrine solution instead of an appropriately diluted solution (1 : 10,000 or 1 : 100,000 concentrations)

WHY PATIENTS AND CAREGIVERS FAIL TO INJECT EPINEPHRINE PROMPTLY

- Lack of recognition of anaphylaxis symptoms/failure to diagnose anaphylaxis
- Episode appears mild, or there is a history of previous mild episode(s)*
- H_1 antihistamine or asthma puffer is used initially instead, relieving early warning signs such as itch and cough, respectively
- Prescription for epinephrine autoinjectors (EAIs) not provided by physician
- Prescription for EAIs provided but not filled at pharmacy (e.g. if not affordable)
- Patients do not carry EAIs consistently (due to size and bulk, or 'don't think they'll need it')
- Patients and caregivers are afraid to use EAIs (fear of making an error when giving the injection, or a bad outcome)
- Patients and caregivers are concerned about injury from EAIs
- Competence in using EAIs is associated with regular allergy clinic visits; it decreases as time elapses from first EAI instruction; regular re-training is needed
- Difficulty in understanding how to use EAIs (15% of mothers with no EAI experience could not fire an EAI immediately after a one-on-one demonstration)
- Errors in EAI use can occur despite education, possibly related to the design of some EAIs

WHY PATIENTS OCCASIONALLY FAIL TO RESPOND TO EPINEPHRINE INJECTION

- Delayed recognition of anaphylaxis symptoms; delayed diagnosis
- Error in diagnosis: problem being treated (e.g. foreign body inhalation) is not anaphylaxis
- Rapid progression of anaphylaxis†
- Epinephrine†:
  - injected too late, dose too low on mg/kg basis, dose too low because epinephrine solution has degraded (e.g. past the expiration date, stored in a hot place, etc.)
  - injection route or site not optimal; dose took too long to be absorbed
  - patient suddenly sits up or walks or runs, leading to the empty ventricle syndrome
  - concurrent use of certain medications, e.g. β-adrenergic blockers

Adapted from references 2,4,36,82–84,91–113.

*Subsequent anaphylaxis episodes can be more severe, less severe or similar in severity.

†Median times to respiratory or cardiac arrest are 5 minutes in iatrogenic anaphylaxis, 15 minutes in stinging insect venom anaphylaxis, and 30 minutes in food anaphylaxis; however, regardless of the trigger, respiratory or cardiac arrest can occur within 1 minute in anaphylaxis.

validated instruments. The impact is highly variable, ranging from death, disability due to hypoxic-ischemic encephalopathy, severe impact that sometimes necessitates referral to a psychologist or a psychiatrist, minimal impact, or no impact at all if anaphylaxis is unrecognized or undiagnosed, or if the possibility of recurrence is denied or ignored[1,12–14,118–120] (Figure 58-3).

Multiple complexities in anaphylaxis contribute to anxiety. These might include difficulty or lack of confidence in avoiding allergen triggers,[121–123] different allergen thresholds for development of reactions[124] and variation in a patient's personal allergen threshold due to exercise, intercurrent infection, perimenstrual status, emotional stress and other co-factors.[29-31] Patients and caregivers also report anxiety about carrying and using EAIs.[125]

Personalized long-term anaphylaxis management aims to achieve a state of minimal impact, in which patients and caregivers are aware of the risk of recurrences but confident that if preventive measures fail, they are prepared to recognize and manage an anaphylactic episode.[1]

Long-term risk reduction measures include emergency preparedness to treat anaphylaxis in community settings, follow-up with a physician, preferably an allergy/immunology specialist, as well as contact with parent/patient support groups.[99–113,126] Additional important measures include investigations to confirm the triggers,[36,50,127–132] prevention of recurrences through avoidance and, where relevant, immune modulation,[36,50,51,125,133–143] and optimal management of asthma and other co-morbidities[1–3] (Box 58-6, Figure 58-4).

EMERGENCY PREPAREDNESS TO TREAT ANAPHYLAXIS IN COMMUNITY SETTINGS

Anaphylactic episodes can occur despite vigilant efforts to avoid known confirmed triggers.[121–123]

Self-Injectable Epinephrine

Those at risk for anaphylaxis in the community and/or their caregivers, should be taught how to recognize anaphylaxis and inject epinephrine correctly and safely using an EAI (Table 58-2, Box 58-5). Only two pre-measured fixed doses of epinephrine, 0.15 mg and 0.3 mg, in autoinjector formulations are available in the USA and Canada. The 0.15 mg dose is high for infants weighing10 kg or less and for some young children. The 0.3 mg dose might be low for some overweight or obese children and adolescents. Written instructions should be provided along with a website link demonstrating the correct EAI technique. EAIs are not available in many countries. Patients at risk of anaphylaxis who travel abroad should therefore carry more than two EAIs.[1–4,99]

Currently available alternatives to EAIs are not recommended. These include use (by a non-healthcare professional) of a 1 mL syringe to draw up and measure an epinephrine dose from an ampule (problems: delay in drawing up the epinephrine and inaccurate dosing) and use of an unsealed syringe prefilled with the epinephrine dose (problem: loss of dose within 3 or 4 months due to air exposure and rapid epinephrine solution degradation).[83,100,101]

Deaths from anaphylaxis typically occur in community settings,[12–14] yet some physicians fail to prescribe EAIs for their patients at risk of anaphylaxis recurrences in the community. Moreover, many patients do not carry their EAIs consistently or use them when anaphylaxis occurs, even for severe symptoms including throat tightness, difficulty breathing, wheezing and loss of consciousness.[102,103] Many mothers cannot 'fire' an EAI

https://CafePezeshki.IR

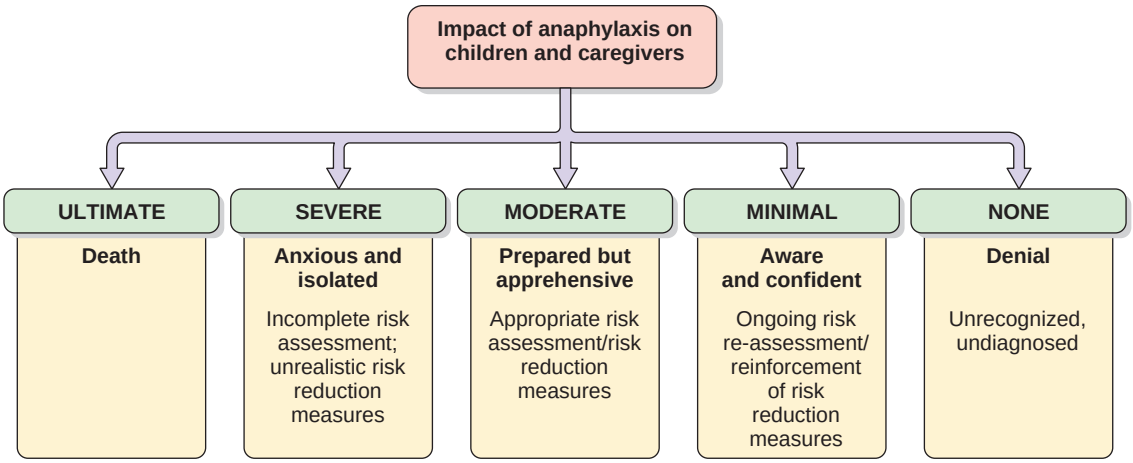

Figure 58-3 The impact of anaphylaxis on infants, children, teens and their caregivers and families ranges from the ultimate impact, death, to no impact at all. Long-term risk reduction measures include emergency preparedness to treat anaphylaxis recurrences in community settings, confirmation of the triggers and prevention of recurrences through avoidance and, where relevant, immune modulation. Other measures, including optimal management of co-morbidities such as asthma and contact with parent/patient support groups, are also important in minimizing the impact of anaphylaxis on pediatric patients, their caregivers and families. *(Adapted from references 1,118–120.)*

BOX 58-6 STRATEGIES TO PREVENT ANAPHYLAXIS IN COMMUNITY SETTINGS

AVOID SPECIFIC ALLERGEN TRIGGERS*

- Foods, including hidden or cross-reacting foods and food additives, e.g. spices, colorants, vegetable gums, contaminants
- Insect stings and bites
- Drugs
- Biologic agents
- Natural rubber latex
- Novel allergens†

AVOID DIRECT MAST CELL TRIGGERS, IF RELEVANT

- Exercise: do not avoid exertion, but avoid co-triggers and co-factors‡
- Cold air, cold water
- Heat
- Sunlight/ultraviolet radiation
- Medications, e.g. opioids

IMMUNE MODULATION, IF RELEVANT

- Foods: natural desensitization to milk and egg often occurs and can be facilitated; see text for details
- OIT and SLIT to milk, egg and peanut: research settings only (see text for details)
- Insect venoms: subcutaneous allergen immunotherapy
- Medications, e.g. penicillins and other antibiotics: desensitization

PHARMACOLOGIC PROPHYLAXIS, IF RELEVANT

- Idiopathic anaphylaxis: favorable natural history. Prophylaxis with a glucocorticoid, e.g. prednisone, an H_1 antihistamine, e.g. cetirizine, and, if indicated, omalizumab can be given

Adapted from references 35–37,50–63,70,133–143.
NSAIDs – Nonsteroidal antiinflammatory drugs; OIT – oral immunotherapy; RCT – randomized controlled trials; SLIT – sublingual immunotherapy.
*Suggested by the history and confirmed by skin tests and allergen-specific IgE levels.
†Save the allergen, e.g. food or insect for identification, and save the patient's serum for allergen-specific IgE measurements.
‡Avoid relevant co-triggers such as foods, cold air and cold water, and avoid relevant co-factors such as NSAIDs.

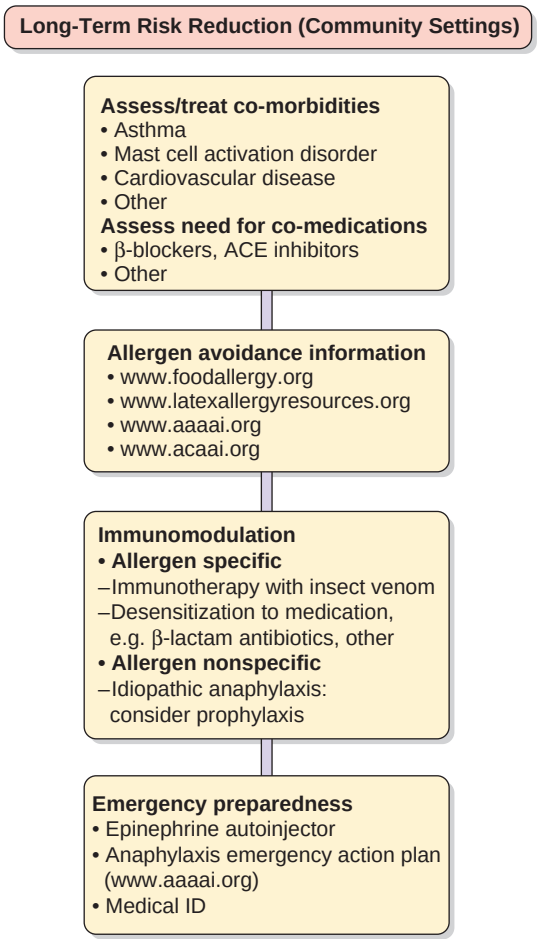

Figure 58-4 Summary of the approach to long-term management. Optimal management of co-morbidities such as asthma decreases the risk of severe or fatal anaphylaxis. Avoidance measures are allergen specific. Immune modulation is currently used to prevent anaphylaxis recurrences from insect stings and from some medications. Emergency preparedness measures, including epinephrine autoinjectors, written, personalized, anaphylaxis emergency action plans and medical ID are critically important. *ID* – Medical identification (e.g. bracelet, wallet card). *(Adapted from references 1–3,126,144.)*

https://CafePezeshki.IR

trainer correctly when tested immediately after one-on-one instruction.[104] Many parents fear using EAIs due to the possibility of hurting or injuring their child, or a bad outcome.[105,121] Thousands of unintentional injections and injuries to digits and other body parts have been reported with pen-type EAIs.[106] Training to use EAIs increases accuracy and speed; however, these skills are lost within a few months.[107,108] For all these reasons, anaphylaxis recognition and EAI technique should be reviewed at frequent regular intervals[102–108,121] (Box 58-5).

A novel, user-friendly EAI introduced in the USA and Canada in 2013 was designed with input from children, teens, and adult caregivers. It is compact, robust and intuitive to use correctly. It has audio and visual prompt systems that tell the user what to do and signal when injection is complete. It also protects from unintentional injections before and after use because the safety guard and needle guard are on the same end of the device; additionally, the needle is fully retractable.[109,110]

Pediatric allergists were surveyed about when they typically began to transfer responsibilities for anaphylaxis recognition and EAI use from adult caregivers to children and teenagers at increased risk of anaphylaxis in community settings. They expected that by age 12 to 14 years, their patients should begin to share these responsibilities. They started to train early and individualized the time of transfer based on patient factors such as presence of asthma and absence of cognitive dysfunction. However, caregivers of at-risk children and teenagers expected to begin transfer of responsibilities considerably earlier, when children are age 6 to 11 years.[111,112]

Anaphylaxis Emergency Action Plan

Epinephrine autoinjectors should be prescribed in the context of a written, personalized, anaphylaxis emergency action plan; for examples, see www.aaaai.org, www.acaai.org or www.anaphylaxis.ca. Such plans typically list common symptoms and signs of anaphylaxis, and list the steps for initial anaphylaxis treatment: call 9-1-1 or EMS, inject epinephrine promptly from an EAI and avoid sitting up, standing, walking or running. Plans should include reminders that H_1 antihistamines and asthma puffers should not be used as initial treatment or as the only treatment. As documented in an RCT, healthcare professionals' knowledge about recognition and treatment of anaphylaxis improved significantly after brief study of a wallet card-size plan.[1,2,4,36,113,126]

Medical Identification

Patients at risk for anaphylaxis recurrences should wear medical identification listing their confirmed trigger(s) and their relevant co-morbidities such as asthma. Options include medical identification jewelry, eg. Medic-Alert (Turlock, CA, www.medicalert.org), cards (available at www.aaaai.org) for carrying in a wallet, purse or backpack, and T-shirts or cloth badges imprinted with allergy alert messages for infants and young children. Medical identification needs to be updated regularly.[1,2,36,126]

INVESTIGATIONS TO CONFIRM THE TRIGGER(S)

Patients with a history of an anaphylactic episode benefit from assessment by a trained and certified allergy/immunology specialist who takes the time required to obtain a meticulous history of the event as the basis for selection of allergens for skin tests and specific IgE levels in serum, and for interpretation of test results[2,35–37,50,57–62,127–129] (Figure 58-5).

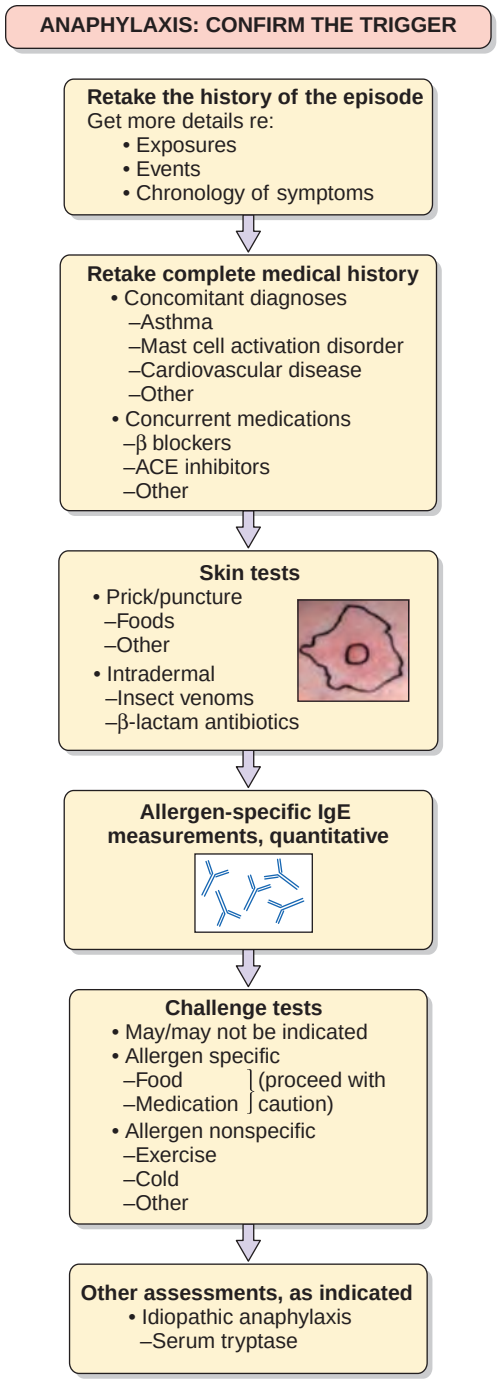

Figure 58-5 Algorithm for confirming anaphylaxis triggers. The importance of the history, and information about skin tests and specific IgE measurements to determine allergen sensitization are described in detail in the text. In selected patients, physician-monitored challenge tests are needed to determine the clinical relevance of sensitization. *(Adapted from references 1,2,35–37,50,57–62,127–132.)*

Skin prick tests are performed to assess sensitization to foods, stinging insect venoms, medications, natural rubber latex and other allergens. Fresh foods, for example fresh fruits and vegetables, can be tested using the prick-prick technique. Intradermal tests are contraindicated in the work-up for food-induced anaphylaxis;[35–37,127–129] however, they are useful in the work-up for venom-induced anaphylaxis[50] and drug-induced anaphylaxis.[57–62]

https://CafePezeshki.IR

Allergen-specific IgE levels are typically measured using the ImmunoCap assay (ThermoFisher Scientific, Waltham, MA). Reference ranges developed for milk-, egg-, peanut-, tree nut- and fish-specific IgE levels are based on this immunoassay and are not necessarily interchangeable with those based on other immunoassays.[35]

Positive allergen skin tests and/or increased allergen-specific IgE levels confirm sensitization to the allergens tested. They are not diagnostic of anaphylaxis because allergen sensitization without food-induced anaphylaxis is extremely common in the general pediatric population and in patients with atopic dermatitis. Although children with positive allergen skin tests and positive allergen-specific IgE levels have an increased probability of clinical reactivity to the allergens tested, the level of positivity of these tests does not necessarily predict the severity of future anaphylactic episodes.[35–37,127–129]

Physician-monitored incremental food challenge (provocation) tests are sometimes needed to determine the clinical relevance of borderline positive allergen skin tests or absent or low-positive allergen-specific IgE levels in patients who have an equivocal history of anaphylaxis. Food challenge tests should be conducted in well-equipped healthcare facilities staffed by professionals trained and experienced in patient selection, performing and interpreting these tests and recognizing and treating anaphylaxis. A positive (failed) challenge provides a sound basis for continued avoidance of the food. A negative (passed) challenge allows introduction or re-introduction of the food into the diet. Food challenge tests have recently been standardized. The caveat 'First, do no harm' applies. Patients with a convincing history of a food-induced reaction and evidence of sensitization to that food should *not* undergo oral food challenge tests because of their risk of anaphylaxis.[35–37,130]

The need for potentially risky challenge tests can be reduced by use of allergen component tests that differentiate clinical reactivity associated with IgE binding to potent stable allergens such as casein in milk, ovomucoid (Gal d 1) in egg, or Ara h 2 in peanut from less clinically relevant sensitization (allergens binding to heat-labile proteins).[131,132]

Physician-supervised challenge tests are contraindicated in patients with venom-induced anaphylaxis, unless performed in the context of an RCT.[50] Challenges are indicated in selected patients with a history of drug-induced anaphylaxis.[57–62]

Before making the diagnosis of idiopathic anaphylaxis, physicians should rule out a hidden or novel anaphylaxis trigger, perform a meticulous examination of the skin and obtain a baseline serum tryptase level to rule out a mast cell activation syndrome.[71]

AVOIDANCE OF TRIGGER(S)

Printed personalized information about avoidance of specific trigger(s) should be provided and reviewed at regular intervals (Box 58-6).

Foods

Complete avoidance of exposure to some foods such as milk, egg or peanut is easier said than done and is easier done than maintained over years or decades. Unintentional exposures are common. The constant vigilance required every day in order to avoid hidden, cross-contacting and cross-reacting food triggers can negatively affect quality of life of patients, caregivers and family members. Bullying of food-allergic children and teens is widespread and often occurs without parental awareness.[35–37,41,42,118–120]

Reliable resources for accurate, practical information are maintained and updated by Food Allergy Research & Education (FARE) (www.foodallergy.org) and by Anaphylaxis Canada (www.anaphylaxis.ca). For patients with multiple dietary restrictions, a licensed nutritionist can provide helpful information about essential nutrients, basic food groups and safe substitutes.[35–37]

Stinging Insects

Avoidance of exposure involves professional extermination of yellow jacket or wasp nests or fire ant mounds around the patient's home, and having the patient avoid uncovered sources of food and beverages at barbecues, picnics and campgrounds and wear protective clothing including shoes and socks when outdoors. Personal insect repellents such as DEET are not effective in preventing *Hymenoptera* stings, although they prevent insect bites.[50] Children less than 6 years old are more likely to be stung than older children but systemic allergic reactions increase with age.[52]

Drugs and Biologic Agents

Culprit drugs or agents should be avoided. An alternative non-cross-reacting agent should be substituted, preferably from a different therapeutic class but sometimes from the same class (for example, a third-generation cephalosporin for a first-generation cephalosporin).[57–62]

Exercise

Patients with exercise-induced anaphylaxis should not avoid exertion; however, they should avoid their relevant co-triggers/co-factors (foods, ethanol, NSAIDs, cold water or cold air, and high pollen counts). If none can be identified, they should have a trial of fasting for 4 to 6 hours before exertion. Also, they should never exercise alone, and if any symptom develops, they should stop exercise immediately and avoid running for help. They should carry one or more EAIs and, if relevant (e.g. during skiing), carry a cell phone for dialing 9-1-1/EMS.[1,4,30]

IMMUNE MODULATION

Immune modulation is currently recommended for prevention of anaphylaxis triggered by insect venoms and some drugs. It is not yet recommended for prevention of food-induced anaphylaxis, except in the context of an RCT[50,57–63,137–142] (Box 58-6, Figure 58-4).

Food-Induced Anaphylaxis

Natural desensitization occurs in many infants and children with clinical reactivity to food such as milk or egg, especially in those with relatively low allergen-specific IgE levels, small prick test wheal sizes and mild initial reactions. A history of tolerating small amounts of unintentionally ingested extensively heated (baked) milk or egg is a marker of transient IgE-mediated allergy. Addition of baked milk or egg to the diet of these patients accelerates the development of tolerance to unheated milk or egg during childhood and adolescence. In contrast, ongoing reactivity to small amounts of baked milk or egg suggests a more severe phenotype and the need to continue strict dietary avoidance.[133–136]

RCTs of oral immunotherapy (OIT) or sublingual immunotherapy (SLIT) of foods such as milk, egg or peanut can lead to

https://CafePezeshki.IR

clinical tolerance (desensitization). Immunologic tolerance is more elusive. Adverse effects are common. Food OIT should be undertaken only in well-equipped centers by physicians who are specifically trained and experienced in administering OIT and in diagnosing and treating anaphylaxis. Adverse effects during food OIT can potentially be reduced by pretreatment and co-treatment with omalizumab. SLIT to prevent food-induced anaphylaxis causes fewer adverse effects than OIT but is less effective.[137–140]

Insect Sting-Induced Anaphylaxis

Anaphylaxis from bee, yellow jacket, wasp and hornet venom(s) can be prevented in 97% to 98% of children and teenagers with a history of systemic reactions treated with a 3- to 4-year course of subcutaneous injections of the relevant standardized stinging insect venom(s). The protective effect can last 10 to 20 years after venom injections are discontinued. For prevention of anaphylaxis from fire ant stings, subcutaneous injections with whole body fire ant extract are indicated.[50–52,54,93,141]

Drug-Induced Anaphylaxis

For prevention of anaphylaxis recurrence from a drug such as an antibiotic, an NSAID, a chemotherapeutic agent, or a monoclonal antibody, when no safe substitute is available, desensitization can be conducted by an experienced allergy/immunology specialist using incremental doses and a published protocol. This technique is safe and effective for one uninterrupted course of treatment; however, long-lasting immunologic tolerance is not achieved and symptoms typically recur when the drug or biologic agent is restarted after being discontinued.[57–63,142]

Idiopathic Anaphylaxis

The natural history of idiopathic anaphylaxis is favorable. In the absence of RCTs of pharmacologic prophylaxis, management recommendations are based on expert opinion. If episodes are frequent (≥ 6 per year, or ≥ 2 per 2 months), prophylaxis with an oral glucocorticoid such as prednisone and a nonimpairing, nonsedating H_1 antihistamine such as cetirizine should be considered. Omalizumab can be helpful in patients refractory to conventional treatment.[71]

Pharmacologic Prophylaxis of Anaphylaxis

There are few RCTs of pharmacologic prophylaxis; however, one RCT has confirmed that epinephrine pretreatment reduces anaphylaxis to anti-snake venom by 43% and is more effective prophylaxis than H_1 antihistamine and/or glucocorticoid pretreatment.[143]

PREVENTION OF ANAPHYLAXIS IN SPECIFIC SETTINGS

Unique aspects of anaphylaxis prevention in the physician's office or clinic setting and in school settings will be reviewed briefly.

Physician's Office or Clinic

Anaphylaxis in this setting, although probably inevitable, is not a random event. It can be triggered by a food or drug challenge test, infusion of a biologic agent, subcutaneous allergen-specific immunotherapy and, rarely, by allergen skin tests or vaccinations to prevent infectious diseases. In this setting, the allergen and time of exposure are known and the healthcare professionals involved are likely aware of the patient's co-morbidities, concurrent medications and body mass (weight).[1]

Prevention of anaphylaxis in an office or clinic setting involves awareness of procedure-related risk factors and patient-related risk factors, careful selection of patients for diagnostic and therapeutic interventions, reassessment of patients before each intervention and deferral of interventions when clinically indicated, for example in a patient with an asthma exacerbation or an FEV_1 of ≤ 70% predicted.[1]

Specific wait times after diagnostic and therapeutic interventions are suggested to ensure patient safety; for example, 30 minutes after allergen immunotherapy, one hour after completion of a food challenge and 30 minutes to 2 hours after omalizumab injections for asthma. As patients and caregivers can be inconvenienced by waiting, and sometimes try to leave early, an EAI should be prescribed and they should be trained to recognize anaphylaxis symptoms and use the EAI promptly if symptoms occur after they leave the office or clinic.[50,67,68]

Anaphylaxis in Schools and Other Community Settings

Twenty percent of children experience their first anaphylaxis episode at school. The first episode can be fatal. Increased availability of stock (unassigned) EAIs that are not prescribed for a specific child but available for use in any child with anaphylaxis is anticipated to reduce morbidity and mortality in this setting. Prevention of anaphylaxis recurrences in schools, and preparedness to recognize and treat it, involves the student, the family, the student's physician and the school[145–148] (Box 58-7).

In community settings, broader training in prompt recognition and treatment of anaphylaxis is needed not only for teachers and all other school personnel, but also for coaches, camp directors, childcare providers, restaurant and food industry workers, airline personnel and the public. The goal of training is to increase awareness that anaphylaxis is not a trivial lifestyle problem but rather a killer allergy that needs to be recognized and treated promptly. Increased availability of stock EAIs in public places such as shopping malls and sports facilities will contribute to decreased morbidity and mortality from anaphylaxis in community settings.[1,2,144–150]

Anaphylaxis education for everyone involved with infants, children and teens should emphasize the sudden onset and potentially rapid progression to multisystem involvement and life-threatening symptoms during an anaphylactic episode, the need to be prepared, to recognize and treat it promptly, and to understand the critical role of allergen avoidance in prevention of anaphylaxis recurrences.[1,2,144–150]

Conclusions

The rate of occurrence of anaphylaxis is increasing in the pediatric population. The pathologic mechanism typically involves allergen-specific IgE and high-affinity IgE receptors (FcεR1 receptors) on mast cells and basophils. Food is by far the most common trigger; however, any trigger is possible. Some patients, for example those with severe or uncontrolled asthma, are at increased risk for severe and fatal anaphylaxis.

Diagnosis of anaphylaxis is based on recognition of sudden onset of characteristic symptoms and signs within minutes to a few hours after exposure to a known or likely trigger or activity. Validated clinical criteria for diagnosis are available for use. Prompt recognition and initial treatment of an acute anaphylactic episode are essential. Call for assistance. Inject epinephrine 0.01 mg/kg in the mid-outer thigh (maximum 0.15 mg in an infant, 0.3 mg in a child, and 0.5 mg in a teenager). When

https://CafePezeshki.IR

BOX 58-7 ANAPHYLAXIS IN SCHOOLS

STUDENT'S RESPONSIBILITIES*

Food-allergic students at risk of anaphylaxis:

- Avoid ingesting known food allergen(s), trading food with others, or eating snacks or treats containing unknown ingredients

All students at risk of anaphylaxis:

- Notify an adult immediately if inadvertently exposed to trigger or if symptoms develop
- Wear medical identification jewelry/carry an anaphylaxis identification card in backpack or wallet
- Carry an epinephrine auto-injector if age-appropriate and if permitted by local regulations

FAMILY'S RESPONSIBILITIES*

- Notify the school in writing of the student's risk for anaphylaxis and his/her confirmed trigger(s)
- Educate student about trigger avoidance
- Provide medical documentation from the student's physician, including a written, personalized, anaphylaxis emergency action plan
- Discuss the student's personalized anaphylaxis emergency action plan with school personnel
- Provide a properly labeled epinephrine autoinjector
- Replace epinephrine autoinjector after use, or if past expiry date
- Provide emergency contact information for parents/caregivers

PHYSICIAN'S RESPONSIBILITIES*

- Provide appropriate medical information to student and parents/caregivers
- Provide an accurate assessment of the student's risk of anaphylaxis recurrence
- Recommend relevant risk reduction strategies (e.g. allergen avoidance, venom immunotherapy)
- Prescribe an epinephrine auto-injector
- Train student and parents to recognize anaphylaxis and use epinephrine autoinjector
- Recommend medical identification jewelry/anaphylaxis identification card
- Develop a written, personalized, anaphylaxis emergency action plan with the student, and/or if age-appropriate, the parents/caregivers, listing allergen trigger(s), relevant concurrent co-morbidities such as asthma, and medications
- If the student has asthma, help him/her maintain optimal control of symptoms

SCHOOL'S RESPONSIBILITIES*

- Develop a comprehensive school policy for prevention, recognition and treatment of anaphylaxis that includes after-hours events and school-sponsored excursions
- Identify students at risk of anaphylaxis and review their health records†
- Identify a team: principal, teachers, school nurses, food service workers and food suppliers to help prevent anaphylaxis in the school
- Designate the school personnel who are trained to recognize anaphylaxis and administer epinephrine injections using EAIs
- Rehearse the response to an anaphylactic episode: (1) call 9-1-1 or emergency medical services (EMS); (2) inject epinephrine promptly; (3) do not let the student sit up suddenly, walk or run; (4) lastly, contact parents/caregivers

Adapted from reference 146 and www.foodallergy.org; www.anaphylaxis.ca; www.whyriskit.ca.

*All information should be reviewed annually before the start of the school year and at additional intervals as needed, e.g. if an episode of anaphylaxis occurs, or if a student's allergen triggers change.

†Of the many students at risk for anaphylaxis in schools, those with milk, peanut, tree nut or shrimp allergy, and those with concomitant asthma are at highest risk for severe or fatal anaphylaxis.

needed, provide supplemental oxygen, administer IV fluids and initiate CPR. Mild anaphylaxis symptoms such as hives and cough can worsen with astonishing rapidity and progress to fatality within minutes.

Patients and caregivers should be prepared for recurrences of anaphylaxis in community settings through development and use of written, personalized, anaphylaxis emergency action plans that describe how to recognize symptoms promptly and inject epinephrine promptly using an EAI. Medical identification should be worn.

Long-term management focusses on prevention of anaphylaxis recurrences. It includes confirmation of anaphylaxis triggers suggested by the history, vigilant avoidance of relevant triggers, and immune modulation where relevant, for example *Hymenoptera* venom immunotherapy.

Anaphylaxis education aims to increase awareness of the importance of prompt recognition and treatment of acute episodes and the need for prevention of anaphylactic episodes.
